The Immersion Grating Infrared Spectrometer (IGRINS) is a revolutionary instrument that exploits broad spectral coverage at high-resolution in the near-infrared. There are no cryogenic mechanisms in IGRINS and its high-throughput white-pupil design maximizes sensitivity. IGRINS on the 2.7 meter Harlan J. Smith Telescope at McDonald Observatory is nearly as sensitive as CRIRES at the 8 meter Very Large Telescope. However, IGRINS at R=45,000 has more than 30 times the spectral grasp of CRIRES. IGRINS employs a silicon immersion grating as the primary disperser of the white pupil, and volume-phase holographic gratings cross-disperse the H and K bands onto Teledyne Hawaii-2RG arrays. The use of an immersion grating facilitates a compact cryostat while providing simultaneous wavelength coverage from 1.45 - 2.45 microns. Here we summarize the performance of IGRINS from the first 300 nights of science since commissioning in Summer 2014. With IGRINS, observers have targeted Solar System objects like Pluto and Ceres, comets, nearby young stars, star forming regions like Taurus and Ophiuchus, the interstellar medium, photodissociation regions, the Galactic Center, planetary nebulae, galaxy cores and super novae. The rich near-infrared spectra of these objects motivate unique science cases, which then provide information on instrument performance. There are more than seven submitted IGRINS papers and dozens more in preparation. With IGRINS, we realize signal-to-noise ratios greater than 100 for K=10.3 magnitude sources in one hour of exposure time. Although IGRINS is Cassegrain mounted, instrument flexure is sub-pixel thanks to its compact design. Detector characteristics and stability have been tested regularly, allowing us to adjust the instrument operation and improve science quality. Science observations have motivated many new tools for analyzing high-resolution spectra including multiplexed spectral extraction, atmospheric model fitting, rotational velocity, radial velocity, unique line identification, and circumstellar disk modeling. Here we discuss details of instrument performance, give example results, and show the characteristics of IGRINS as a versatile near-infrared spectrograph and forerunner of future immersion grating spectrographs.

9908-12, Session 3

VISIR upgrade overview: all's well that ends well

Florian Kerber, Hans-Ulrich Käufl, European Southern Observatory (Germany); Konrad Tristram, Daniel Asmus, Pedro Baksai, European Southern Observatory (Chile); Nicola Di Lieto, Danuta Dobrzycka, European Southern Observatory (Germany); Philippe R. Duhoux, European Southern Observatory (Chile); Gert Finger, Christian Hummel, Derek J. Ives, Gerd H. Jakob, Leander H. Mehrgan, European Southern Observatory (Germany); Eric J. Pantin, CEA-Ctr. de SACLAY (France); Miguel Riquelme, European Southern Observatory (Chile); Stefan Sandrock, Ralf Siebenmorgen, Jörg Stegmeier, European Southern Observatory (Germany); Alain Smette, European Southern Observatory (Chile); Julian Taylor, Mario van den Ancker, European Southern Observatory (Germany); Guillermo Valdes, European Southern Observatory (Chile); Lars Venema, ASTRON (Netherlands)

We present an overview of the VISIR instrument after its upgrade and return to science operations. VISIR is the mid-infrared imager and spectrograph at ESO's VLT. The project team is comprised of ESO staff and members of the original VISIR consortium: CEA Saclay and ASTRON. The project plan was based on input from the ESO user community with the goal of enhancing the scientific performance and efficiency of VISIR by a combination of measures: installation of improved hardware, optimization of instrument operations and software support. The cornerstone of the upgrade is the 1k by 1k Si:As AQUARIUS detector array (Raytheon) which has been carefully characterized in ESO's IR detector test facility (modified TIMMI 2 instrument). A new prism spectroscopic mode covers the N-band in a single observation. New scientific capabilities for high resolution and high-contrast imaging will be offered by sub-aperture mask (SAM) and

phase-mask (AGPM) coronagraphic modes. In order to make optimal use of favourable atmospheric conditions a water vapour monitor has been deployed on Paranal, allowing for real-time decisions and the introduction of a user-defined constraint on water vapour. During the commissioning in 2012 it was found that the on-sky sensitivity of the AQUARIUS detector was significantly below expectations. Extensive testing of the detector arrays in the laboratory and on-sky enabled us to diagnose the cause for the shortcoming of the detector as excess low frequency noise (ELFN). It is inherent to the design chosen for this detector and can't be remedied by changing the detector set-up. Since this is a form of correlated noise its impact can be limited by modulating the scene recorded by the detector. After careful analysis we have implemented fast (up to 4 Hz) chopping (with field stabilization) using the secondary mirror (M2) of the VLT. The over sampling of VISIR (0.045"/pix) for a 0.3" PSF, hence reducing the background-induced current in the device, is also essential for rejecting ELFN. During commissioning the upgraded VISIR has been confirmed to be more sensitive than the old instrument (imaging) and for spectroscopy at 10 ?m a gain of a factor >6 is realized in observing efficiency. After overcoming several additional technical problems (mechanical flexure, stability of temperature regulation) VISIR is back in Science Operations since April 2015. In addition an upgrade of the IT infrastructure related to VISIR is being conducted now in order to support burst-mode operations. Science Verification of the new modes is scheduled for Feb 2016. The upgraded VISIR is a powerful instrument providing close to background limited performance for diffraction-limited observations at an 8-m telescope. It offers synergy with facilities such as ALMA, JWST, VLTI and SOFIA, while a wealth of targets is available from survey work (e.g. VISTA, WISE). In addition it will bring confirmation of the technical readiness and scientific value of several aspects of future mid-IR instrumentation at Extremely Large Telescopes. We will present several lessons learned during the project.

9908-13, Session 4

Operational performance of MOSFIRE with its cryogenic configurable slitmask unit at the W. M. Keck Observatory

Marc Kassis, W. M. Keck Observatory (United States); Ian S. McLean, Univ. of California, Los Angeles (United States); Charles C. Steidel, Keith Y. Matthews, California Institute of Technology (United States); Sean M. Adkins, W. M. Keck Observatory (United States); Jason L. Weiss, Univ. of California, Los Angeles (United States); James E. Lyke, Dwight D. Chan, W. M. Keck Observatory (United States); Peter Spanoudakis, Olivier Chételat, Christophe Meier, Philippe Schwab, Leszek Lisowski, Emmanuel Onillon, Patrick Theurillat, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland)

The Multi-Object Spectrograph for Infrared Exploration (MOSFIRE) achieved first light on the W. M. Keck Observatory's Keck I telescope on 4 April 2012, and since, MOSFIRE has become the most popular Keck I instrument, used on 40 percent of the available nights. One of the primary reasons for the instrument's popularity is that it uses a configurable slitmask unit (CSU) developed by the Centre Suisse d'Electronique et Microtechnique (CSEM SA) to isolate the light from up to 46 objects simultaneously with mask reconfiguration times taking five minutes or less. Astronomers take advantage of MOSFIRE's sensitivity and flexibility to accommodate a wide range of scientific research programs from studies of exoplanet atmospheres to those measuring redshifts of the most distant galaxies in the universe. Because it is nimble and reliable, the instrument leads the field in multi-object infrared spectroscopy.

In collaboration with the instrument development team and CSEM engineers, the Keck observatory staff look back over the last four years and identify the decisions that contributed to the success of routine and relatively trouble free nighttime operations. From our operational perspective, we present how our observing community uses the instrument including types of CSU mask configurations and their observing strategies. Sophisticated, user friendly software, coupled with orchestrated observing procedures, make MOSFIRE and the CSU efficient and robust to on-sky errors. A few operational issues such as delays in data write times, slit drift, and CSU faults contribute to lost time, observing inefficiencies, and throughput losses. Thus, we present completed - and in some cases ongoing - mitigation efforts to further improve what is already a highly efficient instrument.

9908-14, Session 4

Performance updates of HAWK-I and preparation for the commissioning of the system GRAAL+HAWK-I

Pascale Hibon, European Southern Observatory (Chile); Miska Le Louarn, European Southern Observatory (Germany); Emanuela Pompei, European Southern Observatory (Chile)

The High Acuity Wide field K-band Imager (HAWK-I) instrument is a cryogenic wide field imager operating in the wavelength range 0.8 to 2.5 microns.

It has been in operations since 2007 on the UT4 at the Very Large Telescope Observatory in seeing-limited mode. In 2017, GRound layer Adaptive optics Assisted by Lasers module (GRAAL) will be in operation and the system GRAAL + HAWKI will be commissioned. It will allow: deeper expositions for nearly point-source objects, or shorter exposition times for reaching the same magnitude, and/or deeper detection limiting magnitude. With GRAAL, HAWK-I will operate more than 80% of the time with an equivalent K-band seeing of 0.55" (instead of 0.7" without GRAAL).

We discuss here the latest updates on performance from HAWKI without Adaptive Optics (AO) and the preparation for the commissioning of the system GRAAL+HAWKI.

9908-15, Session 4

Making SPIFFI SPIFFIER: upgrade of the SPIFFI instrument for use in ERIS and performance analysis from re-commissioning

Elizabeth M. George, Helmut Feuchtgruber, Michael Hartl, Dominik Gräff, Frank Eisenhauer, Richard Davies, Alexander Buron, Heinrich Huber, Max-Planck-Institut für extraterrestrische Physik (Germany); Christian Rau, Max Planck Institut für Extraterrestrische Physik (Germany); Markus Plattner, Erich Wiezorrek, Max-Planck-Institut für extraterrestrische Physik (Germany); Harald Weisz, WEISZ Ing.-Bureau für den Maschinenbau (Germany); Paola Amico, Andreas Glindemann, George Hau, Harald Kuntschner, European Southern Observatory (Germany)

SPIFFI (SPectrometer for Infrared Faint Field Imaging) is an adaptive optics fed near-infrared imaging spectrograph that has been operational as a facility instrument for the ESO VLT as part of the SINFONI project since 2005. The instrument has been enormously scientifically productive in several areas over its 11-year lifetime, and is currently in use for several high-profile scientific programs. An upgraded version of the instrument

will be included in the new VLT AO instrument ERIS (Enhanced Resolution Imager and Spectrometer) as the IFU subsystem SPIFFIER (SPectrometer for Infrared Faint Field Imaging Enhanced Resolution).

We describe the planned changes for the upgraded instrument, which include upgrades to almost all subsystems in the instrument, including new motors and electronics, new pre-optics, new filters, new spectrometer collimator mirrors, a new diffraction grating, and a new detector. Technology developments in many areas during the last 15 years enable us to upgrade this highly successful instrument to be competitive as a second-generation instrument on the VLT and make good use of the new 4 laser guide star adaptive optics facility (AOF) on VLT UT4. These developments include modern multi-layer coatings for lenses and filters, more precise diamond turning processes in mirror manufacturing, immersion grating development, and quantum efficiency improvements in new generations of infrared detectors. We discuss the technology developments that enable us to make the SPIFFI instrument SPIFFIER, as well as the scientific performance gains expected from these upgrades.

In January 2016, we performed an “early upgrade” to some of the subsystems in the SPIFFI instrument so that ongoing scientific programs can make use of enhanced performance before ERIS arrives in 2020. In this upgrade, the optical components making up the pre-optics subsystem, bandpass filters, and spectrometer collimator mirrors were exchanged, resulting in substantial throughput and spectral resolution gains. We report the performance of SPIFFI after this early upgrade, including substantial gains in throughput and spatial and spectral resolution. Finally we show results from the re-commissioning highlighting the scientific potential for on-going and new science programs using the new capabilities of the upgraded instrument.

9908-16, Session 4

PANIC: a general purpose panoramic near-infrared camera for the Calar Alto Observatory, instrument overview and performance at telescope

Matilde Fernandez Hernandez, María Concepción Cárdenas Vázquez, Instituto de Astrofísica de Andalucía (Spain); Irene M. Ferro Rodríguez, Instituto de Astrofísica de Andalucía - CSIC (Spain); Bernhard Dorner, Max-Planck-Institut für Astronomie (Germany); Jose-Miguel Ibáñez Mengual, Instituto de Astrofísica de Andalucía (Spain)

PANIC is the new PAnoramic Near-Infrared camera for Calar Alto, a project jointly developed by the MPIA in Heidelberg, Germany, and the IAA in Granada, Spain, for the German-Spanish Astronomical Center at Calar Alto Observatory (CAHA, Almería, Spain). This new instrument is able to work at the 2.2m and 3.5m CAHA telescopes covering a field of view of 30’x30’ and 15’x15’, respectively, with a sampling of 4096x4096 pixels. It is designed for the spectral bands from Z to KS, and can be equipped with also narrow-band filters. The instrument was delivered to the observatory in fall 2014 and it was commissioned at both telescopes in spring 2015. The scientific verification of the instrument at the 2.2m and 3.5m telescopes has been successfully carried out in late 2015 and the expected camera performances comply with the scientific requirements. The camera is currently available to the astronomy community.

We describe the design, the Assembly, Integration and Verification process, the final laboratory tests and the performance of the PANIC instrument. First-light data obtained during commissioning and science verification phases are presented as well.

The laboratory final test confirmed the expected camera performances, complying with the scientific requirements. Commissioning phase on-sky has been accomplished.

PANIC works under cryogenic conditions, at about 100K, except for the detector, that works at 82K. The optical design has been optimized for the operation temperature (100K) but the mechanical design, manufacturing and assembly have been done at room temperature (300K). The mounts of the optical elements have been designed to ensure survival when temperature changes between 300K and 100K and also to position the elements at the right distances at operation temperature.

The detector, a mosaic of four 2kx2k HAWAII-2RG, and its readout electronics have been characterized and optimized. An overview of the performance will be given. The median dark current of one of the four arrays (SG4) is severely influenced by hot pixel degradation. Another array (SG3) shows signs of starting degradation. This has to be taken into account in the observation planning and the data processing.

Besides the low level software, which deals with the data acquisition at the detector level, several tools have been developed for the observation and for the data reduction. The Observation Tool (OT) is a user friendly interface for preparing the Observing Blocks, that are sets of instructions as telescope pointing, dithering patterns, filter selection or calibration observations. The Quick Look (QL) allows to keeptract of the preliminary results and it is essential to ensure that the observation plan proceeds as expected. For the scientific data reduction two pipelines have been developed: PAPI (PANIC Pipeline) for the general procedures and LEMON, for the data reduction and analysis of time series observations. The interplay of the software packages and the instrument, and the functionality of the processing pipelines, have been successfully tested during the commissioning and scientific verification.

9908-17, Session 4

The “+” for CRIRES: enabling better science at infrared wavelength and high spectral resolution at the ESO VLT

Reinhold J. Dorn, European Southern Observatory (Germany); Roman Follert, Thüringer Landessternwarte Tautenburg (Germany); Paul Bristow, Claudio Cumani, Jason Grunhut, Andreas Haimerl, European Southern Observatory (Germany); Artie P. Hatzes, Thüringer Landessternwarte Tautenburg (Germany); Ulrike Heiter, Uppsala Univ. (Sweden); Renate Hinterschuster, Derek J. Ives, Yves Jung, Florian Kerber, Barbara Klein, European Southern Observatory (Germany); Alexis Lavail, Uppsala Univ. (Sweden) and European Southern Observatory (Germany); Jean-Louis Lizon, European Southern Observatory (Germany); Tom Löwinger, Thüringer Landessternwarte Tautenburg (Germany); Thomas Marquart, Uppsala Univ. (Sweden); Ignacio Molina-Conde, Belinda Nicholson, European Southern Observatory (Germany); Ernesto Oliva, INAF - Osservatorio Astrofisico di Arcetri (Italy); Livia Origlia, INAF - Osservatorio Astronomico di Bologna (Italy); Luca Pasquini, Jérôme Paufique, European Southern Observatory (Germany); Nikolai A. Piskunov, Uppsala Univ. (Sweden); Ansgar Reiners, Ulf Seemann, Georg-August-Univ. Göttingen (Germany); Jörg Stegmeier, European Southern Observatory (Germany); Eric Stempels, Uppsala Univ. (Sweden); Sebastien Tordo, Hans-Ulrich Käufl, European Southern Observatory (Germany)

The adaptive optics (AO) assisted CRIRES instrument is an IR (0.92 - 5.2 ?m) high-resolution spectrograph which has been in operation from 2006 to 2014 at the Very Large Telescope (VLT). CRIRES was a unique instrument, accessing a parameter space (wavelength range and spectral

resolution) which up to now was largely uncharted. In its setup, it consisted of a single-order spectrograph providing long-slit (40 arcsecond) spectroscopy with a resolving power up to R=100 000. However the setup was limited to a narrow, single-shot, spectral range of about 1/70 of the central wavelength, resulting in low observing efficiency for many modern scientific programmes requiring a broad spectral coverage. The CRIRES upgrade project, CRIRES+, transforms this VLT instrument into a cross-dispersed spectrograph to increase the simultaneously covered wavelength range by a factor of ten. A new detector focal plane array of three Hawaii 2RG detectors with 5.3 ?m cut-off wavelength will replace the existing detectors. For advanced wavelength calibration, custom-made absorption gas cells and an etalon system will be added. A spectropolarimetric unit will allow the recording of circular and linear polarized spectra. This upgrade will be supported by dedicated data reduction software allowing the community to take full advantage of the new capabilities offered by CRIRES+. CRIRES+ has now entered its assembly and integration phase and will return with all new capabilities by the beginning of 2018 to the Very Large Telescope in Chile.

9908-81, Session PS1

Introducing SpUpNIC (Spectrograph Upgrade: Newly Improved Cassegrain) on the South African Astronomical Observatory's 74-inch telescope

Lisa A. Crause, David B. Carter, Alroy Daniels, Geoffrey P. Evans, Pieter A. Fourie, David Gilbank, Malcolm Hendricks, Willie P. Koorts, South African Astronomical Observatory (South Africa); Deon Lategan, Denel Spaceteq (South Africa); Egan Loubser, Sharon Mouries, South African Astronomical Observatory (South Africa); Darragh E. O'Donoghue, Southern African Large Telescope (South Africa); James E. O'Connor, Stephen B. Potter, Craig Sass, Amanda A. Sickafoose, John W. Stoffels, Pieter Swanevelder, Keegan Titus, Carel H. D. R. van Gend, Martin Visser, Hannah L. Worters, South African Astronomical Observatory (South Africa)

We present SpUpNIC (Spectrograph Upgrade: Newly Improved Cassegrain) - the extensively upgraded Cassegrain spectrograph for the South African Astronomical Observatory's 74-inch (1.9-m) telescope. This instrument has existed in various forms over the past four decades. Initially it employed a photographic plate fed by an image intensifier, then progressed to a photon-counting system. That was followed by a pair of one-dimensional photodiode arrays known as the Reticon Photon Counting System, which was subsequently replaced by a 1798x266 SITe CCD in the mid-1990's. The latest incarnation of the spectrograph is essentially a new instrument, although certain original components - such as the slit mechanism - remain in use. The inverse-Cassegrain collimator mirrors, as well as the woefully inefficient Maksutov-Cassegrain camera optics have been replaced, as was the original CCD detector and SDSU controller. All of the moving mechanisms within the instrument (actuated by a combination of pneumatic cylinders and stepper motors) are now governed by a programmable logic controller. Thus the entire instrument is remotely configurable through the intuitive new graphical user interface run under Linux (Ubuntu) on the dedicated instrument control PC. This has also allowed time-consuming manual tasks like the Hartmann focus routine for the camera to be automated. The existing nine surface-relief diffraction gratings with various blaze wavelengths (between 340 and 1000 nm) and groove densities (ranging between 300 and 1200 lines/mm) remain available. The system also still employs a plano-convex field lens and inverse-Cassegrain collimator, but the new collimator assembly produces a larger beam to fill the grating and match the optically faster Folded-Schmidt camera design. The new camera assembly consists of a fused silica Schmidt plate, a slotted fold flat and a spherically figured primary mirror (both made of Zerodur) and a fused silica field-flattener lens that also forms the cryostat window. These optics alone have more than doubled the spectrograph throughput across the entire wavelength range by reducing the camera's central obscuration (from the slot in the fold mirror) to almost match that of the shadows from the telescope and collimator secondaries. The new CCD is a 2048x512 e2V device with 13.5-micron pixels. Being a frame-transfer chip, only half of the array is ever exposed, and the active area is usually binned (1x2) in the spatial direction to further reduce read-noise. The physically larger and more sensitive detector has extended the useful wavelength range of the spectrograph; weak copper-argon arc lines are now detectable down to 325 nm and the red end extends beyond 1100 nm. The improved performance is particularly dramatic in the blue due to the CCD being thinned and back-illuminated. The introduction of a rear-of-slit viewing camera has streamlined the acquisition process and further increased the instrument throughput. A small, pneumatically-actuated fold mirror is inserted into the beam between the collimator mirrors, allowing a Starlight Xpress Lodestar camera to image the slit from below. This facilitates accurate target positioning on the slit and optimisation of the telescope focus. An interactive quick-look data reduction tool further enhances the observing efficiency and user-friendliness of SpUpNIC.

9908-82, Session PS1

Detector upgrade of Subaru's multi-object infrared camera and spectrograph

Maximilian H. Fabricius, Joshua Walawender, Nobuo Arimoto, Brian Elms, Subaru Telescope, National Astronomical Observatory of Japan (United States); Yasuhito Hashiba, The Univ. of Tokyo (Japan); Takashi Hattori, Subaru Telescope, National Astronomical Observatory of Japan (United States); Yen-Sang Hu, Institute of Astronomy and Astrophysics - Academia Sinica (Taiwan); Ikuru Iwata, Tetsuo Nishimura, Naruhisa Takato, Ichi Tanaka, Shiang-Yu Wang, Matthew Wung, Subaru Telescope, National Astronomical Observatory of Japan (United States)

During the past year, the Multi-Object InfraRed Camera and Spectrograph (MOIRCS) at Subaru has undergone an upgrade of its science detectors, the housekeeping electronics and the instrument control software. This overhaul aims at increasing MOIRCS' sensitivity, observing efficiency and stability. In this presentation I will speak specifically about the installation and the alignment procedure of the two Hawaii 2RG detectors and the design of a cryogenic focus mechanism. The new detectors are expected to significantly lower the readnoise, increase its quantum efficiency, and lower the readout time. I will present results on gain, readnoise, crosstalk and latency and conclude with our mitigation strategy of alpha radiation originating from the lens coatings.

9908-83, Session PS1

Commissioning SITELLE: an imaging Fourier transform spectrometer for the Canada France Hawaii Telescope

Marc R. Baril, Canada-France-Hawaii Telescope (United States); Frédéric J. Grandmont, Julie Mandar, ABB Inc. (Canada); Laurent Drissen, Thomas Martin, Univ. Laval (Canada); Gregory Barrick, Daniel Devost, Canada-France-Hawaii Telescope (United States); Laurie Rousseau-Nepton, Univ. Laval (Canada); Steve R. Levesque, ABB Analytical Measurement (Canada); Denis

Brousseau, Simon Thibault, Univ. Laval (Canada)

We describe the commissioning of the SITELLE instrument at the Canada France Hawaii Telescope (CFHT) following the pre-shipment testing and acceptance of the instrument built by ABB/Bomem at l'Université Laval in Québec, Québec, Canada. The performance of the instrument in terms of expected versus actual image quality and modulation efficiency, and the challenges of accurately determining these metrics will be presented. Early in the instrument integration problems were found obtaining clear measurements of the modulation efficiency (ME) primarily due to overfilling of the instrument pupil by the calibration illumination source placed at the collimator input. This led to further confusion concerning the fringe contrast as a function of optical path difference once the instrument was received at CFHT. Also, due to the lack of a telescope optical simulator, a clear picture of the image quality prior to shipping was difficult to obtain, and an unexpected elongation of the star images, particularly on one port of the interferometer, was observed. The resolution of these problems and mis-conceptions concerning the ME performance will be presented. We also provide a characterization of the stability of the metrology system as a function of instrument orientation, which varies considerably due to its mounting at the Cassegrain port of the CFH's equatorially mounted telescope.

9908-84, Session PS1

Faint skylines in the near-infrared: observational constraint for IFU instruments

Hector Flores, Myriam Rodrigues, Mathieu Puech, Yanbin Yang, François Hammer, Observatoire de Paris à Meudon (France)

Night sky emission is a major issue in the study of the spectrum of distant objects. More effective methods to subtract the sky are largely used today with a new generation of optical and near-infrared spectrograph. But even using long exposures to subtract the sky, the S/N is never enough to remove completely its signature, in particular for the faint lines. Using VLT/KMOS observations, we have studied the temporal and spatial behavior of these faint skylines. We found that even after using new methods to subtract the sky, these small skylines some times still remain in the data cube. Even more, we found that the flux of these skylines changes spatially at the arcseconds scale being this still detected after combining several exposures. For the future exploitation of 3D observations, this behavior must be considered when kinematics is extracted from galaxies. We present some examples where the shape of the emission lines in the spectrum of a galaxy is affected by these faint skylines.

9908-85, Session PS1

Regaining the FORS: making optical ground-based transmission spectroscopy of exoplanets with VLT+FORS2 again possible

Henri M. J. Boffin, Elyar Sedaghati, European Southern Observatory (Germany); Guillaume Blanchard, OPA OPTICAD S.A. (France); Oscar Gonzalez, Sabine Moehler, Neale Gibson, Mario van den Ancker, Jonathan Smoker, Joseph Anderson, Christian Hummel, Danuta Dobrzycka, Alain Smette, Gero Rupprecht, European Southern Observatory (Germany)

Since a few years, the study of exoplanets has evolved from being purely discovery and exploratory in nature to being quite quantitative. In particular, transmission spectroscopy now allows the study of exoplanetary atmospheres. Such studies rely heavily on space-based or large ground-based facilities, as one needs to perform time-resolved, high signal-to-noise spectroscopy, with residuals at the 100 ppm level. For some time already, it was known that precision spectrophotometry with the ESO Very Large Telescope's FORS2 instrument suffered from systematic errors that made quantitative observations of planetary transits impossible. We identified the Longitudinal Atmospheric Dispersion Compensator (LADC) as the most likely culprit, and therefore embarked in a project to remove the anti-reflection coating of the LADC prisms of the twin, but no more used, FORS1 instrument and put them at the telescope. This led to a significant improvement in the depth of FORS2 zero points of 0.05 to 0.1 magnitudes, a drastic reduction in the systematic noise, and led to a renewed interest for this instrument as shown by the number of proposals submitted to perform transmission spectroscopy of exoplanets. We will present here in detail the various phases of the upgrade project, present the recommissioning results and show the level of improvement obtained in transit studies of exoplanets, with several examples. FORS2 may become the instrument of choice for ground-based transmission spectroscopy of exoplanets.

9908-86, Session PS1

Mosaic3: A red-sensitive upgrade for the prime focus camera at the Mayall 4m telescope

Arjun Dey, National Optical Astronomy Observatory (United States); David Rabinowitz, Yale Univ. (United States); Armin Karcher, Christopher J. Bebek, Lawrence Berkeley National Lab. (United States); Charles Baltay, Yale Univ. (United States); David Sprayberry, Francisco G. Valdes, Robert J. Stupak, John Donaldson, National Optical Astronomy Observatory (United States); William Emmet, Tom Hurteau, Yale Univ. (United States); Behzad Abareshi, Robert Marshall, Michael J. Fitzpatrick, National Optical Astronomy Observatory (United States); Philip N. Daly, Large Binocular Telescope Observatory (United States); Richard Joyce, National Optical Astronomy Observatory (United States); David J. Schlegel, Lawrence Berkeley National Lab. (United States); Heidi Schweiker, WIYN Observatory (United States); Lori Allen, Robert Blum, National Optical Astronomy Observatory (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured over the course of the experiment. In order to provide spectroscopic targets for the DESI survey, we are carrying out a three-band (g,r,z) imaging survey of the sky using telescopes on Kitt Peak and Cerro Tololo. At Kitt Peak National Observatory, we will use an upgraded version of the prime focus imaging camera (Mosaic3) at the Mayall 4m telescope to carry out a z-band survey of the Northern Galactic Cap at declinations > 30 deg. We have equipped an existing dewar with four 4kx4k fully depleted 500 micron-thick CCDs manufactured by the Lawrence Berkeley National Laboratory. These CCDs have the thickest active area fielded at a telescope, and increase the z-band system throughput of the system by a factor of 1.6. We are commissioning the camera and are scheduled to begin the survey observing in February, 2016. The Mosaic3 z-band survey will utilize 230 nights during the 2016 and 2017 spring observing semesters, and will be complemented by g-band and r-band observations using the Bok telescope on Kitt Peak. We describe the upgrade and performance of the Mosaic3 instrument and the scope of the northern survey.

9908-87, Session PS1

Operational challenges for astronomical instrumentation in Antarctica: results from five years of environmental monitoring of AMICA at Dome C

Mauro Dolci, Angelo Valentini, Amico Di Cianno, Oscar Straniero, INAF - Osservatorio Astronomico di Teramo (Italy); Daniele Tavagnacco, INAF - Osservatorio Astronomico di Trieste (Italy)

The Antarctic Plateau is one of the best observing sites on Earth, especially for Infrared Astronomy. The extremely low temperatures (down to -80 C during winter), the low pressure (around 650 mbar) and the very reduced content of Precipitable Water Vapour (PWV less than 1 mm) allow indeed for a very clear and dark atmosphere, as well as for a passive, bery low instrumental background. These unique properties, however, make it very difficult to install and operate astronomical instrumentation, especially during winter. Mechanical and electronic COTS equipments cannot work at those temperatures and need to be insulated. Insulation, however, can cause an unexpected overheating inside electronic and electrical cases, because the substantial absence of humidity makes heat transfer extremely inefficient. Heat removal is also a real problem when managing heavy-duty devices, like cryocoolers, where excess power removal needs to be fast and efficient. The presence of wind (although weak) and of the related diamond ice dust phenomenon is at the origin of ice covering of surfaces and ice inlet through any opening width as small as 0.6 mm. Finally, the lack of an electrical ground in the high-plateau (3300 m and more) bases generates a wide variety of transient electrical phenomena which often make electronic instrumentation rather unstable.

The Antarctic Multiband Infrared CAmera (AMICA) is an instrument for astronomical imaging in the 2 - 25 micron wavelength range, installed at Dome C since 2010. Its automatic Environmental Control System (ECS) has been working continuously over the last 5 years, providing a large set of operational data that revealed themselves very useful in the evaluation of the instrument performance and its dependence on the environmental conditions.

This poster reports an analysis and discussion on the challenges represented by the environmental and operational conditions for an instrument working in a typical Antarctic Plateau site. Some conclusions are drawn, essentially stressing the need of a sort of “space qualification” for instruments designed for Antarctic operations.

9908-88, Session PS1

FIFI-LS diffraction grating vibration on SOFIA

Felix Rebell, Univ. Stuttgart (Germany); Simon Beckmann, Deutsches SOFIA Institut (Germany); Aaron Bryant, Univ. Stuttgart (Germany); Sebastian Colditz, Christian Fischer, Deutsches SOFIA Institut (Germany); Fabio Fumi, Univ. Stuttgart (Germany); Rainer Hoenle, Univ. of Stuttgart (Germany); Norbert Geis, Max-Planck-Institut für extraterrestrische Physik (Germany); Christof Iserlohe, Deutsches SOFIA Institut (Germany); Randolf Klein, SOFIA / USRA (United States); Alfred Krabbe, Deutsches SOFIA Institut (Germany); Leslie W. Looney, Univ. of Illinois at Urbana-Champaign (United States); Albrecht Poglitsch, Max-Planck-Institut für extraterrestrische Physik (Germany); Walfried Raab, European Space Research and Technology Ctr. (Netherlands); Maureen L. Savage, SOFIA / USRA (United States)

FIFI-LS (the Field Imaging Far Infrared Line Spectrometer for SOFIA) was successfully commissioned in 2014 during 6 flights on SOFIA. FIFI-LS has two symmetric channels capable of detecting infrared light in the wavelength ranges 51-120μm and 115-203μm. The infrared beam from the SOFIA telescope is diffracted by one reflective grating per channel. In each channel the observed wavelength is set by rotating the grating to a defined angular position. The wavelength span results in a total tilt angle of ±20°. The angle is constantly measured with a rotary Inductosyn transducer providing a resolution of down to 0.077 arc-seconds. The grating angle set position is reproducible within an accuracy of 4 arc-seconds. The inside of the instrument is cooled down to cryogenic temperatures in order to minimize contamination from the infrared background. Therefore, the grating, its rotating mechanisms and the measurement system need to operate at temperatures from 300K down to 6K. The positional stability of the grating is immensely important, since the position directly represents the observed wavelength. In the lab the cryostat is not exposed to any significant vibrations or accelerations. In flight vibrations of the telescope assembly are transferred to the attached cryostat and picked up by the grating assembly inside the instrument. Due to the inertial stabilization of the telescope, the power levels of the vibrations are extremely low. Nonetheless, they result in an increased movement of the grating. Due to this vibration the observed wavelength oscillates on the detector. In order to describe the dynamic behavior of the grating during flight, several tests have been performed on the commissioning flights.

Acceleration data was taken with a sensor on the outside of the instrument to quantify the vibrations FIFI-LS is exposed to in flight. Simultaneously the grating vibration itself was measured using the internal Inductosyn transducer. The acceleration sensor data reveals the vibrational spectrum and its intensity transferred through the structure of the telescope and the science instrument flange onto the instrument itself. Additionally the data taken on the inside displays the combined frequencies of the external vibrations and the natural frequencies of the grating assembly. Based on this data the impact on the image quality of FIFI-LS is further investigated.

The data enables two approaches to quantify the effect of the vibrations on the image quality, in particular the spectral resolution. First a theoretical approach was taken to calculate the oscillation of an emission line and estimate the apparent widening of this line. In a second approach lab measurements have been conducted, where the measured vibration was ‘replayed’, so the inflight grating movement was reproduced in the lab. That way, it was possible to compare emission line measurements with and without vibration directly.

The submitted paper will present the measured data and analyze the effect on the image quality of FIFI-LS.

9908-89, Session PS1

Final implementation and photon-efficiency verification of Hobby Eberly Telescope facility calibration unit

Hanshin Lee, Gary J. Hill, Brian L. Vattiat, The Univ. of Texas at Austin (United States); Marco H. Häuser, Univ.-Sternwarte München (Germany); Linda Elliot, Sarah E. Tuttle, Taylor S. Chonis, Trent W. Peterson, Randy Bryant, The Univ. of Texas at Austin (United States)

The upgraded Hobby-Eberly Telescope (HET) has been equipped with new Facility Calibration Unit (FCU). The FCU is in support of the novel VIRUS instrument and other facility instruments and consists of the head and source box. The FCU head, connected to the source box through two liquid light guides, is attached to the bottom of the WFU Wide-Field Corrector (WFC) and can be deployed into the beam to inject calibration light through the WFC whenever calibration is needed. A set of Fresnel lenses is used in the FCU head to mimic the caustics of M1 as much as possible to re-produce the telescope’s focal plane illumination pattern.

Various imaging/non-imaging optical components are used for efficient coupling between different types of calibration line lamps and light guides. The final implementation also features the extremely uniform and bright Laser-Driven Light Source (LDLS) for spectroscopic flat field calibration. Altogether, the FCU efficiently provides calibration photons at wavelengths from 350nm to 2100nm. This paper presents the system's final hardware/software implementation and discusses its photon-efficiency relative to the on-sky spectrophotometric standard data taken through the HET's new Low-Resolution Spectrograph 2.

9908-90, Session PS1

The WIYN One Degree Imager: project update 2016

Daniel R. Harbeck, WIYN Observatory (United States); Michael P. Lesser, David Ouellete, The Univ. of Arizona (United States); Wilson M. Liu, WIYN Observatory (United States); Robert J. Stupak, Ron George, Ron Harris, National Optical Astronomy Observatory (United States); Michael P. Smith, Dustin Mason, Univ. of Wisconsin-Madison (United States); Gary A. Poczulp, Charles Corson, National Optical Astronomy Observatory (United States); Peter M. Onaka, Greg Chin, Univ. of Hawai'i (United States); Ralf Kotulla, Univ. of Wisconsin-Milwaukee (United States); Jayadev K. Rajagopal, National Optical Astronomy Observatory (United States); Arvind Gopu, Michael D. Young, Indiana Univ. (United States)

We report on recent upgrades to the One Degree Imager (ODI) camera at the WIYN 3.5 meter telescope at the Kitt Peak Observatory. Following an initial test phase with thirteen detectors, the focal plane has been expanded by 16 new detectors, and is in shared risk science operations since the summer 2015. With currently a total of 30 Orthogonal Transfer Array CCD detectors, the total field of view is 40' x 48' on the sky. The newly added detectors underwent a design revision to address an issue where the the charge transfer efficiency is compromised under low light conditions. We discuss the imaging performance and challenges in the photometric calibration of the expanded array with multiple detector generations. In addition we describe the modification of ODI's filter change mechanism, where a degrading worm-gear drive was replaced by a chain drive. Finally, we will comment on the lessons learned from nearly three years of operating the instrument and its integration with the WIYN 3.5m telescope.

9908-92, Session PS1

Motivation for and design of a new imaging camera for the OSIRIS instrument at Keck

Gunther Witzel, Sylvana Yelda, Michael P. Fitzgerald, Theodore Aliado, Pauline Arriaga, Anna Boehle, John M. Canfield, Tuan Do, Thomas Esposito, Andrea M. Ghez, Christopher A. Johnson, James E. Larkin, Kenneth G. Magnone, Eric Wang, Jason L. Weiss, Univ. of California, Los Angeles (United States); Renate Kupke, Univ. of California, Santa Cruz (United States); Sean M. Adkins, Jon Chock, Allan Honey, James E. Lyke, Peter L. Wizinowich, W. M. Keck Observatory (United States)

The OSIRIS Instrument at W. M. Keck Observatory provides AO-assisted imaging and integral-field spectroscopy. We are providing a new imaging camera to the instrument. This new camera will improve the imaging sensitivity over a field of view not well-served by the other AO-imaging camera at WMKO, NIRC2, also improving its utility in measuring point-spread function references for IFS data reduction. We are additionally motivated to provide a stable camera useful for astrometry, such as for mapping motion of stars in the Galactic Center. We will briefly summarize the scientific and technical motivations for this new camera and discuss its telecentric OAP-based optical design, which provides a 20" x 20" field of view sampled at 10 mas/pix by a Hawaii-2RG detector. This design includes new filter wheels and improved cold pupils, and is tuned for accurate photometry and astrometry. We will also discuss aspects of the optomechanical, electronic, and software subsystems.

9908-93, Session PS1

The nuMOIRCS project: detector upgrade overview and early commissioning results

Joshua Walawender, Maximilian H. Fabricius, Nobuo Arimoto, David Cook, Brian Elms, Subaru Telescope, National Astronomical Observatory of Japan (United States); Yasuhito Hashiba, The Univ. of Tokyo (Japan); Yen-Sang Hu, Institute of Astronomy and Astrophysics - Academia Sinica (Taiwan); Ikuru Iwata, Tetsuo Nishimura, Koji Omata, Naruhisa Takato, Ichi Tanaka, Subaru Telescope, National Astronomical Observatory of Japan (United States); Shiang-Yu Wang, Institute of Astronomy and Astrophysics - Academia Sinica (Taiwan); H. Mark Weber, Matthew Wung, Subaru Telescope, National Astronomical Observatory of Japan (United States)

In 2014 and 2015 the Multi-Object InfraRed Camera and Spectrograph (MOIRCS) instrument at the Subaru Telescope on Maunakea is undergoing a significant modernization and upgrade project. We are upgrading the two Hawaii2 detectors to Hawaii2-RG models, modernizing the cryogenic temperature control system, and rewriting much of the instrument control software.

The detector upgrade is replacing the Hawaii2 detectors which use the Tohoku University Focal Plane Array Controller (TUFPAC) electronics with Hawaii2-RG detectors using SIDECAR ASIC (a fully integrated FPA controller system-on-a-chip) and a SAM interface card. We expect an improvement in read noise by a factor of about 2-3 with this detector and electronics upgrade.

The cryogenic temperature control upgrade focuses on modernizing the components and making the procedures for warm up and cool down of the instrument safer. We have moved PID control loops out of software and in to Lakeshore model 336 cryogenic temperature controllers and have added interlocks on the warming systems to prevent overheating of the instrument.

Much of the instrument control software has also been re-written. This was necessitated by the different interface to the detector electronics (ASIC & SAM vs. TUFPAC) and by the desire to modernize the interface to the telescope control software which has been updated to Subaru's "Gen2" system since the time of MOIRCS construction and first light. The new software is also designed to increase reliability of operation of the instrument, decrease overheads, and be easier for night time operators and support astronomers to use.

9908-94, Session PS1

Upgraded cameras for the HESS Imaging Atmospheric Cherenkov Telescopes

Gianluca Giavitto, Deutsches Elektronen-Synchrotron (Germany); Terry J. R. Ashton, Univ. of Leicester (United Kingdom); Arnim Balzer, David Berge, Univ. van Amsterdam (Netherlands); Francois Brun, Thomas Chaminade, Eric Delagnes, Commissariat à l'Énergie Atomique (France); Gérard Fontaine, Ecole Polytechnique (France) and Institut National de Physique Nucléaire et de Physique des Particules (France); Matthias Füssling, Deutsches Elektronen-Synchrotron (Germany); Berrie Giebels, Ecole Polytechnique (France) and Institut National de Physique Nucléaire et de Physique des Particules (France); Jean-François Glicenstein, Commissariat à l'Énergie Atomique (France); Tobias Graeber, Deutsches Elektronen-Synchrotron (Germany); James A. Hinton, Albert Jahnke, Max-Planck-Institut für Kernphysik (Germany); Stefan Klepser, Marko Kossatz, Axel Kretzschmann, Deutsches Elektronen-Synchrotron (Germany); Valentin Lefranc, Commissariat à l'Énergie Atomique (France); Holger Leich, Hartmut Lüdecke, Deutsches Elektronen-Synchrotron (Germany); Pascal Manigot, Ecole Polytechnique (France) and Institut National de Physique Nucléaire et de Physique des Particules (France); Vincent Marandon, Max-Planck-Institut für Kernphysik (Germany); Emmanuel Moulin, Commissariat à l'Énergie Atomique (France); Mathieu de Naurois, Ecole Polytechnique (France) and Institut National de Physique Nucléaire et de Physique des Particules (France); Patrick Nayman, Institut National de Physique Nucléaire et de Physique des Particules (France); Marek Penno, Deutsches Elektronen-Synchrotron (Germany); Duncan Ross, Univ. of Leicester (United Kingdom); David Salek, Univ. van Amsterdam (Netherlands); Markus Schade, Deutsches Elektronen-Synchrotron (Germany); Thomas Schwab, Max-Planck-Institut für Kernphysik (Germany); Rachel Simoni, Univ. van Amsterdam (Netherlands); Christian Stegmann, Deutsches Elektronen-Synchrotron (Germany); Julian Thornhill, Univ. of Leicester (United Kingdom); François Toussnel, Institut National de Physique Nucléaire et de Physique des Particules (France)

The High Energy Stereoscopic System (H.E.S.S.) is an array of five imaging atmospheric Cherenkov telescopes (IACT), sensitive to cosmic gamma rays with energies between ~30 GeV and several tens of TeV. Four of them started operations in 2003 and their 960 photomultiplier tube (PMT) cameras are currently undergoing a major upgrade, with the goals of improving the overall performance of the array and reducing the failure rate of the ageing systems. This camera upgrade assures the operation of the H.E.S.S array at its full sensitivity until and possibly beyond the end of the decade. With the exception of the PMTs, all camera components have been replaced: these include the readout and trigger electronics, the power, ventilation and pneumatic systems and the control and data acquisition software. New designs and technical solutions have been introduced: the readout electronics is based on the NECTAr analog memory chip, which sample and store the PMT signals at a frequency of 1 GHz with a dynamic range of 12 bits. In all subsystems, the control of the hardware is carried out by an FPGA coupled to an embedded ARM computer, a modular design which has proven to be very fast and reliable. The control and data acquisition software is based on modern C++ libraries such as Apache Thrift, ZMQ and Protocol buffers, offering very good performance, robustness, flexibility and ease of development. Both hardware and software have undergone extensive testing both during the development of the upgrade, and during the deployment and commissioning of the first camera, which happened in July-December 2015. The other three cameras are going to be upgraded in September 2016. This contribution describes the design, the on-field performance, the results of the tests and the lessons learned from the first upgraded H.E.S.S. camera.

9908-95, Session PS1

On-sky and laboratory tests of polarization gratings for visible and near infrared astronomy

Maxwell A. Millar-Blanchaer, Dunlap Institute for Astronomy & Astrophysics (Canada); Dae-Sik Moon, Univ. of Toronto (Canada); James R. Graham, Univ. of California, Berkeley (United States)

We report on the design, characterization and on-sky performance of a prototype slit-based spectropolarimeter instrument that employs a polarization grating (PG) optimized for operation from 0.5 to 0.9?m. PGs are a type of diffraction grating that take advantage of liquid crystal polymers to simultaneously act as a polarizing beam splitter and as a classical diffraction grating. The uniaxial birefringent properties of the liquid crystal polymers cause incident light to diffract into the m=+1 or m=-1 order, depending on its circular polarization state. With the addition of a quarter-wave plate PGs can be made sensitive to linear polarized light. Furthermore, PGs are capable of providing high diffraction efficiency (> 90%) over a very broad wavelength range. These properties make PGs ideal for spectropolarimetry and/or high throughput, broad wavelength observations for a range of astronomical objects. We have designed and constructed an instrument that uses a PG, which we have mounted on the 16" University of Toronto Campus telescope. The optical design consists of a slit, collimating optics, a rotating quarter-wave plate, a PG, camera optics and a 4k x 4k detector. We have used this instrument to carry out observations of the polarized twilight sky, as well as polarized standard stars. These observations act as a proof of concept to demonstrate the applicability of polarization gratings for astronomical applications in the visible regime. In addition, we describe our laboratory characterization work on a polarization grating designed for high diffraction efficiency between 0.6 and 1.8?m.

9908-96, Session PS1

Gemini instrument upgrade program

Ruben Diaz, Stephen J. Goodsell, Catherine Blough, Scot J. Kleinman, Gemini Observatory (United States)

Gemini is introducing a new program to produce user-motivated upgrades to our operating instruments at both Gemini sites. The objective is to simultaneously help keep the observatory current instruments competitive in the field and better serve the scientific needs of Gemini users. Part of this strategy involves launching public request of proposals for instrument upgrades of existing operational instrumentation, creating a new instrument capability at the observatory. During 2015 a first public request of proposal for small projects was launched, and in 2016 medium projects (~0.5M USD) proposals will be requested. In this work we summarise the work done and the results so far obtained within the instrument upgrade program.

9908-97, Session PS1

Commissioning the polarimetric modes of the Robert Stobie spectrograph on the Southern African Large Telescope

Stephen B. Potter, South African Astronomical Observatory (South Africa); Kenneth H. Nordsieck, Univ. of Wisconsin-Madison (United States); Encarnacion Romero Colmenero, Steven M. Crawford, Petri H. Vaisanen, Éric Depagne, David A. H. Buckley, Anthony R. Koeslag, Janus D. Brink, Christian Hettlage, Keith R. J. Browne, South African Astronomical Observatory (South Africa); Alan Schier, James Allington, The Pilot Group (United States)

The Robert Stobie Spectrograph is currently the prime spectroscopic instrument on the Southern African Large Telescope (SALT), which has been undergoing regular scientific operations since 2011. The visible beam of RSS was designed to perform polarimetry in all its modes, imaging and grating spectroscopy (with Multi Object Spectroscopy capability) from 3200 to 9000 A˚. The polarimetric field of view is 4?8 arcmin.

Initial early polarimetric commission was stalled because a coupling fluid leak developed in the polarizing beamsplitter after less than a year of operation. It was decided to redesign the beamsplitter to use a different optical couplant. This is complicated by the unusual thermal expansion properties of the calcite optic, and by the necessity of aligning the individual elements in the beamsplitter mosaic (RSS is the first to use a mosaic beamsplitter). Laboratory work selected a new couplant, a gel, Nye 451, which has been used by astronomers, including on calcite. Testing was completed with satisfactory results on a “sacrificial” calcite prism with the same geometry as an actual mosaic element. A successful assembly was performed and the beamsplitter was re-installed in SALT in mid-2015.

We describe results from the renewed commissioning to characterise polarimetry from SALT and include some early performance verification science.

9908-98, Session PS1

Data quality and reductions for the high-resolution spectrograph on the Southern African Large Telescope

Steven M. Crawford, Lisa A. Crause, South African Astronomical Observatory (South Africa); Éric Depagne, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa); Christian Hettlage, Southern African Large Telescope (South Africa) and South African Astronomical Observatory (South Africa); Alexei Kniazev, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa); Encarnacion Romero Colmenero, Southern African Large Telescope (South Africa) and South African Astronomical Observatory (South Africa); Anja Schroeder, South African Astronomical Observatory (South Africa); Petri H. Vaisanen, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa)

The High Resolution Spectrograph (HRS) on the Southern African Large Telescope (SALT) is a dual beam, fiber-fed echelle spectrograph providing high resolution capabilities to the SALT observing community. The instrument has four modes of operation, including low resolution (R~15000), medium resolution (R~36000), high resolution (R~65000), and a high stability mode, with each mode having a pair of object and sky fibers. The high stability mode also has a resolution of R~65000, but includes a fiber double-scrambler and the choice of either an iodine cell or simultaneous injection of thorium-argon arc light into the sky fiber to improve the wavelength calibration. The higher resolution modes employ image slicing to balance seeing limitations with the goal of achieving high resolution observations.

On-telescope commissioning of the instrument took place over a one year period between November 2013-2014 and confirmed that the instrument met specification. Full science operation followed at the end of 2014 and the spectrograph has successfully provided data for a wide range of scientific programs since. However, the scientific productivity of the HRS has been limited by two main issues: 1) a lack of data reduction software for each of the modes and 2) poor understanding of the long term stability of the instrument. These two aspects have been intertwined, since the lack of reduction software prevented regular, long-term monitoring of the instrument characteristics.

In order to solve these two issues, we embarked on several focus projects to develop tools to reduce the data and to measure the quality of the observations. The primary reduction software for HRS is the pyhrs (https://github.com/saltastro/pyhrs) software package. pyhrs is a pure python package built on several open collaboration software packages, including the astropy affiliated package ccdproc for basic CCD reductions. The spectroscopic reductions were developed based on the PySALT data reduction package. The pyhrs package includes tools for basic CCD reductions, wavelength calibration, and spectral extraction. A number of tests and observations have since been carried out to further quantify the performance of the instrument and to evaluate the quality of the data products generated by the reduction software.

An additional set of tools has recently been developed to provide feedback about the quality and stability of calibration frames such as biases, arcs and flat-fields. The different frame types were interrogated to characterise key aspects of the HRS and they are now used, in conjunction with extensive logging of environmental data, to continuously monitor the health of the instrument. HRS parameters of interest include the overscan and bias levels, the responses of the two detectors, stray light, focus, system throughput and the all-important stability of the wavelength solution. With these tools in place, regular monitoring of the HRS characteristics could be incorporated into the SALT Dashboard (see Hettlage et al. 2016).

9908-99, Session PS1

CCD system upgrading of the Kyoto3DII and integral field spectroscopic observation with the new system

Kazuma Mitsuda, Yasuhito Hashiba, The Univ. of Tokyo (Japan); Yosuke Minowa, National Astronomical Observatory of Japan (United States); Yutaka Hayano, National Astronomical Observatory of Japan (Japan); Hajime Sugai, Atsushi Shimono, The Univ. of Tokyo (Japan); Kazuya Matsubayashi, Kyoto Univ. (Japan); Takashi Hattori, National Astronomical Observatory of Japan (United States); Yukiko Kamata, Shinobu Ozaki, National Astronomical Observatory of Japan (Japan); Mamoru Doi, Shigeyuki Sako, The Univ. of Tokyo (Japan)

Understanding the physical mechanisms governing the formation and evolution of galaxies is one of the most important topics in modern astronomy. Spatially resolved observation such as Integral Field Spectroscopy (IFS) is able to reveal important properties of galaxies for

instance the dynamics, energetics, and ionization structures. Kyoto3DII is an optical integral field spectrograph mounted on the Subaru telescope as a PI instrument. Using IFS data provided by Kyoto3DII, we have discussed scientific issues about the activities of active galactic nuclei, starburst galaxies, and interacting galaxies, including galactic winds, as well as their effects on galactic environments and galaxy evolution. We have also investigated the lensing galaxy structure including dark matter based on gravitational lensed quasar images.

Kyoto3DII was originally mounted at the Cassegrain focus of the Subaru telescope where the wide wavelength range coverage from 3600 to 9200 angstroms was available, but the spacial resolution was limited by seeing. Thanks to the excellent optical performance and fine spatial sampling, Kyoto3DII is capable of resolving small structures. To fully exploit the spatial resolution, Kyoto3DII was moved to the Nasmyth focus after the installation of AO188, the adaptive optics (AO) system of the Subaru telescope. Since then, Kyoto3DII has provided us unique opportunities of optical IFS with AO resolution.

As AO188 can improve the spatial resolution in the red wavelength region and the blue light is reflected by a dichroic mirror to the wavefront sensor for AO correction, the important observable wavelength with Kyoto3DII becomes 6200-9200 angstroms. However, the quantum efficiency of the CCD was low in the red wavelength region because it was optimized to the non-AO observations at the Cassegrain focus.

To optimize Kyoto3DII to AO observations, we have upgraded the CCD system, including CCD, readout system, dewar, and refrigerator. We have newly installed the red-sensitive Hamamatsu fully depleted CCD, which enhances the total efficiency by a factor of ~2 in the red wavelength range. Fringes are dramatically reduced thanks to the thick silicon layer. The readout system and refrigerator help us decrease the readout noise to 3.2-3.4e-, smaller by a factor of ~3 than that of the previous system. We carried out laboratory tests related to vacuum, cooling, and readout of the CCD. We installed the new system on Kyoto3DII, and completed the optical experiments with AO188 in May 2015.

We carried out engineering and scientific observations on September 23 and 24 in 2015. We observed two standard stars (V=9.5 and 9.2) in the Natural Guide Star (NGS) mode. We also observed four galactic nuclei of nearby galaxies, two of which were observed in NGS mode, and others in the Laser Guide Star (LGS) mode. We found the spatial resolution of ~0.1 arcsec FWHM by using the 9.5 magnitude standard star in NGS mode and ~0.2 arcsec in LGS mode estimated from the galactic nucleus. We will present the performance of Kyoto3DII with the new CCD system such as total efficiency based on the observational data.

9908-101, Session PS1

A new Cassegrain calibration lamp unit for the Blanco Telescope

Sean D. Points, David J. James, Roberto Tighe, Andrés Montané, Nicole David, Manuel Martínez, Cerro Tololo Inter-American Observatory (Chile)

The f/8 RC-Cassegrain Focus of the Blanco telescope at CTIO, hosts two new instruments: COSMOS, a multi-object spectrograph in the visible wavelength range (350-1030nm), and ARCoIRIS, a NIR cross-dispersed spectrograph featuring 6 spectral orders spanning 0.8 -2.4 microns. Here we describe a calibration lamp unit designed to deliver the required illumination at the telescope focal plane for both instruments. These requirements are: (1) an F/8 beam of light covering a spot of 100mm diameter (or 11 arcmin) for a wavelength range of ~350nm through 2.5um and (2) no saturation of flat-field calibrations for the minimal exposure times permitted by each instrument, and (3) few saturated spectral lines when using the wavelength calibration lamps for the instruments. To meet these requirements this unit contains an adjustable quartz halogen lamp for flat-field calibrations, and one hollow cathode lamp and four penray lamps for wavelength calibrations. The wavelength calibration lamps are selected to provide optimal spectral coverage for the instrument mounted and can be used individually or in sets. The device designed is based on an 8-inch diameter integrating sphere, the output of which is optimized to match the F/8 calibration input delivery system which is a refractive system based on fused-silica lenses. We describe the optical design, the opto-mechanical design, the electronic control and give results of the performance of the system.

9908-102, Session PS1

Commissioning and first observations with Wide FastCam at the Telescopio Carlos Sánchez

Sergio Velasco, Instituto de Astrofísica de Canarias (Spain); Urtats Etxegarai, IDOM Ingenieria y Consultoria S.A. (Spain); Alejandro Oscoz, Roberto L. López, Instituto de Astrofísica de Canarias (Spain); Gaizka Murga, IDOM Ingenieria y Consultoria S.A. (Spain)

The FastCam instrument platform, jointly developed by the IAC and the UPCT, allows, in real-time, acquisition, selection and storage of images with a resolution that reaches the diffraction limit of medium-sized telescopes. FastCam incorporates a specially designed software package to analyze series of tens of thousands of images in parallel with the data acquisition at the telescope.

Wide FastCam is a new instrument which, using the same software for data acquisition, do not look for lucky imaging, but fast observations in a much larger field of view. Wide FastCam uses a 1k x 1k EMCCD detector and different optics offering a ~8 arcmin FOV.

IDOM designed and supplied the optical bench integrating the main optical elements, except for the detector that was integrated at the IAC, in 2014. This paper describes the commissioning process and first observations with Wide FastCam at the Telescopio Carlos Sánchez (TCS) in the Teide Observatory.

9908-103, Session PS1

Damage and removal of the coating on the first lens of the MegaCam wide-field corrector

Gregory Barrick, Tom Benedict, Derrick Salmon, Canada-France-Hawaii Telescope (United States)

The coating on the exposed surface of the 810 mm diameter first element of the MegaCam wide-field corrector at the Canada-France-Hawaii Telescope (CFHT) was found to be degraded in the fall of 2014. An investigation showed that the coating was, in fact, damaged over a large part of the exposed surface and was causing major scattering, severely degrading the performance of the instrument. The coating was subsequently removed from the lens by CFHT, restoring the majority of the instrument performance. The investigation of the degradation and the procedure used to remove the coating will be described in this paper.

9908-104, Session PS1

Upgrade of the detector in the integral field spectrograph OSIRIS at the W. M. Keck Observatory

Anna Boehle, James E. Larkin, Univ. of California, Los Angeles (United States); Sean M. Adkins, W. M. Keck

Observatory (United States); Theodore Aliado, Michael P. Fitzgerald, Christopher A. Johnson, Univ. of California, Los Angeles (United States); James E. Lyke, W. M. Keck Observatory (United States); Kenneth G. Magnone, Ji Man Sohn, Eric Wang, Jason L. Weiss, Univ. of California, Los Angeles (United States)

We present the results of the upgrade of the spectrograph detector in the integral field spectrograph, OSIRIS. OSIRIS is a near-infrared (1 to 2.5 microns) integral field spectrograph on the Keck I telescope. This instrument produces up to 3,000 spectra simultaneously over a contiguous rectangular field of view with a spectral resolution of ~3,800. OSIRIS works with the Keck Adaptive Optics system to achieve diffraction-limited spatial resolution and has four plate scales ranging from 0.02 to 0.10 arcseconds. At first light in 2005, the spectrograph portion of the instrument was equipped with a Rockwell Hawaii-2 detector. We have now upgraded this to a Teledyne Hawaii-2RG (H2RG) with lower read noise, lower dark current, and higher quantum efficiency. In addition to the upgraded detector, we also mounted the detector head on a linear stage, allowing the position of the detector to be accurately adjusted along the optical path when the instrument is at cryogenic temperatures (~80 K).

9908-105, Session PS1

Optical design of the slit-viewing camera for the NIRSPEC upgrade

Emily C. Martin, Michael P. Fitzgerald, Ian S. McLean, Eric Wang, Univ. of California, Los Angeles (United States)

NIRSPEC is a 1-5 um medium and high-resolution echelle spectrograph for the Keck II telescope, currently being upgraded to replace detectors and electronics in the spectrograph and slit-viewing camera (SCAM). The existing SCAM design is limited to the 1-2.5 um regime and optimized for the PICNIC 256x256 40 um pixel array. The upgrade to a Teledyne H1RG 1024x1024 18 um pixel array will allow imaging of the slit from 1-5 um, increasing observing efficiency in the L and M bands. The extension of SCAM's wavelength coverage and significant decrease of the pixel size require a redesign of the SCAM system and allow for re-optimization of pixel sampling and field of view. We present opto-mechanical modeling of the SCAM design, optimized for the replacement detector. We discuss lens choices, anti-reflective coatings, and the addition of blocking filters to mitigate the high background levels in the thermal infrared.

9908-106, Session PS1

On-sky commissioning of Hamamatsu CCDs in GMOS-S

German Gimeno, Gemini Observatory (Chile); Katherine C. Roth, Kristin Chiboucas, Gemini Observatory (United States); Pascale Hibon, European Southern Observatory (Chile); Vinicius Placco, Univ. of Notre Dame (United States); Luc Boucher, Gemini Observatory (Chile); John K. White, Matthew J. Rippa, Gemini Observatory (United States); Kevin Hanna, SOFA / USRA (United States); Manuel Lazo, Gabriel R. Pérez, Rolando Rogers, Roberto Rojas, Gemini Observatory (Chile)

GMOS-S has been recently upgraded with Hamamatsu deep depletion CCDs replacing the original EEV detector array. The new CCDs have superior quantum efficiency (QE) at wavelengths longer than 680nm, with significant sensitivity extending beyond 1 micron. Furthermore, the fringing level in GMOS-S data is now much lower due to the much thicker CCDs, further improving delivered sensitivity above that afforded by quantum efficiency alone. Soon after the Hamamatsu CCDs were installed in June 2014, some issues were noticed that impacted some science programs. In particular, saturated stars or spectral features created bands of artifacts on the amplifier containing the saturated features. A bright glowing pixel rendered one of the amplifiers essentially useless for one of the amplifiers in long exposures. In addition, an intermittent noise issue caused significant problems for observations using the Nod & Shuffle mode. In October 2015 the ARC controller electronics were upgraded and a cable was replaced, and since then GMOS-S has again been taking science data with the Hamamatsu detectors with no sign of these previous unfortunate limitations. We present the results of the GMOS-S on-sky commissioning of the Hamamatsu detector array, and provide an update on the status of the GMOS-N portion of the project.

9908-107, Session PS1

Easy mounting interface for compact instruments at TNG

Adriano Ghedina, Luis Riverol, Fundación Galileo Galilei - INAF (Spain)

TNG is able to offer an F/11 Nasmyth focal station with an easy mount for small devices or compact instruments. One or more of the 5 slit masks at the focal plane of the LRS spectrograph can be removed in few minutes from the selector stage. A FoV of 9x9arcmin^2 is available and a small instrument can be mounted on a mechanical interface of 240x120mm on the sides. The size of the instrument along the optical axis is limited by the support of the collimation lens of the spectrograph.

This solution has already been used successfully for small devices like a CCD camera or a SH sensor and a compact instrument consisting of 3 Hamamatsu photometers. From 2016 one of the slits position will permanently host the folding optical relay for the GIARPS Instrument. This interface is an opportunity to test new instruments, prototypes or demonstrators in a not invasive or time consuming way at a 4m class telescope.

9908-108, Session PS1

A method for reducing atmospheric noise without chopping for ground-based mid-infrared observations

Tomohiko Nakamura, Takashi Miyata, Shigeyuki Sako, Takafumi Kamizuka, The Univ. of Tokyo (Japan); Kentaro Asano, Japan Aerospace Exploration Agency (Japan); Mizuho Uchiyama, National Astronomical Observatory of Japan (Japan); Kazushi Okada, The Univ. of Tokyo (Japan)

Fluctuation of atmospheric radiation causes serious noise in ground-based mid-infrared observations, especially at 20-micron or longer wavelengths. Chopping is a common and conventional technique to estimate the atmospheric emission at the time of imaging, by means of taking short exposures to the object and the sky alternately. This is effective if the chopping frequency is higher than the typical timescale of the sky turbulence (>2 Hz). However such high frequency chopping increases the overhead time and decreases the observing efficiency.

The fact that the chopping technique can reduce the atmospheric turbulence noise indicates that the difference of atmospheric emission between a few ten arcseconds is negligible in short time scale. Therefore the spatial structure of the atmospheric emission could be expressed as low-order models. Such approaches to reproduce the sky frame have been tried by some groups, but failed in making sufficient models with accuracy better than 1 part in 10,000.

We have found a method for estimating the sky frame empirically and removing the atmospheric noise effectively. In this method, a “good sky frame” is defined as the frame that has the same spatial pattern as the target frame. Since the atmospheric emission has not complicated spatial patterns and varies continuously, the good sky frame can be composed by the superposition of several sky frames. Specifically, we calculate weighted average coefficients that minimize the standard deviation of blank sky region on the sky-subtracted images. The coefficients can be found by solving an equation with the method of Lagrange multiplier. This is named as “weighting average method”.

The verification of this method has been conducted with applying to the actual observation data of MAX38 which is mounted on miniTAO 1-m telescope. The observed data of a standard star HD168625 has been processed in two ways. One is a conventional reduction; a simply averaged image of the off-source frames was subtracted from that of the on-source images. Another one is our new method, using only the on-source frames and weighted averaging instead of the simple averaging. The results clearly show that the residual patterns were reduced by the weighted average method. This is quite meaningful since the residual patterns by the atmospheric turbulence can be reduced without the chopping technique. This is very useful not only for improving the observing efficiency but also for taking images of extended objects larger than the chopping throw.

In this paper we will report the details of this weighting average method and demonstrate its performance against the practical observing data.

9908-109, Session PS1

SOFIA’s secondary mirror assembly: in-flight performance and control approach

Andreas Reinacher, Univ. Stuttgart (Germany); Yannick Lammen, Univ. of Stuttgart (Germany); Hans-Peter Röser, Univ. Stuttgart (Germany)

The Stratospheric Observatory for Infrared Astronomy (SOFIA) is a 2.5m infrared telescope built into a Boeing 747 SP. In 2014 SOFIA reached its Full Operational Capability milestone and nowadays takes off about three times a week to observe the infrared sky from altitudes above most of the atmosphere’s water vapor content.

An actively controlled 352mm SiC-Secondary Mirror is used for infrared chopping with peak-to-peak amplitudes of up to 10 arcmin and chop frequencies of up to 20Hz and also as actuator for fast pointing corrections.

The Swiss-made Secondary Mirror Mechanism (SMM) is a complex and highly integrated and compact flexure based mechanism that has been performing with remarkable reliability during recent years. Above mentioned capabilities are provided by the Tilt Chopper Mechanism (TCM) which is one of the two stages of the SMM. In addition the SMM it is also used to establish a collimated telescope and to adjust the telescope focus depending on the environmental temperature which ranges from about 40°C at takeoff in Palmdale, CA to about 40°C in the stratosphere. This is achieved with the Focus Center Mechanism (FCM) which is the base stage of the SMM on which the TCM is situated.

Initially the TCMwas affected by strong vibrations at about 300Hz which led to unacceptable image smearing.

After some adjustments to the PID-type controller it was finally decided to develop a completely new control algorithm in state space. This pole placement controller matches the closed loop system poles to those of a

Bessel filter with a corner frequency of 120Hz for optimal square wave behavior. To reduce noise present on the position sensors and to estimate the velocity a simple static gain Kalman Filter was designed and implemented.

A system inherent delay is incorporated in the Kalman filter design and measures were applied to counteract the actuators’ hysteresis. For better performance over the full operational temperature range and to represent an amplitude dependent non-linearity the underlying model adapts in real-time to those two parameters. This highly specialized controller was developed over the course of years and only the final design is introduced here.

The main intention of this paper is to present the currently achieved performance of the SOFIA chopper over the full amplitude, frequency, and temperature range. Therefore a range of data gathered during in-flight tests aboard SOFIA are displayed and explained. The SMM’s three main performance parameters are the transition times between two chop positions, the stability of the Secondary Mirror when exposed to the low pressures, low temperatures, aerodynamic, and aeroacoustic excitations present when the SOFIA observatory operates in the stratosphere at speeds of up to 850 km/h, and finally the closed-loop bandwidth available for fast pointing corrections.

9908-110, Session PS1

Development of the FPI+ as facility science instrument for SOFIA cycle four observations

Enrico Pfüller, Manuel Wiedemann, Jürgen Wolf, Alfred Krabbe, Univ. of Stuttgart (Germany)

The Stratospheric Observatory for Infrared Astronomy (SOFIA) is a heavily modified Boeing 747SP aircraft, accommodating a 2.7m infrared telescope. This airborne observation platform takes astronomers to flight altitudes of up to 13.7 km (45,000ft) and therefore allows an unobstructed view of the infrared universe at wavelengths between 0.3 μm and 1600 μm.

SOFIA is currently completing its third cycle of observations and utilizes seven different imaging and spectroscopic science instruments. New instruments for SOFIA’s cycle 4 observations, starting in February of 2016, are the High-resolution Airborne Wideband Camera-plus (HAWC+) and the Focal Plane Imager (FPI+). The latter is an integral part of the telescope assembly and is used on every SOFIA flight to ensure precise tracking on the desired targets. The FPI+ will be used as a visual-light photometer in its role as facility science instrument.

Since the upgrade of the FPI camera and electronics in 2013, it uses a thermoelectrically cooled science grade EMCCD sensor inside a commercial-off-the-shelf Andor camera. The back-illuminated sensor has a peak quantum efficiency of ~95% and the dark current is as low as 0.01 e-/pix/sec. With this new hardware the telescope has successfully tracked on 16th magnitude stars and thus the sky coverage, e.g. the areas of sky that have suitable tracking stars, has increased to 99%.

Before its use as an integrated tracking imager, the same type of camera has been used as a standalone diagnostic tool to analyze the telescope pointing stability at frequencies up to 200 Hz (imaging with 400 fps). These measurements helped to improve the telescope pointing control algorithms and therefore reduce the image jitter in the focal plane. Science instruments benefit from this improvement with smaller image sizes for longer exposure times.

The FPI has also been used to support astronomical observations like stellar occultations by the dwarf planet Pluto and a number of exoplanet transits. Especially the observation of the occultation events benefit from the high camera sensitivity, fast readout capability and the low read noise and it was possible to achieve high time resolution on the photometric light curves.

This paper will give an overview of the development from the standalone diagnostic camera to the upgraded guiding/tracking camera, fully integrated into the telescope, while still offering the diagnostic capabilities and finally to the use as a facility science instrument on SOFIA.

9908-18, Session 5

The Gemini Planet Imager: first years on the sky *(Invited Paper)*

Bruce A. Macintosh, Stanford Univ. (United States)

The Gemini Planet Imager (GPI) is first facility-class high-contrast imaging system operational on the Gemini South telescope. It combines a high-order adaptive optics system with an apodized-pupil Lyot coronagraph and a low spectral resolution integral field spectrograph. After first light in late 2013, GPI began science operations. The GPI Exoplanet Survey has observed 150 stars and produced a large database of instrument performance metrics such as contrast, both in individual images and after post processing, together with adaptive optics telemetry and environmental conditions such as tau0 and r0, allowing us to explore the factors determining contrast. We present an evaluation of system performance after 2 and a half years on the sky, with science highlights, lessons learned, and areas for potential future improvement.

9908-19, Session 5

SPHERE: on-sky results

Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Markus Feldt, Max-Planck-Institut für Astronomie (Germany); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, ONERA (France); Markus E. Kasper, European Southern Observatory (Germany); François Wildi, Observatoire de Genève (Switzerland); Anne Costille, Lab. d'Astrophysique de Marseille (France); Gaël Chauvin, Institut de Planétologie et d'Astrophysique de Grenoble (France); Jean-François Sauvage, ONERA (France); Andrea Baruffolo, Bernardo Salasnich, INAF - Osservatorio Astronomico di Padova (Italy); Maud P. Langlois, Ctr. de Recherche Astronomique de Lyon (France); Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Raffaele G. Gratton, Riccardo U. Claudi, INAF - Osservatorio Astronomico di Padova (Italy); Hans Martin Schmid, ETH Zürich (Switzerland); Ronald Roelfsema, Johan H. Pragt, ASTRON (Netherlands); Norbert Hubin, Christian Soenke, Marcos Suarez, European Southern Observatory (Germany); Patrice Martinez, Lab. J.L. Lagrange (France); Julien H. V. Girard, European Southern Observatory (Chile); Anthony Boccaletti, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Anne-Marie Lagrange, Institut de Planétologie et d'Astrophysique de Grenoble (France); Thomas Henning, Max-Planck-Institut für Astronomie (Germany); Claire Moutou, Lab. d'Astrophysique de Marseille (France); François Ménard, Institut de Planétologie et d'Astrophysique de Grenoble (France); Carsten Dominik, Univ. van Amsterdam (Netherlands); Massimo Turatto, INAF - Osservatorio Astronomico di Padova (Italy); Stéphane Udry, Observatoire de Genève (Switzerland); Farrokh Vakili, Lab. J.L. Lagrange (France)

SPHERE (Spectro-Polarimetric High-contrast Exoplanet Research in Europe) is a second-generation instrument for the ESO Very Large Telescope (VLT) dedicated to the direct detection and spectral characterization of giant extra-solar planets, which is one of the most exciting but also one of the most challenging areas in modern astronomy due to the very large contrast between the host star and the planet at very small angular separations. SPHERE combines an extreme adaptive optics system, various coronagraphic devices and a suite of focal instruments providing imaging, integral field spectroscopy and polarimetry capabilities in the visible and near-infrared spectral ranges. After 10 years of development, SPHERE obtained its first light in May 2014, has been successfully commissioned at the VLT during the past year and is now offered to the community since April 2015. We will give an overview of the science objectives and main instrument features, review the performance achieved during the commissioning period and present some highlights of the first science results.

9908-20, Session 5

Very high-contrast performances status with the infrared differential imager and spectrograph for SPHERE

Maud P. Langlois, Ctr. de Recherche Astronomique de Lyon (France); Anne-Marie Lagrange, Institut de Planétologie et d'Astrophysique de Grenoble (France); Anthony Boccaletti, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); consortium SPHERE, CNRS-IPAG (France)

SPHERE (Spectro-Polarimetric High-contrast Exoplanet Research) is a second-generation instrument for the VLT, optimized for very high-contrast imaging around bright stars. Its primary goal is the detection and characterization of new giant planets around nearby stars, together with the observation of early planetary systems and disks. The Infrared Dual Imager and Spectrograph (IRDIS), one of the three SPHERE subsystems, providing dual-band imaging in the near-infrared, among with other observing modes such as long slit spectroscopy, classical imaging and infrared polarimetry, is able to achieve extremely high contrast with the help of extreme-AO turbulence compensation, coronography, exceptional image quality, very accurate calibration strategies and advanced data processing. The SPHERE garanteed time Survey observations has started early 2015, and so far approximately 150 stars have already been observed. IRDIS achieves the sensitivity and resolution compatible with detection planetary companions with separations of 0.2" to 1" around a very large set of selected stars. We will review the high contrast performances achieved at this stage of the GTO observations with IRDIS/SPHERE and we will highlight the main results obtained during this first year of operation.

9908-21, Session 5

AOLI: near-diffraction limited imaging in the visible on large ground-based telescopes

Craig D. Mackay, Univ. of Cambridge (United Kingdom); Rafael Rebolo, Instituto de Astrofísica de Canarias (Spain); David M. P. King, Univ. of Cambridge (United Kingdom); Roberto Lopez, Marta Puga, Instituto de Astrofísica de Canarias (Spain); Antonio Pérez Garrido, Carlos Colodro, Univ. Politécnica de Cartagena (Spain); Juan Jose Valdivia, Univ. de La Laguna (Spain); Luis Fernando Rodrigo-Ramos, Sergio Velasco, Instituto de Astrofísica de Canarias (Spain); Lucas Labadie, Balaji Muthusubramanian, Univ. zu Köln (Germany); José Manuel Rodríguez Ramos, Univ. de La Laguna (Spain); Alejandro

Oscoz, Instituto de Astrofísica de Canarias (Spain)

AOLI (Adaptive Optics Lucky Imager) is the first of a new class of instruments intended to deliver near-diffraction limited images in the visible on 4-10 meter class ground-based telescopes. It builds on the experience gained on the Palomar 5 m telescope that delivered images in the visible with a resolution approximately 3 times that of the Hubble space telescope. AOLI uses a combination of Lucky Imaging with an array of photon counting EMCCDs, together with low order adaptive optics. A key requirement for AOLI is the ability to work with very faint natural guide stars over much of the sky. A novel design of wavefront sensor uses a near-pupil plane curvature sensor that allows the use of very faint natural guide stars. At present, AOLI is configured to use a geometric wavefront sensor which gives relatively high order correction with bright reference stars but even with very faint (~17m in I band) will allow significant low order correction. This allows the system to be operated over much of the sky even at high galactic latitudes. Such an instrument will be key to providing extremely high resolution images in the visible in the post-Hubble era. This paper will report on the current status of the instrument as well as early results from the first observing run on the WHT 4.2 m telescope on La Palma. Future plans envisage the transfer of AOLI to the GTC 10.5 m telescope on La Palma which should deliver images with a resolution in the region of 20 milliarcseconds in I band under median seeing conditions.

9908-22, Session 5

LINC-NIRVANA at LBT: final preparations for first light

Thomas M. Herbst, Max-Planck-Institut für Astronomie (Germany); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Thomas Bertram, Peter Bizenberger, Florian Briegel, Ralph Hofferbert, Martin Kürster, Max-Planck-Institut für Astronomie (Germany)

We present an update on LINC-NIRVANA (LN), an innovative, high-resolution infrared imager for the Large Binocular Telescope (LBT). LN employs Multi-Conjugate Adaptive Optics (MCAO) to deliver a diffraction-limited field of view two arcminutes across, although the current science camera field is considerably smaller. LINC-NIRVANA actually has two identical MCAO systems, one for each of the 8.4 m mirrors of the LBT. The instrument accepts light from both telescopes and is designed for incoherent overlap or interferometric beam combination with off-axis fringe tracking. When implemented, the latter mode will provide panoramic Fizeau-mode imagery over much of the sky with the 10 mas spatial resolution corresponding to a 23-meter diameter telescope.

Since the last SPIE, the LINC-NIRVANA team has completed lab integration, system level tests, and preparation of the early science plan. This effort culminated in Preliminary Acceptance Europe in May 2015, followed by several months of final testing, disassembly and shipping. We report on these efforts with a focus on laboratory performance demonstration and testing of the various AO loops in the lab and on-sky.

LINC-NIRVANA is now in the mountain laboratory at the Large Binocular Telescope undergoing final alignment and testing prior to first on-sky measurements in Fall 2016. An initial craning and fit-test in November 2015 placed the instrument on the telescope itself within the capture range of the LBT bulk optics. Transportation and installation of such a large, complex instrument involved 10 shipping containers holding more than 35 tonnes of hardware. Executing the move from Europe to Arizona presented a number of challenges. We report on several technical and logistical issues that are very relevant to the next generation of extremely large telescopes.

Bringing LINC-NIRVANA into operation will involve a hierarchical sequence of internal instrument alignment, followed by alignment of the telescope, and finally on-sky verification and commissioning. We report on this strategy and its interaction with the Early Science plan, which has been designed to maximize the astronomical return of the instrument during this complicated phase between installation and routine operations.

9908-23, Session 6

Laboratory testing and commissioning of the CHARIS integral field spectrograph

Tyler D. Groff, N. Jeremy Kasdin, Michael Galvin, Gillian R. Knapp, Michael A. Carr, Princeton Univ. (United States); Timothy D. Brandt, Institute for Advanced Study (United States); Mary Anne Peters-Limbach, Craig P. Loomis, Norman Jarosik, Princeton Univ. (United States); Olivier Guyon, Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Masahiko Hayashi, Subaru Telescope, National Astronomical Observatory of Japan (Japan)

The Coronagraphic High Angular Resolution Imaging Spectrograph (CHARIS) is an integral field spectrograph (IFS) that has been built for the Subaru telescope. CHARIS has two imaging modes; the ‘high-resolution’ mode is R82, R69, and R82 in J, H, and K bands respectively while the ‘low-resolution’ discovery mode uses a second ‘low-resolution’ prism with R19 spanning 1.15-2.37 microns (J+H+K bands). The discovery mode is meant to augment the low inner working angle of the Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) adaptive optics system, which feeds CHARIS a coronagraphic image. The goal is to detect and characterize brown dwarfs and hot Jovian planets down to contrasts five orders of magnitude dimmer than their parent star at an inner working angle as low as 80 milliarcseconds. CHARIS constrains spectral crosstalk through several key aspects of the optical design. Additionally, the repeatability of alignment of certain optical components is critical to the calibrations required for the data pipeline. Specifically the relative alignment of the lenslet array, prism, and detector must be highly stable and repeatable between imaging modes. We report on the measured repeatability and stability of these mechanisms, measurements of spectral crosstalk in the instrument, and the propagation of these errors through the data pipeline. Another key design feature of CHARIS is the prism, which pairs Barium Fluoride with Ohara L-BBH2 high index glass. The dispersion of the prism is significantly more uniform than other glass choices, and the CHARIS prisms represent the first NIR astronomical instrument that uses L-BBH2 as the high index material. This material choice was key to the utility of the discovery mode, so significant efforts were put into cryogenic characterization of the material. The final performance of the prism assemblies in their operating environment is described in detail. The spectrograph is going through final alignment, cryogenic cycling, and is being delivered to the Subaru telescope in April 2016. This paper is a report on the laboratory performance of the spectrograph, and its current status in the commissioning process so that observers will better understand the instrument capabilities. We will also discuss the lessons learned during the testing process and their impact on future high-contrast imaging spectrographs for wavefront control.

9908-24, Session 6

FRIDA: diffraction-limited imaging and integral-field spectroscopy for the GTC

Alan M. Watson, Univ. Nacional Autónoma de México (Mexico); José A. Acosta-Pulido, Instituto de Astrofísica de Canarias (Spain); Luis C. Álvarez-Núñez, Univ. Nacional Autónoma de México (Mexico); Vicente Bringas-Rico, Ctr. de Ingenieria y Desarrollo Industrial (Mexico); Nicolás Cardiel, Univ. Complutense de Madrid (Spain); Salvador Cuevas Cardona, Oscar Chapa, Univ. Nacional

Autónoma de México (Mexico); José Javier Díaz García, Instituto de Astrofísica de Canarias (Spain); Stephen S. Eikenberry, Univ. of Florida (United States); Carlos Espejo, Rubén A. Flores-Meza, Jorge Fuentes-Fernández, Univ. Nacional Autónoma de México (Mexico); Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); José Leonardo Garcés Medina, Univ. Nacional Autónoma de México (Mexico); Francisco Garzón López, Instituto de Astrofísica de Canarias (Spain); Peter Hammersley, European Southern Observatory (Germany); Ana Carolina Keiman, Gerardo Lara, José Alberto López, Univ. Nacional Autónoma de México (Mexico); Pablo L. López, Instituto de Astrofísica de Canarias (Spain); Diana Lucero, Ctr. de Ingenieria y Desarrollo Industrial (Mexico); Heidy Moreno Arce, Instituto de Astrofísica de Canarias (Spain); Sergio Pascual Ramirez, Univ. Complutense de Madrid (Spain); Jesús Patrón Recio, Almudena Prieto, Instituto de Astrofísica de Canarias (Spain); Alberto José Rodríguez, Ctr. de Ingenieria y Desarrollo Industrial (Mexico); José Marco de la Rosa, Instituto de Astrofísica de Canarias (Spain); Beatriz Sánchez, Univ. Nacional Autónoma de México (Mexico); Jorge A. Uribe, Ctr. de Ingenieria y Desarrollo Industrial (Mexico)

FRIDA is a diffraction-limited imager and integral-field spectrometer that is being built for the adaptive-optics focus of the Gran Telescopio Canarias. FRIDA has been designed and is being built as a collaborative project between institutions from México, Spain and the USA. In imaging mode FRIDA will provide scales of 0.010, 0.020 and 0.040 arcsec/pixel and in IFS mode spectral resolutions of 1000, 4000 and 30,000. FRIDA is starting systems integration and is scheduled to complete fully integrated system tests at the laboratory by the end of 2017 and be delivered to GTC shortly after. In this contribution we present a summary of its design, fabrication, current status and potential scientific applications.

9908-25, Session 6

Three years of harvest with the vector vortex coronagraph in the thermal infrared

Olivier Absil, Univ. de Liège (Belgium); Dimitri Mawet, California Institute of Technology (United States); Mikael Karlsson, Uppsala Univ. (Sweden); Denis Defrère, Univ. de Liège (Belgium); Christian Delacroix, Cornell Univ. (United States); Bruno Femenia Castella, W. M. Keck Observatory (United States); Julien H. V. Girard, European Southern Observatory (Chile); Philip M. Hinz, The Univ. of Arizona (United States); Elsa Huby, Univ. de Liège (Belgium); Keith Y. Matthews, California Institute of Technology (United States); Eric J. Pantin, CEA-Ctr. de SACLAY (France); Gene Serabyn, Jet Propulsion Lab. (United States); Konrad Tristram, European Southern Observatory (Chile); Peter L. Wizinowich, W. M. Keck Observatory (United States); Brunella Carlomagno, Valentin Christiaens, Univ. de Liège (Belgium); Pontus Forsberg, Uppsala Univ. (Sweden); Carlos A. Gomez Gonzalez, Serge Habraken, Aïssa Jolivet, Univ. de Liège (Belgium); Julien Milli, European Southern Observatory (Chile); Pierre Piron, Maddalena Reggiani, Jean Surdej, Ernesto Vargas Catalan, Olivier Wertz, Univ. de Liège (Belgium)

Vector vortex coronagraphy is one of the most promising techniques to reach the long-term goal of imaging Earth-like exoplanets in the habitable zone of nearby main sequence stars. In their most basic version, vector vortex coronagraphs (VVC) are based on the use of a vortex phase mask (helical phase ramp) in a focal plane, followed by a Lyot stop in a downstream pupil plane. They feature a very small inner working angle, a high throughput, a 360° degree discovery space, and can work on broadband filters. For about 10 years, our team has been developing an implementation of the vortex phase mask based on concentric sub-wavelength gratings, referred to as the Annular Groove Phase Mask (AGPM). Sub-wavelength gratings produce form birefringence, which we use to synthesize a helical phase ramp for the two polarization states of light separately. Synthetic diamond was chosen as an appropriate material to produce these devices, thanks to its superb optical, mechanical and thermal properties. Because the grating period scales with the observing wavelength, we have started for technical reasons with the production of AGPMs for the thermal infrared, which ranges between 3 and 13 microns. First science-grade AGPMs were produced in 2012, and were soon installed on state-of-the-art infrared cameras, including VLT/NACO and VLT/VISIR (installation in 2012), LBT/LMIRCam (2013), and Keck/NIRC2 (2015). Here, we report on the first scientific results and on-sky performance of our thermal infrared vortex coronagraphs on these four cameras, and on the lessons learned from the first three years of on-sky operations (2013-2016). More specifically, we will describe how the vortex coronagraph performance depends on the design of the various telescopes and instruments, and on wave front quality delivered by the adaptive optics system (where available). We will discuss the efforts that have been undertaken to streamline the observing sequence, including the acquisition of the star and the chopping/nodding needs, as well as the implementation of our real-time pointing algorithm based on the science images. The importance of non-common path aberrations will be illustrated. Finally, we will discuss the perspectives for AGPMs, including operations at shorter wavelengths, adaptation to higher topological charges for reduced sensitivity to pointing errors, combination with optimal pupil-plane apodization, and applications on future extremely large telescopes.

9908-27, Session 6

Efficiently feeding single-mode fiber photonic spectrographs with an extreme adaptive optics system: on-sky characterization and preliminary spectroscopy

Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Nick Cvetojevic, The Univ. of Sydney (Australia); Christian Schwab, Macquarie Univ. (Australia); Barnaby R. Norris, The Univ. of Sydney (Australia); Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States); Simon Gross, Macquarie Univ. (Australia); Christopher H. Betters, The Univ. of Sydney (Australia); Garima Singh, Jet Propulsion Lab. (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States); Frantz Martinache, Observatoire de la Côte d'Azur (France); Peter Tuthill, The Univ. of Sydney (Australia)

Extreme adaptive optics systems enabling >90% Strehl ratios in the H band are now operational. Although primarily designed for high-contrast imaging, the compact point-spread-function and flat wavefront are also ideal for coupling into single-mode photonic devices efficiently. Photonic technologies operate at the diffraction-limit and so although they offer

numerous advanced functionalities like spatial and spectral filtering, they have thus far been greatly overlooked in next generation instrumentation owing to the difficulty with efficiently coupling light into them.

To address this concern we have built a fiber injection behind the extreme AO system inside the SCExAO instrument at the Subaru Telescope. The system includes custom pupil apodization optics which reformat the light in order to eliminate the 82% coupling efficiency limit between an Airy pattern and a Gaussian beam, a long standing problem when coupling from a telescope. We utilize the low order wavefront sensor in SCExAO which offers sub-millarcsecond pointing to keep the beam well registered with respect to the core of the fiber. We show that in laboratory characterization with a turbulence simulator we can achieve coupling efficiencies approaching 80% in the H-band when the wavefront error is in the extreme AO correction regime.

To take advantage of this highly efficient fiber feed, we utilize a compact spectrograph based on an arrayed waveguide grating (AWG). This is a spectrograph contained on a single photonic chip measuring only several square centimeters in size. The single mode fiber is bonded directly to the chip and the output reimaged on to a detector with two lenses and a prism as a cross-dispersor. This simple and compact spectrograph offers a R~3000-5000 in the J/H bands and has a very high transmission of 44+/-3%.

In this body of work we present the on-sky results and full characterization of our fiber injection setup behind the ExAO system in SCExAO in the NIR. In addition we demonstrate the on-sky performance of the extremely efficient AWG-based photonic spectrograph and show numerous on-sky spectra collected of calibrator and post AGB stars.

9908-28, Session 6

The Balloon Experimental Twin Telescope for Infrared Interferometry (BETTII): towards the first flight

Maxime J. Rizzo, Univ. of Maryland, College Park (United States); Stephen A. Rinehart, Dale J. Fixsen, NASA Goddard Space Flight Ctr. (United States); Peter A. R. Ade, Cardiff Univ. (United Kingdom); Dominic J. Benford, NASA Goddard Space Flight Ctr. (United States); Arnab Dhabal, Univ. of Maryland, College Park (United States); Roser Juanola-Parramon, NASA Goddard Space Flight Ctr. (United States); Matthew J. Griffin, Cardiff Univ. (United Kingdom); David T. Leisawitz, Stephen F. Maher, John E. Mentzell, NASA Goddard Space Flight Ctr. (United States); Lee G. Mundy, Univ. of Maryland, College Park (United States); Andreas Papageorgiou, Enzo Pascale, Cardiff Univ. (United Kingdom); Henry P. Sampler, NASA Goddard Space Flight Ctr. (United States); Giorgio Savini, Univ. College London (United Kingdom); Elmer H. Sharp III, Robert F. Silverberg, Johannes G. Staguhn, Todd J. Veach, Jordi Vila, NASA Goddard Space Flight Ctr. (United States)

The Balloon Experimental Twin Telescope for Infrared Interferometry (BETTII) features two 50-cm collectors separated by 8 meters and a cryogenic beam-combining instrument at the center of a carbon fiber and steel truss. The instrument will enable spatially-resolved spectroscopy of nearby, bright star-forming clusters. We should be able to reach 0.5-1" spatial resolution between 30 and 90 microns. We will present the context for the instrument, as well as its significance in NASA's efforts to achieve higher angular resolution at all wavelengths.

The SPIE conference will happen 1 month before the payload needs to be ready to ship for the launch site in Fort Sumner, New Mexico, USA, in order to fly during the Fall 2016 campaign. We will report on some key design aspects of the payload, that were chosen to mitigate major challenges. We will discuss technical topics among the following: thermal design and materials selection, aluminum optics manufacturing, alignment procedures and techniques, detector design, momentum control mechanisms, flight electronics, attitude estimation and control, and embedded software.

We will present recent results from the alignment and testing campaign in all of these various areas.

9908-29, Session 7

Opening a new window on the southern stars for less money: PAIX the first Antarctica polar mission photometer *(Invited Paper)*

Merieme Chadid, Jean Vernin, Lyu Abe, Abdelkarim Agabi, Observatoire de la Côte d'Azur (France); Li Yong Liu, Yongqiang Yao, National Astronomical Observatories (China); Éric Aristidi, Observatoire de la Côte d'Azur (France)

Stellar pulsations and Asteroseismogy are currently among the fundamental techniques to improve our understanding of the internal structure of stars and the hydrodynamics of their atmosphere. On the observational side, progress is limited by the data accuracy needed to detect numerous modes of oscillations with small amplitudes and by the discontinuous nature of typical ground-based data strings which often introduce ambiguities in the determination of oscillation frequencies. Space missions such as MOST, CoRoT and KEPLER enable to overcome both difficulties, and indeed have considerably enhanced the scope of pulsation and Asteroseismology methods. However, the outcome of the space missions on the stellar oscillation fields shows large gaps in terms of flexibility during the observing runs, the choice of targets, the repair of failures and the inexorable high costs. Now the time has come to implement a new way to study the stellar oscillations with long uninterrupted and continuous observations over 150 days from the ground. South polar site –Dome Charlie– the great image quality and the high time coverage with PAIX -Photometer AntarctIca eXtinction-. This programme is made of the low–cost commercial components, and achieves astrophysical measurement time-series of stellar pulsation fields, challenging photometry from space. PAIX gives new insight to cope with unresolved stellar enigma and stellar oscillation challenges and offers a great opportunity to benefit from an access to one of the best astronomical site on Earth –Dome Charlie– where the seeing reaches a median value of 1 arcsec during the polar night. PAIX is attached to the Cassegrain focus of a 40-cm Ritchey-Chrétien optical telescope, with a F/D ratio of 10, located at Dome C in the open field, without any shelter, installed at ice level. PAIX challenges space telescopes and even has more advantages than CoRoT and KEPLER in observing in UBVRI bands and then collecting multicolor light curves simultaneously of several targets within the same 12.4 x 8.3 arcmin field of view.

PAIX has been antarctized to run under extreme weather conditions with temperatures as low as -80 deg.C, and has been robotized, designed and built by PaixTeam whose operating headquarters are located at Universié de Nice Sophia–Antipolis and Observatoire de la Côte d'Azur.

In this talk, we describe the first polar mission PAIX -Photometer AntarctIca eXtinction- and the first outcome of stellar pulsation from the heart Antarctica during 1 polar night. We briefly discuss our new results and perspectives on the polar instrumentation development and stellar evolution from Antarctica, especially the connection between temporal hydrodynamic phenomena and cyclic modulations and how PAIX challenges space telescopes and even has more advantages in observing in UBVRI bands and then collecting multicolor photometric measurements. Finally, we highlight the impact of PAIX -the robotic Antarctica photometer- on the stellar pulsation and evolution study.

9908-30, Session 7

Six winters of photometry from Dome C, Antarctica: challenges, improvements, and results from the ASTEP experiment

Nicolas Crouzet, Dunlap Institute for Astronomy & Astrophysics (Canada) and Univ. of Toronto (Canada); Djamel Mékarnia, Tristan Guillot, Lyu Abe, Abdelkarim Agabi, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France) and Observatoire de la Côte d'Azur (France); Jean-Pierre Rivet, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France); Yan Fantéï-Caujolle, Lab. J.L. Lagrange (France) and Observatoire de la Côte d'Azur (France); Carole Gouvret, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France) and Observatoire de la Côte d'Azur (France); Thomas Fruth, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Mauro Barbieri, Univ. de Atacama (Chile); Daniel Bayliss, Observatoire de Genève (Switzerland); George Zhou, The Australian National Univ. (Australia); Éric Aristidi, Judit Szulágyi, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France) and Observatoire de la Côte d'Azur (France); Anders Erikson, Heike Rauer, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Erick Bondoux, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France) and Observatoire de la Côte d'Azur (France); Zalpha Challita, Aix-Marseille Univ. (France) and Lab. d'Astrophysique de Marseille (France); François Fressin, Harvard-Smithsonian Ctr. for Astrophysics (United States); Franck Valbousquet, Optique et Vision (France); Serge Bonhomme, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France); François Bouchy, Institut d'Astrophysique de Paris (France); Jérôme Gerakis, Lab. J.L. Lagrange (France) and Univ. de Nice Sophia Antipolis (France); Guillaume Bouchez, Univ. de Versailles Saint Quentin en Yvelines (France)

ASTEP (Antarctica Search for Transiting ExoPlanets) is a pilot project that aims at searching and characterizing transiting exoplanets from Dome C in Antarctica and to qualify this site for photometry in the visible. The uninterrupted night during the Antarctic winter and the favorable atmospheric conditions are highly beneficial to time-series photometric observations. Two instruments were installed at Dome C and ran during the winters between 2008 and 2013. The first instrument, ASTEP South, is a fixed 10 cm lens and CCD camera system placed in a thermalized box pointing continuously towards a 3.88° x 3.88° field of view centered on the celestial South pole. The second instrument, ASTEP400, is a pointable 40 cm Newton telescope with a 1° x 1° field of view equipped with a science CCD camera and a guiding system, designed and built by our team to achieve high precision photometry under the extreme conditions of the Antarctic winter. The analysis of the data collected by ASTEP South and ASTEP400 over four winters each, with two overlapping winters, is nearly complete. In this paper, we present the technical challenges, solutions, and limitations of these instruments in light of the quality of the extracted lightcurves. By observing a single field continuously during four winters, ASTEP South provides a unique and uniform database that allows us to monitor the photometric quality as a function of meteorological and instrumental parameters. On the other hand, pointing the ASTEP400 telescope at different fields of view over the winters yields precious information on operating and automatizing an optical telescope in Antarctica. We investigate correlations between instrumental and external parameters in order to understand the behavior of the instruments. We detail issues and improvements made over the years and their impact on the operations and quality of the data. We show that instruments installed on the ice are stable and have a negligible motion over several winters. We show that with very large and rapid fluctuations of the ambient temperature, thermalizing and controlling the temperatures at various locations on the instruments is crucial to achieve photometric stability. We show that seeing fluctuations at the ground level strongly affect the photometry, and we suggest ways to overcome this issue. We demonstrate the quality of Dome C for photometry in the visible from the lightcurves themselves using the large ASTEP South database. We present logistical improvements made to the Concordia station during these years that helped running the ASTEP experiment and will be crucial for future telescopes installed at this location. Finally, we summarize the observation strategies and the key scientific results obtained by the ASTEP project. These results demonstrate the quality of Dome C for transiting exoplanet observations and for photometry in general, and will help identify the most relevant science cases for future instruments at Dome C. Based on the ASTEP experience, we also suggest ways to fully exploit the potential of this unique observing site, focusing on exoplanet science. Overall, results from the ASTEP experiment will serve as a basis to design and operate future optical and near infrared telescopes in Antarctica.

9908-31, Session 7

GLUT: a balloon-borne high-cadence UV monitoring telescope for supernova shock breakouts and exoplanet atmospheres

Rob Sharp, Bradley Tucker, The Australian National Univ. (Australia)

(300 mm primary) on a series of long-duration high-altitude balloon flights. The wide field camera (7 square degrees) will perform high cadence (10-120 second rolling integrations) each "night" for campaign durations of three to six months. The principle science mission is the early-time detection of supernova shock-breakout at near-UV wavelengths. Additionally, early design analysis has shown the system is also able to probe the atmospheric composition of exoplanet atmospheres through the combination of UV transit measurements with ground-based measurements at longer wavelengths. In this presentation we will present the suitability of a long-duration balloon platform for such a mission, focusing on the necessary mission requirements (sensitivity, sky coverage, cadence etc.) and the available platform suitability. Particular attention is payed to platform stability, and, the accessible wavelength range as a function of flight altitude and atmospheric transmission.

9908-32, Session 7

The Evryscope: developing the cameras for the first full-sky gigapixel-scale telescope

Jeffrey Ratzloff, Nicholas M. Law, Octavi Fors, Philip Wulfken, The Univ. of North Carolina at Chapel Hill (United States)

The Evryscope is a new type of telescope which covers the entire accessible sky in each exposure. Its 8000-square-degree field-of-view 691 MPix telescope is sensitive to exoplanet transits and other short

timescale events not discernible from existing large-sky-area astronomical surveys. The telescope, which places 24 separate individual telescopes into a common mount which tracks the entire accessible sky with only one moving part, is building 1%-precision, many-year-length, high- cadence light curves for every accessible object brighter than ~16th magnitude. The camera readout times are short enough to provide near-continuous observing, with a 97% survey time efficiency. The Evryscope has the largest survey grasp of any current ground-based survey, and is the only existing survey within an order of magnitude of LSST's étendue. We deployed the Evryscope, funded by NSF/ATI, at CTIO in late May 2015.

We will present the overall instrument design, in particular detailing the design of our new "Robotilter" camera units, which provide robotic four-degree-of-freedom image quality optimization using low-cost and robust components suitable for our 24-camera deployment. The Evryscope now has over 100 actuators, all under full robotic control, and we will present the challenges and solutions for operating such a complex instrument.

The Evryscope is producing a night-by-night two-minute cadence record of all Southern sky events down to at least 16th magnitude, enabling searches for rapid-timescale variability phenomena ranging from exoplanet transits to gamma-ray-bursts. The system's enormous field of view allows us to simultaneously monitor very large numbers of targets that would otherwise require individual targeting by dedicated telescopes. The Evryscope is sensitive to transiting exoplanets around white dwarfs, M-dwarfs, and the nearest and brightest stars, and is the first to be able to rapidly monitor most of the sky for nearby-star microlensing events. The Evryscope obtains precise and high-cadence eclipse timing for all Southern eclipsing binaries brighter than 16th magnitude, simultaneously monitors a host of compact-object pulsation and accretion phenomena, and is searching for young stars by their photometric activity. When relatively rare transients events occur, such as gamma-ray bursts (GRBs), nearby supernovae, or even gravitational wave detections from the Advanced LIGO/Virgo network, the telescope will return minute-by-minute light curves and upper limits without needing pointing towards the event as it occurs. By co-adding images, the system will reach V?18 in one-hour integrations, enabling the monitoring of faint objects. Finally, by recording all data, the Evryscope will be able to provide pre-event imaging at two-minute cadence for bright transients and variable objects, enabling the first high-cadence searches for optical variability before, during and after rapid events detected at other wavelengths. The system has already produced hundreds of thousands of images and over 20TB of data, is meeting our image quality goals, and is achieving at least 5 mmag photometric precision in light curves. We will also present our plans for further development: a Polar Evryscope which takes advantage of the continuous winter darkness in the Arctic and Antarctic to achieve much higher detection efficiency for long-period exoplanets, and larger-aperture systems which would be capable of rapidly detecting faint extragalactic events.

9908-26, Session PS2

Near-Infrared Imaging Spectro-polarimeter (NIRIS) of the New Solar Telescope at Big Bear Solar Observatory

Wenda Cao, Kwangsu Ahn, Nicolas Gorceix, Sergey Shumko, Philip R. Goode, Big Bear Solar Observatory (United States)

Near InfraRed Imaging Spectro-polarimeter (NIRIS) has been outfitted to the 1.6-meter New Solar Telescope (NST) in at Big Bear Solar Observatory (BBSO) which is the largest aperture solar telescope. NIRIS offers unprecedented high resolution spectroscopic and polarimetric imaging data of the solar atmosphere from the deepest photosphere through the base of the corona. With the aid of the BBSO adaptive optics (AO) system, the spatial resolution is close to the diffraction limit of the NST. The spectroscopic cadence reaches one second, while polarimetric measurements, including Stokes I, Q, U, V profiles, remain at a better than 20 s cadence. Polarization sensitivity is expectedto be reach ? 10^{?4}Ic. NIRIS covers a broad spectral range from 1.0 to 1.7 micron, with particular attention to two unique spectral lines: the FeI 1565 nm doublet has already proven to be the most sensitive to Zeeman effect for probing the magnetic field in the deepest photosphere; the HeI 1083 nm multiplet is one of the best currently available diagnostic of upper chromospheric magnetic fields that allows one to map the vector field at the base of the corona. NIRIS is built on dual Fabry-Pérot Interferometers (FPIs), each of which has an aperture of 100 mm. The larger aperture of FPIs allows the available field-of-view up to 85" with a spectral power of ? 10^5.

9908-111, Session PS2

Avalanche photo diodes in the observatory environment: lucky imaging at 1-2.5 microns

Rob Sharp, Annino Vaccarella, Michael Ireland, The Australian National Univ. (Australia); Antonin H. Bouchez, George H. Jacoby, GMTO Corp. (United States)

The recent availability of large format near-infrared detectors with sub-election readout noise is revolutionising our approach to wavefront sensing for adaptive-optics. However, as with all near-infrared detector technologies, challenges exist in moving from the comfort of the laboratory test-bench into the harsh reality of the observatory environment. As part of the broader adaptive optics program for the GMT, we are developing a near-infrared Lucky Imaging camera for operational deployment at the ANU 2.3m telescope at Siding Spring Observatory. The system provides an ideal test-bed for the rapidly evolving Selex/SAPHIRA eAPD technology while providing scientific imaging at angular resolution rivalling HST. We will present our Lucky Imaging system, with a focus on the development of components fundamental to the future of near-infrared wavefront sensing for ELT instruments such as the GMT integral field spectrograph, GMTIFS. This includes the necessary cryogenic amplification to minimise pick-up noise, and the capabilities of the eAPD technology for photon counting at high frame-rates.

9908-112, Session PS2

Final integration and alignment of LINC-NIRVANA

Javier Moreno-Ventas Mateos, Peter Bizenberger, Thomas Bertram, Kalyan Kumar Radhakrishnan Santhakumari, Frank Kittmann, Harald Baumeister, Lars Mohr, Thomas M. Herbst, Max-Planck-Institut für Astronomie (Germany); Luca Marafatto, Univ. degli Studi di Padova (Italy)

The LBT (Large Binocular Telescope), located at about 3200m in Mount Graham (Tucson, Arizona) is an innovative project undertaken by institutions from Europe and USA. LINC-NIRVANA is an instrument which provides MCAO (Multi-Conjugate Adaptive Optics) interferometry, combining the light from the two 8.4m telescopes coherently. This configuration offers 23m-baseline optical resolution and the sensitivity of a 12m mirror, with a 2 arcminute diffraction limited field of view.

The integration, alignment and testing of such a big instrument requires a well-organized choreography and AIV planning which has been developed in a hierarchical way. The instrument is divided in largely independent systems, and each consists of various subsystems. Every subsystem integration ends with a verification test and an acceptance procedure. When a certain number of systems are finished and accepted, the instrument AIV phase starts. This hierarchical approach allows testing at early stages with simple setups. The philosophy is to have internally aligned subsystems to be integrated in the instrument optical path, and

extrapolate to finally align the instrument to the telescope.

In this paper we describe the integration of the instrument going through its three basic divisions. Warm optics includes collimator, beam-splitter, derotator, FP-20 camera up to the high-layer AO sensor, plus the alignment of eight star enlargers on each high-layer sensor. Cold optics inside the cryostat is a Cassegrain optical design operating at 60K at wavelengths from 1 to 2.4 microns. Functional testing of the hardware (filter wheel and tip-tilt mirror mainly) and sensitivity at different bands is described. Calibration units are smarts setups for calibration and analysis of the field of view. A fold mirror allows to inject the beams from 24 different fibers strategically placed at different positions.

Results are presented for every step, and a final section outlines the future work to be done until its final commissioning.

9908-113, Session PS2

An instrumental puzzle: the modular integration of AOLI

Alejandro Oscoz, Marta Puga Antolín, Roberto L. López, Sergio Velasco, Luis Fernando Rodríguez-Ramos, Rafael Rebolo-López, Instituto de Astrofísica de Canarias (Spain); Craig D. MacKay, David M. P. King, Univ. of Cambridge (United Kingdom); Antonio Pérez Garrido, Carlos Colodro, Univ. Politécnica de Cartagena (Spain); José Manuel Rodríguez Ramos, Univ. de La Laguna (Spain); Lucas Labadie, Univ. zu Köln (Germany); Juan José Valdivia, Instituto de Astrofísica de Canarias (Spain)

AOLI, Adaptive Optics Lucky Imager, is an instrument developed to deliver the highest spatial resolution ever obtained in astrophysics in the visible, ~20 mas, from ground-based telescopes.

This instrument is planned as a double system to use adaptive optics (AO) and lucky imaging (LI), the two most successful techniques to obtain extremely high resolution. LI offers excellent and cheap results on small and medium size telescopes, but it only allows achieving a resolution similar to that of the HST. The addition of low order AO with a new, and really important for the project, geometric wavefront sensor to the system before the LI camera enhances the reachable resolution as it removes the highest scale turbulences maximizing the LI process at larger telescopes.

Aiming at this challenging goal we have built AOLI putting together the expertise of IAC, IoA, UTPC, Univ. Cologne and Univ. La Laguna, each group in charge of a different part of the puzzle. To face the defiance that AOLI represents we have implemented a new philosophy of instrumental prototyping by modularizing all its components: simulator/calibrator, deformable mirror, science and WFS modules. This modular concept, which is really suitable for AOLI, offers huge flexibility regarding the instrument to be developed, the telescope to which this instrument is planned or the addition of future developments and improvements. AOLI has now been restructured not only to make the AIV phase well but also to be able to integrate this system in different ways (f/#, scale, WFS-type,) or to adapt it to different telescopes.

Here we will give the answer to major questions about AOLI's modularity: the why and how of doing it (really well). With such purpose we present a description of the whole instrument, reveal key details of the integration of all its modules and of the verification phase, a crucial step in the development, as well as the preliminary results after its first observing run on the WHT.

9908-114, Session PS2

Accurate high-contrast imaging polarimetry with SPHERE/IRDIS

Rob G. van Holstein, Technische Univ. Delft (Netherlands); Frans Snik, Jozua de Boer, Leiden Observatory (Netherlands) and Leiden Univ. (Netherlands); Julien H. V. Girard, European Southern Observatory (Chile); Daphné M. Stam, Technische Univ. Delft (Netherlands); Jean-Luc Beuzit, David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Maud P. Langlois, Ctr. de Recherche Astronomique de Lyon (France) and Ecole Normale Supérieure de Lyon (France) and Univ. Claude Bernard Lyon 1 (France); Arthur Vigan, Lab. d'Astrophysique de Marseille (France) and Aix-Marseille Univ. (France); Alice Zurlo, Univ. Diego Portales (Chile) and Univ. de Chile (Chile); Remco J. de Kok, Leiden Observatory (Netherlands) and Leiden Univ. (Netherlands) and SRON Netherlands Institute for Space Research (Netherlands)

We present a comprehensive, numerical model of the instrumental polarization and the polarimetric sensitivity of the SPHERE/IRDIS instrument on the VLT. This model allows us to establish the feasibility of combining Angular Differential Imaging (ADI) with accurately calibrated polarimetry for measuring the degree of linear polarization of directly imaged (sub)stellar companions at near-infrared (NIR) wavelengths. This degree of polarization can be up to ~2% if a companion, such as a gaseous exoplanet or a brown dwarf, is equatorially flattened due to a rapid rotation or if it has patchy clouds in its atmosphere that scatter (and polarize) the thermal radiation that is upwelling from below.

We assess the polarimetric sensitivity of SPHERE/IRDIS by feeding our model real ADI observations of (sub)stellar companions and by applying a range of data-reduction methods and PSF-subtraction algorithms. Combining polarimetry with ADI observations improves the suppression of the (unpolarized) speckle halo, enhancing the contrast by an order of magnitude. We establish the polarimetric accuracy of SPHERE/IRDIS with a Mueller matrix model that describes the complete optical system, thus the telescope and the instrument, and validate this model with internal calibration measurements and observations of unpolarized standard stars. We estimate that after application of the model and associated calibrations, the absolute polarimetric accuracy of SPHERE/IRDIS is a fraction of a percent.

To actually perform combined ADI and polarimetry, pupil-tracking needs to be implemented for IRDIS' polarimetric mode in order to maximize the stability of the quasi-static speckle halo. Whether or not pupil-tracking reduces IRDIS' polarimetric throughput has to be investigated: pupil-tracking limits the range of possible derotator angles, while it is found that at certain angles the derotator induces significant cross-talk.

9908-115, Session PS2

Study of the performance of the SPHERE atmospheric dispersion correctors

Pascale Hibon, European Southern Observatory (Chile); Kjetil Dohlen, Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France)

SPHERE was installed at the UT3 Nasmyth focus of the Very Large Telescope in April 2014 and first light occurred on May 4th that year.

Its common path and infrastructure (CPI) features two Atmospheric Dispersion Correctors (ADCs) : a Near Infrared one, and a Visible one. In this paper, we give an overview of the characterisation and performance of these ADC units obtained on sky.

9908-116, Session PS2

The V-SHARK high contrast imager at LBT

Fernando Pedichini, Filippo Ambrosino, Mauro Centrone, Fabrizio Fiore, Emanuele Giallongo, Gianluca Li Causi, INAF - Osservatorio Astronomico di Roma (Italy); Enrico Pinna, Alfio T. Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Marco Stangalini, Vincenzo Testa, INAF - Osservatorio Astronomico di Roma (Italy)

In the framework of the SHARK project the visible channel is a novel instrument synergic to the NIR channel and exploiting the performances of the LBT XAO at visible wavelengths. The status of the project is presented together with the design study of this innovative instrument optimized for high contrast imaging by means of high frame rate. Its expected results will be presented comparing the simulations with the real data of the "4runner" experiment taken at 630nm.

9908-117, Session PS2

The vector vortex coronagraph observing mode on the Subaru SCExAO instrument: current status and performances

Jonas G. Kuhn, ETH Zürich (Switzerland) and Jet Propulsion Lab. (United States) and California Institute of Technology (United States); Eugene Serabyn, Farisa Y. Morales, Jet Propulsion Lab. (United States) and California Institute of Technology (United States); Garima Singh, Jet Propulsion Lab. (United States) and California Institute of Technology (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States); Nemanja Jovanovic, Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States); Frantz Martinache, Observatoire de la Côte d'Azur (France); Janis Hagelberg, Univ. of Hawai'i (United States); Dimitri Mawet, California Institute of Technology (United States)

We introduce the Vector Vortex Coronagraph (VVC) observing mode that is part of the Subaru Coronagraphic Extreme AO (SCExAO) instrument, the second-generation near-infrared high-contrast imager of the Subaru Telescope. This focal plane coronagraph mode is now available for use on the SCExAO platform, which is on-track to deliver extreme AO correction for the HiCIAO imager by the 2016A observing period onwards. The SCExAO vortex coronagraph device operates at H-band and can provide better than 100:1 raw starlight rejection at high-Strehl, combined with competitive inner-working angle performances (2 l/D, or 80 mas at H-band) with the Subaru Telescope pupil. Pointing accuracy of better than 1 mas is provided by a dedicated Lyot-based low-order wavefront sensor, combined with AO-generated incoherent "satellite spots" for additional accuracy and photometric calibration. In addition, SCExAO now provides a "speckles nulling" mode available on-sky, using Coherent Differential Imaging (CDI) to beat down the speckle contrast floor. Future improvements currently being considered include the use of a MPIAA lens to remap the telescope pupil to discard the secondary obscuration, effectively improving contrast and inner-working angle (down to 0.9 l/D, the theoretical value for a VVC), as well as the replacement of the HiCIAO imager by an MKIDS array.

We present an overall description of the VVC mode, describe its current and expected near-future performances, and present the most recent on-sky results from the commissioning and early science runs. The VVC coronagraphic mode is straightforward to operate with no extra optics, and is the first H-band vortex to be installed on an 8+m class telescope in the Northern hemisphere.

9908-118, Session PS2

SPHERE IRDIS and IFS astrometric strategy and calibration

Anne-Lise K. Maire, Max-Planck-Institut für Astronomie (Germany); Silvano Desidera, INAF - Osservatorio Astronomico di Padova (Italy); Julien H. V. Girard, European Southern Observatory (Chile); Raffaele G. Gratton, INAF - Osservatorio Astronomico di Padova (Italy); Maud P. Langlois, Ctr. de Recherche Astronomique de Lyon (France); Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Riccardo U. Claudi, INAF - Osservatorio Astronomico di Padova (Italy); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Markus Feldt, Max-Planck-Institut für Astronomie (Germany); David Mouillet, Pascal Puget, Institut de Planétologie et d'Astrophysique de Grenoble (France); Massimo Turatto, INAF - Osservatorio Astronomico di Padova (Italy); François Wildi, Observatoire de Genève (Switzerland)

We present the results of the on-sky astrometric characterization of the VLT planet finder SPHERE since the beginning of the instrument operations in May 2014. We first describe the criteria for the selection of the astrometric fields used for calibrating the science data: binaries, multiple systems, and globular clusters. The analysis includes measurements of the pixel scale and the position angle with respect to the north of both detectors of the IRDIS camera and the integral field spectrometer IFS, as well as the on-sky optical distortion of the IRDIS camera. The IRDIS distortion is shown to be dominated by an anamorphism of 0.60+/-0.02% between the horizontal and vertical directions of the detector, i.e. 6 mas at 1 arcsec. The anamorphism is produced by the cylindrical mirrors in the common path structure hence common to all three SPHERE science subsystems (IRDIS, IFS, and ZIMPOL), except for the relative orientation of the detectors. The current estimates of the pixel scale and north angle for IRDIS are 12.25+/-0.01 milliarcseconds/pixel and -1.70+/-0.07 deg. Analyses of the IFS data indicate a pixel scale of 7.46+/-0.01 milliarcseconds/pixel and a north angle of -102.16+/-0.15 deg. Experience on sky showed that the scale is slightly dependent on the environment temperature. Once corrected for this effect, the scale is determined with an error of less than 0.1%. We finally discuss plans for providing astrometric calibration to the SPHERE users outside the instrument consortium.

9908-119, Session PS2

Modeling the transmission and thermal emission in a pupil image behind the Keck II adaptive optics system

Pauline Arriaga, Michael P. Fitzgerald, Univ. of California, Los Angeles (United States); James E. Lyke, Randall D. Campbell, Peter L. Wizinowich, Sean M. Adkins, W. M.

Keck Observatory (United States); Keith Y. Matthews, California Institute of Technology (United States)

The design and performance of astronomical instruments depend critically on the total system throughput as well as the background emission from the sky and instrumental sources. In designing a pupil stop for background-limited imaging, one seeks to balance throughput and background rejection to optimize measurement signal-to-noise ratios. Many sources affect transmission and emission in infrared imaging behind the Keck Observatory's adaptive optics systems, such as telescope segments, segment gaps, secondary support structure, and AO bench optics. Here we describe an experiment, using the pupil-viewing mode of NIRC2, to image the pupil plane as a function of wavelength. We are developing an empirical model of throughput and background emission as a function of position in the pupil plane. This model will be used in part to inform the optimal design of cold pupils in future instruments, such as the new imaging camera for OSIRIS.

9908-120, Session PS2

GPI observational calibrations XIV: polarimetric contrasts and new data reduction techniques

Maxwell A. Millar-Blanchaer, Dunlap Institute for Astronomy & Astrophysics (Canada); Marshall D. Perrin, Space Telescope Science Institute (United States); Sebastian Bruzzone, Western Univ. (Canada); Li-Wei Hung, Michael P. Fitzgerald, Univ. of California, Los Angeles (United States); James R. Graham, Univ. of California, Berkeley (United States)

The Gemini Planet Imager (GPI) is a recently commissioned instrument installed on the 8-m Gemini South telescope designed for the direct detection and characterization of exoplanets and circumstellar disks. Its optical train consists of an extreme adaptive optics system coupled to a Lyot coronagraph that feeds into an integral field spectrograph. In addition, GPI is equipped with a dual channel polarimetry mode designed to take advantage of the inherently polarized light scattered off circumstellar material, to further suppress the residual seeing halo left uncorrected by the adaptive optics. Here we provide an update on the performance of GPI's polarimetry mode and report on the ongoing development of data reduction techniques. We include an analysis of observations of polarized and unpolarized standard stars, measurements of the polarized twilight sky, as well as observations obtained throughout the GPI Exoplanet Survey (GPIES). In addition, we provide polarimetry contrast curves that demonstrate typical performance throughout the GPIES campaign. We explore how recent advances in data reduction techniques improve upon the achievable contrast in polarimetry mode. In particular, we consider different flux extraction techniques when constructing datacubes from raw data and different methods of subtracting instrumental polarization.

9908-121, Session PS2

Gemini Planet imager observational calibrations XI: pipeline improvements and enhanced calibrations after two years on sky

Marshall D. Perrin, Space Telescope Science Institute (United States); Patrick J. Ingraham, LSST (United States); Jérôme Maire, Dunlap Institute for Astronomy & Astrophysics (Canada) and Univ. of Toronto (Canada); Katherine B. Follette, Stanford Univ. (United States); Sebastian Bruzzone, Western Univ. (Canada); Zachary H. Draper, Univ. of Victoria (Canada); Li-Wei Hung, Univ. of California, Los Angeles (United States); Maxwell A. Millar-Blanchaer, Univ. of Toronto (Canada); Eric Nielsen, SETI Institute (United States) and Stanford Univ. (United States); Jean-Baptiste Ruffio, Stanford Univ. (United States); Dmitry Savransky, Cornell Univ. (United States); Schuyler G. Wolff, Johns Hopkins Univ. (United States); Jason J. Wang, Univ. of California, Berkeley (United States)

The Gemini Planet Imager has been successfully obtaining images and spectra of exoplanets, brown dwarfs, and debris and protoplanetary circumstellar disks, using its combined integral field spectrograph and polarimeter. GPI observations are reconstructed into high-quality astrometrically and photometrically calibrated datacubes using the GPI Data Reduction Pipeline, an open-source software framework continuously developed by our team and available to the community. This paper provides a broad overview of the GPI pipeline, summarizes key lessons learned, and describes improved calibration methods and new capabilities available in the latest release. Enhanced automation better supports observations at the telescope with streamlined and rapid data processing, for instance through real-time assessments of contrast performance and more automated calibration file processing. Several accompanying papers describe in more detail specific aspects of the calibration of GPI data in both spectral and polarimetric modes.

9908-122, Session PS2

Gemini planet imager observational calibration XIII: wavelength calibration improvements with a nonlinear spectral dispersion

Schuyler G. Wolff, Johns Hopkins Univ. (United States); Kimberly Ward-Duong, Arizona State Univ. (United States); Joe Zalesky, Univ. of California, Berkeley (United States); Alexandra Z. Greenbaum, Johns Hopkins Univ. (United States); James R. Graham, Univ. of California, Berkeley (United States)

We present improvements to the wavelength calibration for the lenslet-based Integral Field Spectrograph (IFS), that serves as the science instrument for the Gemini Planet Imager (GPI). The GPI IFS features a 2.7" x 2.7" field of view and a 190 x 190 lenslet array (14.1 mas/lenslet) with spectral resolving power ranging from R ? 35 to 78. A unique wavelength solution is determined for each lenslet characterized by a two-dimensional position, an n-dimensional polynomial describing the spectral dispersion, and the rotation of the spectrum with respect to the detector axis. We investigate the non-linearity of the spectral dispersion across all Y, J, H, and K bands through both a comparison to on-sky arc lamp data and simulated instrument performance. Additionally, the 10-hole non-redundant masking mode on GPI provides an alternative measure of wavelength dispersion within a datacube by cross-correlating reference PSFs with science images. This approach can be used to confirm deviations from linear dispersion in the reduced datacubes. We find that the inclusion of a quadratic term provides a factor of 10 improvement in wavelength solution accuracy over the linear solution and is necessary to achieve uncertainties of a few hundredths of a pixel in J band to a few thousands of a pixel in the K bands. This corresponds to a wavelength uncertainty of less than 0.05 nm across all filters. We also investigate the stability of the measured dispersion over time (e.g. correlations with flexure, temperature, seasonal effects).

9908-123, Session PS2

Design of the ERIS calibration unit

Mauro Dolci, Angelo Valentini, INAF - Osservatorio Astronomico di Teramo (Italy); Gianluca Di Rico, Simone Esposito, Debora Ferruzzi, Armando Riccardi, Paolo Spanò, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The Enhanced Resolution Imager and Spectrograph (ERIS) is a new-generation instrument for the Cassegrain focus of UT4/VLT telescope, aimed at performing AO-assisted imaging and medium resolution spectroscopy in the 1-5 micron wavelength range. ERIS consists of the 1-5 micron imaging camera NIX, the 1-2.5 micron integral field spectrograph SPIFFIER (a modified version of SPIFFI, currently operating on SINFONI), the AO module and the internal Calibration Unit (ERIS CU).

The purpose of this unit is to provide facilities to calibrate the scientific instruments in the 1-2.5 micron range and to perform troubleshooting and periodic maintenance tests of the AO module (e.g. NGS and LGS WFS internal calibrations and functionalities, ERIS differential flexures) in the 0.5-1 micron range.

The ERIS CU must therefore be designed in order to provide, over the full 0.5-2.5 micron range, the following capabilities: 1) illumination of both the telescope focal plane and the telescope pupil with a high-degree of uniformity; 2) artificial point-like and extended sources onto the telescope focal plane, with high accuracy in both positioning and FWHM; 3) wavelength calibration;4) high stability of these characteristics.

In this poster the design of the ERIS CU, and the solutions adopted to fulfill all these requirements, is described. The CU construction is foreseen to start at the end of 2016.

9908-124, Session PS2

Gemini planet imager observational calibration XII: photometric calibration in the polarimetry mode

Li-Wei Hung, Univ. of California, Los Angeles (United States); Sebastian Bruzzone, Western Univ. (Canada); Maxwell A. Millar-Blanchaer, Univ. of Toronto (Canada); Stanimir Metchev, Western Univ. (Canada) and Stony Brook Univ. (United States); Michael P. Fitzgerald, Univ. of California, Los Angeles (United States); Anand Sivaramakrishnan, Space Telescope Science Institute (United States)

The Gemini Planet Imager (GPI) is a high-contrast instrument specially designed for direct imaging and spectroscopy of exoplanets and debris disks. GPI can also operate as a dual-channel integral field polarimeter. The instrument primarily operates in a coronagraphic mode, enabling high-contrast observations at inner working angles as low as 0.15 arcsec. Traditional coronagraphy poses an obstacle for photometric calibrations since the majority of on-axis starlight is blocked. To enable accurate photometry relative to the occulted central star, a diffractive grid in a pupil plane is used to create a set of faint copies, named satellite spots, of the occulted star at specified locations and relative intensities in the field of view. We describe the method we developed to perform the photometric calibration of coronagraphic observations in polarimetry mode using these fiducial satellite spots. Although this calibration method is based on the same principle as what is currently being used in spectroscopy mode, a separate set of data processing procedures is needed for performing the photometric calibration on broadband polarimetric images instead of spectral cubes. In polarimetry mode, the satellite spots are not diffraction-limited PSFs but are smeared out into long oval shapes due to their chromaticity. We characterize the uncertainty associated with this calibration method and describe the implementation of these techniques into the GPI Data Reduction Pipeline. Alternatively, the photometric calibration can be performed by scaling the photometry in polarimetry mode to the photometrically calibrated response in spectroscopy mode. We explore this scaling factor by characterizing the flux ratio of satellite spots between the polarimetry and spectroscopy observing modes.

9908-125, Session PS2

An ADC for the SAM on the SOAR Telescope

Roberto Tighe, Andrei Tokovinin, Patricio Schurter, Manuel Martínez, Rolando E. Cantarutti, National Optical Astronomy Observatory (United States)

SAM (Soar Adaptive-optics Module), the SOAR (Southern Observatory for Astrophysical Research) GLAO facility is in service since 2009, first with NGS (Natural Guide Star) and since 2011, with a UV, 355nm, LGS (Laser Guide Star).

The atmospheric WF error is therefore measured at 355nm and the star images are corrected in the visible range (BVRI bands). An ADC is required for High Resolution imaging at low telescope elevation, especially in the shorter Wavelengths range of the visible spectrum.

The ADC is based on 80mm diameter rotating prisms, it is a compact unit, fully automated, can be inserted or removed from the tightly constrained SAM collimated beam space-envelope, adjusts to the Parallactic angle and corrects the Atmospheric Dispersion magnitude.

Here we present the optical and opto-mechanical design, the control design, the operational strategy and performance results obtained from extensive use in on-sky HR Speckle Imaging.

9908-126, Session PS2

Infrared photometry with 'wall-eyed' pointing at the Large Binocular Telescope

Eckhart Spalding, The Univ. of Arizona (United States); Andrew J. Skemer, The Univ. of Arizona (United States) and Univ. of California, Santa Cruz (United States); Philip M. Hinz, John M. Hill, The Univ. of Arizona (United States)

Ground-based observations in the thermal infrared are complicated by the brightness and temporal variability of the night sky at these wavelengths, as well as the dearth of wide-field detectors sensitive to >2 microns. Small-field detectors have traditionally forced observers to slew telescopes back-and-forth between science and comparison targets to perform precision photometry, except in the rare event that both targets are just a few arcseconds apart. This leads to a loss of observing efficiency, and the possible introduction of instrumental systematics. Here we present a new pointing mode of the Large Binocular Telescope to circumvent these issues. The Large Binocular Telescope, located in southern Arizona, has two 8.4-m primary mirrors which can be aimed separately at science and comparison targets, with acceptable separations of as much as ~2 arcminutes. Both light paths receive separate AO corrections, and the Large Binocular Telescope Interferometer instrument can perform simultaneous direct imaging with both telescope sides, with either a 3-5 micron or 7-25 micron detector. We applied this 'wall-eyed' pointing mode to an observation of an exoplanet transiting in front of its host star at 3.3 microns, deep in the atmospheric bog of the thermal infrared. We used a 10x10 arcsecond detector, and yet could use a comparison star 31.2 asecs away from the transiting system. We will present constrains on the photometric precision we found, and elaborate on possible improvements and science avenues this would level of precision would open up.

9908-127, Session PS2

SPHERE on-sky performance compared with budget predictions

Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Pascal Puget, Institut de Planétologie et d'Astrophysique de Grenoble (France); Anne Costille, Lab. d'Astrophysique de Marseille (France); Jared O'Neil, Juan Carlos Guerra, European Southern Observatory (Chile); Mamadou N'Diaye, Space Telescope Science Institute (United States); Julien H. V. Girard, European Southern Observatory (Chile); Emmanuel Hugot, Lab. d'Astrophysique de Marseille (France); Hans Martin Schmid, ETH Zürich (Switzerland); Maud P. Langlois, Ctr. de Recherche Astronomique de Lyon (France); Raffaele G. Gratton, INAF - Osservatorio Astronomico di Padova (Italy); François Wildi, Observatoire de Genève (Switzerland); Thierry Fusco, Jean-François Sauvage, ONERA (France)

The SPHERE (spectro-photometric exoplanet research) extreme-AO planet hunter saw first light at the VLT observatory on Mount Paranal in May 2004 after ten years of development. Great efforts were put into modelling its performance, particularly in terms of achievable contrast, and to budgeting instrumental features such as wavefront errors, optical transmission, dust contamination, surface cosmetics, etc. In this paper we aim at comparing predicted performance with measured performance at each of the instrument's three focal planes, the near infrared dual imaging camera IRDIS, the near infrared integral field spectrograph IFS and the visible polarimetric camera ZIMPOL. In addition to comparing on-sky contrast curves and calibrated transmission measurements obtained for each camera, we also compare the PSD-based wavefront error budget with the PSD calculated from in-situ wavefront maps obtained thanks to a Zernike phase mask, ZELDA, implemented in the infrared coronagraph wheel.

One of the most critical elements of the SPHERE system is its high-order deformable mirror, a prototype 40x40 actuator piezo stack design developed in parallel with the instrument development. The development was a success, as witnessed by the instrument performance, in spite of some bad surprises discovered on the way. The devastating effects of operating without taking properly into account the loss of several actuators and the thermally and temporally induced variations in the HODM shape will be analyzed, and the actions taken to mitigate these defects through the introduction of specially designed Lyot stops and activation of one of the mirrors in the optical train will be described.

9908-128, Session PS2

Near-infrared adaptive optics imaging and spectro-polarimetry with the infrared camera and spectrograph of the Subaru Telescope

Makoto Watanabe, Hokkaido Univ. (Japan); Tae-Soo Pyo, Subaru Telescope, National Astronomical Observatory of Japan (United States); Hiroshi Terada, National Astronomical Observatory of Japan (Japan); Takashi Hattori, Subaru Telescope, National Astronomical Observatory of Japan (United States); Yutaka Hayano, National Astronomical Observatory of Japan (Japan); Yosuke Minowa, Subaru Telescope, National Astronomical Observatory of Japan (United States); Shin Oya, National Astronomical Observatory of Japan (Japan); Masayuki Hattori, National Institute for Basic Biology (Japan); Tomoyuki Kudo, Subaru Telescope, National Astronomical Observatory of Japan (United States); Mikio Morii, RIKEN (Japan); Jun Hashimoto, National Astronomical Observatory of Japan (Japan)

We have developed the near-infrared high-spatial resolution imaging and spectro-polarimetric modes with the laser guide adaptive optics system (AO188) and the Infrared Camera and Spectrograph (IRCS) of the 8.2-m Subaru telescope. A LiNbO3 Wollaston prism (as dual beam analyzer) and focal plane masks were installed into the camera section of the IRCS cryostat, enabling us to perform the low- and medium resolution grism spectro-polarimetry (R = 100-1960) as well as the imaging polarimetry, in conjunction with a half-wave retarder, which had been introduced for the HiCIAO instrument primarily, at the front of the AO188 system. The designed wavelength coverage of the Wollaston prism is 0.8-5 micron, although the present coverage of polarimetry is 0.95-2.5 micron due to limitations on the retarder and the dichroic beam splitter of AO188. The focal plane masks, which are reflecting mirror or slits made with tungsten carbide, provide two or four rectangular focal plane apertures with an individual field of view of 4.4 arcsec x 21 arcsec or 4.4 x 54 arcsec for the imaging polarimetry, or two or four slits with a width of 0.10, 0.15, 0.225, and 0.60 arcsec and a length of 4.4 arcsec for the spectropolarimetry. The Wollaston prism and polarimetry masks were installed on June and July 2013, and the polarimetric modes had the first light on October 2013. The polarization efficiency is 88-96% and 55-80% at maximum for the imaging- and spectro-polarimetry, respectively, and it depends heavily on the angle of image rotator of AO188. The measured instrumental polarization, which is introduced by the telescope tertiary mirror mainly, is 0.3-0.7%. We describe the design and current performance of the polarimetric function.

9908-129, Session PS2

NIX, the imager for ERIS: the AO instrument for the VLT

William D. Taylor, David Pearson, UK Astronomy Technology Ctr. (United Kingdom); Richard Davies, Max-Planck-Institut für extraterrestrische Physik (Germany); Beth A. Biller, The Royal Observatory, Edinburgh (United Kingdom); Walter Bachmann, ETH Zürich (Switzerland); Helmut Feuchtgruber, Elizabeth M. George, Max-Planck-Institut für extraterrestrische Physik (Germany); Xiaofeng Gao, UK Astronomy Technology Ctr. (United Kingdom); Adrian M. Glauser, ETH Zürich (Switzerland); David Henry, UK Astronomy Technology Ctr. (United Kingdom); Sasha Hinckley, Univ. of Exeter (United Kingdom); John F. Lightfoot, David W. Lunney, Michael J. MacIntosh, UK Astronomy Technology Ctr. (United Kingdom); Stephen D. March, Michael R. Meyer, Sascha P. Quanz, ETH Zürich (Switzerland); Eckhard Sturm, Max-Planck-Institut für extraterrestrische Physik (Germany); Chris Waring, UK Astronomy Technology Ctr. (United Kingdom)

ERIS will be the next generation AO facility on the VLT, combining the heritage of NACO imaging with the spectroscopic capabilities of an upgraded SPIFFI. Here we report on the all-new NIX imager that will deliver diffraction-limited imaging from the J to Mp band. The instrument will be equipped with both apodizing phase plates and sparse aperture masks to provide high-angular resolution imagery, especially suited for exoplanet imaging and characterisation. This paper will detail the

instrument's design and how it is expected to address a broad range of science cases, from detailed investigations of the galactic centre at the highest resolutions, to studying stellar populations and the evolution of more distant galaxies.

9908-130, Session PS2

Pushing down with the contrast: scientific performances with SPHERE-IFS

Riccardo U. Claudi, Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Enrico Cascone, Vincenzo De Caprio, INAF - Osservatorio Astronomico di Capodimonte (Italy); Silvano Desidera, Valentina D'Orazi, Daniela Fantinel, Enrico Giro, Raffaele G. Gratton, INAF - Osservatorio Astronomico di Padova (Italy); Anne-Lise K. Maire, Max-Planck-Institut für Astronomie (Germany); Dino Mesa, Bernardo Salasnich, INAF - Osservatorio Astronomico di Padova (Italy); Salvatore Scuderi, INAF - Osservatorio Astrofisico di Catania (Italy); Elena Sissa, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli studi di Padova (Italy); Massimo Turatto, INAF - Osservatorio Astronomico di Padova (Italy); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Anthony Boccaletti, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Gaël Chauvin, Institut de Planétologie et d'Astrophysique de Grenoble (France); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Gert Finger, European Southern Observatory (Germany); Julien H. V. Girard, Markus Kasper, European Southern Observatory (Chile); Norbert Hubin, European Southern Observatory (Germany); Maud P. Langlois, Lab. d'Astrophysique de Marseille (France); Jean-Louis Lizon, European Southern Observatory (Germany); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Pascal Puget, Institut de Planétologie et d'Astrophysique de Grenoble (France); François Wildi, Observatoire de Genève (Switzerland)

The VLT second generation instrument SPHERE was commissioned in the Summer of 2014, and offered to the community in the Spring of 2015. SPHERE is a high contrast imager that exploits its three scientific channels in order to observe and discover young warm exoplanets in the glare of their host stars. The three scientific instrument are: ZIMPOL, a polarization analyzer and imager that works in the visible range of wavelength, IRDIS a dual band imager and spectro polarimetric Camera that works in the NIR range up to K band, and IFS, an integral field spectrograph working in the YJH band.Very important is the complementarity between IRDIS and IFS. The former has a larger Field of view (about 12 arcseconds) while the IFS push its examination very close to the central star (FoV ~ 1.7 arcsec). In one year of operational time a lot of very interesting scientific cases were investigated and very nice results were gathered. In this paper we would like to focus the attention on the high quality results and performances obtained with the IFS

9908-131, Session PS3

H2RG detector characterization for RIMAS and instrument efficiencies

Vicki L. Toy, Univ. of Maryland, College Park (United States); Alexander S. Kutyrev, NASA Goddard Space Flight Ctr. (United States); John I. Capone, Univ. of Maryland, College Park (United States); Thomas Hams, Frederick D. Robinson, Gennadiy N. Lotkin, NASA Goddard Space Flight Ctr. (United States); Sylvain Veilleux, Univ. of Maryland, College Park (United States); Samuel H. Moseley, Neil A. Gehrels, NASA Goddard Space Flight Ctr. (United States); Stuart N. Vogel, Univ. of Maryland, College Park (United States)

The Rapid infrared IMAger-Spectrometer (RIMAS) is a near-infrared (NIR) imager and spectrometer that will quickly follow-up gamma-ray burst afterglows on the 4.3-meter Discovery Channel Telescope (DCT). RIMAS has two optical arms which allows simultaneous coverage over two bandpasses (YJ and HK) in either imaging or spectroscopy mode. RIMAS utilizes two Teledyne HgCdTe HXRG detectors controlled by Astronomical Research Cameras, Inc. (ARC/Leach) drivers. We report the laboratory characterization of RIMAS's detectors: read noise, linearity, dark current, conversion gain, and quantum efficiency. We also present RIMAS's instrument efficiency from atmospheric transmission models and optics data (both telescope and instrument).

9908-132, Session PS3

Optical design for wide-field imaging and multi-object spectrograph for Antarctic Infrared Telescope (AIR-C)

Takashi Ichikawa, Tomokazu Obata, Tohoku Univ. (Japan)

The design of the wide-field infrared camera for Antarctic 2.5m Infrared telescope, which is planned to construct at Dome F, is presented. The camera was designed with off-axis optics and achieved the image quality of refraction limited for 2.5m telescope at 1-5 micron meters. The array sensors with two 2K by 2K InSb and one 2K by 2K HgCdTe will be equipped, which allow the simultaneous three-band observations. The field of view is 7.5'x7.5' with 0.21"/pixel. To enjoy the stable atmosphere with extremely low perceptible water vapor and the cadence of the polar winter, the camera will be dedicated to the transit observations of exoplanets. The function of a multi-object spectroscopic mode with low spectra resolution (r~50-100) will be added for the spectroscopic transit observation at 1-5 micron. The capability will be very useful for the study of water vapor in the atmosphere of, e.g., super earths.

9908-134, Session PS3

DOTIFS: spectrograph optical and opto-mechanical design

Haeun Chung, Seoul National Univ. (Korea, Republic of) and Korea Institute for Advanced Study (Korea, Republic of); Anamparambu N. Ramaprakash, Pravin Khodade, Chaitanya V. Rajarshi, Sabyasachi Chattopadhyay, Pravinkumar A. Chordia, Vishal Joshi, Inter-Univ. Ctr. for Astronomy and Astrophysics (India); Amitesh Omar, Aryabhatta Research Institute of Observational Sciences (India); Swara Ravindranath, Space Telescope Science

Institute (United States); Changbom Park, Korea Institute for Advanced Study (Korea, Republic of)

In this work, we present spectrograph optical and opto-mechanical design of the Devasthal Optical Telescope Integral Field Spectrograph (DOTIFS), which is a new multi-Integral Field Unit (multi-IFU) Spectrograph to the new 3.6m Devasthal Optical Telescope. DOTIFS is being fabricated by Inter University Center for Astronomy and Astrophysics instrumentation group in Pune, India.

Light coming from multiple extended sources are gathered by 16 deployable IFUs and transferred to 8 indentical spectrographs via optical fibers. Each IFU has 8.7" x 7.4" field of view with 144 (12 x 12) spaxel elements with 0.8" hexagonal shape sampling. Lights coming from IFUs are dispersed by eight identical single channel spectrographs. With a single exposure, spectra of 2,304 spatial elements from entire 370nm - 740nm wavelength range is obtained with R~1800.

DOTIFS spectrograph is comprised of fiber slit, f=520mm collimator, broadband filter, dispersion element, f=195mm camera and 4K by 2K CCD in order. The 8cm fiber slit is comprised of 288 fibers coming from two IFUs. The F/4 collimator is comprised of 3 singlets and 2 doublets, and the fast F/1.5 camera is comprised of 3 singlets and 3 doublets. Collimator and camera optics are designed base on South African Large Telescope Robert Stobie Spectrograph, which has similar optical properties. The design is fully re-optimized to fulfill requirements of DOTIFS. Every surfaces are spherical to make ease of fabrication and alignment process. To maintain good transmission down to 370nm, calcium fluoride and high transmission optical glasses have been used. Pupil size is determined as 130mm from spectral resolution and budget requirements. Volume Phase Holographic grating is selected as a dispersion element to maximize the grating efficiency and to minimize the size of the optics. The blazed wavelength of the VPH grating is shifted to blueward from the center to minimize contamination by Littrow ghost. Wide band filter is used to sort out light other than working wavelength range. Filter is tilted by 10 degrees to effectively eliminate ghost reflection coming from the camera optics. E2V 4K by 2K CCD is used and graded coated to maximize quantum efficiency. Fiber slit is oriented along 2K direction and the light is dispersed along the 4K direction although only 3K pixels will be used. On CCD, image height of each spectra is 2.5 pixel and the center to center separation between fiber spectrums is determined as ~7 pixels.

Spectrograph opto-mechanics are designed to accommodate spectrograph optics in gravity-variant environment. Spectrographs will be located around main Cassegrain port instrument of the telescope and oriented in various direction with respect to the gravity.

We will assemble two spectrographs first and extend it to eight in total in future. The design is finalized, and the components are ordered and being fabricated by manufacturers. We expect to begin assembly in the middle of 2016.

9908-135, Session PS3

GravityCam: wide-field, high-resolution imaging and high-speed photometry instrument

Craig D. MacKay, Univ. of Cambridge (United Kingdom); Martin Dominik, Univ. of St. Andrews (United Kingdom)

GravityCam is a new instrumental concept designed to provide simultaneously wide field imaging (>30 arcmin) with high-resolution (~0.15 arcsec) and high time resolution photometry (~40 msec) on 2-5m class ground-based telescopes.

The science case for GravityCam is very strong indeed. It can provide unique datasets for studies of exoplanets, asteroseismology, Kuiper belt and Oort Cloud populations and dark matter surveys in distant clusters of galaxies by weak gravitational shear studies.

GravityCam will increase dramatically the number of detectable planets down to masses less than that of the Earth. At present known exoplanet detection is easiest with large Jupiter mass objects orbiting close to the central star. It is widely believed that the population of exoplanets is much greater at lower masses where detection is extremely difficult. Microlensing occurs when one star passes in front of another, greatly increasing the brightness of the more distant object. The symmetry of the light curve may be broken by the presence of a planet in orbit ground the lensing star. Even very small objects, down to perhaps the mass of the moon can be detected. GravityCam will look at 6 relatively unobscured fields such as Baade's window, close to the centre of our galaxy, each extending over a field of about 30 arcminute square. An array of electron multiplying CCDs operating in Lucky Imaging mode will record photometric data on approximately 20 million stars night after night. On telescopes such as the NTT 3.6 m telescope we predict a few new microlensing events will be detected each night and that planetary detections should occur perhaps once per week. Such a survey would give for the first time a reliable planetary mass function.

GravityCam will also for the first time give extensive statistics on the short medium and long-term variability of a large population of stars, providing a unique data set for asteroseismology and variable star studies.

The high time resolution of GravityCam will allow access to the small end of the Kuiper belt size distribution and potentially the Oort cloud by studying serendipitious occultations of stars by small solar system bodies. These occultations can reveal atmospheres, satellites and rings around these occulting objects.

By observing the fields of rich clusters of galaxies, GravityCam also has the capacity to greatly improve the quality and sensitivity of weak shear studies that are critical to understanding the nature and distribution of dark matter in the universe. Such studies are usually limited by the relatively poor angular resolution possible on even the best ground-based observatories.

9908-136, Session PS3

Advances in the development of a Mach-Zehnder interferometric Doppler imager for seismology of giant planets

Ivan Gonçalves, François-Xavier Schmider, Olivier Preis, Julien Dejonghe, Yves Bresson, Sylvie Robbe-Dubois, Frédéric Morand, Observatoire de la Côte d'Azur (France); Patrick Gaulme, Jason Jackiewicz, New Mexico State University (United States); Patrick Boumier, Institut d'Astrophysique Spatiale, Université Paris Sud (France); Thierry Appourchaux, Institut d'Astrophysique Spatiale (France); Jean-Christophe Leclec'h, Institut d'Astrophysique Spatiale, Université Paris Sud (France)

Seismology of giant planets allows the study of internal structure, as helioseismology did for the Sun. With the detection of acoustic oscillations on Jupiter (Gaulme et al, 2011) and surface modes on Saturn (Hedman and Nicholson, 2013), a new window on the interior of giant planet is now open.

The best way to measure the frequencies of global modes consists in recording periodic variations of the Doppler shifts of solar lines reflected at the surface of planets. Sounding different depths into the planet requires a sufficient spatial resolution to distinguish the different mode degrees and a long enough time series to get a good precision on the frequency measurements. The JOVIAL project, in collaboration with France, USA, and Japan, foresees the installation of three instruments around the Earth for almost continuous observations during several weeks.

The instrument is an imaging Fourier tachometer. It is based on a Mach-Zehnder interferometer with fixed optical path difference that maximizes the sensitivity. At any point on the surface of the planet, the projected velocity on the line of sight induced a linear shift in the phase of the fringe pattern. The Mach-Zehnder interferometer provides four output images with interferometric fringes separated by a phase of pi/2. A combination of the four outputs, based on the ABCD algorithm (Shao et al,1988) permits the reconstruction of the phase map, therefore of the velocity field at the surface of the planet. The precise calibration of the four outputs is made possible by a modulation of the optical path difference. The thermal stability of the optical path difference is a crucial condition of the measurements. The choice of the optical components and the design of the interferometer were chosen to minimize the thermal sensitivity.

A first prototype of the instrument was built at Observatoire de la Côte d'Azur and tested at the laboratory and on the sky. Atmospheric turbulence and guiding errors affects the measurements. A fast tip-tilt mirror was used to limit the degradation. The bias due to remaining motions was estimated and a correction can be applied. A large-field Adaptive Optics correction will be applied for future observations.

The achieved performance in term of sensitivity and stability are close to theoretical values and will allow detection of modes with amplitudes as low as 5 cm/s on Jupiter after two weeks of observations, in the frame of the JOVIAL network. A precision of a few m/s in wind measurements is expected. The instrument was studied and designed in view of a future space mission. The present results demonstrate the technical readiness of the concept for missions for Saturn or for the ice giant planets.

9908-137, Session PS3

Cryogenic transmissive optics for the rapid infrared imager/spectrometer

John I. Capone, Univ. of Maryland, College Park (United States); Alexander S. Kutyrev, NASA Goddard Space Flight Ctr. (United States); Vicki L. Toy, Univ. of Maryland, College Park (United States); Frederick D. Robinson, NASA Goddard Space Flight Ctr. (United States); Gennadiy N. Lotkin, Beacon Systems, Inc. (United States); Thomas Hams, NASA Goddard Space Flight Ctr. (United States); Sylvain Veilleux, Univ. of Maryland, College Park (United States); Samuel H. Moseley, Neil A. Gehrels, NASA Goddard Space Flight Ctr. (United States); Stuart N. Vogel, Univ. of Maryland, College Park (United States)

The Rapid infrared IMAger-Spectrometer (RIMAS) is a near infrared (NIR) instrument designed for operation on Lowell Observatory's 4.3 meter Discovery Channel Telescope (DCT) located in Happy Jack, Arizona. Once commissioned, RIMAS will complement the Swift space observatory by quickly responding to transient astronomical sources. Due to space and weight limitations on the telescope's "instrument cube", the instrument design is fully refractive to make it as compact as possible. The optics include a collimator, a dichroic beamsplitter, two cameras and a set of filters and gratings for each of the two optical paths. Wavelengths from 0.97-1.33 microns are reflected by the dichroic and 1.48-2.39 microns are transmitted. RIMAS is cooled to cryogenic temperatures (~60 K) to reduce thermal radiation at the longest wavelengths of this spectral range. A thermal compensator design has been implemented to assist alignment at room temperature. The performance of the aligned and cooled optical system is presented.

9908-138, Session PS3

Design, assembly, and performance of the low-resolution spectrograph 2 integral field unit

Brian L. Vattiat, Hanshin Lee, Taylor S. Chonis, Gary J. Hill, The Univ. of Texas at Austin (United States); Christian Haubitz-Reinke, Berlin-Fibre (Germany)

The Low Resolution Spectrograph 2 (LRS2) was recently deployed on the Hobby-Eberly Telescope (HET). LRS2 consists of four spectrographic channels, each covering adjacent wavelength bands from 360-1050nm which are fed with a fiber optic integral field unit (IFU). The integral field unit developed for this instrument represents a transformative approach to expanding the wavelength coverage of integral field spectrographs. The unique input feed of the IFU serves two functions; combining the wavelength coverage of two spectrographic channels to one spatial field on sky, and expanding the field of view of each individual fiber to eliminate the interstitial space between fibers on sky. The spectral multiplexing is achieved with dichroic beam splitter and collimator, while the focal reduction is achieved with a pair of micro lens arrays. The optical components required micron scale alignment precision in a compact mechanical package to allow integration on the telescope focal surface. Here we report on the design, assembly, and performance of the IFU.

9908-139, Session PS3

Development of a prototype of the Tomo-e Gozen wide-field CMOS camera

Shigeyuki Sako, Ryou Osawa, Hidenori Takahashi, Yuki Kikuchi, Mamoru Doi, Naoto Kobayashi, Kentaro Motohara, Takashi Miyata, Tomoki Morokuma, Tsutomu Aoki, Takao Soyano, Ken'ichi Tarusawa, Yuki Sarugaku, Hiroyuki Mito, Yoshikazu Nakada, Mitsuru Kokubo, Kazuma Mitsuda, Yuki Taniguchi, Makoto Ichiki, Jumpei Yamaguchi, Noriyuki Matsunaga, Fumihiko Usui, Ataru Tanikawa, The Univ. of Tokyo (Japan); Junichi Watanabe, Masaomi Tanaka, Hiroyuki Maehara, Ko Arimatsu, National Astronomical Observatory of Japan (Japan); Nozomu Tominaga, Konan Univ. (Japan); Yoshifusa Ita, Hiroki Onozato, Tohoku Univ. (Japan); Seitaro Urakawa, Japan Space Guard Association (Japan); Toshihiro Kasuga, Chiba Institute of Technology (Japan); Mikiya Sato, Kawasaki Municipal Science Museum (Japan)

The Tomo-e Gozen is an extremely wide-field optical camera optimized for time-domain surveys by the Kiso 105-cm Schmidt telescope of the University of Tokyo. It is capable of taking time-series frames with sub-second resolution and a field of view of 20 square degrees achieved by 84 chips of front-illuminated 2k x 1k CMOS sensors with microlensed 19 microns pixels. The sensitive wavelength range is approximately 400 nm to 650 nm. The sensors are placed on the spherical focal plane of the telescope with a curvature radius of 3,300 mm and operated at room temperature without mechanical coolers owing to low dark current. Optical filters are exchanged manually in daytime. The simple design, not using a cryostat and moving parts, enables us to make a light-weight camera system with good maintainability. The time-domain surveys by the Tomo-e Gozen will produce an enormous amount of movie data unlike ever experienced before. The data production rate reaches 30 TByte/night in continuous full-frame acquisitions at 2 Hz. Faint and transient events are searched from the movie big-data by using a real-time processing system with technologies on movie recognition and machine learning.

We have developed a prototype model of the Tomo-e Gozen (Tomo-e PM) with eight sensor chips arranged in a line along the RA direction to evaluate the basic design for the Tomo-e Gozen. The field of view of each chip is 39.7 arcmin in RA x 22.4 arcmin in DEC. The spatial gaps between adjacent chips are 25 arcmin. The maximum frame rate is 2 frames/sec in full-frame read out. The sensor chips are fixed on a flat base-plate via column blocks, the tops of which are diagonally cut precisely, to place them parallel to the spherical focal plane. The base plate with sensors is housed in a light-weight chassis with eight transparent windows of 50 mm x 50 mm, which can be exchanged to optical filters independently. The total weight of the camera body is approximately 30 kg. Video data from

the eight sensor chips is processed by eight pieces of 16-channel 16-bit 500 kHz AD converter boards and then transferred to I/O boards on two control PCs via LVDS serializer/deserializer boards. The read out noise and full-well are 7 e- / 55,000 e-, 4 e- / 23,000 e-, and 2 e- / 6,100 e- in low-, mid-, and high-gain modes, respectively. Estimated 10-sigma limiting magnitudes with no-filter are 16.0, 17.6, 18.8, and 20.2 mag at 0.1, 1, 10, and 100 sec integration times, respectively. Commissioning runs for Tomo-e PM have been successfully performed in the end of 2015. Fast-moving objects such as faint meteors, satellites, and asteroids have been observed for checking performance of Tomo-e PM in high frame rate observations.

9908-140, Session PS3

The Wide Integral Field Infrared Spectrograph (WIFIS): optomechanical design and development

R. Elliot Meyer, Dae-Sik Moon, Univ. of Toronto (Canada); Suresh Sivanandam, Dunlap Institute for Astronomy & Astrophysics (Canada); Charles P. Henderson, Basil Blank, PulseRay (United States); Ke Ma, Univ. of Toronto (Canada); Chueh-Yi Chou, Institute of Astronomy and Astrophysics - Academia Sinica (Taiwan); Miranda Jarvis, Univ. of Toronto (Canada); Jeffrey K. Chilcote, Dunlap Institute for Astronomy & Astrophysics (Canada) and Univ. of Toronto (Canada); Stephen S. Eikenberry, Univ. of Florida (United States)

We present the optomechanical design and development of the Wide Integral Field Infrared Spectrograph (WIFIS). When commissioned on the 2.3 m Bok Telescope, WIFIS will provide an unrivaled integral field size of 20” ? 50” for an infrared integral-field spectrograph at the spectral resolving power R = 2000?3000. Its spectral range covers the zJ- and most of the H-band (0.9–1.7 ?m) with a focus on the former. The main optics of WIFIS consists of a set of re-imaging off-axis parabolic mirrors and an image slicer-based integral field unit, which are followed by a collimator system, a reflective grating as a disperser, and a spectrograph camera composed of six lenses. The re-imaging optics is readily replaceable to fit a different telescope beam, and this makes WIFIS a highly versatile instrument that can be easily used at a different telescope. Its grating shift mechanism allows for two selective reflective angles from the same grating for the zJ- and H-band, respectively. The majority of the WIFIS optical components are mounted inside an aluminum optical bench at a room temperature. A cryogenic dewar operating at liquid nitrogen temperature contains a field lens of the spectrograph camera, a filter wheel, an Hawaii-2RG 1.7 ?m-cutoff detector array and its focusing stage, and readout electronics. There are two optical subsystems for WIFIS: the calibration unit and the guide camera system. The calibration unit consists of an integrating sphere for flat fielding, a thorium-argon lamp for wavelength calibration, and an optical system to simulate the telescope beam. The guider camera system provides an auxiliary photometric capability of griz- and H?-band for a 5? ? 5? off-axis field in addition to the basic guiding capability.

By virtue of its large integral-field size, WIFIS will be a highly competitive instrument for seeing-limited astronomical investigations of the dynamics and chemistry of extended objects in the near-infrared wavebands. Targets for the WIFIS first-light sciences include young supernova remnants and star-forming regions in the Galaxy, stellar populations in nearby elliptical and spiral bulges, massive star formation in nearby spiral galaxies, and galaxy mergers at moderate redshifts. We plan to commission WIFIS on the Bok Telescope in early 2016.

9908-141, Session PS3

Suspended particulate matter effects on daytime star sensor design and performance

Shabnam Yazdani, Jafar Roshanian, K.N. Toosi Univ. of Technology (Iran, Islamic Republic of); Masoud Ebrahimi, Tarbiat Modares Univ. (Iran, Islamic Republic of); Mahmood Reza Sahebi, K.N.Toosi Univ. of Technology (Iran, Islamic Republic of)

Within the last few years, efforts to find a more reliable replacement for Global Positioning System has increased. Various reasons for trying to compensate GPS exist. From its vulnerability to jamming and spoofing in severe conditions to its unavailability in interplanetary missions such as NASA’s 2030 Mars exploration. This challenge is even more critical for developing countries not owning national satellite navigation system. Usually poor legitimate alternative coverage of regional satellite positioning systems such as GLONASS, IRNSS or BeiDou is also provided for such countries. One of the strong candidates for recruiting this comprehensive navigation system is believed to be celestial navigation. In order to utilize star sensors as a mean of celestial navigation in lieu of GPS, important modifications such as altering the performing wavelength from visible light of night sky to infrared imaging of daytime stars is obligatory. Electronic imaging devices such as Infrared Focal Plane Array (IRFPA) for capturing shortwave infrared wavelength (SWIR) are available for applications such as night vision or target search and tracking. However extension of their application to ground based astronomy imaging in place of massive telescopes is yet to be investigated. Especially in lower altitudes that atmosphere effects are bold and influential. Atmospheric layers absorb, scatter and diffract star lights in J, H and K bands of SWIR more as the altitude is decreased. The Effect of natural phenomenon of elements consisting atmosphere such as atmospheric opacity due to excessive Carbone Dioxide accumulation in central cities and water vapor close to oceans and lakes are considerable. But the main concern rests with the undesirable effect of atmospheric suspended Particulate Matter (PM) from dessert dust augmenting these days. These particles vary in size below 2.5 ?m and intensify Mie and Non-selective scattering effect since PMs are either the same size as K band of infrared wavelength or larger. In this paper component design of infrared camera for ground based position determination is considered. Infrared detectors such as InGaAs are suitable choices available off the shelf. The contrast between selection of infrared bands and environmental condition requires accurate consideration therefore decision making between operating wavelength, magnitude, field of view, exposure time, signal to noise ratio, quantum efficiency, full well capacity etc. for different altitudes from on the ground up to typical surveillance flight height is analyzed. Using MODTRAN software for aerosol analysis, optical properties of infrared camera are determined with various PM intensity. Potential regions of interest are extracted according to forecast site reports and the minimum appropriate altitude for holding an infrared star sensor to air is determined. While dry regions suffers from semi-unnatural atmospheric phenomenon which confines the performance, the analysis can improve the insight on celestial navigation future for precise position determination globally.

9908-142, Session PS3

Optical design of a multi-resolution, single-shot spectrograph

François B. Hénault, Institut de Planétologie et d’Astrophysique de Grenoble (France); Florence Laurent, Ctr. de Recherche Astronomique de Lyon (France)

Multi-object or integral field spectrographs today are recognized techniques for achieving simultaneous spectroscopic observations of different or extended sky objects with a high multiplex factor. In this communication is described a complementary approach for realizing similar measurements under different spectral resolutions at the same time. Herein is explained the basic principle of this new type of spectrometer, that is based on the utilization of an optical pupil slicer. An optical design inspired from an already studied instrument is then presented and commented for the sake of illustration. Technical issues about the pupil slicer and diffractive components are also discussed. We finally conclude on the potential advantages and drawbacks of the proposed system.

9908-143, Session PS3

Survey of materials and coatings suitable for controlling stray light from the near-UV to the near-IR

Tom Benedict, Gregory Barrick, Canada-France-Hawaii Telescope (United States); John Pazder, NRC - Herzberg Institute of Astrophysics (Canada)

Controlling stray light through the use of black surfaces is common practice in the design of astronomical instruments and telescopes. While the geometry of the elements that make up the stray light design – baffles, enclosures, masks, etc. – is key, so too are the materials and coatings used to make them. We present a survey of reflective spectra from 300nm to 2500nm of a range of materials used for stray light control, as well as other materials commonly found in instrumentation and telescopes.

9908-144, Session PS3

NIR camera and spectrograph SWIMS for TAO 6.5m telescope: overview and development status

Kentaro Motohara, Masahiro Konishi, Hidenori Takahashi, Natsuko M. Kato, Yutaro Kitagawa, Yutaka Kobayakawa, Yasunori Terao, Hirofumi Ohashi, Ken Tateuchi, Soya Todo, Tsutomu Aoki, Mamoru Doi, Takafumi Kamizuka, Kotaro Kohno, Takeo Minezaki, Takashi Miyata, Tomoki Morokuma, Kiyoshi Mori, Ryou Ohsawa, Kazushi Okada, Shigeyuki Sako, Takao Soyano, Yoichi Tamura, Toshihiko Tanabé, Masuo Tanaka, Ken'ichi Tarusawa, Masahito S. Uchiyama, Jumpei Yamaguchi, Yuzuru Yoshii, The Univ. of Tokyo (Japan)

Simultaneous-color Wide-field Infrared Multi-object Spectrograph, SWIMS, is one of the first generation instruments for University of Tokyo Atacama Observatory 6.5m Telescope now being constructed at the summit of Co. Chajnantor in northern Chile. Thanks to the high altitude (5640m altitude) and dry climate (precipitable water vapor~0.5mm) of the site, almost continuous atmospheric window from 0.9 to 2.5 um appears.

SWIMS has a field of view of 9.6 arcmin in diameter, and a dichroic mirror is inserted in the collimated beam to split it into two arms, one covering 0.9-1.45 micron and the other 1.45-2.5 micron. It is capable of two-color simultaneous imaging or R~1000 multi-object spectroscopy at 0.9-2.5 micron wavelength range with a single exposure, and enables us to carry out efficient NIR imaging/spectroscopic surveys.

Focal plane of each arm is planned to be covered by four HAWAII-2RGs focal-plane arrays, however, currently only two arrays are procured which provide FoV of 8.6 x 4.3 square arcminutes, with a pixel scale of 0.126arcmin.

The telescope focal plane is covered by a separate dewar for a multi-object slit mask exchange unit (MOSU), which has a carousel to store multi-object slits (MOS) masks and gate valve to separate the main dewar from the MOSU dewar.

MOS masks cover 5 x 8.6 arcmin, and maximum ~30 slits with length of 15 arcsec can be arranged on it. The masks are installed in a rotating carousel in the MOSU dewar which can store maximum 20 of them, and a robotic hand place them at the focal plane or house into the carousel. An IFU module covering 17 x 13 arcsec with 26 slitlets of 0.5arcsec width are also being developed. It is designed to be compact enough that it can be stored in the MOSU carousel and can be handled by the robotic hand as well.

The main cryostat dewar has a cylindrical shape 1.5m in height and 1.3m in diameter, and cooled down below 100K by a single GM-cycle cooler. Cool down time is almost one week with assistance of liquefied nitrogen, and temperatures reach <100K at optical components and <80K at detectors. The MOSU has an additional GM-cycle cooler whose cool down time is less than 2 days without any assist.

The cryostats are contained in a box of 2m x 2m x 2m, and its total weight is approximately 2.5ton. The whole instrument is installed on the Nasmyth focus of the TAO 6.5m telescope with an instrument rotator.

SWIMS is expected to be transported to the Subaru telescope in 2016 and planned to be install on the Cassegrain focus of the telescope to carry out first-light and engineering observations. After the completion of the 6.5m telescope, its collimator lens system will be exchanged to that for the 6.5m telescope, as the optical parameters are different, and will be sent to Chile and see the scientific first light in FY 2018.

9908-145, Session PS3

Developing scanning-slit spectrograph for imaging the Sun

Hemanth Pruthvi, K.B. Ramesh, Sajal Kumar Dhara, B. Ravindra, Indian Institute of Astrophysics (India)

Spectral imaging is one of the important ways to directly obtain the images of the solar atmosphere at different heights. Computing doppler shift for each spatial position gives the line of sight velocity maps. For chosen spectral line, as each part of it forms at different heights in solar atmosphere, obtaining spectral information near simultaneously at all spatial locations can give a rough idea about three dimensional view. The instrument is a back-end for a telescope with tracking system i.e. stable image of the sun is projected onto the focal plane at all times. The instrument consists of three modules – image stabilization system, scanning-slit assembly and spectrograph assembly. Image stabilization system is a closed loop control system to maintain the finer stability of the image. Scanning-slit assembly is a module that can linearly move in one direction to sweep the region of interest in the image. Spectrograph assembly consists of another slit, optics and dispersing element along with the detector so that spectral information about spatial locations on the slit can be obtained. This module is designed to obtain Intensity vs. (y,?) (y – along the slit) and as the scanning-slit is swept along the x-direction, Intensity vs. (x,y,?) information is built. The spatial resolution will be seeing limited as there's no correction system. Field of view is 3 arc minute along the slit direction, as the features of interest include sunspots and surrounding region. For testing, a front end system of 140mm clear aperture with f/16 is being used. The dispersing element is a reflecting grating with 1200 grooves/mm. For 656.3 nm (H-alpha line) spectral resolution is 3.5 pm in second order. Linear dispersion is about 3.8 pm/pixel for pixel size of 7.5 um, indicating that slit-width limited spectral resolution can be obtained. Image stabilization system is aimed to achieve a stability of 1.5 arcsec using image correlation maximization technique. It is also aimed to complete one set of observations (120 frames) in 300 seconds.

9908-146, Session PS3

Development status of the mid-infrared two-field camera and spectrograph MIMIZUKU for the TAO 6.5-m Telescope

Takafumi Kamizuka, Takashi Miyata, Shigeyuki Sako, Ryou Ohsawa, Kazushi Okada, Masahito S. Uchiyama, Kiyoshi Mori, Jumpei Yamaguchi, The Univ. of Tokyo (Japan); Kentaro Asano, Institute of Space and Astronautical Science (Japan); Mizuho Uchiyama, National Astronomical Observatory of Japan (Japan); Itsuki Sakon, Takashi Onaka, The Univ. of Tokyo (Japan); Hirokazu Kataza, Sunao Hasegawa, Institute of Space and Astronautical Science (Japan); Fumihiko Usui, The Univ. of Tokyo (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Tsutomu Aoki, Mamoru Doi, Natsuko M. Kato, Yutaro Kitagawa, Yutaka Kobayakawa, Kotaro Kohno, Masahiro Konishi, Takeo Minezaki, Tomoki Morokuma, Kentaro Motohara, Hirofumi Ohashi, Takao Soyano, Hidenori Takahashi, Yoichi Tamura, Toshihiko Tanabé, Masuo Tanaka, Ken'ichi Tarusawa, Yasunori Terao, Yuzuru Yoshii, The Univ. of Tokyo (Japan)

MIMIZUKU is the first-generation mid-infrared instrument for the University of Tokyo Atacama Observatory (TAO) 6.5-m telescope. The site is the summit of Co. Chajnantor in northern Chile. Thanks to its high altitude (5640 m) and dry climate, good atmospheric windows are available from near-infrared to 38-micron region. To utilize this uniqueness, MIMIZUKU covers the 2 - 38 micron region with three channels (NIR, MIRS, and MIRL). NIR covers the 2 - 5.3 micron region with a HAWAII-1RG array. MIRS covers the 6.8 - 26 micron region with an AQUARIUS array. And MIRL covers the 24 - 38 micron region with a Si:Sb array developed by DRS. The field of view is 1.2', 2.0', and 31'' on a side for the NIR, MIRS, and MIRL, respectively. Each channel also has a capability of low-resolution spectroscopy (R = 64 - 620). In addition, MIMIZUKU is capable of observing two separate fields (distance < 25') simultaneously by using a unique mechanism called "Field Stacker". By allocating the fields to target and calibrator, time-variable atmospheric transmittance can be calibrated accurately. This capability improves photometric and spectroscopic accuracy, and difficult observations like long-term monitoring and spectroscopy in low-transmittance bands will be realized even in ground-based mid-infrared observations.

The development of MIMIZUKU is in the final phase, and the cryogenic system and cryogenic optics have got ready. The development of the Field Stacker and detector controlling system are given by Uchiyama et al. and Okada et al., respectively. In this presentation, the overview, current development results (especially for the cryogenic system and optics), and future prospects of MIMIZUKU will be reported.

As for the cryogenic system, its goal is to cool the optics and detectors down to sufficiently low temperature for suppressing instrumental background and detector dark current. The temperature required for the optics is 27 K, and that for the detector is 5, 7, and 37 K for the NIR, MIRS, and MIRL, respectively. These temperatures had not been achieved previously because of insufficient thermal conductivity of thermal paths. After improving contact thermal conductance and refurbishing the paths with oxygen-free high-conductivity copper, the required temperatures got achieved even with adding detector thermal dissipation.

As for the optics, its re-fabrication and re-assembly are successfully finished. The optics consists of gold-plated aluminum mirrors to maximize throughput and to match thermal expansion coefficient with the aluminum optical bench. However, the combination of gold and aluminum is weak against galvanic corrosion, and our mirrors have been degraded once. After the fabrication and assembly, the imaging performance of the optics is checked by optical imaging test, and enough capability to achieve diffraction-limited mid-infrared image and seeing-limited near-infrared image is confirmed.

The development works are to be completed in FY 2015. After that, MIMIZUKU will be transferred to the Subaru telescope for its commissioning, and initial science operation is planned in FY 2017 - 2018. After the completion of TAO 6.5-m telescope, MIMIZUKU will be delivered to the TAO, and the first light at the TAO will be around FY 2019.

9908-147, Session PS3

Conceptual design of wide-field focal plane with InGaAs image sensors

Yutaka Komiyama, Hidehiko Nakaya, Nobunari Kashikawa, National Astronomical Observatory of Japan (Japan); Tomohisa Uchida, High Energy Accelerator Research Organization, KEK (Japan)

The success of Sloan Digital Sky Survey (SDSS) had forced us to recognize the importance of wide-field survey and many imaging survey projects, such as Dark Energy Survey, Hyper Suprime-Cam (HSC), LSST, have been started to probe the universe much deeper than SDSS. On the other hand, ground-based wide-field survey project in infrared wavelength with comparable width and depth to the optical surveys seems to be inactive and, instead, it looks that the effort is concentrated on space mission such as Euclid and WFIRST.

Recently, an application of InGaAs image sensor which is sensitive to the infrared wavelength (1-1.7um) for astronomy has been considered seriously (Nakaya et al. in this conference). The merit to adopt this sensor is the availability with reasonable cost (compared to the other infrared sensors) since the sensor is designed for industrial use. Nakaya et al. intensively tested InGaAs image sensor of 128 x 128 pixel format with 20 um pixel pitch developed by Hamamatsu Photonics K. K., although it is not the largest format provided by Hamamatsu (640 x 512 format). They found that the InGaAs image sensors have promising performance (e.g. linearity, wavelength response, intra-pixel response) except for the readout noise and dark current. Such shortcomings are suggested to be improved by replacing the CMOS readout IC. Therefore, once the technique to enlarge the sensor format is developed, the InGaAs image sensors could be used for astronomy and open a new window for the wide-field infrared imaging survey.

We consider the possibility to employ this sensor for astronomical instrument based on our experience accumulated during the development of HSC (Miyazaki et al. 2012; Komiyama et al. 2010). On the focal plane of HSC, 116 2k4k CCDs are tiled with minimum gaps (0.3mm) between CCDs together with a focal plane flatness of +/-17um, attaining 90% filling factor of focal plane). Our experience is of great help to realize the wide-field camera of InGaAs sensors with higher survey capability. In the present paper, we summarize the technical difficulties for developing camera with many InGaAs sensors and show the appropriate solutions for the difficulties.

The most difficult part would be the development of focal plane assembly. We show the basic idea how to mount the sensors, feed the cable for the front-end electronics, and form as a dewar. The chip size considered here is 22 x 22 mm, which comes from the maximum size of the CMOS readout IC. The design should be scalable so that the number of sensors can be maximized to realize the field of view as wide as possible.

The other difficulty is that the required operating temperature of InGaAs image sensor is -130 deg which is 30 deg lower than operating temperature of CCDs (-100 deg). We carried out the thermal calculation and estimate the power required to cooling down the sensor adequately. We also show an idea to reduce the dominant thermal inflow by radiation from the entrance window.

9908-148, Session PS3

The SKA low frequency aperture array: from design to verification systems

Jan-Geralt Bij de Vaate, Pieter Benthem, ASTRON (Netherlands)

The deployment of the Square Kilometre Array (SKA) starts with a ~10% instrument, phase 1, commencing with construction in 2018. This includes the SKA1-LOW, a sparse Aperture Array (AA) covering 50 to at least 350MHz. SKA1-LOW will consist of 512 stations, each with 256 antennas creating a total of more than 130.000 antennas. The configuration will be very closed packed with 90-95% of the antennas within a 3km radius inner area and the remaining collecting area situated on three spiral arms, extending to a radius of ~45km.

The Aperture Array Design and Construction (AADC) Consortium is responsible for the design of the stations, the signal transport to a processing facility and the station beamforming, including the local software. The design of this system poses a number of challenges, not only in terms of performance but also due to the sheer volume of the parts (antennas, receivers etc.) and the output data rate. In order to mitigate the design risks, verification systems have and will be realized. Initially small 16 antenna systems have been build, both in the UK as well as near the proposed SKA site in Western Australia. Next step is the realization of a 400 antenna system. This verification system will consist of one full size station (256 antennas) and three smaller test stations. For correlation of the station signals the Murchison Widefield Array (MWA) back-end will be used.

Key technology development include: wide band antenna, low cost Radio over Fiber (RFoF) and compact high performance signal processing. In SKA1-low signals of all antennas will be digitized, effectively generating a software controlled aperture which can be flexible configured. Allowing correlation rich aperture synthesis, new calibration approaches and very high dynamic range imaging with the sparse array.

Partners in AADC include ASTRON, Cambridge University, ICRAR, INAF, KLAASA, Oxford University and STFC.

9908-149, Session PS3

SAAO’s new robotic telescope and WiNCam (Wide-field Nasmyth Camera)

Hannah L. Worters, James E. O’Connor, David B. Carter, Egan Loubser, Pieter A. Fourie, Amanda A. Sickafoose, Pieter Swanevelder, South African Astronomical Observatory (South Africa)

The South African Astronomical Observatory (SAAO) is designing and manufacturing a wide-field camera for use on two of its telescopes. The initial concept was of a prime focus camera for the 74-inch Grubb Parsons telescope, where it would employ a 61mmx61mm detector to cover a 23 arcmin field of view. However, while in the design phase, SAAO embarked on the process of acquiring a bespoke 1-metre robotic alt-az telescope with a 43 arcmin field-of-view, which would need a homegrown instrument suite. The prime focus camera design was thus adapted of use on either telescope, increasing the detector size to 92mmx92mm. Since the camera would be mounted on the Nasmyth port of the new telescope, it was dubbed WiNCam (Wide-field imaging Nasmyth Camera). This paper will describe both WiNCam and the new telescope.

Producing an instrument that could be swapped between two very different telescopes posed some unique challenges. At the Nasmyth port of the alt-az telescope there was ample circumferential space, while on the 74-inch the available envelope was constrained by the optical footprint of the secondary to prevent further obscuration. This forced the design into a cylindrical volume of 600mm diameter x 250mm height. The back focal distance was tightly constrained on the new telescope, shoehorning the shutter, filter unit, guider mechanism and a tip/tilt mechanism for the detector into 100mm depth. The iris shutter and filter wheel planned for prime focus could no longer be accommodated. Instead, a compact shutter with a thickness of less than 20mm has been designed in-house, using a sliding curtain mechanism to cover an aperture of 125mmx125mm, while the filter wheel has been replaced with 2 peripheral filter cartridges (6 filters each) and a gripper to move a filter into the beam. We intend using through-vacuum wall PCB technology across the cryostat vacuum interface, instead of traditional hermetic connector-based wiring. This has advantages in terms of space saving and improved performance.

Measures have been taken to minimise the risk of damage during an instrument change. The detector is cooled by a Stirling cooler, which can be disconnected from the cooler unit without risking damage. Each telescope will have a dedicated cooler unit into which the coolant hoses of WiNCam will plug. To overcome an inherent drawback of Stirling coolers, an active vibration damper is incorporated. During an instrument change, the autoguider remains on the telescope, and the filter magazines, shutter and detector package are removed as a single unit.

The new alt-az telescope, manufactured by APM-Telescopes, is a 1-metre f/8 Ritchey-Chrétien with optics by LOMO. The field flattening optics were designed by Darragh O’Donoghue to have high UV throughput and uniform encircled energy over the 100mm diameter field. WiNCam will be mounted on one Nasmyth port, with the second port available for SHOC (Sutherland High-speed Optical Camera) and guest instrumentation. The telescope will be located in Sutherland, where an existing dome is being extensively renovated to accommodate it. Commissioning is expected by mid-2016.

9908-150, Session PS3

Requirement analysis for a modular low resolution spectrograph

Andrzej S. Piascik, Iain A. Steele, Robert J. Smith, Stuart D. Bates, Liverpool John Moores Univ. (United Kingdom)

The utility of a high-throughput, low resolution, optical long-slit spectrograph for rapid object classification has been demonstrated with the 2015 deployment of SPRAT, a small single target spectrograph, on the 2.0m Liverpool Telescope (LT). SPRAT, was specifically designed for use on the LT but has generated interested from other observatories wishing to duplicate it. Presented here is a discussion for extending the design of this spectrograph to a produce an adaptable and more compact modular instrument suitable for general deployment to other robotic or manual 2.0m class telescopes. The design uses a common optical/mechanical core to which standard off the shelf optical elements are added to tailor the final desired instrument characteristics. The mechanical and electrical design aim is for a small-footprint, self-contained instrument allowing ease of deployment on the target telescope. To maintain optimal performance in the event of reconfiguration of the optical characteristics an alignment assembly for use between deployments is included as part of the instrument design.

9908-151, Session PS3

OCTOCAM: a fast multi-channel imager and spectrograph proposed for the Gemini Observatory

Antonio de Ugarte Postigo, Instituto de Astrofísica de Andalucía - CSIC (Spain) and Niels Bohr Institute (Denmark) and Univ. of Copenhagen (Denmark); Peter W. A. Roming, Southwest Research Institute (United States); Christina C. Thöne, Instituto de Astrofísica de Andalucía (Spain); Alexander van der Horst, The George Washington Univ. (United States); Susan Pope, Southwest Research Institute (United States); María Luisa García Vargas, Ernesto Sánchez-Blanco Mancera, Manuel Maldonado Medina, FRACTAL S.L.N.E (Spain); Robert Content, Australian Astronomical Observatory (Australia); Frans Snik, Leiden Observatory (Netherlands); Ronnie L. Killough, Gregory S. Winters, Kristian B. Persson, Sandee Jeffers, Southwest Research Institute (United States); Alberto Riva, INAF - Osservatorio Astronomico di Torino (Italy); Andrea Bianco, Alessio Zanutta, INAF - Osservatorio Astronomico di Brera (Italy)

OCTOCAM has been proposed to the Gemini observatory as a workhorse imager and spectrograph that will fulfill the needs of a large number of research areas in the 2020s. It is based on the use of high-efficiency dichroics to divide the incoming light in eight different channels, four optical and four infrared, each optimized for its wavelength range. In its imaging mode, it will simultaneously observe a field of 3'x3' in g, r, i, z, Y, J, H, and Ks bands. It will obtain long-slit spectroscopy covering the range between 3700 and 23500 Å with a resolution of 4000 and a slit length of 3 arcminutes. To avoid slit losses, the instrument will be equipped with an atmospheric dispersion corrector operating in the complete spectral range. Thanks to the use of state of the art detectors, OCTOCAM will allow high time-resolution observations and will have negligible overheads in the classical observing modes. It will be equipped with a unique integral field unit that will observe in the complete spectral range with an on-sky coverage of 9.7"x6.8". The integral field uint is based on an image slicer design composed by 17 slitlets, 0.4" wide each. Finally, a state-of-the-art polarimetric unit will allow full Stokes spectropolarimetry in the complete spectral range between 3700 and 22000 Å. In this presentation I will give an overview the optomechanical design of the instrument and will review in detail the most critical and outstanding elements of the project.

9908-152, Session PS3

The new SOXS instrument for the ESO NTT

Pietro Schipani, INAF - Osservatorio Astronomico di Capodimonte (Italy); Riccardo U. SOXS (Son Of X-Shooter) will be a unique spectroscopic facility for the ESO NTT telescope able to cover the optical/NIR band (350-1750 nm), based on the heritages of the X-shooter at the ESO-VLT and of the NOT Transient Explorer (NTE) at the Nordic Optical Telescope. The design foresees a high-efficiency spectrograph with a Resolution-Slit product of 4500, capable of simultaneously observing over the entire band the complete spectral range 350 - 1750 nm with a good sensitivity. The limiting magnitude of R~20-20.5 (1 hr at S/N~10) is suited to study transients identified from on-going imaging surveys. Imaging capabilities in the optical are also foreseen to allow for multi-band photometry of the faintest transients with a field of view of at least 3 arcmin. The instrument has been selected by ESO within the framework of a competitive call for scientific ideas. This paper outlines the status of the project.

9908-153, Session PS3

Design and modeling of a moderate-resolution astronomic spectrograph with volume-phase holographic gratings

Eduard R. Muslimov, Kazan State Technical Univ. (Russian Federation); Gennady G. Valyavin, Sergey N. Fabrika, Special Astrophysical Observatory (Russian Federation); Nadezhda K. Pavlycheva, Kazan State Technical Univ. (Russian Federation)

We present a detailed optical design of astronomic spectrograph based on a cascade of volume-phase holographic gratings. The cascade consists of three gratings. Each of them provides moderately high spectral resolution in a relatively narrow range of 83 nm and has low diffraction efficiency outside of the working region. Thus the spectrum image represents three rows, which cover region from 430 to 680 nm without gaps. Wedge-shaped substrates of the gratings allow to center the spectrum rows in the tangential plane and align them in the sagittal plane. A simple triplet lens is used as the collimator and 4-lens all-spherical objective is used in the camera part. Estimated spectral resolving power for 30um-entrance slit is 5300-7900 relative units. The spectrograph overall dimensions are ~755?440?170 mm. Results of diffraction efficiency modeling shows that the required maximum efficiency and spectral selectivity are achievable even when ordinary gratings with quasi-sinusoidal profile recorded on DCG layers are used. For manufacturable grating parameters we obtained estimation of the optical system overall throughput equal to 75% for central wavelengths of each sub-range and about 45% for the seams of sub-ranges. Results of ray tracing in a non-sequential mode demonstrate that stray light introduced by crosstalk of the gratings can be considered as negligible. Further we designed an optical system for coupling of the instrument with an astronomic telescope. The primary mirror diameter was assumed to be 6 m and relative aperture was F/4. The spectrograph can be mounted either in the primary focus or in the Nasmyth focus. For the first case we developed and modeled a 4-fold image slicer, for the second one a combination of 7.8x focal reducer and 6-fold image slicer is designed.

The developed systems allow to work with images with angular size of 0".8 and 1."5 respectively. Finally, tolerance analysis for the spectrograph optical scheme was performed and a concept of instrument's optomechanical design was proposed. Thus we demonstrated that the holographic grating spectrograph has relatively high functional specifications which can give it some advantages in comparison with existing instruments. It's notable for combination of moderately high spectral resolution in a wide region with high throughput (and, subsequently, high sensitivity). In addition, the spectrograph can be built with available manufacturing technologies. We suppose that such spectral instrument would be of special interest for solving of such tasks as investigation of supernovae, low-mass compact objects as white dwarfs, search and investigation of exoplanets etc.

9908-154, Session PS3

Science with OCTOCAM: a new workhorse instrument proposed for Gemini

Christina C. Thöne, Instituto de Astrofísica de Andalucía (Spain); Antonio de Ugarte Postigo, Instituto de Astrofísica de Andalucía - CSIC (Spain); Peter W. A. Roming, Southwest Research Institute (United States); Alexander van der Horst, The George Washington Univ. (United States); Susan Pope, Ronnie L. Killough, Southwest Research Institute (United States)

OCTOCAM is an 8-channel VIS-IR (g to K-band) imager and medium-resolution spectrograph proposed as new workhorse instrument for the 8m Gemini telescopes. In addition to simultaneous imaging and long-slit spectroscopy it offers additional observing modes of high time resolution, integral-field spectroscopy and spectropolarimetry, making it a very versatile instrument for many science cases in the 2020ies. A special focus of OCTOCAM will be the detection and follow-up of transient sources such as gamma-ray bursts, supernovae, magnetars, active galactic nuclei and yet to be discovered new objects, delivered by large-scale surveys like LSST available in the 2020ies. The diverse nature of transients will require the full range of OCTOCAM capabilities allowing more information in very short time about the source than with any other current instrument and adaptable almost in real time. Another main science topic will be to probe the high redshift Universe and the first stars for which OCTOCAM will be highly suited due to its wide wavelength coverage and high sensitivity. However, OCTOCAM is also suited for a large range of other science cases including transneptunian objects, exoplanets, stellar evolution and supermassive black holes. Our science team comprises more than 50 researchers reflecting the large interest of the Gemini community in the capabilities of OCTOCAM. We will highlight a few important science cases demonstrating the different capabilities of OCTOCAM and their need for the scientific community.

9908-155, Session PS3

The Wendelstein three channel imager (3KK): alignment, commissioning, and first results

Florian Lang-Bardl, Univ.-Sternwarte München (Germany); Ralf Bender, Univ.-Sternwarte München (Germany) and Max-Planck-Institut für extraterrestrische Physik (Germany); Claus A. Gössl, Univ.-Sternwarte München (Germany); Frank U. Grupp, Univ.-Sternwarte München (Germany) and Max-Planck-Institut für extraterrestrische Physik (Germany); Hans-Joachim Hess, Univ.-Sternwarte München (Germany); Klaus W. Hodapp, Institute for Astronomy (United States) and Univ. of Hawai'i at Manoa (United States); Ulrich Hopp, Univ.-Sternwarte München (Germany) and Max-Planck-Institut für extraterrestrische Physik (Germany); Shane M. Jacobson, Institute for Astronomy (United States) and Univ. of Hawai'i at Manoa (United States); Jennifer Kaminski, Helmut Kravcar, Univ.-Sternwarte München (Germany); Anna Monna, Max-Planck-Institut für extraterrestrische Physik (Germany); Wolfgang Mitsch, Jörg Schlichter, Michael Wegner, Univ.-Sternwarte München (Germany)

The Ludwig-Maximilians-Universität München operates an astrophysical observatory on the summit of Mt. Wendelstein which was equipped with a modern 2m-class robotic telescope in 2011 (see Hopp et al, #7733, #8444, #9145).

One of the two Nasmyth ports is designed to deliver the excellent (<0.8" median) seeing of the site for a FoV of 60 sqarcmin without any corrector optics at optical and NIR wavebands. This port hosts a three channel imager where the design was already presented in Lang-Bardl et al, #7735. It will mainly be used for observations of targets of opportunities like Gamma-Ray-bursts or efficient photometric redshift determination of sources identified by surveys like PanSTARS, Planck (SZ) or eROSITA. The covered wavelength range is 340 nm to 2.3 microns. The camera provides standard broadband filters (Sloan, Y, J, H, Ks) and 5 narrowband filters (BrGamma, H2, OI, Halpha, SII).

We will present the final design of the camera, the assembly and alignment procedure performed in the laboratory before we transported the instrument to the observatory. We will also show first results of the achieved on sky performance concerning image quality and efficiency of the camera in the different filter passbands.

9908-156, Session PS3

Gamma/hadron separation in HAWC using neural networks

Tomás Capistrán Rojas, Ibrahim Daniel Torres Aguilar, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Eduardo Moreno Barbosa, Benemérita Univ. Autónoma de Puebla (Mexico)

The High Altitude Water Cherenkov (HAWC) Observatory is a ground based air-shower array of 300 water Cherenkov detectors (WCDs) located on the slope of Volcan Sierra Negra, Mexico. Each WCD has 4 photonmultipler tubes (PMTs) that detect secundary particles of air-showers produced by gamma-rays and cosmic rays (CRs). Those CRs are the main problem in the gamma-ray sources analysis, therefore, we need to separate between both particles. Currently, the HAWC data is divided in 10 bins that depend on the number of PMTs activated in each event. For the supression of CRs background, HAWC uses two variables, Compactness and PINCness, that are used to apply a simple cutoff in each bin. In this work we trained a neural network (NN) that uses these two variables as input parameters in oder to obtain one output parameter and use it as a cutoff. We used simulated proton and gamma events to train the NN and we found an optimal cutoff, that we applied to the Crab Nebula. This work predicts a better gamma/hadron separation in some bins when we use Monte Carlo (MC) data.

9908-157, Session PS3

The prototype cameras for trans-Neptunian automatic occultation survey

Shiang-Yu Wang, Yen-Sang Hu, Academia Sinica (Taiwan); John C. Geary, Stephen M. Amato, Harvard-Smithsonian

Ctr. for Astrophysics (United States); Hsin-Yo Chen, Hung-Hsu Ling, Yin-Chang Chang, Pin-Jie Huang, Academia Sinica (Taiwan); Jerome Pratlong, e2v technologies plc (United Kingdom); Andrew Szentgyorgyi, Harvard-Smithsonian Ctr. for Astrophysics (United States); Matthew J. Lehner, Academia Sinica (Taiwan); Jamie Forrest, Paul R. Jorden, e2v technologies plc (United Kingdom); Timothy J. Norton, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The Transneptunian Automated Occultation Survey (TAOS II) is a three robotic telescope project to detect the stellar occultation events generated by TransNeptunian Objects (TNOs). TAOS II project aims to monitor about 10000 stars simultaneously at 20Hz or higher to enable statistically significant event rate. The TAOS II camera is designed to cover the 1.7 degree diameter field of view of the 1.3m telescope with 10 mosaic 4.5k?2k, 16 micron pixel CMOS sensors. The new CMOS sensor (e2v CIS 113) has a back illumination thinned structure and high sensitivity to provide similar performance to that of the back-illumination thinned CCDs. Due to the requirements of high performance and high speed, the development of the new CMOS sensor is still in progress.

Before the science arrays are delivered, three prototype cameras are developed to help on the commissioning of the robotic telescope system. The prototype cameras use the small format e2v CIS 107 devices but with the same dewars for the TAOS II science camera. CIS 107 sensor is a device for development purpose with 10 different variations of pixel designs. The control clocks of CIS 107 are very similar to the control signal for CIS 113 devices. The sensor has 1500 x 2000, 7 micron pixels with 4 outputs. Each variation covers 1500 x 200 pixels. The 4T pixels are with high resistivity epitaxial silicon and back thinned to 11 microns. At 200K, the device shows peak QE higher than 90%, readout noise around 4e- and dark current <0.1e-/s/pix.

Two prototype cameras have only one sensor at the center of focal plane while the third camera has 5 sensors to assess the optical quality of the telescope at the field edge. The sensors, mounted on a single Invar plate, are cooled to the operation temperature of about 200K by a cryogenic cooler. The Invar plate is connected to the dewar body through a supporting ring with three G10 bipods.

The control electronics consists of analog part and a Xilinx FPGA based digital circuit. One FPGA is needed to control and process the signal from CIS 107. For each field star, 7?7 pixels box will be readout at 20Hz, up to 40Hz. The pixel rate for each channel is about 1Mpix/s. The FPGA module also calculates the total flux and also the centroid coordinates for every field star in each exposure. For the camera with five sensors, a vacuumed sealed PCB is used to pass the signals outside of the vacuum dewar. A synchronization circuit between each FPGA and each camera is also provided to ensure the exposure duration error of each sensor to be within 1ms.

In this report, the performance of the prototype cameras will be presented. The status of the CIS 113 sensors will also be covered.

9908-158, Session PS3

Acousto-optical imaging spectropolarimeter

Konstantin B. Yushkov, Sergey P. Anikin, Sergey I. Chizhikov, National Univ. of Science and Technology “MISiS” (Russian Federation); Valentin F. Esipov, Lomonosov Moscow State Univ. (Russian Federation); Vladimir Ya. Molchanov, National Univ. of Science and Technology “MISiS” (Russian Federation); Andrey M. Tatarnikov, Lomonosov Moscow State Univ. (Russian Federation)

Imaging spectropolarimetry provides information about distribution of light polarization in astrophysical objects both in spectral and spatial domains. Polarization of the radiation is observed in a variety of astronomical objects: AGN and quasars, circumstellar envelopes of the symbiotic stars, supernova remnants, star-forming regions, planetary and protoplanetary nebulae. Polarization often strongly depends on the wavelength of light. By means of the spectral polarimetric observations we can obtain the information about the spatial structure of objects and magnetic fields in them.

Acousto-optic tunable filters (AOTFs) are used as tunable monochromators with wide angle aperture for HSI. An AOTF is sensitive to polarization of light, and in common HSI applications linear polarizers are used before and after AOTFs. Thus, the image intensity corresponds to projection of light polarization to one axis which is either parallel or perpendicular the diffraction plane. A single AOTF can also be used for spectropolarimetry when a special optical system is used (V.Ya. Molchanov et al., Proc. SPIE, V. 9147, P. 91472T, 2014; S.P. Anikin et al., Pat. RU 2569907 C1, filed 28.08.2014) . In September 2015, we commissioned an imaging spectropolarimeter based on a single AOTF at the 0.6-meter telescope of the SAI Crimean Station in Nauchny. During observations, we discovered some of its disadvantages: asymmetric transfer function of this configuration reduces the throughput and causes noticeable spectral artifacts for beams with focal ratio higher than F/20. That inspired us to design a spectropolarimeter that is free of these drawbacks.

The prototype of the new instrument uses two similar AOTFs consequently. Each of them operates in a noncritical phase matching (NPM) geometry, but the Bragg angles for two filters correspond to different polarizations. As the result, two diffracted beams after the AOTFs are parallel to each other. Further, the beams are separated by means of the Wollaston prism and imaged with the relay optical system. The transfer function of the AOTFs in NPM geometry is almost circularly symmetric and the acceptance angle is suitable for the beams with F/10 focal ratio. The spectropolarimeter can be used without modifications at 1-meter and 2-meter class telescopes. Spectral range of the device can cover an octave-spanning band within the range of 370 – 3500 nm. In the report, we compare the performance of the designed two-stage spectropolarimeter with that of the previous single-AOTF configuration.

9908-159, Session PS3

GCT: an end-to-end Schwarzschild-Couder telescope prototype for the Cherenkov Telescope Array

Jean-Laurent René Dournaux, Observatoire de Paris à Meudon (France); Abdel Abchiche, Ctr. National de la Recherche Scientifique (France); Jean-Philippe Amans, Observatoire de Paris à Meudon (France); Thomas P. Armstrong, Durham Univ. (United Kingdom); Arnim Balzer, David Berge, Univ. van Amsterdam (Netherlands); Catherine Boisson, Jean-Jacques Bousquet, Observatoire de Paris à Meudon (France); Anthony M. Brown, Durham Univ. (United Kingdom); Mark P. Bryan, Univ. van Amsterdam (Netherlands); Paula M. Chadwick, Durham Univ. (United Kingdom); Heide Costantini, Aix-Marseille Univ. (France); Garret Cotter, Univ. of Oxford (United Kingdom); Michael K. Daniel, Univ. of Liverpool (United Kingdom); Andrea De Franco, Univ. of Oxford (United Kingdom); Fatima de Frondat, Delphine Dumas, Gilles Fasola, Observatoire de Paris à Meudon (France); Stefan Funk, Erlangen Ctr. for Astroparticle Physics (Germany); Johann Gironnet, Observatoire de Paris à Meudon (France); Tim Greenshaw, Univ. of Liverpool

(United Kingdom); Olivier Hervet, Observatoire de Paris à Meudon (France); James A. Hinton, Max-Planck-Institut für Kernphysik (Germany); Jean-Michel Huet, Isabelle Jégouzo, Observatoire de Paris à Meudon (France); Tobias Jogler, Erlangen Ctr. for Astroparticle Physics (Germany); Jon S. Lapington, Univ. of Leicester (United Kingdom); Philippe Laporte, Observatoire de Paris à Meudon (France); Akira Okumura, Max-Planck-Institut für Kernphysik (Germany); Duncan Ross, Univ. of Leicester (United Kingdom); Harm Schoorlemmer, Max-Planck-Institut für Kernphysik (Germany); Luigi Tibaldo, Max-Planck-Institut für Kernphysik (Germany); Hélène Sol, Observatoire de Paris à Meudon (France); Jason J. Watson, Univ. of Oxford (United Kingdom); Richard White, Max-Planck-Institut für Kernphysik (Germany); Andréas Zech, Observatoire de Paris à Meudon (France); Adrian Zink, Erlangen Ctr. for Astroparticle Physics (Germany)

The Cherenkov Telescope Array (CTA) project aims to build the next generation ground-based Very High Energy imaging Cherenkov instrument. It will be devoted to the observation of gamma rays over a band of energy, from ~20 GeV to above 100 TeV. Given this wide energy range, three size classes of telescopes with different mirror areas are foreseen to cover the low, intermediate and high-energy domains. Among them, the Small Size Telescopes (SSTs) are devoted to the highest energy range, becoming most sensitive from 5 TeV to above 100 TeV. At these energies, the limiting factor is not the number of Cherenkov photons produced in the extended air shower, but rather the number of showers observed. Therefore, the SSTs, though possessing a modest mirror diameter of about 4 m, will be spread over an area greater than about 4 km2, to maximise the effective area of the array.

GCT (Gamma-ray Cherenkov Telescope) is an Australian-Dutch-French-German-Japanese-UK-US sub-consortium of CTA, currently building a dual-mirror prototype for the SSTs. The telescope is based on a Schwarzchild-Couder (SC) optical design, an innovative solution for ground-based Cherenkov astronomy, which allows a compact telescope structure, a lightweight large field-of-view camera and enables good angular resolution across the entire field-of-view (FoV).

The telescope mechanical structure was designed with the philosophy to provide a lightweight, simple and compact structure compatible with CTA specifications in terms of stiffness, cost or lifetime; to decrease manufacturing costs by using commercial-off-the-shelf modules and similar systems in the telescope; and to ease the assembly and maintenance phases. The optical structure consists of two metallic lightweight mirrors and a camera. Two prototype cameras will be tested on the prototype structure. These two cameras have a similar physical size and weight (about 50 kg), a curved focal plane and a diameter of roughly 45 cm, instrumented with 2048 pixels. With a pixel FoV of ~0.2°, the camera's total FoV is about 9°. They differ only by the photosensors used since the first camera prototype uses MultiAnode Photo-Multipliers tiles whereas the second one uses Silicon Photo-Multipliers tiles. The cameras are designed to record the very fast flashes (about tens of nanosecond) of Cherenkov light produced in the atmosphere from gamma-initiated electromagnetic showers. The telescope was assembled from April to November of 2015. On-site tests and measurements with the first prototype camera began at the end of 2015.

This paper reviews the different components of the telescope, from mechanics and optics to the telescope control system, and presents the first on-sky measurements made with the telescope. Plans for the pre-production and the CTA production in the next years are also discussed.

9908-160, Session PS3

The GMOX science case: resolving galaxies through cosmic time

Mario Gennaro, Massimo Robberto, Space Telescope Science Institute (United States); Timothy M. Heckman, Stephen A. Smee, Robert H. Barkhouser, Johns Hopkins Univ. (United States); Zoran Ninkov, Rochester Institute of Technology (United States); Angela Adamo, Stockholm Univ. (Sweden); George Becker, Univ. of California, Riverside (United States); Andrea Bellini, Space Telescope Science Institute (United States); Luciana Bianchi, Johns Hopkins Univ. (United States); Arjan Bik, Stockholm Univ. (Sweden); Rongmon Bordoloi, Massachusetts Institute of Technology (United States); Annalisa Calamida, Space Telescope Science Institute (United States); Daniela Calzetti, Univ. of Massachusetts Amherst (United States); Gisella De Rosa, Susana E. Deustua, Jason Kalirai, Jennifer Lotz, John W. MacKenty, Space Telescope Science Institute (United States); Carlo Felice Manara, European Space Agency (France); Margaret Meixner, Space Telescope Science Institute (United States); Camilla Pacifici, NASA Goddard Space Flight Ctr. (United States); Elena Sabbi, Kailash Sahu, Jason Tumlinson, Space Telescope Science Institute (United States)

We present the key scientific questions that can be addressed by GMOX, a Multi-Object Spectrograph selected for feasibility study as a 4th generation instrument for the Gemini telescopes. Using commercial digital micro-mirror devices (DMDs) as slit selection mechanisms, GMOX can observe hundred of sources at R~5000 between the U and K band simultaneously. Exploiting the narrow PSF delivered by the Gemini South GEMS MCAO module, GMOX can synthesize slits as small as 40mas reaching extremely faint magnitude limits, and thus enabling a plethora of applications and innovative science.

Our main scientific driver in developing GMOX has been "Resolving galaxies through cosmic time": GMOX at GeMS can take spectra of regions as small as 300 pc at redshift 1.5. At lower or higher redshift, where the angular diameter distance decreases, GMOX can resolve even smaller regions, allowing us to probe the growth and evolution of galaxies with unprecedented detail throughout the History of the Universe. GMOX's multi-object capability and high angular resolution enable efficient studies of crowded fields, such as the Milky Way globular clusters and bulge, the Magellanic Clouds, Local Group dwarf galaxies and galaxy clusters.

The wide-band simultaneous coverage and the very fast slit configuration mechanisms also make GMOX ideal for followup of LSST transients.

9908-161, Session PS3

PRAXIS: a near-infrared spectrograph optimised for suppression of the OH background with fibre Bragg gratings

Simon Ellis, Jonathan S. Lawrence, Robert Content, Anthony Horton, Nicholas F. Staszak, Ross Zhelem, Pascal Xavier, Keith Shortridge, Scott Case, Naveen Pai, Urs Klauser, Julia Tims, Australian Astronomical Observatory (Australia); Joss Bland-Hawthorn, Emma Y. Lindley, Seong-Sik Min, Sergio G. Leon-Saval, The Univ. of Sydney (Australia); Roger Haynes, Martin Roth, Hans-Gerd

Löhmannsröben, Domenico Giannone, Eloy Hernandez, Thomas Fechner, Svend-Marian Bauer, Leibniz-Institut für Astrophysik Potsdam (Germany)

The problem of atmospheric emission from OH molecules is a long standing problem for near-infrared astronomy.

PRAXIS is a unique spectrograph, currently in the build-phase, which is fed by a fibre feed that removes the OH background. The OH suppression is achieved with fibre Bragg gratings, which were tested successfully on the GNOSIS instrument. PRAXIS will use the same fibre Bragg gratings as GNOSIS in the first implementation, and new, cheaper and more efficient, multicore fibre Bragg gratings in the second implementation. The OH lines are suppressed by a factor of ~1000, and the expected increase in the signal-to-noise in the interline regions compared to GNOSIS is a factor of ~9 with the GNOSIS gratings and a factor of ~17 with the new gratings.

PRAXIS will enable the full exploitation of OH suppression for the first time, which was not achieved by GNOSIS due to high thermal emission, low spectrograph transmission and high detector noise. PRAXIS will have extremely low thermal emission, through the cooling of all significantly emitting parts, including the fore-optics, the fibre Bragg gratings, a long length of fibre, and the fibre slit, and an optical design that minimises leaks of thermal emission from outside the spectrograph. PRAXIS will achieve low detector noise through the use of a Hawaii-2RG detector, and a high throughput through a efficient VPH based spectrograph.

PRAXIS will determine the absolute level of the interline continuum and enable observations of individual objects via an IFU. PRAXIS will first be installed on the AAT, then later on an 8m class telescope.

9908-162, Session PS3

Update on BOMBOLO: a 3-arm, wide-field, near-UV/optical imager for the 4-meter SOAR telescope

Eduardo Garcés Santibañez, Dani Guzmán, Pontificia Univ. Católica de Chile (Chile); Damien Jones, Prime Optics (Australia); Rodolfo Angeloni, Thomas Puzia, Pontificia Univ. Católica de Chile (Chile)

BOMBOLO is our instrument proposal for covering a series of scientific cases, in the not-so-explored time window of tens of seconds to minutes exposures, to be installed at SOAR observatory. BOMBOLO is a wide field imager, capable of simultaneous, synchronous and independent observations in three different bands of the near-UV and visible wavelengths.

BOMBOLO will be located at one of the Bent Cassegrain focal stations. Given its length, weight and mounting limitations, we discuss the current mechanical and opto-mechanical design of the instrument, given flexures caused by a changing gravity vector. In order to validate our designs, a Monte-Carlo simulation is used to explore different observing conditions, as the starting point for static and dynamic studies of the structure using FEA tools.

A quick update on the current state of the instrument related to the optical design and manufacturing as well as the CCD cameras is included.

9908-163, Session PS3

LRS2: design, assembly, testing, and commissioning of the second-generation low-resolution spectrograph for the Hobby-Eberly Telescope

Taylor S. Chonis, Gary J. Hill, Hanshin Lee, Sarah E. Tuttle, Brian L. Vattiat, Niv Drory, Briana L. Indahl, Trent W. Peterson, Jason Ramsey, The Univ. of Texas at Austin (United States)

The second generation Low Resolution Spectrograph (LRS2) is a new facility instrument for the Hobby-Eberly Telescope (HET). Designed as a powerful spectroscopic follow-up platform, LRS2 is based on the design of the HET's new Visible Integral-field Replicable Unit Spectrograph (VIRUS) and provides integral field spectroscopy for two seeing-limited fields of 6x12 arcseconds with unity fill factor. The replicable design of VIRUS has been leveraged for LRS2 to gain broad wavelength coverage from 370 nm to 1.0 micron, spread between two fiber-fed dual-channel spectrographs that operate in unison but observe independent fields that are separated by 100 arcseconds. The blue spectrograph pair, LRS2-B, covers 364 - 467 nm and 454 - 700 nm at fixed spectral resolving powers of ~2500 and ~1400, respectively, while the red spectrograph pair, LRS2-R, covers 643 - 845 nm and 823 - 1056 nm with both of its channels having spectral resolving powers of ~2500. In this paper, a detailed description of the instrument's design, assembly, and laboratory testing is provided in which the focus is placed on the departures from the basic framework of the design and processes previously established for VIRUS. Both LRS2 spectrograph pairs have been successfully deployed on the HET, and commissioning efforts are ongoing. Using on-sky data, the performance of the spectrograph is compared to models of the instrumental sensitivity. The measured performance of LRS2 indicates that the instrument will provide efficient spectroscopic follow-up observations of individual targets, and will be especially powerful when combined with the extensive survey capabilities of VIRUS for HETDEX.

9908-164, Session PS3

Cryogenic near infrared spectropolarimeter for the Daniel K. Inouye Solar Telescope

Andre Fehlmann, Cynthia Giebink, Jeffrey R. Kuhn, Ernesto J. Messersmith, Donald L. Mickey, Institute for Astronomy (United States) and Univ. of Hawai'i (United States); Isabelle F. Scholl, Institute for Astronomy (United States); Don James, Kirby Hnat, Greg Schickling, Richard Schickling, Universal Cryogenics (United States)

The Cryogenic Near Infrared Spectropolarimeter (CryoNIRSP) is a first light instruments for the Daniel K Inouye Solar Telescope (DKIST). This dual-beam instrument is designed to sensitively measure the full polarization state (Stokes I, Q, U and V) of solar spectral lines at wavelengths from 1 μm (500 nm goal) to 5 μm. The high dynamic range of the instrument allows measurements of the solar disk, near-limb and faint corona where the near-limb and coronal observations depend on DKIST's coronagraphic capabilities. It has the widest field-of-view and longest wavelength coverage of the four first-light DKIST facility instruments. These capabilities will provide sensitive measurements of the solar disk in the carbon monoxide (CO) bands; unique observations of spicules, prominences, flares and eruptive events in the low corona; and unprecedented sensitive measurements of the coronal magnetic field.

The CryoNIRSP instrument is divided into three optical subsystems: the feed optics, the spectrograph and the context imager.

The room temperature feed optics directs the light to 1) the spectrograph only 2) the context imager only 3) the spectrograph and context imager simultaneously. It also provides means to scan the field of view across the spectrograph slit, includes calibration lamps and accommodates the polarization modulator.

The spectrograph is an all reflective design to provide high overall throughput and broad spectral coverage. A 408 mm wide R2 echelle grating is required to achieve the desired resolution at the longest wavelengths. In order to reduce the thermal background for the IR

observations, we use closed helium cycle cryo-coolers to cool the filters, imaging optics, grating, polarization analyzer and detector to 77 K. The spectrograph will operate in a high resolution (R=100,000) disk mode and a low resolution (R=30,000) coronal mode with spatial resolutions of 0.15 and 0.5 arcsec and fields of view of 1.5 x 1.5 and 4 x 3 arcmin respectively. A multi-slit operation mode is also available that efficiently uses detector pixels for large area single-line spectropolarimetry.

The context imager is a separate optical system that records a 100 x 100 arcsec field around the slit at wavelengths of coronal emission lines of interest. The feed optics scan mirror can be used to mosaic the whole coronal mode field of view. The bandpass filters and detector inside the imager are cooled to cryogenic temperatures as well.

Both, spectrograph and context imager use a 2048 x 2048 HAWAII 2 array produced by Teledyne Scientific & Imaging. The PB1HS array controller was developed at the University of Hawaii, Institute for Astronomy in Hilo. This new controller reads the H2RG in slow and fast mode and allows for external triggering which is essential for synchronization to the polarization modulator.

CryoNIRSP has been fully assembled and initial laboratory tests were performed. This paper discusses the CryoNIRSP design and lessons learned during cryo-mechanical, grating rotation stage, and polarization analyzer sub-assembly testing.

9908-165, Session PS3

Balloon UV experiments for astronomical and atmospheric observations

Sreejith Aickara Gopinathan, Jayant Murthy, Margarita Safonova, Joice Mathew, Mayuresh N. Sarpotdar, Nirmal K., Ambily Suresh, Indian Institute of Astrophysics (India)

The near-ultraviolet (NUV) window from 200 to 400 nm has been largely unexplored through balloons for astronomy. This window includes several lines important to atmospheric chemistry (eg. SO2, O3, HCHO,BrO). We discuss the development of a compact near ultraviolet spectrograph with fibre optics input for balloon flights. It is a modified Czerny-Turner system using off the shelf optics. The system is portable and scalable to different telescopes. The use of reflecting optics reduces the transmission loss in UV. It uses an image intensified CMOS sensor operating in photon counting mode as the detector of choice. A light weight pointing system which have been developed for stable pointing of astronomical sources will also be discussed, together with methods to improve it's accuracy like using in-house build star sensor etc. Our primary scientific objectives include the observation of bright solar system objects like visible eye comets, moon and planets. The studies of planets will give us valuable information about the aurorae of planets, this will help us model and compare atmosphere's of other planets and earth. The other major objective is to look at the diffuse ultraviolet atmospheric emission features (airglow lines) and column densities of trace greenhouse gases, A spectrograph helps us in simultaneous measurement of various trace gases as well as provide better accuracy at higher altitudes compared to electromechanical trace gas measurement sondes. These lines contaminate most astronomical observations but are poorly characterized. Other objectives will include sprites in the atmosphere and meteor flashes from high altitude burn-outs. Our recent experiments and observations with high altitude balloons will be discussed.

9908-166, Session PS3

Development of high reflectivity coatings for large format Fabry-Perot etalons

Michael Sigwarth, Thomas J. Kentischer, Wolfgang Schmidt, Kiepenheuer-Institut für Sonnenphysik (Germany); Laurent Pinard, IN2P3-Lab. des Matériaux Avancés (France); Wilbur J. Reichman, Zygo Corporation (United States); Jörg Baumgartner, Alexander Bell, Kiepenheuer-Institut für Sonnenphysik (Germany); Gianpetro Cagnoli, IN2P3-Lab. des Matériaux Avancés (France); Andreas Fischer, Clemens Halbgewachs, Frank Heidecke, Kiepenheuer-Institut für Sonnenphysik (Germany); Robert Kestner, Zygo Corporation (United States); Peter Kuschnir, ZygoLOT GmbH (Germany); Oskar F. von der Lühe, Kiepenheuer-Institut für Sonnenphysik (Germany); Christophe Michel, Benoit Sassolas, IN2P3-Lab. des Matériaux Avancés (France); Thomas Scheiffelen, Kiepenheuer-Institut für Sonnenphysik (Germany)

The Visible Tunable Filter (VTF) is a diffraction-limited narrowband tunable instrument for imaging spectropolarimetry in the wavelength range between 520 and 860 nm. It is based on large-format Fabry Perots. The instrument will be one of the first-light instruments of the 4m aperture Daniel K. Inoue Solar Telescope (DKIST) that is currently under construction on Maui (Hawaii).

To provide a field of view of 1 arcmin and a spectral resolution ?/?? of about 100.000, the required free aperture of the Fabry Perots is 240mm. The high reflectivity coatings for the Etalon plates must preserve the plate figure specifications of better ?/100, and a micro roughness of < 0.1nm rms.

Coated surfaces with similar specifications have successfully been made for reflecting mirrors on thick substrates but not for larger format Fabry-Perot systems. Ion Beam Sputtering (IBS) based coatings provide stable, homogeneous, and smooth coatings. But IBS coatings also introduce stresses to the substrate that influence the plate figure in our case at the nm level.

In a joint effort with a industry partner and a French CNRS research laboratory, we developed and tested processes on small and full size substrates, to provide coated Etalon plates to the required specifications. Zygo Extreme Precision Optics, Richmond, CA, USA, is polishing and figuring the substrates, doing the metrology and FE analysis. LMA (Laboratoire Matériaux Avancés, Lyon, France) is designing and making the IBS coatings and investigating the detailed behavior of the coatings and related processes. Both partners provide experience from manufacturing coated plane optics for gravitational wave detection experiments and EUV optics. The Kiepenheuer-Institut für Sonnenphysik, Freiburg, Germany is designing and building the VTF instrument and is leading the coating development.

We present the characteristics of the coatings and the substrate processing concept, as well as results from tests on sample size and from full size substrate processing. We demonstrate that the tight specifications for a single Etalon plate are reached.

9908-167, Session PS3

The PAU Camera carbon fiber cryostat and filter interchange system

Cristóbal Padilla, Laia Cardiel-Sas, Otger Ballester, Ferràn Grañena, Luis Lopez, Ester Majà, Institut de Física d'Altes Energies (Spain); Francisco J. Castander, Institut de Ciencies de l'Espai (Spain) and Institut d'Estudis Espacials de Catalunya (Spain)

The PAU Camera is a novel instrument designed to make studies of Dark Energy. It is equipped with a system of 40 narrow-band (12.5 nm wide in spots of 10 nm) filters spanning the wavelength range from 450 nm to 850 nm, and with 6 wide-band filters (u, g, r, i, z, Y). It aims at observing ~100 deg2 of sky and provide up to 3 million redshifts to i(AB)~22.5 with

a z-uncertainty of ~ 3 per mill, in which shape and deep Broad-Band photometric measurements have already been obtained by CFHTLenS and KIDS, an in which spectroscopic redshifts for calibration are available from the GAMA, VIPERS, DEEP2 and zCOSMOS redshift surveys. The survey will be a few magnitudes deeper than current completed large flux limited surveys (such as Gamma) and 10 times larger than current completed deep flux limited surveys (such as VVDS/VIPERS/Deep2).

The camera is installed at the William Herschel Telescope. The focal plane, composed of 18 Hamamatsu photonics 2k x 4 k 200 microns thick fully depleted CCD's covers ~1 deg2 FoV, every 15 micron pixel corresponding to 0.26''. The PAU Camera is a technologically pioneer instrument built with a large carbon fiber enclosure in order to minimize weight at the WHT prime focus. Since the 8 central CCd's cover the observation of the 40 Narrow Band filters, a system of five movable filter trays arranged in juke-box like mechanism is installed. In order to minimize the dead areas in the focal plane, the filter trays are located as close as possible to the CCD's inside the cryostat. The cryogenic system includes a dual system: a Nitrogen system to make a fast cool down during installation of the instrument and a cryocooler system to maintain the operational temperature during the observations. The device operates within the range of temperatures from 150K to 300K at the absolute pressure of 10-7 mbar, being class-100 compliant.

A description of the challenges of having the largest carbon fiber cryostat in a camera of tis characteristics and its movable non accessible movable tray system is given, together with the experience in commissioning and operating such systems in the WHT telescope during the last year, since the camera was first installed in June 2015.

9908-168, Session PS3

Qualification of HEIDENHAIN linear encoders for picometer resolution metrology

Clemens Halbgewachs, Thomas J. Kentischer, Kiepenheuer-Institut für Sonnenphysik (Germany); Karsten Sändig, DR. JOHANNES HEIDENHAIN GmbH (Germany); Jörg Baumgartner, Alexander Bell, Andreas Fischer, Frank Heidecke, Thomas Scheiffelen, Wolfgang Schmidt, Michael Sigwarth, Kiepenheuer-Institut für Sonnenphysik (Germany); Erwin Spanner, Peter Speckbacher, DR. JOHANNES HEIDENHAIN GmbH (Germany); Oskar F. von der Lühe, Kiepenheuer-Institut für Sonnenphysik (Germany)

The Visible Tunable Filter (VTF) is a narrowband tunable instrument for imaging spectropolarimetry in the wavelength range between 520 and 860 nm. It is based on large-format Fabry Perots with a free aperture of 240mm. The instrument will be one of the first-light instruments of the 4m aperture Daniel K. Inoue Solar Telescope (DKIST) that is currently under construction on Maui (Hawaii).

To provide stable and repeatable spectral scanning by tuning the air gap distance of the Etalons, a metrology system with 20 pm resolution and drift stability of better 100 pm per hour is needed. The integration of the metrology system must preserve the tight optical specifications of the Etalon plates.

The HEIDENHAIN LIP 382 linear encoder system has a selected linear scale for low noise high signal interpolation. The signal period is 128nm and the interpolated signal from the sensor can be read out at 128nm/14bit = 7.8125pm.

To qualify the LIP 382 system for the VTF, we investigated the resolution and stability under nominal VTF operation conditions and verified a mounting concept for the sensor heads.

We present results that demonstrate that the LIP 382 system fulfills the requirements for the VTF Etalons. We also present a design for the sensor head mounts.

9908-169, Session PS3

MOPTOP: a multi-colour optimised optical polarimeter

Helen E. Jermak, Iain A. Steele, Robert J. Smith, Liverpool John Moores Univ. (United Kingdom)

We present the design and science case for a fourth-generation polarimeter; MOPTOP: a Multicolour OPTimised Optical Polarimeter which is optimised for sensitivity and bi-colour observations. Its location on the world's largest fully autonomous robotic telescope, the Liverpool Telescope (LT), will allow it to become the community's most powerful instrument for probing transient astronomical sources such as powerful gamma-ray bursts, blazars and X-ray binaries. It will enable the first measurements of dust production rates and surface composition in a large sample of solar system objects currently being discovered by the ESA Gaia space mission.

Building on the scientific success of the predecessor polarimeter, RINGO, we introduce an optimised polarimeter which is only limited by the photon counting efficiency of the detectors. Using a combination of four CMOS cameras, a continuously rotating half-wave plate and a wire grid polarizing beamsplitter, we can accurately measure the polarisation of sources down to ~19th magnitude with much lower systematics (<0.1%) and variability timescales as short as a few seconds. This will allow accurate measurements of the intra-nightly variability of the polarisation of sources such as gamma-ray bursts and blazars (AGN orientated with the jet pointing toward the observer), allowing the constraint of magnetic field models revealing more information about the formation, ejection and collimation of jets.

Although the MOPTOP design was produced for the specifications of the LT, we also intend the instrument design to be fully accessible to the public domain and we encourage copies to be placed on other facilities to allow better sampling of transient sources.

9908-170, Session PS3

The PAUCam readout electronics system

Jorge Jiménez Rojas, José María Illa, Laia Cardiel-Sas, Institut de Física d'Altes Energies (Spain); Juan de Vicente, Javier Castilla, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Ricard Casas, Institut de Ciències de l'Espai (Spain)

The PAUcam is an optical camera with a wide field of view of 1 deg x 1 deg and up to 45 narrow and broad band filters. The camera is already installed on the William Herschel Telescope (WHT) in the Canary Islands, Spain and successfully commissioned during the first period of 2015.

The camera is composed of a mosaic of 18 scientific-grade Hamamatsu Photonics CCDs type S10892-04, 2k x 4k pixels, back-side illuminated and fully depleted. The CCDs configuration can be changed on-the-fly by software to use the whole focal plane for science (normal mode) or to use the top and bottom CCDs as guiders (guider mode). The readout speed for the science mode is 150 KHz and for guiding mode, the readout speed can be increased up to 300 KHz while reading one region of interest (ROI).

In order to fulfill with the specifications for the camera readout system, there was necessary to use four MONSOON (NOAO) crates: two of them reading out eight CCDs each one and the other two crates reading out just one CCD per crate in order to reach different speeds and exposure times for guiding issues. There is also involved a preamplification stage (PREAMP), one per CCD, located inside the camera cryostat, so it was designed to be suitable for low outgassing and reduced power consumption/dissipation. The fan out boards (MIX) connect signals from

the inner PREAMP stage to the MONSOON crates trough a DSUB50 hermetic feedthrough connector and they are able to drive up to 5 CCDs signals for the long size MIX's pcb and up to 3 CCDs for the short one.

The camera is mounted on the primary focus and due the limited weight supported by the telescope at this point, there was necessary to mount the whole readout electronics power supplies at the nasmyth level which required more than 30 meters of cables to connect the front-end and demanding a dedicated filter stage to stabilize the power supplies and to guarantee the required low noise power sources.

Besides that, there was necessary to avoid any uncontrolled grounding loop around the readout electronics system since the camera is equipped with several servo-motors, pumps and cryocoolers controlled by a PLC, then on this way and from the very beginning, the camera design was conceptually focused to a "star-ground" configuration with enough flexibility to be adapted to the telescope conditions.

Finally and during the camera commissioning, there were performed some standard tests using dome flats and then the validation on sky showed the good performance of the whole readout electronics system with a mean readout noise of ~9 e- rms which main results are presented on this paper.

9908-171, Session PS3

Characterization and performance of PAUCam filters

Ricard Casas, Institut de Ciències de l'Espai (Spain); Laia Cardiel-Sas, Institut de Física d'Altes Energies (Spain); Francisco J. Castander, Institut de Ciències de l'Espai (Spain) and Institut d'Estudis Espacials de Catalunya (Spain); Carlos Díaz, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Javier Gaweda, Jorge Jiménez Rojas, Institut de Física d'Altes Energies (Spain); Sergio Jiménez, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Mikel Lamensans, Cristóbal Padilla, Institut de Física d'Altes Energies (Spain); Francisco Javier Garcia Rodriguez, Ctr. de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional (Spain); Eusebio Sanchez Alvaro, Ignacio Sevilla Noarbe, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain)

PAUCam is a large field of view camera designed to cover the full useful field in the corrected prime focus of the William Herschel Telescope (WHT), at the Observatorio del Roque de los Muchachos (La Palma, Canary Islands, Spain). To cover this field of view, 18 CCD detectors of 2K ? 4K and 15 ?m of pixel size, manufactured by Hamamatsu Photonics K. K., are distributed in a square of 20 ? 20 cm, with a pixel scale of 0.265 arcsec/pix.

The main purpose of this camera is to create a low resolution spectrum (R ~40–80) for all objects in the field of view up to magnitude 22.5. The camera has five trays, each with eight different narrow band filters, placed in front of the eight central detectors. The rest of the CCDs are covered with broad band filters for calibration and/or guiding. Six additional trays with six large broad band filters cover the full focal plane.

In this contribution, we describe the performance of these filters both in the characterization tests at the laboratory and on-site.

The large broad band filters were manufactured by Asahi Spectra Co. Ltd. covering the photometric bands of DECam (at NOAO's Blanco Telescope): u, g, r, i, z and Y. The physical size of these filters is 203.4 mm ? 208.8 mm ± 0.1 mm with a chamfer of 3.0 mm and a thickness of 3.0 ± 0.1 mm. The difference transmission in the filter surface at a given wavelength is up to 1%, and the transmission out-of-band is smaller than 1%. The acceptance and post-calibration tests were carried out at the IFAE laboratories determining the transmission in different points of the filter with a good agreement with the expected profiles.

The narrow band filters, and the small broad band filters were manufactured by the Iridian Spectral Technologies. In this case, the physical size of each filter is 65.7 mm ? 33.8 mm ± 0.1 mm, with a thickness of 3.0 ± 0.1 mm, and the rectangular profile of each one, with a FWHM of 14 nm are centered in the range between 455 and 845 nm in steps of 10 nm. The small filters, narrow and broad-band, were tested at the CIEMAT laboratories using a spectrophotometer and measuring the filters in eighteen positions with an excellent agreement with the profiles design.

All filters are placed within a few millimeters from the focal plane in a focalized beam. This produces a change the effective transmission profile. On the other hand, the incidence's angle changes, radially in the focal plane, between 0º in the center up to 3º in the external filters. Moreover, the filters are operating in vacuum at 240K, which produces a small shift in the wavelength. All of these effects are more important for the narrow band filters than for the broad band ones for which they can be neglected.

The first light of PAUCam was in June 2015, the commissioning of the camera confirming its expected performance.

9908-172, Session PS3

PLC-controlled cryostats for the BlackGEM detectors

Gert Raskin, Johan Morren, Wim Pessemier, KU Leuven (Belgium); Steven Bloemen, Marc Klein Wolt, Radboud Univ. Nijmegen (Netherlands); Ronald Roelfsema, NOVA Optical Infrared Instrumentation Group (Netherlands); Paul J. Groot, Radboud Univ. Nijmegen (Netherlands); Conny Aerts, KU Leuven (Belgium)

BlackGEM is an array of wide-field telescopes, currently under development at the Radboud University Nijmegen and at NOVA (Netherlands Research School for Astronomy). It targets the detection of the optical counterparts of gravitational waves. The first three BlackGEM telescopes are planned to be installed in 2017 at the La Silla observatory (Chile). A single prototype telescope, named MeerLICHT, will already be commissioned by the end of 2016 in Sutherland (South-Africa) to provide an optical complement for the MeerKAT radio array. The BlackGEM array consists of, initially, a set of three identical Dall-Kirkham Cassegrain telescopes with a 65-cm primary mirror in a carbon fiber structure. Each telescope is equipped with a single STA1600 CCD detector with 10k x 10k 9-micron pixels that covers a 2.7 square degrees field of view. The cryostats for housing these detectors are developed and built at the Institute of Astronomy of the KU Leuven University (Belgium).

The operational model of BlackGEM requires long periods of reliable hands-off operation. Therefore, we designed the cryostats for long vacuum hold time and we make use of a closed-cycle cooling system, based on Polycold PCC Joule-Thomson coolers. A single programmable logic controller (PLC) controls the cryogenic systems of several BlackGEM telescopes simultaneously, resulting in a highly reliable, cost-efficient and maintenance-friendly system. PLC-based cryostat control offers some distinct advantages, especially for a robotic facility. Apart of temperature monitoring and control, the PLC also monitors the vacuum quality, the power supply and the status of the PCC coolers (compressor power consumption and temperature, pressure in the gas lines, etc.). Furthermore, it provides an alarming system and safe and reproducible procedures for automatic cool down and warm up. The communication between PLC and higher-level software takes place via the OPC-UA protocol, offering a simple to implement, yet very powerful interface. Finally, a touch-panel display on the PLC provides the operator with a user-friendly and robust technical interface. In this contribution, we present the design of the BlackGEM cryostats and of the PLC-based control system.

9908-173, Session PS3

Innovative polarization-holographic imaging Stokes spectropolarimeter for astronomy: first results of laboratory and field tests

Teimuraz Kvernadze, Georgi Kurkhuli, E. Kharadze Abastumani Astrophysical Observatory (Georgia) and Ilia State Univ. (Georgia); Barbara N. Kilosanidze, George Kakauridze, Institute of Cybernetics (Georgia) and Georgian Technical Univ. (Georgia)

An innovative real-time imaging Stokes spectropolarimeter is presented. The main unit of the polarimeter is an integral polarization-holographic diffraction element, which enables the complete analysis of the polarization state of light to be carried out in real time. An element is recorded by a special holographic schema using circularly and linearly polarized beams. As a result it decomposes an incoming light into orthogonal circular and linear diffraction orders.

The simultaneous CCD intensity measurements of the corresponding points or areas in the diffraction orders and further data reduction through the calibration parameters we get real-time Stokes images of a light source. The further reduction of Stokes images allows to determine detailed polarization state of a light coming from a point or extended space object in a narrow or a wide spectral range.

The operating spectral range of the polarimeter is 500-1600 nm with diffraction efficiency equal to 20% at 532 nm, 16% at 635 nm and 2% at 1550 nm.

The laboratory calibration tests were obtained with a quasi-monochromatic point size depolarized light source which further were circularly or linearly polarized with known polarization parameters and a degree of polarization near to 100%.

The theoretical model of relations between measured intensities in different diffraction orders and Stokes parameters, earlier developed by the authors (Kilosanidze B., Kakauridze G. SPIE Proceedings, vol. 8082-126, 2011), were used to calibrate the polarimeter for different spectral ranges. The laboratory tests show that the resulting errors are near of 1% or better.

For field test the polarimeter were installed on the f/10 refractor with 10cm aperture and CCD autoguiding. The bright polarization standard stars and the selected areas of moon with known polarization were observed through different light filters during several nights. Further reduction confirms the results of laboratory tests and ability of this new polarimeter to successfully be used for under 1% accuracy polarimetry. The possibility of increasing the accuracy by one order is discussed. The polarimeter is very compact, light weight and could be installed both on ground-based large or small and airborne telescopes.

9908-174, Session PS3

End-to-end simulations of the visible tunable filter for the Daniel K. Inouye Solar Telescope

Wolfgang Schmidt, Matthias Schubert, Jörg Baumgartner, Alexander Bell, Andreas Fischer, Clemens Halbgewachs, Frank Heidecke, Thomas J. Kentischer, Oskar F. von der Lühe, Thomas Scheiffelen, Michael Sigwarth, Kiepenheuer-Institut für Sonnenphysik (Germany)

The Visible Tunable Filter (VTF) is a narrowband tunable filter system for imaging spectroscopy and spectropolarimetry based on large-format Fabry Perot Etalons. The instrument will be one of the first-light instruments of the Daniel K. Inouye Solar Telescope (DKIST) that is currently under construction on Maui (Hawaii). The VTF is being developed by the Kiepenheuer Institut fuer Sonnenphysik in Freiburg, as a German contribution to the DKIST.

We perform end-to-end simulations of spectropolarimetric observations with the VTF to verify the science requirements of the instrument. The instrument simulator includes the two Etalons in telecentric configuration, illuminated by an f:200 beam, and prefilters for different wavelength bands with widths between 0.4 and 0.8 nm.

The clear aperture of the Etalons is 250 mm, corresponding to an angular field of view with a diameter of 60 arcsec. The detectors in the focal plane have a resolution of 0.014 arcsec. The instrument simulator takes into account that the two Etalons are indeed not exactly in telecentric configuration (i.e., mounted in a focal plane), but are displaced from the focal plane by about 500 mm each. The micro-roughness of the Etalon is included in the simulations, as well as large-scale figure errors of the plates. We use an ideal modulator with equal modulation coefficients of 3-1/2 for the polarization modulation.

The micro-roughness of the Etalon's high-reflectivity coatings was measured to 0.095 nm RMS on a full-size prototype plate. This value is included in the simulations. To model the large-scale figure errors we employ low-order Zernike polynomials (power and spherical aberration) with amplitudes of 2.5 nm RMS.

We synthesize Stokes profiles of two neutral iron lines (630.15 nm and 630.25 nm) for a range of magnetic field values and for several inclination angles using the SIR code. We estimated the photon noise on the basis of the DKIST and VTF transmission values, the atmospheric transmission and the spectral flux from the Sun. For the simulations, we employ a signal-to-noise ratio of SNR=675, a typical value for VTF measurements.

To determine the magnetic field sensitivity, we performed a spectral inversion of the simulated observations and compared the resulting values for the magnetic field strength with the input values. We obtain a sensitivity of 20 G for the longitudinal component and for 100 G for the transverse component, in agreement with the science requirements for the VTF.

9908-175, Session PS3

Bokeh mirror alignment for Cherenkov telescopes

Sebastian Achim Mueller, ETH Zürich (Switzerland)

Segmented reflectors are a great choice for Imaging Atmospheric Cherenkov Telescopes (IACTs). They are light weight and mass produced. Huge and fast apertures of segmented reflectors provide good image quality to recognize the few gamma ray air showers in the vast majority of cosmic ray showers.

However, the alignment of the individual mirror facets of an segmented reflector remains a challenge. We present a new alignment method which is using the Bokeh of the imaging reflector.

Every non zero aperture imaging system has a non trivial Bokeh function. In case of thin imaging systems, the Bokeh function is very close related to the aperture function of the system. The Bokeh function of any imaging system can be observed when recording images with this system of a point like light source in an out of focus configuration.

On segmented reflectors, the aperture function shows special features because of the gaps in between the mirror facets. In approximation of thin apertures, the Bokeh function turns out to fit the aperture function up to a scaling factor which depends on the object and image sensor distance. Therefore also the Bokeh function of a segmented reflector shows the special features of the segmented aperture.

But, the Bokeh function only matches the aperture function when the mirror facets are well aligned which marks the starting point for Bokeh alignment.

Bokeh alignment is a more general form of the 2f alignment where a light source in distance 2f is observed to align the facets. We observe

and optimize the Bokeh of a segmented reflector to determine the facet orientations and to align the mirror facets. We create templates for the desired Bokeh function of our reflector and make the facet orientations match these. A first template can be obtained very easy by taking a picture of the segmented reflector aperture function, scale it, and make it the Bokeh template.

A more precise Bokeh template, which overcomes the limitations of the thin aperture approximation, is taken from ray tracing simulations.

Bokeh alignment can be done any time and does not need star light or clear sky.

When a flash light is used to observe the Bokeh, it can even be done during the day. Bokeh alignment is geometrically much more flexible then 2f alignment. It can reach the inner most facets of a reflector more easily, and it can be done off axis. Further, the orientation determination of the mirror facets can be done very fast, since the alignment of the facets can be deduced from a single Bokeh record. Bokeh alignment scales better with the number of facets then methods observing star images which have to use their facet actuation extensively to overcome the image to facet ambiguities.

We present a first usage of Bokeh alignment on FACT, a 4m IACT on Canary island La Palma, Spain and further development of the method on the CTA MST prototype in Brelin Adlershof.

9908-176, Session PS3

Normalized and asynchronous mirror alignment for Cherenkov telescopes

Sebastian Achim Mueller, ETH Zürich (Switzerland)

Segmented reflectors are a great choice for Imaging Atmospheric Cherenkov Telescopes (IACTs). They are light weight and inexpensive due to mass production. Huge and fast apertures of segmented reflectors provide good image quality to recognize the few gamma ray air showers in the vast majority of cosmic ray showers.

However, the alignment of the individual mirror facets of a segmented reflector remains a challenge. We present a robust star tracking alignment method which is not restricted to perfectly clear nights and scales excellently with large numbers of facets. We call it NAMOD because it records asynchronous of the drive and normalizes the facet reflection responses to do the mirror orientation determination. NAMOD adopts the ideas of the VERITAS raster scan method but enhances it with an additional camera to become more flexible and robust.

While the telescope is wobbling close by a star, a reflector camera records the reflections in the mirror facets seen from the reflectors focal point. In addition a star camera is mounted parallel to the reflectors optical axis and records the sky seen by the telescope. The relative pointing direction of the telescope, with respect to the star, is calculated using the star camera image. Further, the star light reflections seen in the reflector camera images are normalized using the star light found in the star camera image. Both cameras are radiometrically calibrated, the star camera also is geometrically calibrated. For arbitrary wobble positions, the relative telescope pointing and the normalized mirror facet responses are recorded. From these records, the individual facet point spread functions and the facet orientations are reconstructed.

Since the normalized mirror facet responses are independent of the reference star, records on different reference stars can be combined what makes NAMOD more flexible. Further, partially cloud coverage is taken into account, too. When the reference star signal becomes too dim, recording is paused automatically.

As NAMOD records asynchronous of the drive, there is no communication between the drive and NAMOD which makes the method easy to install.

NAMOD does not need mirror facet actuation to determine the facet orientations, but it can create alignment instructions for the actuators. The full alignment state of the segmented reflector can be recorded without touching a single facet which is handy to feed the Monte Carlo simulations the current reflector state.

We present the Mini FACT test bench which was used to develop NAMOD to minimize the overlap with gamma ray observation time. We present the alignment results on FACT, a 4m IACT on Canary island La Palma, Spain. In addition, we compare NAMOD's alignment power to the optimum found in ray tracing simulations and present individual mirror facet point spread reconstructions.

9908-177, Session PS3

First results and future plans of the Canarias Infrared Camera Experiment (CIRCE) for the Gran Telescopio Canarias

Cabrera-Lavers, Stephan Geier, Peter Pessev, Gran Telescopio de Canarias, S.A. (Spain); Ata Sarajedini, Univ. of Florida (United States); Alberto J. Castro-Tirado, Instituto de Astrofísica de Andalucía (Spain)

CIRCE is a near-infrared (1-2.5 micron) imager (upgrading to low-resolution spectrograph and polarimeter in Spring 2016) in operation as a visitor instrument on the Gran Telescopio Canarias 10.-4m telescope. It was built largely by graduate students and postdocs, with help from the UF Astronomy engineering group, and is funded by the University of Florida and the U.S. National Science Foundation. CIRCE is helping to fill the gap in time between GTC first light and the arrival of EMIR, and will also provide the following scientific capabilities to compliment EMIR after its arrival: high-resolution imaging, narrowband imaging, high-time-resolution

photometry, imaging- and spectro-polarimetry, and low-resolution spectroscopy. In this poster we present the first light and commissioning results for CIRCE, as well as review its current and future capabilities.

9908-178, Session PS3

Development of the NASA MCAT auxiliary telescope for orbital debris research

James M. Frith, The Univ. of Texas at El Paso (United States); Susan Lederer, NASA Johnson Space Ctr. (United States); Heather M. Cowardin, The Univ. of Texas at El Paso (United States); Brent A. Buckalew, Jacobs Technology, Inc. (United States); Paul Hickson, The Univ. of British Columbia (United States); Phillip D. Anz-Meador, Jacobs Technology, Inc. (United States)

The National Aeronautical and Space Administration (NASA) has recently deployed the Meter Class Autonomous Telescope (MCAT) to Ascension Island. MCAT will provide NASA with a dedicated optical sensor for observations of orbital debris with the goal of statistically sampling the orbital and photometric characteristics of the population from low Earth to Geosynchronous orbits. Additionally, a small auxiliary telescope, co-located with MCAT, is being deployed to augment its observations by providing near-simultaneous photometry and astrometry, as well as offloading low priority targets from MCAT's observing queue. It will also serve to provide an independent measurement of the seeing conditions to help monitor the quality of the data being produced by the larger telescope.

Comprised of off-the-shelf-components, the MCAT Auxiliary Telescope will have a 16-inch optical tube assembly, Sloan g'r'i'z' and Johnson/Cousins BVRI filters, and a fast tracking mount to help facilitate the tracking of objects in low Earth orbit. Tracking modes and tasking will be similar to MCAT except an emphasis will be placed on observations that provide more accurate initial orbit determination for the objects detected by MCAT. The near-simultaneous observations will also provide the opportunity for multi-filter color information of the debris objects to be obtained. Color information can further distinguish the individual objects within the population and provide insight into the reflectance properties of their surface material. The specific hardware, software, and tasking methodology of the MCAT Auxiliary Telescope is presented here.

9908-179, Session PS3

High-resolution camera system for very precisely measuring meteor velocities

Felix C. M. Bettonvil, NOVA Optical Infrared Instrumentation Group (Netherlands)

For the determination of meteor orbits in our solar system, trajectories are required of meteor trails inside our atmosphere, together with an estimate of the velocity. The velocity is traditionally measured with a rotating shutter in front of the lens or in between lens and film or detector. The accuracy of this modulation, as well as the modulation speed and astrometric accuracy of the exposure determine how well the velocity of the meteor can be estimated.

An alternative method for modulation is proposed, which does not rely on rotating choppers but instead on a Liquid Crystal (LC) optical shutter, which periodically switches between dark state and transparent, which was with success first applied to a meteor all-sky camera. Recent developments of this technology have now made available even faster LCs, which allows for modulation frequencies in the 100Hz – 1kHz range. This opens the way to observations with higher resolution, which should enable determination of orbits with higher accuracy, which is of large importance as the velocity parameter is the most sensitive parameter in determination of the orbit. Obtaining orbits with higher accuracy is highly interesting as it allows detection of fine structure in meteoroid streams at a more detailed level.

This paper, i) describes the details of high-resolution camera based on the LC shutter technology, ii) presents the first results obtained with this system, iii) discusses them and iv) discussed improvements for an even higher resolution system.

9908-180, Session PS3

CYRA: a cryogenic infrared spectrograph for the 1.6 meter new solar telescope at Big Bear Solar Observatory

Wenda Cao, Big Bear Solar Observatory (United States); Matt Penn, National Solar Observatory (United States); Claude Plymate, Nicolas Gorceix, Roy Coulter, Philip R. Goode, Big Bear Solar Observatory (United States)

CYRA (CrYogenic solar spectrogRAph) is a facility instrument of the 1.6 meter New Solar Telescope (NST) at the Big Bear Solar Observatory (BBSO), which is the highest resolution solar telescope in the U.S. in a generation. CYRA focuses on the study the near-infrared solar spectrum between 1 and 5 microns, an unexplored region which is not only fertile ground for photospheric magnetic diagnostics, but also allows a unique window into the chromosphere lying atop the photosphere. CYRA is the first fully cryogenic spectrograph in any solar observatory with its two predecessors, on the McMath-Pierce and Mees Telescopes, being based on warm optics except for the detectors and order sorting filters. CYRA is used to probe magnetic fields in various solar features and the quiet photosphere. CYRA measurements will allow new and better 3D extrapolations of the solar magnetic field and will provide more accurate boundary conditions for solar activity models. Superior spectral resolution of 150,000 and better allows enhanced observations of the chromosphere in the carbon monoxide (CO) spectral bands and will yield a better understanding of energy transport in the solar atmosphere. The CYRA instrument is divided into of two optical sub-systems: the Fore-Optics Module and the Spectrograph. The Spectrograph is the heart of the instrument and contains the IR detector, grating, slits, filters, and imaging optics all in a cryogenically cooled dewar (cryostat). The detector is based on a 2048 by 2048 pixels HAWAII 2 array produced by Teledyne Scientific & Imaging, LLC. The interior of the cryostat and the readout electronics are maintained at 70 Kelvin by helium refrigerant based cryo-coolers, while the IR array is cooled to 30 Kelvin. The Fore-Optics Module stabilizes the solar image, provides scanning capabilities, and transfers the light to the Spectrograph. CYRA has been installed and is undergoing its commissioning phase. This paper reports on the design and the implementation of CYRA in detail. First light scientific observations are presented and discussed.

9908-181, Session PS3

TAUKAM: a new prime-focus camera for the Tautenburg Schmidt Telescope

Bringfried G. W. Stecklum, Jochen Eisloeffel, Sylvio Klose, Uwe Laux, Tom Löwinger, Helmut Meusinger, Michael Pluto, Johannes Winkler, Thüringer Landessternwarte Tautenburg (Germany)

The Thueringer Landessterwarte Tautenburg is upgrading the prime focus camera of the 2-m telescope. In its Schmidt configuration with the 1.34-m correction plate mounted, it is still the world's largest imaging Schmidt system. While the full CCD coverage of the 3.3 x 3.3 square degree field of view is prohibitive, the new 6k x 6k camera will provide an almost fourfold gain in field coverage (80' x 80' vs. 42' x 42') over that provided by the 2k

x 2k CDD currently still in use. A contract was signed with Photon Lines SAS for the delivery of a Spectral Instruments 1110S camera in 2017. The camera will be equipped with an e2v CCD PN 231-C6-1-G11 detector. The pixel size of 15 microns corresponds to 0.77 arcsec which is tailored to the seeing conditions (median 2 arcsec) at our site. The detector will be of deep-depletion type sporting an astro-multi-2 anti-reflection coating. The cooling will be provided by a closed-cycle cooler. Extra long cooling lines will permit to place the closed-cycle cooler into the basement, thus avoiding heat circulation in the dome. This, however, requires special suspension of the cooling lines to allow for the telescope movement. With the new camera we will move from Johnson-Cousins to SDSS filters, accompanied by a selection of special filters, e.g. narrow-band Halpha and [SII]. Due to the increased size of the filters (120 mm square) housing in a filter wheel is no longer possible because it would obstruct too much light in the tube. Instead, a robotic device will be used to grab a filter from a storage in the corner of the tube (which has a square cross-section), and move it into the optical path. The camera shutter of compact type will be delivered by Bonn Shutter. First light is foreseen in autumn 2017. Prime science objectives which will profit from the enhanced imaging capabilities are monitoring of potentially hazardous asteroids, variability of young stars and brown dwarfs, long-term variability of quasars, and gamma-ray burst afterglows. The project is funded by the federal state of Thuringia within the framework of infrastructure development.

9908-182, Session PS3

Calibrating the SN factory Integral Field Spectrograph (SNIFS) with SCALA

Daniel Küsters, Simona Lombardo, Marek Kowalski, Jakob Nordin, Mickael Rigault, Humboldt-Univ. zu Berlin (Germany); Greg Aldering, Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

We present upgrades and preliminary results of SCALA - a calibration device for the Supernova Integral Field Spectrograph (SNIFS). SCALA illuminates the University of Hawaii 2.2 m (UH88) telescope and monitors the emitted light with calibrated photodiodes. A monochromator is used as a tunable bandpass for a white light source, after which the light is fed through a fiber bundle towards six integrating spheres which illuminate 18 openings homogeneously. These homogeneously illuminated surfaces are projected onto the focal plane of the telescope, effectively creating an artificial planet with a constant surface brightness. This setup produces a flat field for the telescope which can be tuned in wavelength and calibrated with the photodiodes.

In Spring 2015 we performed calibrations together with spectrophotometric observations of standard stars.

The setup was improved with respect to the one described in Lombardo S. et al 2014, by the installation of an entrace pupil mask. The mask corrects for spatial throughput variations in the entrance pupil of the telescope and for systematic differences in flatfields, which are produced by SCALA. We will present preliminary throughput measurements of the system consisting of telescope and SNIFS.

One source of systematics is the influence of the calibration device on stray light and ghosts. In Spring 2015 we used different beam properties of SCALA to examine its influence on stray light. In the photometric observations we used the filters U, G, R, I, Z to sample the wavelength dependency. The observations do not show ghosts but have dust grain imprints. Ratios images of the different beam configurations show smooth variations across the field of view, which do not depend on the selected filter. The change in stray light is driven by the size of the artificial planet, and is only slightly influenced by the shape of the entrance pupil.

The mask will allow us to decrease the collecting area of the UH88 telescope by a factor of 10, effectively allowing for observations of brighter stars. In combination with closing some of the holes in the mask it will be possible to observe Vega or Sirius with the same instrument as used for supernovae.

9908-183, Session PS3

Visible Imaging Spectrometer (VIS) of the New Solar Telescope at Big Bear Solar Observatory

Wenda Cao, Nicolas Gorceix, Sergey Shumko, Philip R. Goode, Big Bear Solar Observatory (United States)

The Visible Imaging Spectrometer (VIS) has been developed and outfitted to the largest solar telescope, the 1.6-m New Solar Telescope (NST) at Big Bear Solar Observatory (BBSO). VIS is based on a single Fabry-Pérot Interferometer and interference filters to provide high resolution spectroscopic observation over a field-of-view of 74” by 64” in the visible wavelength range from 550 nm to 700 nm. With the aid of the BBSO adaptive optics (AO) system, the spatial resolution is close to the diffraction limit of the NST. The spectroscopic cadence reaches 10 seconds with a multi-frame sampling at each wavelength over the spectral lines. Currently available spectral lines include Ha (656.3 nm) and Na I D2 line (589 nm). This paper reports on the design, implementation, calibration and operation of VIS in detail. First light scientific observations are presented and discussed.

9908-185, Session PS3

JPCam: development of a 1.2 g-pixel camera for the J-PAS survey

Keith Taylor, Antonio Marín-Franch, Ctr. de Estudios de Física del Cosmos de Aragón (Spain); René Laporte, Instituto Nacional de Pesquisas Espaciais (Brazil); Fernando G. Santoro, ASTRO Electro-Mechanical Engineering, LLC (United States)

JPCam is a 14-CCD mosaic camera, using the new e2v 9k-by-9k 10 m-pixel, 16-channel detectors to be deployed on a dedicated 2.55 m wide-field telescope at the OAJ (Observatorio Astrofísico de Javalambre) in Aragon, Spain. The camera is designed to perform a Baryon Acoustic Oscillations (BAO) survey of the northern sky. The J-PAS survey strategy will use 54 relatively narrow-band (13.8 nm) filters equi-spaced between 370 and 920 nm plus 3 broad-band filters to achieve unprecedented photometric red-shift accuracies for faint galaxies over 8000 square degrees of sky. This paper presents an overview of JPCam as well as a brief outline of the main J-PAS project.

9908-186, Session PS3

Design and development of control unit and software for the ADFOSC instrument of the 3.6 m Devasthal optical telescope

Tripurari S. Kumar, Aryabhatta Research Institute of Observational Sciences (India)

In this paper, we describe the details of inhouse developed control unit and GUI software for positioning two filter wheels, a slit wheel and a grism wheel of the ARIES Devasthal faint object spectrograph camera (ADFOSC) instrument. This ADFOSC instrument is a first generation instrument being built for the 3.6 m Devasthal optical telescope (DOT). The control hardware consists of five electronic boards based on low cost 8-bit PIC microcontrollers and are distributed over I2C bus. The four wheels are controlled by four identical boards which are configured in I2C slave mode while the fifth board acts as an I2C master and sends and receives commands with the slave boards. The master also communicates with the interfacing PC over TCP/IP protocol using simple ASCII commands. For

moving the wheels stepper motors along with suitable amplifiers have been employed and homing

is achieved using hall effect sensors. By implementing distributed control units having identical design modularity is achieved enabling easier maintenance and upgradation. A GUI based software for commanding the instrument is developed in Microsoft Visual C++. For operating the system during observations a user selects normal mode while during maintenance engineering mode is used. A detailed time-stamped log of commands and operation is continuously generated. Both the control unit and the software have been successfully tested and integrated with the ADFOSC instrument.

9908-187, Session PS3

The opto-mechanical design for GMOX: a next-generation instrument concept for Gemini

Stephen A. Smee, Robert H. Barkhouser, Johns Hopkins Univ. (United States); Massimo Robberto, Johns Hopkins Univ. (United States) and Space Telescope Science Institute (United States); Zoran Ninkov, Rochester Institute of Technology (United States); Mario Gennaro, Space Telescope Science Institute (United States); Timothy M. Heckman, Johns Hopkins Univ. (United States)

We present the opto-mechanical design of GMOX, the Gemini Multi-Object eXtra-wide-band spectrograph, a potential next-generation (Gen-4 #3) facility-class instrument for Gemini. GMOX is a wide-band, multi-object, spectrograph with spectral coverage spanning 350 nm to 2.4 um with a nominal resolving power of R~5000. Through the use of Digital Micromirror Device (DMD) technology, GMOX will be able to acquire spectra from hundreds of sources simultaneously, offering unparalleled flexibility in target selection. Utilizing this technology, GMOX can rapidly adapt individual slits to either seeing-limited or diffraction-limited conditions. The optical design splits the bandpass into three arms, blue, red, and near infrared, with the near-infrared arm being split into three channels covering the Y+J band, H band, and K band. A slit viewing camera in each arm provides imaging capability for target acquisition and fast-feedback for adaptive optics control with either ALTAIR (Gemini North) or GeMS (Gemini South). Mounted at the Cassegrain focus, GMOX is a large (1.3 m x 2.8 m x 2.0 m) complex instrument, with six dichroics, three DMDs (one per arm), five science cameras, and three acquisition cameras. Roughly half of these optics, including one DMD, operate at cryogenic temperature. To maximize stiffness and simplify assembly and alignment, the opto-mechanics are divided into three main sub-assemblies, including a near-infrared cryostat, each having sub-benches to facilitate ease of alignment and testing of the optics. In this paper we present the conceptual opto-mechanical design of GMOX, with an emphasis on the mounting strategy for the optics and the DMDs, as well as thermal design details related to the near-infrared cryostat.

9908-188, Session PS3

Photonic Lightbuckets for astronomical optical spectrographs

Amanda J. Townsend, Stephen S. Eikenberry, Craig D. Warner, Hipatia Veronica Donoso, Univ. of Florida (United States)

In order to achieve low-cost large-aperture ground-based optical spectroscopy systems, we are using inexpensive commercial-off-the-shelf (COTS) telescopes and components (such as acquisition/guide CCDs and control computers) together with innovative 3D printed components to create semi-autonomous small telescope arrays and fiber-fed spectrographs. Small telescopes used conjointly ("photonic lightbuckets") and connected by our new fiber-optic linkage have the effective light-gathering area of a larger telescope for about one-tenth of the cost. We are currently putting together a four-telescope version of the instrument to be used with the bHROS spectrograph in San Juan, Argentina. Target applications for photonic lightbuckets include compact object mass measurements, LSST follow up, LIGO/LISA electromagnetic counterpart follow up to gravitational wave observations, exoplanet atmosphere measurements, and cosmological acceleration measurements.

9908-189, Session PS3

The AST3-NIR camera for the Kunlun Infrared Sky Survey

Jonathan S. Lawrence, Australian Astronomical Observatory (Australia); Michael C. Ashley, Michael G. Burton, The Univ. of New South Wales (Australia); Vladimir Churilov, Robert Content, Peter R. Gillingham, Australian Astronomical Observatory (Australia); Anna M. Moore, California Institute of Technology (United States); Jeremy Mould, Swinburne Univ. of Technology (Australia); Nicholas F. Staszak, Julia Tims, Australian Astronomical Observatory (Australia); Peter G. Tuthill, The Univ. of Sydney (Australia); Lifan Wang, Texas A&M Univ. (United States) and Purple Mountain Observatory (China); Xiangyan Yuan, KaiYuan Zhang, Nanjing Institute of Astronomical Optics & Technology (China); Ross Zhelem, Jessica R. Zheng, Australian Astronomical Observatory (Australia)

AST3-NIR is a new infrared camera for deployment with the AST3-3 wide-field Schmidt telescope to Dome A on the Antarctic plateau. This project is designed to take advantage of the low Antarctic infrared sky thermal background (particularly within the 'Kdark' near infrared atmospheric window at 2.4 micron) and the long Antarctic nights to provide high sensitivity temporal data from astronomical sources. AST3-NIR is a funded project, currently in the preliminary design phase, that is due for deployment in early 2017. The facility will be used to conduct the Kunlun Infrared Sky Survey (KISS), with science goals addressing research across a range of galactic and extragalactic areas.

The baseline instrument concept consists of a 2.5 micron cut-off HgCdTe detector array, mounted in a cryostat with relay optics, Kdark filter, internal baffling, a cold stop, and a focus drive. The optical relay provides a focal-plane plate-scale that is optimised for high-sensitivity wide-field observations given the expected seeing conditions, the telescope diffraction limit, and the lens fabrication and alignment tolerances. The Kdark filter bandwidth and centre wavelength is designed to maximise sensitivity for the expected atmospheric thermal emission spectrum and the telescope thermal emission properties. The cryostat design is driven towards reliability and simplicity by the extreme environmental conditions and the requirement for remote operation with only a yearly service interval.

The AST3-NIR camera mounts to a flange on the AST3-3 telescope at the Newtonian focus. The telescope optical prescription is identical to the first two AST3 telescopes, which were designed for wide field of view optical application. The telescope is a modified Schmidt type with a 0.5 m plano-aspheric corrector plate followed by a 0.68 m ellipsoid primary mirror with a flat folding secondary mirror. The telescope tube is enclosed and the corrector window has an indium-tin-oxide coating to avoid frost formation. The telescope and instrument include a control system that interfaces to a remote PLATO system for power generation, communications and control.

The Kunlun Infrared Sky Survey's uniqueness is in detection of changes in luminosity of astronomical sources in the infrared. This leads to a range of science goals that includes the physics of active galactic nuclei,

supernovae and gamma ray bursters, the terminal phases of red giants and initial phases of protostars, the discovery of exoplanets, and the level of the cosmic infrared background and its angular fluctuations.

9908-190, Session PS3

The optical design of GMOX: a next-generation instrument concept for Gemini

Robert H. Barkhouser, Johns Hopkins Univ. (United States); Massimo Robberto, Johns Hopkins Univ. (United States) and Space Telescope Science Institute (United States); Stephen A. Smee, Johns Hopkins Univ. (United States); Zoran Ninkov, Rochester Institute of Technology (United States); Mario Gennaro, Space Telescope Science Institute (United States); Timothy M. Heckman, Johns Hopkins Univ. (United States)

We present the optical design of GMOX, the Gemini Multi-Object eXtra-wide-band spectrograph. GMOX was selected as part of the Gemini Instrument Feasibility Study to develop capabilities and requirements for the next facility instrument (Gen4#3) for the observatory. We envision GMOX covering the entire optical/near-IR wavelength range accessible from the ground, from 3500 Å in the U-band up to 2.4 μm in the K-band, with nominal resolving power R~5000. To maximize efficiency the bandpass is split into three spectrograph arms – blue, red, and near-infrared – with the near-infrared arm further split into three channels covering the Y+J, H, and K bands. At the heart of each arm is a Digital Micromirror Device (DMD) serving as a programmable slit array. This technology will enable GMOX to simultaneously acquire hundreds of spectra of faint sources in crowded fields with unparalleled spatial resolution, optimally adapting to both seeing-limited and diffraction-limited conditions provided by ALTAIR and GeMS at Gemini North and South, respectively. Fed by GeMS at f/33, GMOX can synthesize slits as small as 40 mas (corresponding to a single HST/WFC3 CCD pixel) over its entire 85 x 45 arcsec field of view. With either ALTAIR or the native telescope focal ratio of f/16, both the slit and field size double. In this paper we discuss the conceptual optical design of GMOX including, for each arm, the pre-slit optics, DMD slit array, off-axis Schmidt collimator, VPH grating, and refractive spectrograph and slit-viewing cameras.

9908-191, Session PS3

Intelligent camera SiPM for astrophysical applications

Massimiliano Belluso, Sergio Billotta, INAF - Osservatorio Astrofisico di Catania (Italy); Vania Da Deppo, CNR - Istituto di Fotonica e Nanotecnologie di Padova (Italy); Vincenzo De Caprio, INAF - Osservatorio Astronomico di Capodimonte (Italy); Daniele Gardiol, Davide Loreggia, INAF - Osservatorio Astronomico di Torino (Italy); Lorenzo Paoletti, INAF - Osservatorio Astronomico di Padova (Italy)

World scale projects dedicated to ground based astronomy require new technology developments in many fields and also for realization of compact focal plane cameras. Usually these cameras are dedicated to specific astrophysical applications and optimized for a particular telescope configuration. However in many cases single telescopes (as well as arrays) can be well suited for scientific studies that were not driving the requirements in the project-planning phase. The objective of this work is an assessment towards the development of an Intelligent Camera SiPM (IC-SiPM) for astrophysical applications, based on silicon multiplier (SiPM) and programmable electronics (FPGA). IC-SiPM should be easily adaptable to different plate scale of currently existing or under construction telescopes for big science projects. The flexibility will be guaranteed by multi-size SiPM arrays, multi-function channels conditioning electronics, auto-focus and centring electro-mechanical system based on FPGA.

9908-192, Session PS3

Blue camera of the Keck cosmic web imager, fabrication and testing

David J. Cowley, Constance Rockosi, Gerald Cabak, Terry Pfister, David Hilyard, Univ. of California, Santa Cruz (United States)

The Keck Cosmic Web Imager (KCWI) is a new facility instrument currently being completed for the Keck II Telescope at the W. M. Keck Observatory. The blue camera for KCWI uses nine all spherical lens elements (including a field flattener as the vacuum window to the CCD dewar). The mounts of all lenses are elastomeric and are required to hold the lens to better than 0.001 inches placement accuracy at the normal operating temperature of 0C without exerting sufficient force to distort the them. The camera was assembled at 21C using a precession turntable, precision micrometers, and height gages, and shims. We achieved an overall placement accuracy within 0.001 inches for the camera, measured mechanically. The optical performance was predicted for 21C and we tested the camera by both finding the back focal distance, and with our Zygo Interferometer. We also cold cycled the camera in our cold chamber. The camera is currently mounted in the KCWI instrument as it is being integrated and tested at the California Institute of Technology in Pasadena, CA.

9908-193, Session PS3

HARDWARE.astronomy: an open-source hardware initiative for astronomy

Carl Ferkinhoff, Winona State Univ. (United States)

The .astronomy conference series, now completing its 8th event, has been successful in bringing together astronomers to develop open-source web tools and software to support research, education and outreach. Meanwhile, outside of astronomy the open design movement has driven a revolution of affordable electronic and electromechanical devices (e.g. Arduino, RaspberryPi) that are easily developed by product developers and consumers alike. An “Open Source Hardware” definition, similar to that for open-source hardware, has enabled this revolution. A key characteristic of these open devices is that their design, firmware & software files a readily published online via open-source licences. Here we introduce a new initiative—HARDWARE.astronomy—that will support open-source hardware the development of astronomical instrumentation. In this paper will discuss the goals of this project to: 1) develop low cost devices for astronomical observations and develop astronomical instruments based on open-hardware devices and principles; 2) make all hardware, software and firmware immediately available to the broader community per the open-source principle; 3) invest undergraduates in the development of astronomical instruments; and lastly 4) develop principles of open hardware for the astronomical community that will enable other researchers to publish their projects through the initiative. In discussing these goals we will briefly introduce two intial open-source projects, a robotic observatory and thermomtry system—The ROBh.aT Network and H.aHK Box, respectively.

9908-194, Session PS3

ha.HK box: the HARDWARE.astronomy housekeeping box

Carl Ferkinhoff, Winona State Univ. (United States)

While often unglamourous yet critical part of most astronomical instruments is cryogenic temperature monitoring and control. Depending on the operating wavelength of the instrument this could mean stable temperatures at 40 to 70 Kelvin or maintaining 100 mK at sub-microKelvin stability as for many submillimeter bolometer systems. Here we describe a project of the HARDWARE.astronomy initiative to build a low-cost open-source temperature monitoring and control system. The HARDWARE. astronomy Housekeeping Box, or ha.HK Box (prounouced "hack") is developed primarily by undergraduates and employs existing open-source devices (e.g Arduino, RaspberryPi) to reduce costs while also limiting the complexity of the development. The ha.HK Box features a base system with a control computer and 10 expansion slots that can be filled with a variety of expansion cards. These cards include AC and DC excited 4-wire bridges, 2-wire bridge, and PID controller card. The base-system will also be able to interface with a to-be-designed motor-control system and other devices over serial port and ethernet. The first deployment of the ha.HK Box will be for the ZEUS-2 submillimeter grating spectrometer though all design, firmware, software and parts list will be published online allowing for other projects to adopt the system and creat custom expansion cards as needed.

9908-195, Session PS3

Colored exosolar atmospheres: a novel approach

Jean-Marc Christille, Osservatorio Astronomico della Regione Autonoma Valle d'Aosta (Italy); Aldo Bonomo, INAF - Osservatorio Astrofisico di Torino (Italy); Francesco Borsa, INAF - Osservatorio Astronomico di Brera (Italy); Deborah Busonero, INAF - Osservatorio Astronomico di Torino (Italy); Paolo Calcidese, Osservatorio Astronomico della Regione Autonoma Valle d'Aosta (Italy); Mario Damasso, Paolo Giacobbe, INAF - Osservatorio Astrofisico di Torino (Italy); Emilio Molinari, INAF - Fundación Galileo Galilei (Spain); Alberto Riva, Alesandro Sozzetti, INAF - Osservatorio Astronomico di Torino (Italy); Daniela Tresoldi, Giorgio Toso, INAF - IASF Milano (Italy)

The exoplanet revolution is well underway. The last decade has seen order-of-magnitude increases in the number of known planets beyond the Solar system.

Detailed characterization of exoplanetary atmospheres provide the best means for distinguishing the makeup of their outer layers, and the only hope for understanding the interplay between initial composition chemistry, dynamics & circulation, and disequilibrium processes.

While pioneering work on the observational side has produced the first important detections of atmospheric molecules for the class of transiting exoplanets, important limitations are still present due to the lack of systematic, repeated measurements with optimized instrumentation at both visible (VIS) and near-infrared (NIR) wavelengths. It is thus of fundamental importance to explore quantitatively possible avenues for improvements. In this paper we report initial results of a feasibility study for the prototype of a versatile multi-band imaging system for very high-precision differential photometry that exploits the choice of specifically selected narrow-band filters and novel ideas for the execution of simultaneous VIS & NIR measurements.

Starting from the fundamental system requirements driven by the science case at hand, we describe a set of three opto-mechanical solutions for the instrument prototype: 1) a radial distribution of the optical flux using dichroic filters for the wavelength separation and narrow-band filters or liquid crystal filters for the observations; 2) a tree distribution of the optical flux (implying 2 separate foci), with the same technique used for the beam separation and filtering; 3) an 'exotic' solution consisting of the study of a complete optical system (i.e. a brand new telescope) that exploits the chromaticity errors of a reflecting surface for directing the different wavelengths at different foci.

In this paper we present the first results of the study phase for the three solutions, as well as the results of two laboratory prototypes (related to the first two options), that simulate the most critical aspects of the future instrument.

9908-196, Session PS3

ROBH.aT network: the robotic observatory by HARDWARE.astronomy and telescope network

Carl Ferkinhoff, Winona State Univ. (United States)

There are over 4,500 institutions of higher education in the United States, of those over 1,800 are Bachelor degree granting institution (2010 Carnegie Classification; National Center for Educations Statistics, IPEDS Fall Enrollment (2009)). Even if only 1 in 10 has a campus observatory, that is still nearly 200 small telescopes spread across the country. While certainly the sites are less than ideal and many campus telescopes will be small, ~30 - 40 cm in diameter, this number of telescopes is still significant and could be especially useful for transient studies in the LSST era. The educational and outreach impact of having robotic observatories at educational institutions is also profound. Realizing the potential of all theses telescopes requires automating and connecting these observatories into a network. The Robotic Observatory by HARDWARE.astronomy and Telescope Network, or ROBH.aT Network (pronounced "robot") aims to do just this by leveraging open-source hardware devices to develop the hardware necessary to robotize a telescope at low-cost and with primarily undergraduate students. Future phases of the project will deploy a task-scheduler for automated observing locally and integrating all telescopes into a large heterogenous-network. Here we report of the initial work in automating the observatory at Winona State University.

9908-197, Session PS3

Concepts of the mosaic array of numerous ultra-small lens (MANUL) design

András Pal, László Mészáros, Konkoly Observatory (Hungary)

The lack precise and accurate time series photometry for very bright (V<=6) stars implies the development of instrumentation capable to perform continuous imaging of these objects. In addition, the advancement of embedded electronics makes feasible to build small-scale highly integrated and dedicated electronics. In this presentation we introduce the main concepts, early prototyping and photometric results of the Mosaic Array of Numerous Ultrasmall Lens (MANUL) system, a palm-sized ``single-board astronomical observatory'' designed for permanent low-resolution, multi-color photometric measurements of the brightest stars -- from Sirius down to the faint limit of V=6-7 magnitudes.

The MANUL system is a configurable setup of small-footprint stacked printed circuit boards, having a diameter of 5 centimeters, on which all of the necessary parts and optical elements are mounted. The circuit boards support the CMOS imaging sensors (up to three), the filters and the lens, the core data acquisition control electronics which are based on an ARM

Cortex-M4 MCU, a TCP/IP and Ethernet interface and various auxiliary parts (e.g. power subsystem, clocking, alternate low-bandwidth control). The MCU itself is powerful enough to perform readout and downlink of the three 5 megapixel CMOS sensors within a second in a round-robin fashion while the sensors are continuously operating in electronic rolling shutter mode. MANUL units can then be combined regarding to the actual needs. For instance, a single-module setup combined with fish-eye optics (e.g. f=2.2mm, f/2.5 lens) can used as an all-sky camera. With larger focal lengths, e.g. with f=6.5mm, f/1.6 lens, a sensor with 2.2 micron pixels has an imaging resolution of 1.2 arcminutes per pixel and seven of such units is capable to cover the visible sky above 30 degrees of horizontal altitude.

As we present here, initial prototyping of the system shows that using a gross of 3 minutes long exposure time (i.e. the combination of 9 rolling shutter frames, 20 seconds of each), one can achieve a signal-to-noise ratio with an average of 4-6 for V=6 stars. In addition, the linearity of the CMOS sensor is also validated within 1.2-sigma by considering 200 stars in the brightness regime of V=0...6 appearing above 50 degrees of horizontal altitude.

Although the the optical setup seems rather simple compared to conventional telescopes, a 7-unit mosaic setup of three-sensor MANUL modules provide an integral etendue of 0.5 deg^2 m^2. Due to the small footprint, the quick development cycle, the lack of moving parts and the low cost, network operations of multi-module MANUL cameras are also feasible. The MANUL design is complementary to the scientific domains of Fly's Eye (or similar) initiatives. It also covers the same regime targeted by Mascara but on a definitely smaller scale and the inclusion of color information. It is therefore an interesting experimental technology for very cheap and complementary astrophysics.

9908-198, Session PS3

DKIST visible broadband imager alignment in laboratory: first results

Friedrich Wöger, Predrag Sekulic, B. Scott Gregory, Steve L. Hegwer, Andrew Ferayorni, Association of Universities for Research in Astronomy, Inc. (United States)

The Visible Broadband Imager (VBI) Blue and Red channels are the first Daniel K. Inouye Solar Telescope (DKIST) instruments that have been aligned and tested in a laboratory. This paper describes the optical alignment method of the VBI as performed in the laboratory. The objective of this preliminary alignment is to test and validate the optical alignment method that will be used during final alignment on the telescope, to measure the VBI performances and to verify that it meets specification. The optical alignment method is defined by three major steps. The first step is realized by combining the optical and mechanical models into the Spatial Analyzer® (SA) software, and extracting the data serving as target values during alignment. The second step is the mechanical alignment and allows to accurately position the optics in the instrument coordinate system by using a Coordinate Measurement Machine (CMM) arm and a theodolite. This step has led to a great initial positioning and has allowed reaching an initial wavefront error before optical alignment close to the specification. The last step, performed by interferometry, allows fine alignment to compensate the residual aberrations created by misalignment and manufacturing tolerances. This paper presents also an alignment method to compute the shifts and tilts of compensating lenses to correct the residual aberrations. This paper describes first results of the VBI instruments performances measured in the laboratory and confirm the validity of the alignment process that will be reproduced during final alignment on the telescope.

9908-199, Session PS3

Nanoradian ground-based astrometry, optical navigation, and artificial reference stars

Chengxing Zhai, Michael Shao, Abhijit Biswas, Todd A. Ely, Christopher S. Jacobs, Joseph W. Lazio, Tomas J. Martin-Mur, William M. Owen Jr., Mayer Rud, Navtej S. Saini, Jagmit S. Sandhu, Slava G. Turyshev, Thomas A. Werne, Jet Propulsion Lab. (United States)

Deep space optical communications will significantly increase data rate over traditional radio frequency communications.

Spacecraft carrying optical communication lasers can be treated artificial stars from an astrometric perspective, which in turn may enable navigation from optically-determined metrics.

ESA's Gaia mission, currently in operation, is surveying a billion stars down to 20th magnitude providing catalog with better than 100 micro arcsecond astrometry at the end of the mission.

Relative astrometry of spacecraft with respect to Gaia reference stars then provides spacecraft positions in the plane-of-sky, forming 3-d positions for optical navigation when combined with optical ranging data.

To be sufficient for navigation, we need to achieve nanoradian accuracy in absolute astrometry, which is comparable to the current Deep Space Network delta-Differential One-way Ranging measurements.

In this paper, we describe our error budget and techniques for achieving nanoradian level ground-base astrometry.

The key to success is to perform very narrow angle astrometry (with angular separation < 20 arcsec) using the abundant Gaia reference stars and to accurately calibrate systematic errors like field distortion, differential atmospheric refraction effects, and detector responses.

In addition, it is crucial to use the synthetic tracking technique for high precision astrometry of a moving object. Synthetic tracking is a technique that we developed for detecting fast moving asteroids by taking multiple short exposure images to replace long exposure images to avoid streaked images, which degrades signal-to-noise ratio and introduces non-common mode atmospheric effect into narrow angle relative astrometry of moving objects. Preliminary results from the Pomona College's 1 meter telescope at Table Mountain Observatory will be presented. We also discuss how these spacecrafts may serve as artificial reference stars for precise astrometry to detect exoplanets and to supply additional measurements for tying the International Celestial Reference Frame with the Gaia reference frame.

9908-200, Session PS3

Characterization of commercial photographic camera lenses for use in astronomical instrumentation

Nicholas P. Mondrik, Darren L. DePoy, Brendan Hill, Daniel Q. Nagasawa, Jennifer L. Marshall, Texas A&M Univ. (United States)

We present measurements of the spectral response function, absolute throughput, and image quality of a sample of commercially available photographic camera lenses. We also investigate the response of the lenses at a range of f-ratio and focal length settings. We show that the lenses have > 50% throughput over 400 < ? < 700 nm and acceptable image quality over a relatively large field of view. We conclude that commercially available lenses are a viable and cost-effective alternative to custom-built optical systems in select astronomical applications.

9908-201, Session PS3

Okayama astrophysical observatory wide-field camera: status and performance

Kenshi Yanagisawa, Yasuhiro Shimizu, Kiichi Okita, Daisuke Kuroda, Hironori Tsutsui, Hiroyuki Toda, Hideyuki Izumiura, National Astronomical Observatory of Japan (Japan); Michitoshi Yoshida, Hiroshima Univ. (Japan); Koji Ohta, Kyoto Univ. (Japan); Nobuyuki Kawai, Tokyo Institute of Technology (Japan)

We present the design, current status and performance of our wide field near infrared camera, OAOWFC, developed at Okayama Astrophysical Observatory, NAOJ. OAOWFC is a near-infrared wide-area imager whose aperture is 0.91m. It works in Y, J, H and Ks bands and the field of view is 0.47 x 0.47 square degrees, which is realized by a HAWAII PACE detector of 1K x 1K pixels. It will be used to survey the Galactic plane for variability and search for transients such as GRBs or optical counterpart of gravitational wave sources. In this paper, we will present the status and performance.

OAOWFC was constructed as a renewal of existing 0.91m telescope manufactured in 1959. Almost all the parts of the telescope are used in the new camera, except for the top-ring and the secondary mirror. We followed the optical design of UKIRT WFCAM and finally realized a field of view of 1.3 degrees or 52mm in diameter. The optics is composed by forward Cassegrain and quasi Schmidt. Once the forward Cassegrain makes an image after secondary mirror, it is relayed by a field lens, and re-imaged by quasi Schmidt. A clear pupil is formed just after the collimator in the quasi Schmidt, so we placed the whole quasi Schmidt optics into a dedicated cryostat and cool them down below 130K for the purpose of enabling the deep K-band imaging. Our refrigerator has enough cooling power, the inside the cryostat is painted with infrared black to reduce stray light as possible. The cooling is accomplished within 24 hours. OAOWFC is mounted on fork-equatorial. The maximum slew speed of 2 deg. /sec enables to point any direction in the sky within 2 minutes. The pointing accuracy is 5 arcsec RMS enough small compared with the wideness of the image area.

We have carried out a mini survey to search for variability in the Galactic plane and got successful results. The survey was made as a part of performance verification. The survey area, 6 square degrees toward Scutum-Centaurus arm, was selected in two aspects. From the astronomical point of view, it is expected that there are many variable stars left undiscovered. From the technical point of view, the area is the toughest region to make an accurate photometry, since the area is highest in number density. If we succeed in photometry with enough accuracy, the reduction method can be applied to any other region in the sky. The survey was made from April to August in 2015, and got about 40 epochs. The PSF fitting photometry with SExtractor and PSFEx was applied and the final photometric error of 2% was confirmed. We have discovered about 700 variable stars in the area and identified 300 long period variables such as Miras, 300 irregular variables and 30 Cepheid candidates. Consequently, we have succeeded to demonstrate that OAOWFC is a useful instrument to investigate the Galactic variability in the NIR.

9908-202, Session PS3

Efficient coupling of starlight into single mode photonics using Adaptive Injection (AI)

Barnaby R. Norris, The Univ. of Sydney (Australia); Nick Cvetojevic, The Univ. of Sydney (Australia) and Ctr. for Ultrahigh bandwidth Devices for Optical Systems (Australia) and Australian Astronomical Observatory (Australia); Simon Gross, Alexander Arriola Martiarena, Macquarie Univ. (Australia) and Ctr. for Ultrahigh bandwidth Devices for Optical Systems (Australia); Peter G. Tuthill, The Univ. of Sydney (Australia); Jonathan S. Lawrence, Australian Astronomical Observatory (Australia); Samuel Nathan Richards, The Univ. of Sydney (Australia) and Australian Astronomical Observatory (Australia); Michael Goodwin, Jessica R. Zheng, Australian Astronomical Observatory (Australia)

By using single-mode fibres, single-mode interferometers and nullers stand to revolutionise ultra-high resolution, high contrast imaging, leading to direct imaging of Earth-like exoplanets. Single-mode spectrographs provide mitigation of modal noise and compact size.

However, the successful use of these technologies faces a major hurdle: the initial injection of starlight into single mode photonics is extremely difficult. Small mode-field diameter (typically less than ten microns) and restrictive NA means that directly injecting the seeing-limited telescope pupil into a single mode fibre is virtually impossible. An extreme adaptive optics system is one solution, but these extremely expensive and complex systems are beyond the reach of all but the major 8 m class telescopes.

Here we present an alternative solution - adaptive injection (AI). Analogous to adaptive optics (AO), this system actively adjusts the wavefront in real-time as it varies with the seeing. However rather than attempting to produce the flattest wavefront possible across the whole pupil, AI optimises the wavefront for the best possible injection into an array of single-mode waveguides or fibres. The telescope pupil is re-imaged onto a MEMS segmented deformable mirror, and thence onto a two-dimensional array of single mode waveguides (with matching microlens array (MLA)). The MEMS mirror segments are matched one-to-one with the single-mode waveguide and MLA, thus dividing the telescope pupil into an array of sub-pupils. The array is sized such that each sub-pupil is roughly the same size as the Fried parameter r0. Via a dichroic mirror, the pupil is also imaged into a separate matched MLA and camera to act as a wavefront sensor.

For single-mode injection, this system has an advantage over an AO system of comparable actuator count. By segmenting the telescope pupil into a series of subapertures with sizes of order r0, the problem of injecting the complex seeing-induced PSF is reduced to a number of simple, independent tip/tilt loops. Due to the extreme sensitivity of injection efficiency on the angle of the incident light, the optimum injection is not achieved with a flat wavefront; rather, the beam of each sub-aperture requires an offset applied as a tip/tilt term to the corresponding MEMS mirror segment (determined beforehand by way of a raster scan). Since each MEMS segment has independent tip/tilt control, the required offset for each waveguide becomes the appropriate zero-point for the AI loop. Adjacent segments can have entirely opposing tip/tilt values if necessary. A traditional membrane DM with the same actuator number would have just over 1 actuator per sub-pupil, and so independent tip/tilt control would not be possible. The remaining coupling losses are due to higher order structure within the sub-aperture, which has been found to be small. For interferometric applications, higher fringe visibilities can be obtained if the matched wavefront sensor is used in a Shack-Hartmann mode, and the appropriate piston terms are also applied to the segments.

In on-sky and laboratory tests, we have found that injection efficiency using the AI system is significantly higher than that using a conventional AO system of similar actuator count.

9908-203, Session PS3

High-resolution abundances distribution in disk galaxy with SITELLE

Laurie Rousseau-Nepton, Laurent Drissen, Carmelle Robert, Thomas Martin, Univ. Laval (Canada)

SITELLE is the new Imaging Fourier Transform Spectrograph (IFTS) of the

Canada-France-Hawaii Telescope (CFHT).

This IFTS can produce an impressive number of 4 million spectra in a single data cube. Its large contiguous spatial coverage (11'x11') and its high spatial resolution (0.32'' pixels and ~ 0.75'' average seeing) allow to study the ionized gas emission surrounding massive star (HII regions) with an unprecedented view. The commissioning and science verification runs revealed the incredible power of this instrument for the study of star formation in the extended disk of galaxies. This poster presents some of the first results obtained on the nearby spiral galaxy NGC628, including the detection of extended star formation using the H? and the [OII]?3727 tracers. Precise intensity and kinematic maps will be shown. With this data sample, we focused on the problematic of characterizing the ionized gas physical properties in thousands of HII regions detected in NGC628. Photoionization models are an essential tool to derive the physical properties of the ionized gas over the whole surface of the galaxy disk. A reliable gas abundance prediction from photoionization models requires strong constraints on the physical conditions of star-forming regions and multiple abundance sensitive line ratios.

A good knowledge of the gas abundances distributions in the galaxies' extended disk can lead to a better understanding of the role played by the different enrichment and mixing processes that modify the content of galaxies and drive their evolution. Within this context, observing and characterizing the star-forming regions located in the outskirts of galaxies is important and SITELLE is well suited for this task.

9908-204, Session PS3

Concept Design of an 80-dual polarization element Cryogenic Phased Array Camera for the Arecibo Radio Telescope

German Cortes-Medellin, Univ. de Antioquia (Colombia) and Cornell Univ. (United States); Stephen C. Parshley, Donald B. Campbell, Cornell Univ. (United States); Karl Warnick, Brian D. Jeffs, Brigham Young Univ. (United States)

Phased array antenna technology enables access to the instantaneous field of view (FoV) of large telescope optics, which combined with fully cryogenic array elements and amplifiers results in survey speed improvements of several orders of magnitude. The proposed Arecibo Observatory L-band cryogenic phased array camera (AO40) will enable faster and/or deeper surveys, with science objectives that include dark matter dominated mini-halos in our Galaxy, the detection of gravitational waves by using precision pulsar timing, and the emerging potential for discovery of the transient radio sky.

We have developed a full concept design of an 80 dual polarized element cryogenic phased array camera for the Arecibo radio telescope. The front-end camera will cover the frequency band from 1.280 GHz to 1.720 GHz. In the new camera design we have incorporated major changes in the vacuum window design, now 1360 mm in diameter, that improves the electromagnetic performance of the array. We have also made changes to the element array configuration that allows us to scale the cryo-mechanical design to 80 dual polarization elements by utilizing four-fold symmetry for the array.

The camera will be capable of producing 40 dual polarized real-time digitally formed beams with a system temperature goal of < 30K. The total bandwidth per channel is 312.5 MHz (tunable within the front-end frequency band), yielding an instantaneous processing bandwidth of 50 GHz. The back-end will provide 800 coarse channels with a bandwidth of 390.625 kHz and 26,600 fine channels with a resolution of 12.2 kHz.

We will present the results of the cryo-design modifications and final concept design of the cryo-PAF camera.

9908-205, Session PS3

The Harlan J. Smith Telescope direct imaging auxiliary functions instrument

Phillip J. MacQueen, Joseph L. Strubhar, Gordon L. Wesley, Peter Samuel Odoms, Robert D. Edmonston, The Univ. of Texas at Austin (United States)

DIAFI, the Direct Imaging Auxiliary Functions Instrument, is a GUI operated instrument used for CCD imaging through filters at the f/8.8 focus of the McDonald Observatory 2.7 m Harlan J. Smith Telescope. It has a maximum field of view of 8.8 arcminutes square, and a 300–1050 nm bandwidth. The functions provided by DIAFI in support of CCD imaging are mounting the CCD detector system to the telescope, a 40-filter filter changer for 76 .2 mm square filters, an image quality corrected offset guider with filters and independent focus control, a zero power dissipation shutter, a deployable frame transfer mask, and a neutral density filter that can be used in series with the science filters.

This paper serves as a reference for the instrument, giving characteristics and performance. It also details the novel engineering aspects of DIAFI. The filter carousel operates with varying gravity vector and temperature at the cassegrain focus, and is highly reliable as a function of mechanical design, detailed electronic interlocks, and diagnostics. The off axis guider includes a toroidal folding flat to achromatically correct the off-axis aberrations of the Ritchie Chretien telescope. The detector mount and guider optical path were quickly and accurately aligned to the mounting flange with a coordinate measuring machine.

9908-206, Session PS3

Astrophysical Research Consortium Telescope Imaging Camera (ARCTIC) facility optical imager for the Apache Point Observatory 3.5m Telescope

Joseph Huehnerhoff, Apache Point Observatory (United States) and Univ. of Washington (United States); William Ketzeback, Alaina Bradley, Jack Dembicky, Apache Point Observatory (United States); Caitlin Doughty, New Mexico State Univ. (United States); Suzanne Hawley, Courtney Johnson, Univ. of Washington (United States); Mark Klaene, Ed Leon, Russet McMillan, Apache Point Observatory (United States); Russell Owen, Conor Sayres, Tyler Sheen, Univ. of Washington (United States); Alysha Shugart, Apache Point Observatory (United States)

The Astrophysical Research Consortium Telescope Imaging Camera, ARCTIC, is a new optical imaging camera now in use at the ARC 3.5m telescope at Apache Point Observatory. As a facility instrument, the design criteria broadly encompassed many current and future science opportunities, and the components were built for quick repair or replacement, to minimize down-time. Examples include a quick change shutter, filter drive components accessible from the exterior and redundant amplifiers on the detector. The detector is a Semiconductor Technology Associates (STA) device with several key properties (e.g. high quantum efficiency, low read-noise, quick readout, minimal fringing, operational bandpass 350-950nm). Focal reducing optics (f/10.3 to f/8.0) were built to control aberrations over a 7.8'x7.8' field, with a plate scale of 0.11" per 15 micron pixel. The instrument body and dewar were designed to be simple and robust with only two components to the structure forward of the dewar, which in turn has minimal feedthroughs and permeation areas and holds a vacuum <10^-8 Torr. A custom shutter was also designed, using pneumatics as the driving force. This device provides exceptional performance and reduces heat near the optical path.

Measured performance is repeatable at the 2ms level and offers field uniformity to the same level of precision. The ARCTIC facility imager will provide excellent science capability with robust operation and minimal maintenance for the next decade or more at APO.

9908-207, Session PS3

Status of Focal Plane Instrumentation (FPI) project of the 4m DAG telescope

Onur Keskin, Isik Üniv. (Turkey); Sinan K. Yerli, Middle East Technical Univ. (Turkey); Cahit Yesilyaprak, Atatürk Üniv. (Turkey); Tolga Guver, Istanbul Univ. (Turkey)

DAG (Eastern Anatolia Observatory in Turkish) will be the newest and largest (4m) observatory of Turkey in both optical and near-infrared with its robust observing site infrastructure. The telescope is designed to house 2 Nasmyth platforms which will be dedicated to IR and VIS observations. In order to benefit both national and international science communities, DAG technical teams in collaboration with ISIK University (for Adaptive Optics Systems), Middle East Technical University (for test, measurement and calibration of DAG instruments), Istanbul University (for new kind of instrumentations, e.g. MKIDs), and Ataturk University (for IR & VIS detectors) formed a collaboration. In this paper the status updates from the co-owned FPI project will be presented along with possible collaboration opportunities.

9908-208, Session PS3

RIMAS: infrared imager-spectrometer for the Discovery Channel Telescope

Alexander S. Kutyrev, NASA Goddard Space Flight Ctr. (United States) and Univ. of Maryland, College Park (United States); Vicki L. Toy, John I. Capone, Univ. of Maryland, College Park (United States); Gennadiy N. Lotkin, Beacon Systems, Inc. (United States) and NASA Goddard Space Flight Ctr. (United States); Neil A. Gehrels, Samuel H. Moseley, NASA Goddard Space Flight Ctr. (United States); Sylvain Veilleux, Stuart N. Vogel, Univ. of Maryland, College Park (United States); Thomas Hams, Univ. of Maryland, College Park (United States) and NASA Goddard Space Flight Ctr. (United States); Frederick D. Robinson, Beacon Systems, Inc. (United States) and NASA Goddard Space Flight Ctr. (United States)

RIMAS is being built for a fast response to transient events detected by Swift high energy observatory. It will also become a general purpose instrument at the Discovery channel telescope. Two spectral arms arrangement with two separate H2RG 2048 x 2048 pixels detectors increases the efficiency of the instrument, allows for compact dosing and makes it possible to acquire the high resolution (R~5000) spectrum over the full spectral range form 950nm to 2350nm in one setting. The imaging mode with the 3 arcminutes (0.35" per pixel plate scale) field of view provide a large enough area for reliable identification and photometry of the transient afterglow candidate. For an accurate pointing and tracking of the telescope in the spectroscopy mode there is a slit viewing detector operating in J band. This viewer is sensitive enough to provide reliable positioning of the source for the full range of the sources brightnesses that can be observed spectroscopically with the instrument.

9908-209, Session PS3

HAWC+ facility far-infrared camera and polarimeter for SOFIA

Charles D. Dowell, Jet Propulsion Lab. (United States); Mandana Amiri, The Univ. of British Columbia (Canada); Dominic J. Benford, NASA Goddard Space Flight Ctr. (United States); Marc Berthoud, The Univ. of Chicago (United States); Ernest D. Buchanan, NASA Goddard Space Flight Ctr. (United States); Nicholas L. Chapman, Northwestern Univ. (United States); David T. Chuss, Villanova Univ. (United States); Jessie L. Dotson, NASA Ames Research Ctr. (United States); Dale J. Fixsen, NASA Goddard Space Flight Ctr. (United States); Mark Halpern, The Univ. of British Columbia (Canada); Louise A. Hamlin, Jet Propulsion Lab. (United States); Doyal A. Harper, The Univ. of Chicago (United States); Gene C. Hilton, National Institute of Standards and Technology (United States); Kent D. Irwin, Stanford Univ. (United States); Christine A. Jhabvala, NASA Goddard Space Flight Ctr. (United States); Attila Kovacs, California Institute of Technology (United States); Leslie W. Looney, Univ. of Illinois at Urbana-Champaign (United States); Stephen F. Maher, Science Systems and Applications, Inc. (United States); Timothy M. Miller, Samuel H. Moseley, NASA Goddard Space Flight Ctr. (United States); Giles Novak, Northwestern Univ. (United States); Enzo Pascale, Cardiff Univ. (United Kingdom); Marcus C. Runyan, Jet Propulsion Lab. (United States); Eric Sandberg, SOFIA / USRA (United States); Fábio P. Santos, Northwestern Univ. (United States); Elmer H. Sharp III, Leroy M. Sparr, NASA Goddard Space Flight Ctr. (United States); Johannes G. Staguhn, Johns Hopkins Univ. (United States); Carole E. Tucker, Cardiff Univ. (United Kingdom); Armen S. Toorian, Jet Propulsion Lab. (United States); Anthony D. Turner, Jet Propulsion Lab. (United States); Caesar Wirth, The Univ. of Chicago (United States); John E. Vaillancourt, SOFIA / USRA (United States); Edward J. Wollack, NASA Goddard Space Flight Ctr. (United States)

We describe the current status of HAWC+, the facility far-infrared camera and polarimeter for NASA's SOFIA airborne observatory. HAWC+ is scheduled to be commissioned in mid 2016, and we will report results from lab system testing and flight observations as available. HAWC+ uses two detectors in a dual-beam imaging polarimeter configuration, with both detectors consisting of 32x40 arrays of transition-edge sensors in a BUG architecture from Goddard, hybridized with SQUID time-domain multiplexers from NIST. The Multi-Channel Electronics system from UBC controls and reads out the detectors. The detectors are operated at 0.13 K via an Adiabatic Demagnetization Refrigerator backed by a 4He sorption cooler. HAWC+ observes in five continuum bands -- one at a time -- from 53 to 216 microns, offering angular resolution as fine as 5" (FWHM) when operated on the SOFIA telescope. A set of monochromatic half-wave plates modulate the input polarization for precise measurement.

9908-210, Session PS3

Design and building of a derotator for the 4 m DAG telescope

Onur Keskin, Isik Üniv. (Turkey); Laurent Jolissaint, HEIG-VD (Switzerland); Cahit Yesilyaprak, Atatürk Üniv. (Turkey); Sinan K. Yerli, Middle East Technical Univ. (Turkey)

Research in astrophysics always requires extremely sensitive and accurate instruments, whose development requires constant advances in all fields of technology. In particular, DAG (Eastern Anatolia Observatory in Turkish) telescope optical configuration has been designed to allow for a perfect mechanical stability of the focal plane instruments, while minimizing the size of the telescope mount structure and dome. DAG is Alt-Az mount with the instruments located on the static (still) Nasmyth platforms. A geometric consequence of this scheme is that the image of an astronomical object will rotate around the optical axis, at an average rate of one rotation per day. While this rotation rate is not large, it needs to be compensated: science exposures can last several hours, and any rotation will totally blur the science image. In this paper the preliminary design of a derotator that will be placed inside the telescope volume to serve all focal plans instruments while generating no additional optical errors on the optical beam, will be presented.

9908-211, Session PS3

The Zwicky transient facility observing system

Richard G. Dekany, Roger M. Smith, Eric C. Bellm, Justin Belicki, John L. Cromer, Alex Delacroix, Gina Duggan, Michael E. Feeney, David Hale, John R. Henning, Stephen Kaye, Thomas Kupfer, Daniel L. McKenna, Peter H. Mao, Patrick Murphy, Michael Porter, Daniel J. Reiley, Reed L. Riddle, Mitsuko Roberts, Hector Rodriguez, Jeff Zolkower, California Institute of Technology (United States); Timothy M. Goodsall, Jet Propulsion Lab. (United States)

The Zwicky Transient Facility (ZTF) Observing System (OS) is the optomechanical subsystem responsible for the data acquisition of ZTF as it conducts a forthcoming three-year wide-area, high-cadence time-domain survey. The ZTFOS consists of the Palomar 48 inch (1.2 meter) aperture Samuel Oschin Telescope and the ZTF Camera (ZTFC), a 47 square degree scientific imaging mosaic sporting sixteen 6k x 6k e2v CCD231-C6 arrays co-mounted on a common focal plate and integrated with four 2k x 2k STA3600 guide, focus, and flexure-compensation CCDs that have been processed 'delta doped' by Jet Propulsion Laboratory for improved sensitivity. Telescope updates include the figuring and installation of a new 50-inch diameter aspheric Schmidt plate, installation of a new instrument ring girder, spiders, and mounting hub, including a camera hexapod mount, and a new filter exchanger mechanism to manage ZTF's 500 x 480 mm optical filters.

9908-214, Session PS3

Wide field of view spectroscopy using solid Fabry-Perot interferometers

Jonathan Nikoleyczik, Univ. of Maryland, College Park (United States); Alexander S. Kutyrev, NASA Goddard Space Flight Ctr. (United States); Sylvain Veilleux, Univ. of Maryland, College Park (United States); Samuel H. Moseley, NASA Goddard Space Flight Ctr. (United States)

We present a telescope consisting of dual solid Fabry-Perot Interferometers. Each Fabry-Perot etalon is made of a single piece of L-BBH2 which has a high index of refraction n~2.07. Each is then coated to give a spectral resolution of R~30,000. Running the etalons in tandem reduces the overlapping orders and allows for a much wider free spectral range. Since the etalon thickness is fixed we use a thermal control system to tune the spacing of both etalons. Thermal changes occur in both thermal expansion and index of refraction which further enhances the FSR. The telescope then moves spatially in order to get spectral information at every point in the field of view. We then select spectral lines for further analysis and create maps of the line depths across the field. Using this technique we are able to measure the fluorescence of chlorophyll in plants and observe zodiacal light. In the chlorophyll analysis we are able to detect the presence of chlorophyll using the line depth in a plant using the sky as a reference solar spectrum. We also use a model of the Fabry-Perot system with an input spectrum to both model the observed output and further constrain the parameters of the etalons. This instrument has possible applications in either a cubesat or aerial observations to measure bulk plant activity over large areas.

9908-215, Session PS3

COATLI: an all-sky robotic optical imager with 0.3 arcsec image quality

Alan M. Watson, Salvador Cuevas Cardona, Luis C. Alvarez Nuñez, Fernando Ángeles, Rosa L. Becerra-Godínez, Oscar Chapa, Alejandro S. Farah, Jorge Fuentes-Fernández, Rosalía Langarica Lebre, Fernando Quirós, Carlos G. Román-Zúñiga, Jaime Ruíz, Carlos G. Tejada, Silvio J. Tinoco, Univ. Nacional Autónoma de México (Mexico)

COATLI is a new instrument and telescope that will provide 0.3 arcsec FWHM images from 550 to 900 nm over a large fraction of the sky. It consists of a robotic 50-cm telescope with a diffraction-limited imager. The imager has a steering mirror for fast guiding, a blue channel using a EMCCD from 400 to 550 nm to measure image motion, a red channel using a standard CCD from 550 to 920 nm, and an active optics system based on a deformable mirror to compensate static and slow aberrations in the red channel. Since the telescope is small, fast guiding will provide diffraction-limited image quality in the red channel over a field of at least 1 arcmin and with coverage of a large fraction of the sky, even in relatively poor seeing. The COATLI telescope will be installed at the Observatorio Astronómico Nacional in San Pedro Mártir, Baja California, México, in February 2016 and will operate initially with a simple interim imager. The definitive COATLI instrument will be installed at the start of 2017.

The reference science programs for COATLI are characterized by requiring optical imaging with better-than-seeing image quality and either large amounts of observing time or time-critical observations. They include observations to place GRBs in the context of their host galaxies, photometry of eclipses in the Orion Trapezium, and broad searches for low-mass companions.

The principal technological challenge of COATLI has been producing a high-performance diffraction-limited imager with two channels, fast guiding, and active optics while meeting the strenuous envelope and mass budget (35 kg) of the small telescope.

In this contribution, we will present the basic theory of diffraction-limited performance using fast guiding on small telescopes, highlight the enabling technologies and technological innovations, present our reference science cases, discuss the state of the project and our future plans, and speculate on future developments.

Accompanying poster presentations by Jorge Fuentes-Fernández and Salvador Cuevas will discuss technical aspects of the instrument in more detail.

9908-216, Session PS3

Optical design of COATLI: an all-sky robotic optical imager with 0.3 arcsec image quality

Jorge Fuentes-Fernández, Salvador Cuevas Cardona, Oscar Chapa, Alan M. Watson, Univ. Nacional Autónoma de México (Mexico)

COATLI is a new instrument and robotic telescope that will provide 0.3 arcsec FWHM images from 550 to 900 nm over a large fraction of the sky. It consists of a robotic 50-cm telescope with a diffraction-limited imager. The imager has a steering mirror for fast guiding, a blue channel using a EMCCD from 400 to 550 nm to measure image motion, a red channel using a standard CCD from 550 to 920 nm, and an active optics system based on a deformable mirror to compensate static and slow aberrations in the red channel. Since the telescope is small, fast guiding will provide diffraction-limited image quality in the red channel over a field of at least 1 arcmin and with coverage of a large fraction of the sky, even in relatively poor seeing. The COATLI telescope will be installed at the Observatorio Astronómico Nacional in Baja California, México, in February 2016 and will operate initially with a simple interim imager. The definitive COATLI instrument will be installed at the start of 2017.

We present the details of the optical design of the instrument, which requires two intermediate pupil planes and must meet the tight envelope size and mass requirements for the small telescope. COATLI is based on collimator-camera pairs using achromatic doublets. Along with the optical design, we present the efficiency, tolerance and thermal studies, necessary to ensure excellent image quality in both channels.

9908-217, Session PS3

Systems design of COATLI: an all-sky robotic optical imager with 0.3 arcsec image quality

Salvador Cuevas Cardona, Alan M. Watson, Luis C. Álvarez-Núñez, Fernando Ángeles, Rosa L. Becerra-Godínez, Oscar Chapa, Alejandro S. Farah, Jorge Fuentes-Fernández, Rosalía Langarica Lebre, Fernando Quiróz, Carlos G. Román-Zúñiga, Jaime Ruiz, Carlos G. Tejada, Silvio J. Tinoco, Univ. Nacional Autónoma de México (Mexico)

COATLI is a new instrument and telescope that will provide 0.3 arcsec FWHM images from 550 to 900 nm over a large fraction of the sky. It consists of a robotic 50-cm telescope with a diffraction-limited imager. The imager has a steering mirror for fast guiding, a blue channel using a EMCCD from 400 to 550 nm to measure image motion, a red channel using a standard CCD from 550 to 920 nm, and an active optics system based on a deformable mirror to compensate static and slow aberrations in the red channel. Since the telescope is small, fast guiding will provide diffraction-limited image quality in the red channel over a field of at least 1 arcmin and with coverage of a large fraction of the sky, even in relatively poor seeing. The COATLI telescope will be installed at the Observatorio Astronómico Nacional in Baja California, México, in February 2016 and will operate initially with a simple interim imager. The definitive COATLI instrument will be installed at the start of 2017.

The principal technological challenge of COATLI has been producing a high-performance diffraction-limited imager with two channels, fast guiding, and active optics while meeting the strenuous envelope and mass budget (35 kg) of the small telescope. Furthermore, the system is robotic and previsions must be taken in account to operate under the observatory environment with minimum maintenance work.

In this work we present the general mechanics, electro-mechanics and opto-mechanics design of COATLI including telescope installations and instrument.

9908-218, Session PS3

Conception of a near-IR spectrometer for ground-based observations of massive stars

Christian Kintziger, Ctr. Spatial de Liège (Belgium) and Univ. de Liège (Belgium); Richard Desselle, Jérôme J. D. Loicq, Ctr. Spatial de Liège (Belgium) and Univ. of Liège (Belgium); Grégor Rauw, GAPHE - Group d'astrophysique des hautes énergies (Belgium) and Univ. of Liège (Belgium); Pierre L. P. M. Rochus, Ctr. Spatial de Liège (Belgium) and Univ. of Liège (Belgium)

Massive stars are very hot and luminous stars which have a tremendous impact on their surroundings via their powerful stellar winds and huge UV luminosities. The combination of these winds, the strong ionizing radiation fields as well as the death of these stars in gigantic supernova explosions make massive stars key players for the evolution of the Universe. The full understanding of astrophysical sources requires access to a rather broad range of wavelengths. Every wavelength domain provides another specific piece of information that is needed to solve the puzzle. The near-IR domain around 1 ?m has an enormous diagnostic potential for stellar activity and winds. Indeed, this domain contains many spectral lines whose profiles provide useful information about these phenomena over almost the entire range of stellar masses. Although those wavelengths can be observed from the ground, this region is somewhat neglected due to technological issues such as the decrease in sensitivity of conventional CCD detectors in that spectral domain.We have designed a near-infrared spectrograph to partially bridge the gap in this area. The final location of the spectrograph will be the vacant Nasmyth focus of the TIGRE telescope in La Luz, Mexico. The instrument's interface consists in a fiber-bundle that feeds the collimator mirror with stellar light from the telescope. On the other hand, a simultaneous sky background measurement is accomplished through the use of dedicated fibers surrounding the central ones, which are located near the target position within the telescope focal plane. This configuration also allows the analysis of multiple target spectra in case of crowded fields such as stellar clusters.In our contribution, we outline the different steps in the design of the instrument. Starting from the derivation of theoretical relationships from the scientific requirements and telescope characteristics, the entire optical design of the spectrograph is presented. Specific optical elements, such as a toroidal lens, are introduced to improve the instrument's performances. Then, the verification of predicted optical performances is investigated through optical analyses such as resolution checking and tolerancing process. Straylight calculations and the calibration unit of the instrument are discussed as well. Eventually, the star positioning system onto the central fiber core is explained in details. This latter incorporates a back-illuminating system of the fiber bundle with the help of a LED located inside the spectrograph housing.

9908-219, Session PS3

LSST camera grid structure made out of ceramic composite material, HB-Cesic

Matthias Krödel, ECM Engineered Ceramic Materials GmbH (Germany); J. Bryan Langton, SLAC National Accelerator Lab. (United States)

LSST is constructing a digital astronomical camera for inclusion in a new observatory. The current schedule for first light is 2020. The LSST

Telescope will have an f1.2 optic and the camera will have 65 cm diameter, 3.2 Giga-pixel focal plane constructed out of a mosaic of 189 science CCD sensors and 12 wave front guider sensors. The main camera structure will be constructed out of a ceramic material called HB-Cesic supplied by ECM, Germany in order to ensure the required stiffness and thermal stability for this challenging focal plane structure.

In this paper we are presenting the ceramic design and the fabrication of the camera structure which is using the unique manufacturing features of the HB-Cesic technology associated with a dedicated metrology device in order to ensure the challenging flatness requirement of 4 micron over the full array.

9908-221, Session PS3

The Fly's Eye camera system: new results with an autonomously observing telescope

László Mészáros, András Pal, Attila Jaskó, Krisztián Vida, Katalin Oláh, Gergely L. Csépány, György Mez?, MTA Research Ctr. for Astronomy and Earth Sciences (Hungary)

The Fly's Eye camera system is a multiple-passband full-sky surveying instrument employing 19 wide-field cameras in a mosaic arrangement on a spherical frame. The cameras are equipped with fast focal ratio lenses and Sloan filters. With this setup we intend to perform time-domain astronomy and observe several kind of astronomical phenomena. The cameras are supported by single mount, while the sidereal tracking, i.e. the compensation for the apparent celestial rotation is performed by a hexapod mount. As discussed in our earlier design-related publications, this tracking is unavoidable when considering 0.3 gigapixel imaging, a field-of-view diameter of 120 degrees and exposure times around a few minutes.

As we demonstrated (see e.g. Jasko et al., 2014, SPIE), this small-scale hexapod design is capable of perform positioning and tracking accuracy of the cameras at the level of an arcsecond, much better than the imaging resolution of the optics (which is 20 arcseconds per pixel). Due to the extremely large simultaneous field-of-view, this accuracy is needed in all of the three rotational degrees of freedom. Hence, the hexapod is an ideal choice to perform a location-independent way to accomplish the aforementioned requirements. This platform has many additional advantages: the redundancy of the hexapod allows smooth operations even if one or two of the legs would stuck. It can calibrate itself by performing astrometry on the detected stars without the need of polar (or any kind of) alignment.

In this presentation we present the details of the performance of the full Fly's Eye Camera System. Currently Fly's Eye is mounted at Piszkés-tet? Observatory in a thermally stabilized protective enclosure. Autonomous observations are performed whenever weather permits, the decision itself is based on the real-time analysis of ambient data and sky quality analysis of all-sky cameras. Here we detail the specifications of the camera-filter-lens optical setup and the custom solutions for fault-tolerant embedded control of the imaging subsystem. As we present here, even with this small-scale optics the accurate sidereal tracking is sufficient to reach millimagnitude precision at the bright-end while the detection of faint sources down to r=15 is also feasible. Scientific data series are then provided for all the five standard Sloan filters while the frequency of filter usage is proportional to the camera quantum efficiency. Namely, every second frame is Sloan r', every 6th is i' and g' while u' and z' have a period of 12 frames. This type of data acquisition setup can be exploited in scientific analysis rather efficiently since the aforementioned scheme is equivalent to high sampling rate of flux measurements and low sampling information about color variations.

The main goal of our project is to provide series of data of continuously monitored various astronomical phenomena, including solar system objects, variability of stars with magnetic activity, transiting exoplanets and bright extragalactic transients. The Fly's Eye camera system provides a complementary dataset to large synoptic surveys (e.g. LSST) since the saturation limit of these instruments is close to faint limit of the Fly's Eye's.

9908-222, Session PS3

An airborne infrared spectrometer for solar eclipse observations

Jenna Samra, Harvard-Smithsonian Ctr. for Astrophysics (United States) and Harvard Univ. (United States); Peter N. Cheimets, Edward E. DeLuca, Thomas M. Gauron, Leon Golub, Giora Guth, Edward Hertz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Philip Judge, High Altitude Observatory (United States); Vanessa Marquez, Harvard-Smithsonian Ctr. for Astrophysics (United States)

This paper presents the design of an innovative solar spectrometer that will fly on the NSF/NCAR High-Performance Instrumented Airborne Platform for Environmental Research (HIAPER) Gulfstream V during the 2017 solar eclipse. The airborne infrared spectrometer (AIR-Spec) is groundbreaking in two aspects: it will image infrared coronal emission lines that have never been measured, and it will bring high resolution imaging to the HIAPER GV.

The instrument development faces the challenges of achieving adequate spectral and spatial resolution in a compact package mounted to a noisy moving platform. To ensure that AIR-Spec meets its research goals, the instrument is undergoing pre-flight modeling and testing. The results are presented with reference to the instrument requirements.

The solar magnetic field enables the heating of the corona and provides its underlying structure. Energy stored in coronal magnetic fields is released in flares and coronal mass ejections and ultimately drives space weather. Therefore, direct measurements of the coronal magnetic field have significant potential to enhance understanding of coronal dynamics and improve solar forecasting models. Of particular interest are observations of coronal field lines in the transitional region between closed and open flux systems, providing important information on the origin of the slow solar wind.

While current instruments routinely observe only the photospheric and chromospheric magnetic fields, AIR-Spec will take a step toward the direct observation of coronal fields by measuring plasma emission in the infrared at high spatial and spectral resolution. During the total solar eclipse of 2017, AIR-Spec will observe five magnetically sensitive coronal emission lines between 1.4 and 4 μm from the HIAPER GV at an altitude above 14.9 km. The instrument will measure emission line intensity, width, and Doppler shift, map the spatial distribution of infrared emitting plasma, and search for waves in the emission line velocities.

AIR-Spec consists of an optical system (feed telescope, grating spectrometer, and infrared detector) and an image stabilization system. The telescope collects light over a 0.4 degree (1.5 solar radius) field of view and feeds it into the spectrometer, which is based on a planar diffraction grating operating near the Littrow condition. The five wavelengths of interest are divided into two channels and imaged onto the cryogen-cooled InSb detector.

The image stabilization system uses a fast steering mirror to correct the line-of-sight for platform perturbations. The mirror command is calculated as a combination of four inputs: the eclipse ephemeris, GPS location, aircraft attitude measured by a set of fiber-optic gyroscopes, and residual drift correction from an operator-controlled joystick. The visible context images that allow the operator to correct for drift will also be used post-flight for spatial registration of the spectrometer data.

9908-223, Session PS3

Project PANOPTES: a citizen-scientist exoplanet transit survey using commercial digital cameras

Wilfred Gee, Univ. of Hawai'i at Hilo (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States) and The Univ. of Arizona (United States); Joshua Walawender, Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Luc Boucher, Gemini Observatory (Chile)

Project PANOPTES (http://panoptes.github.io/) is aimed at establishing a collaboration between professional astronomers, citizen scientists and schools to discover a large number of exoplanets with the transit technique. We have developed digital camera based imaging units to image large parts of the sky and look for exoplanet transits. Each unit costs approximately US$5000, and runs robotically every night. By using low-cost, commercial DSLR cameras, we have developed a uniquely cost-efficient system for wide field astronomical imaging, offering approximately two orders of magnitude better etendue per unit of cost than professional wide-field surveys. Our vision is to have thousands of these units built by schools and citizen scientists gathering data, making this project the most productive exoplanet discovery machine in the world. The full power of the project comes from combining many images, acquired by different units, to increase accuracy and uncover smaller planets. PANOPTES is both a science project and an outreach project, and our ultimate goal is to crowdsource exoplanet discoveries to the public.

We provide a technical description of the project, including the photometric data processing approach we developed to handle RGB color detector arrays, usually known as Bayer arrays. We discuss the expected science output of the network and its current status, including image processing and data handling.

9908-33, Session 8

Hyper Suprime-Cam *(Invited Paper)*

Satoshi Miyazaki, National Astronomical Observatory of Japan (Japan)

Hyper Suprime-Cam (HSC) is a new 1.5 degree field diameter camera built for Subaru prime focus, which realizes seeing limited imaging on Mauna Kea (~ 0.6 arcsec median in i-band) over the entire field of view. HSC began the science observation on March 2014 and the steady operation is fulfilled; nearly 75 % of the night time (expect cloudy night)is used for target exposures. Half of HSC night is allocated for a 5 years legacy survey (HSC survey) and the rest is allocated for general observers including Keck/Gemini communities through the time exchange program. The primary science driver of the HSC survey is cosmology which makes use of weak lensing technique. Thanks to the combination of large aperture and high resolution imaging, the number density of resolved galaxies suited for lensing analysis is quite high (near 40 galaxies per square arc minute). This unique features enables high resolution weak lensing mass map where we could detect the dark matter halo peaks of galaxy cluster scales. We expect stronger cosmological constraints from this halo count combined with the standard two point shear statistics. In this talk, we will present the outline of the camera and highlights of early science results.

9908-34, Session 8

HiPERCAM: a high-speed quintuple-beam CCD camera for the study of rapid variability in the universe

Vik Dhillon, The Univ. of Sheffield (United Kingdom); Tom Marsh, The Univ. of Warwick (United Kingdom); Trevor Gamble, The Univ. of Sheffield (United Kingdom); Naidu N. Bezawada, Martin Black, David M. Henry, David W. Lunney, UK Astronomy Technology Ctr. (United Kingdom); Simon Dixon, Stuart Littlefair, The Univ. of Sheffield (United Kingdom); James Osborn, Timothy J. Morris, Richard W. Wilson, Durham Univ. (United Kingdom)

HiPERCAM is a high-speed camera for the study of rapid variability in the Universe. The project is funded by a 3.5 Meuro European Research Council Advanced Grant. HiPERCAM builds on the success of our previous instrument, ULTRACAM, with very significant improvements in performance thanks to the use of the latest technologies. HiPERCAM will use 4 dichroic beamsplitters to image simultaneously in 5 optical channels covering the u', g', r', i', z' bands. Frame rates of over 1000 per second will be achievable using the ESO CCD controller (NGC), with every frame GPS timestamped. The detectors are custom-made frame-transfer CCDs from e2v, with 4 low-noise (2.5e-) outputs, mounted in small thermoelectrically-cooled heads operated at 180 K, resulting in virtually no dark current. The two reddest CCDs will be deep-depletion devices with anti-etaloning, providing high quantum efficiencies across the red part of the spectrum with no fringing. The instrument will also incorporate scintillation noise correction via the conjugate-plane photometry technique. The opto-mechanical chassis will make use of additive manufacturing techniques in metal to make a lightweight, rigid and temperature-invariant structure. First light is expected on the 4.2m William Herschel Telescope on La Palma in 2017 (on which the field of view will be 10' with a 0.3"/pixel scale), with subsequent use planned on the 10.4 Gran Telescopio Canarias on La Palma (on which the field of view will be 4' with a 0.11"/pixel scale) and the 3.5m New Technology Telescope in Chile.

9908-36, Session 8

The PAU camera at the WHT

Cristóbal Padilla, Institut de Física d'Altes Energies (Spain); Francisco J. Castander, Institut de Ciències de l'Espai (Spain); Otger Ballester, Institut de Física d'Altes Energies (Spain); Anne Bauer, Institut de Ciències de l'Espai (Spain) and Institut d'Estudis Espacials de Catalunya (Spain); Laia Cardiel-Sas, Institut de Física d'Altes Energies (Spain); Jorge Carretero, Port d'Informació Científica (Spain); Ricard Casas, Institut de Ciències de l'Espai (Spain) and Institut d'Estudis Espacials de Catalunya (Spain); Javier Castilla, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Martin Crocce, Institut de Ciències de l'Espai (Spain); Manuel Delfino, Port d'Informació Científica (Spain); Martin B. Eriksen, Institut de Ciències de l'Espai (Spain) and Institut d'Estudis Espacials de Catalunya (Spain); Enrique-Josua Fernández, Institut de Física d'Altes Energies (Spain); Pablo Fosalba, Institut de Ciències de l'Espai (Spain); Juan Garcia-Bellido, Univ. Autónoma de Madrid (Spain); Enrique

Gaztañaga, Institut de Ciències de l'Espai (Spain); Ferràn Grañena, Cales Hernandez, Jorge Jiménez Rojas, Luis Lopez, Pol Martí, Ramon Miquel, Institut de Física d'Altes Energies (Spain); Christian Neissner, Port d'Informació Científica (Spain); Cristobal Pio, Institut de Física d'Altes Energies (Spain); Rafael Ponce, Eusebio Sanchez Alvaro, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Santiago Serrano, Institut de Ciències de l'Espai (Spain); Ignacio Sevilla, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Nadia Tonello, Port d'Informació Científica (Spain); Juan de Vicente, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain)

The PAU Camera is a novel instrument equipped with a system of 40 narrow-band (12.5 nm wide in spots of 10 nm) filters spanning the wavelength range from 450 nm to 850 nm, and with 6 wide-band filters (u, g, r, i, z, Y). It aims at observing ~100 deg2 of sky and provide up to 3 million redshifts to i(AB)~22.5 with a z-uncertainty of ~ 3 per mill, in which shape and deep Broad-Band photometric measurements have already been obtained by CFHTLenS and KIDS, an in which spectroscopic redshifts for calibration are available from the GAMA, VIPERS, DEEP2 and zCOSMOS redshift surveys. The survey will be a few magnitudes deeper than current completed large flux limited surveys (such as Gamma) and 10 times larger than current completed deep flux limited surveys (such as VVDS/VIPERS/Deep2).

The survey data will enable the study of target selections incompleteness and improve Broad Band photo-z estimates (in KIDS, DES and Euclid) to reach the accuracy required for large-scale clustering and weak lensing analysis, produce the most detailed studies of intermediate-scale cosmic structure analysis, provide the first precise measurement of intrinsic alignment at z~0.75 and enable cross-correlation techniques for redshift measurements, magnification and sampling variance cancelation studies.

The camera is installed at the William Herschel Telescope. The focal plane, composed of 18 Hamamatsu photonics 2k x 4 k 200 microns thick fully depleted CCD's covers ~1 deg2 FoV, every 15 micron pixel corresponding to 0.26''. The PAU Camera is a technologically pioneer instrument built with a large carbon fiber enclosure in order to minimize weight at the WHT prime focus. Since the 8 central CCd's cover the observation of the 40 Narrow Band filters, a system of five movable filter trays is installed. In order to minimize the dead areas in the focal plane, the filter trays are located as close as possible to the CCD's inside the cryostat. The cryogenic system includes a dual system: a Nitrogen system to make a fast cool down during installation of the instrument and a cryocooler system to maintain the operational temperature during the observations.

During survey observation mode, the PAU Camera generates around 250 GBytes of data per night. Every image is analyzed by an online monitoring system controlled by the Camera Control system. The PAU Data management system transfers the data and archives it at Portal Informacio Cientifica (PIC) in Barcelona, where the data calibration and processing takes place in order to produce a science-ready catalog. The first processing is done in an automatic nightly pipeline in order to provide fast feedback during the observation periods.

The PAU Camera saw first light on June 3rd, 2015 and, since then, has had several observation periods in which has covered portions of different fields (DEEP2, zCOSMOS, W1, W4,...). This talk gives an overview of the camera and its systems and describes its performance and preliminary scientific results obtained after the commissioning and the various observation periods during the last year.

9908-37, Session 8

A near-infrared SETI experiment: commissioning, data analysis, and performance results

Jérôme Maire, Dunlap Institute for Astronomy & Astrophysics (Canada); Shelley A. Wright, Univ. of California, San Diego (United States); Patrick Dorval, Dunlap Institute for Astronomy & Astrophysics (Canada); Frank Drake, SETI Institute (United States); Andres Duenas, Univ. of California, San Diego (United States); Geoffrey W. Marcy, Andrew P. V. Siemion, Univ. of California, Berkeley (United States); Remington P. S. Stone, Lick Observatory (United States) and Univ. of California, Santa Cruz (United States); Richard R. Treffers, Starman Systems, LLC (United States); Dan Werthimer, Univ. of California, Berkeley (United States)

Over the last two decades optical SETI experiments have been conducted to search for either continuous or pulsed optical laser beacons used for interstellar communication or energy transmission. Near-infrared bandwidth offers a compelling window for signal transmission since there is a decrease in interstellar extinction and Galactic background compared to optical wavelengths. An innovative Near-InfraRed SETI (NIROSETI) instrument has been designed and build to take advantage of a new generation of fast (> 1 Ghz) low-noise near-infrared avalanche photodiodes to search for nanosecond near-infrared (850 - 1650 nm) pulses. The instrument was successfully installed and commissioned at the Nickel telescope (1m) at Lick Observatory in March 2015. We will describe the overall design of the instrument with a focus on the new analysis methods developed for data acquisition and reduction for near-infrared SETI. Time and height analyses of the pulses produced by the detectors are performed to search for periodicity and coincidences in the signals. We will further discuss our SETI survey plans and strategy.

9908-212, Session 8

Performance of the e2v 1.2 GPix cryogenic camera for the J-PAS 2.5m survey telescope

Mark S. Robbins, Matt Bastable, Ashley Bates, Mike Dryer, Stuart Eames, Graham Fenemore-Jones, Gordon Haddow, Paul R. Jorden, Ben Lane, e2v technologies (UK) Ltd. (United Kingdom); Antonio Marín-Franch, Ctr. de Estudios de Física del Cosmos de Aragón (Spain); Jason Mortimer, Ian Palmer, Nathan Puttay, Ryan Renshaw, Mark Smith, e2v technologies (UK) Ltd. (United Kingdom); Keith Taylor, ON (Brazil); Jon Tearle, Paul Weston, Patrick Wheeler, Jude Worley, e2v technologies (UK) Ltd. (United Kingdom)

The J-PAS project will perform a five-year survey from a new 2.5m telescope in Teruel, Spain. The build and factory testing of the commercially supplied cryogenic camera are described. The 1.2 Giga-pixel focal plane is contained within a novel LN2 vacuum cryostat, which maintains the flatness of the 0.45m diameter focal plane to better than 40 µm peak to valley. The focal plane temperature operates at a temperature of -100oC with a variation across the focal plane of better than 10oC and a stability of better than +/- 0.5 oC over long operational periods. The proximity drive electronics is designed to achieve a 5 e- readout noise from the 224-channel CCD system.

e2v technologies have designed and are supplying the camera unit and cooling facility (CryoCam). CryoCam forms a part of the JPCam, which also includes the mechanical subsystem on the telescope, including the shutter and filter assemblies. Cryocam utilises fourteen 82 Megapixel science CCDs, together with peripheral wavefront and autoguider devices, on a precision focal plane, and must operate with high performance and minimum maintenance for at least ten years. All design reviews have been completed for Cryocam and the assembly, integration, verification and test phase of the program is nearing completion. This paper describes how the challenging user requirements have been met by Cryocam, including the demanding mechanical and cooling requirements. Results from the testing activities are presented, including the advanced metrology performed on the focal plane, and cooling trials performed to date. The final paper will include results from most of the verification activities.

Details of the CryoCam have been presented at previous conferences. The e2v camera consists of the following main components; sets of three CCD types in custom packages (14 9kx9k e2v CCD209-99 science devices, 8 2kx2k e2v CCD44-82 frame transfer devices (wavefront sensing) and 4 1kx1k e2v CCD47-20 devices (autoguiders) mounted on a precision focal plane cold plate, a cryogenic vacuum cryostat with precision kinematic mounts for the focal plane, liquid nitrogen delivery and control system, local low-noise electronics, CCD interface electronics and data transfer electronics, all designed for this application, interfaces to mounting system and telescope, together with system control software and API for camera operation.

The following main items will be presented- Opto-mechanical design, mechanical trials and metrology; instrument control and support subsystem; thermal trials; electronic CCD control and readout with impressive readout noise performance data; instrument status and final integration and test results prior to delivery

9908-38, Session 9

CARMENES: an overview six months after first light

Andreas Quirrenbach, Landessternwarte Heidelberg (Germany)

This paper gives an overview of the CARMENES instrument and of the survey that will be carried out with it. More detailed accounts of individual subsystems are given in a set of accompanying papers. CARMENES (Calar Alto high-Resolution search for M dwarfs with Exo-earths with Near-infrared and optical Echelle Spectrographs) is a next-generation instrument that has been built for the 3.5m telescope at the Calar Alto Observatory by a consortium of eleven Spanish and German institutions. The scientific goal of the project is conducting a 600-night radial-velocity survey targeting ~300 M dwarfs with the completed instrument. With a precision of 1 m/s, which is the goal of CARMENES, it will be possible to detect Earth-like planets in the habitable zones of these stars.

The CARMENES instrument consists of two separate échelle spectrographs covering the wavelength range from 0.55 to 1.7 ?m at a spectral resolution of R = 82,000, fed by fibers from the Cassegrain focus of the telescope. The CARMENES instrument consists of two spectrographs, one equipped with a 4k x 4k pixel CCD for the range 550 to 1050 nm, and one with two 2k x 2k pixel HgCdTe detectors for the range from 1.0 to 1.7 ?m. Each spectrograph is coupled to the 3.5m telescope with two optical fibers. The front end contains a dichroic beam splitter and an atmospheric dispersion corrector, to feed the light into the fibers leading to the spectrographs. Guiding is performed with a separate camera; on-axis as well as off-axis guiding modes are implemented. Fibers with octagonal cross-section are employed to ensure good stability of the output in the presence of residual guiding errors. The fibers are continually actuated to reduce modal noise. Additional fibers are available for simultaneous injection of light from emission line lamps or alternatively from a thermally stabilized Fabry-Pérot etalon for RV calibration. The spectrographs are mounted on benches inside vacuum tanks located in rooms, which have been equipped with temperature control systems. Due to the large thermal mass of the optical benches, their temperatures do not drift by more than ±0.01°C over 24h. The visible-light spectrograph is operated near room temperature, the NIR spectrograph is cooled to ~140K.

The subsystems of CARMENES were integrated in Heidelberg and Granada, and moved to Calar Alto in the course of 2015. The completed instrument saw “First Light” at the telescope on Nov 9, 2015, which marks the first time that a radial-velocity instrument optimized for the red and near-infrared wavelength ranges has been put into operation. Further technical tests and collection of data for the characterization of the instrument performance took place during November and December.

The data reduction pipeline for CARMENES has been developed in parallel with the instrument hardware. It has been shown to deliver radial velocities with m/s precision on HARPS data, and is now being optimized for processing the on-sky data from both CARMENES spectrographs. Further work will be done on the calibration procedures, and on the algorithms used for subtracting telluric contamination.

9908-40, Session 9

The habitable-zone planet finder: AI&V status and summary of research and development to achieve high precision NIR Doppler radial velocities

Suvrath Mahadevan, Tyler B. Anderson, Chad F. Bender, Samuel P. Halverson, Frederick R. Hearty, Eric I. Levi, Yiting Li, Andrew J. Monson, The Pennsylvania State Univ. (United States); Matthew J. Nelson, Univ. of Virginia (United States); Lawrence W. Ramsey, Paul M. Robertson, Arpita Roy, The Pennsylvania State Univ. (United States); Christian Schwab, Macquarie Univ. (Australia); Gudmundur K. Stefánsson, Ryan C. Terrien, The Pennsylvania State Univ. (United States)

The Habitable-Zone Planet Finder is a stabilized, fiber-fed, NIR spectrometer built for the 10m Hobby-Eberly telescope (HET) built from the ground up to be capable of discovering low mass planets around mid-late M dwarfs. The optical design of the HPF is an asymmetric white pupil spectrograph layout in a vacuum cryostat cooled to 180 K. The spectrograph uses gold-coated mirrors, a mosaic echelle grating, and a single Teledyne Hawaii-2RG (H2RG) NIR detector with a 1.7-micron cutoff covering parts of the information rich z, Y and J NIR bands at a spectral resolution of R~50,000. The use of 1.7 micron H2RG enables HPF to operate warmer than most other cryogenic instruments. In addition to summarizing the AI&V status and commissioning plans, we outline the results of the several R&D projects that were necessary to assure we will meet our science requirements. We present and summarize the main challenges to achieving precision radial velocities in the NIR, and the high level of R&D effort by our team to solve these problems, including sub-milli Kelvin (RMS) temperature control with bespoke electronics, a very high pressure stability at better than 10^-7 torr, and a double scrambler to achieve both near and far-field fiber scrambling, We also discuss the impact of stellar activity and how the NIR helps mitigate these issues, but also how design choices have been made to ensure that the chosen NIR bandpass contains suitable activity indicators.

9908-41, Session 9

WISDOM: the WIYN spectrograph for Doppler monitoring: a NASA-NSF concept for an extreme precision radial velocity instrument in support of TESS

Gábor F?rész, MIT Kavli Institute for Astrophysics and Space Research (United States); Lars A. Buchhave, Univ. of Copenhagen (Denmark); Mark D. Egan, Richard Foster, Tim Hellickson, Andrew Malonis, MIT Kavli Institute for Astrophysics and Space Research (United States); David F. Phillips, Harvard-Smithsonian Ctr. for Astrophysics (United States); Stephen A. Shectman, Carnegie Observatories (United States); Robert A. Simcoe, MIT Kavli Institute for Astrophysics and Space Research (United States); Ronald L. Walsworth, Harvard-Smithsonian Ctr. for Astrophysics (United States); Josh Winn, MIT Kavli Institute for Astrophysics and Space Research (United States); Deborah F. Woods, MIT Lincoln Lab. (United States)

The Kepler mission highlighted that precision radial velocity (PRV) follow-up is a real bottleneck in supporting transiting exoplanet surveys. The limited availability of PRV instruments, and the desire to break the "1 m/s" precision barrier, prompted the formation of a NASA-NSF collaboration 'NN-EXPLORE' to call for proposals designing a new Extreme Precision Doppler Spectrograph. By securing a significant fraction of telescope time on the 3.5m WIYN at Kitt Peak, and aiming for unprecedented long term precision, this instrument will provide a unique tool for U.S. astronomers in characterizing exoplanet candidates identified by TESS. One of the two funded instrument concept studies is led by the Massachusetts Institute of Technology, in consortium with Lincoln Laboratories, Harvard-Smithsonian Center for Astrophysics and the Carnegie Observatories. This paper describes the instrument concept WISDOM (WIYN Spectrograph for DOppler Monitoring) prepared by this team.

WISDOM is a fiber fed, environmentally controlled, high resolution (R=110k), asymmetric white-pupil echelle spectrograph, covering a wide 380-1300nm wavelength region. Its R4 and R6 echelle gratings provide the main dispersion, symmetrically mounted on either side of a vertically aligned, vacuum-enclosed optical bench. Each grating feeds two cameras and thus the resulting wavelength range per camera is narrow enough that the VPHG cross-dispersers and employed anti-reflection coatings are highly efficient. The instrument operates near room temperature, and so thermal background for the near-infrared arm is mitigated by thermal blocking filters and a short (1.7 micron) cutoff HgCdTe detector. To achieve high resolution while maintaining small overall instrument size (100/125mm beam diameter), imposed by the limited available space within the observatory building, we chose to slice the telescope pupil 6 ways before coupling light into fibers. An atmospheric dispersion corrector and fast tip-tilt system assures maximal light gathering within the 1.2" entrance aperture. The six octagonal fibers corresponding to each slice of the pupil employ ball-lens double scramblers to stabilize the near- and far-fields. Three apiece are coupled into each of two rectangular fibers, to mitigate modal nose and present a rectilinear illumination pattern at the spectrograph's slit plane. Wavelength solutions are derived from ThAr lamps and an extremely wide coverage dual-channel laser frequency comb. Data is reduced on the fly for evaluation by a custom pipeline, while daily archives and extended scope data reduction products are stored on NExScI servers, also managing archives and access privileges for GTO and GO programs.

Note: individual papers, submitted along this main paper, describe the details of subsystems such as the optical design, the environmental control system, the fiber link design, and the pupil slicer.

9908-42, Session 9

The Hobby Eberly Telescope high resolution spectrograph upgrade

Phillip J. MacQueen, Brian J. South, Joseph L. Strubhar, Gordon L. Wesley, Peter S. Odoms, Robert D. Edmonston, The Univ. of Texas at Austin (United States); Stuart I. Barnes, Leibniz-Institut für Astrophysik Potsdam (Germany)

The Hobby Eberly Telescope (HET) High Resolution Spectrograph (HRS) has been inefficiently coupled to the HET since commissioning in 2001, leading to low throughput performance. A significant upgrade is being commissioned during mid-2015. The two surface-relief cross dispersers have been replaced with four VPHGs for wavelength dependent throughput gains between 1.5x and 3x. The VPHG cross dispersers give greater interorder separation (IOS) to support simultaneous object-fiber and sky-fiber image slicers for net throughput gains of 2.1x, 4.5x, and 8.2x at resolving powers 35,000, 70,000, and 105,000, respectively. Sky subtraction capabilities have been added and enhanced considerably. Additionally, octagonal optical fibers have been added along with new auxiliary instrumentation including a fiber mode scrambler, fiber double scramblers, a two-channel exposure meter with bandpass filters, and enhanced temperature stabilization of the instrument. HRS is a reconfigurable spectrograph, operated essentially every clear night in queue scheduled mode, and reconfigured multiple times per night. The upgrade is engineered for reliability, plus the ability to reconfigure with precision repeatability. To maintain spectral coverage with the increased IOS, HRS will become a double spectrograph with the reconfiguration of the previous single arm as the red arm, and the future addition of a blue arm. The blue arm extends the spectral coverage from ~410 nm to 362 nm to broaden the scientific capabilities of HRS, particularly for metal poor star science.

This paper gives the novel engineering details of the HRS upgrade, the new instrument configurations and capabilities, and a performance analysis of the upgraded HRS.

9908-43, Session 9

Performance verification of infrared Doppler for the Subaru Telescope

Takayuki Kotani, National Astronomical Observatory of Japan (Japan); Motohide Tamura, The Univ. of Tokyo (Japan); Jun Nishikawa, National Astronomical Observatory of Japan (Japan); Takashi Kurokawa, Tokyo Univ. of Agriculture and Technology (Japan); Shane M. Jacobson, Klaus W. Hodapp, Univ. of Hawai'i (United States); Akitoshi Ueda, National Astronomical Observatory of Japan (Japan); Tsukasa Kokubo, Tokyo Univ. of Agriculture and Technology (Japan); Takahiro Mori, National Astronomical Observatory of Japan (Japan); Ken Kashiwagi, Tokyo Univ. of Agriculture and Technology (Japan); Masato Ishizuka, The Univ. of Tokyo (Japan); Yosuke Tanaka, Tokyo Univ. of Agriculture and Technology (Japan)

Infrared Doppler (IRD) is an instrument mainly dedicated to a search for Earth-mass planets around nearby M-dwarfs by precise radial velocity measurement in the near-infrared. We report the current status of the IRD instrument development witch is under the final phase of assembly, integration and test. A first light is expected to be done in the middle of 2016 at the Subaru telescope, and a large strategic survey program, 100 nights for 5 years, will be conducted to detect various planets down

to one-Earth mass in their habitable zone. IRD employs many original technologies to achieve ultimate radial velocity measurement stability. The spectrometer consists of a R6 Echelle grating and VPH to achieve a spectral resolution of 70,000 at maximum, covering Y, J, H-bands simultaneously with 2xH2RG detectors. IRD is a fiber-fed spectrometer with a high pointing stability thanks to Adaptive Optics of the Subaru telescope on the Nasmyth platform. Two fibers can be used simultaneously to record spectrum of a star and wavelength reference source, a laser frequency comb. Either a combination of 2 multi-mode fibers, or a multi-mode and single-mode fiber, or 2x single-mode fibers can be used. Thanks to the AO system, a star-light can be injected into a single-mode fiber if a target is bright, without a modal-noise. The spectrometer itself will be placed in a Coude room for good temperature stability. A newly developed laser frequency comb can cover almost Y,J,H-bands with 12.5 GHz frequency span better than 0.3 m/s stability. An ultra-low CTE ceramic component is employed for an optical table, off-axis parabola a flat mirror including their holders, and a slit holder to minimize the effect of temperature variation. Various types of mode scramblers based on a fiber, both static and dynamic, to reduce modal noise which is a major error source in radial velocity measurements in NIR. The instrument will be shipped to the University of Hawaii, instituted of Astronomy to assemble 2xH2RG array detectors, then a final stability test will be done to demonstrate radial velocity measurement precision better than 1m/s.

9908-44, Session 10

The Gemini High-Resolution Optical SpecTrograph (GHOST)

Andrew I. Sheinis, Australian Astronomical Observatory (Australia); Michael J. Ireland, The Australian National Univ. (Australia); Gabriella Baker, Australian Astronomical Observatory (Australia); John Pazder, Gregory S. Burley, NRC - Herzberg Astronomy & Astrophysics (Canada); Ross Zhelem, Scott Case, Lewis G. Waller, Tony J. Farrell, Australian Astronomical Observatory (Australia); Peter J. Young, The Australian National Univ. (Australia); Yuriy Kondrat, Michael Edgar, Vladimir Churilov, Australian Astronomical Observatory (Australia)

The Gemini High-Resolution Optical SpecTrograph (GHOST) is the newest instrument chosen for the Gemini telescopes. It is being developed by a collaboration between the Australian Astronomical Observatory (AAO), the NRC - Herzberg in Canada and the Australian National University (ANU). Using recent technological advances and several novel concepts it will deliver R=50,000 and R=75,000 spectroscopy for up to 2 objects simultaneously. Ghost uses a fiber-image-slicer to allow for a much smaller spectrograph than that described by the resolution-slit–width product. With its fiber feed, we expect GHOST to have a sensitivity in the wavelength range between 363-950 nm that equals or exceeds that of similar directly-fed instruments on world-class facilities. GHOST has entered the build-phase. We report the status of the instrument and describe the technical advances and the novel aspects, such as the lenslet-based slit reformatting. Finally, we describe the unique scientific role this instrument will have in an international context, from exoplanets through to the distant Universe.

9908-45, Session 10

Development and construction of MAROON-X

Andreas Seifahrt, Jacob L. Bean, Julian Stuermer, The Univ. of Chicago (United States); Luke Gers, Deon S. Grobler, Tony Reed, Callaghan Innovation (New Zealand); Damien J. Jones, Prime Optics (Australia)

We report on the development and construction of a new fiber-fed, red-optical (500-900 nm), high-precision radial-velocity spectrograph for the 6.5 m Magellan Telescope in Chile. MAROON-X will be optimized to find and characterize rocky planets around nearby M-dwarfs with an intrinsic per measurement precision of <1m/s. The instrument is based on a commercial echelle spectrograph, a dual-arm KiwiSpec R4-100, customized for high stability and throughput. Thanks to its 100mm beam diameter, anamorphic pupil compression, and dual arm design, the core spectrograph is extremely compact. To achieve a spectral resolving power of R~80,000, we developed a 3x pupil slicer with incorporated double scrambler, based on micro-lens arrays. A laser-locked etalon comb calibrator, developed in house, features a long-term traceable stability of better than 10 cm/s. The core spectrograph with one arm is scheduled for delivery to Chicago in August 2016. A dedicated lab with a tightly temperature controlled environmental enclosure is in place to house the spectrograph and permit extensive lab tests in the second half of 2016. Depending on available funding, MAROON-X could be completed in 2017 and deployed at the Magellan Telescope as early as Q1/2018.

9908-46, Session 10

iLocater: An AO-fed Doppler spectrometer for the Large Binocular Telescope

Justin R. Crepp, Jonathan Crass, Andrew Bechter, Eric Bechter, Ryan Ketterer, Univ. of Notre Dame (United States)

Radial velocity (RV) instruments have been stuck at 1 m/s precision for many years. The reason that overcoming the “1 m/s barrier” is so difficult is that several physical effects become relevant at the same level, creating a complicated systems engineering challenge. A promising path for mitigating the issues that prevent RV spectrographs from reaching their full potential involves using adaptive optics to achieve diffraction-limited performance.

We are building an ultra-precise Doppler instrument for the Large Binocular Telescope (LBT) named “iLocater.” Unlike previous spectrographs which are seeing-limited, iLocater uses single mode fibers and will operate behind an “extreme” adaptive optics system. With a spectral resolution that exceeds R=150,000 in the YJ bands, iLocater will deliver sub-meter-per-second precision when observing nearby stars; it is particularly well-suited for TESS follow-up observations of terrestrial planets located in or near the habitable zone. In this talk, I will explain why planet-finding spectrometers should use adaptive optics. I will also provide an update on our progress designing, building, and testing iLocater. Owing to the fact that the instrument is diffraction-limited and therefore decoupled from the influence of the telescope, the iLocater concept could be identically “cloned” for other adaptive optics facilities.

9908-47, Session 10

GIARPS: the unique VIS-NIR high precision radial velocity facility in this world

Riccardo U. Claudi, Serena Benatti, Ilaria Carleo, INAF - Osservatorio Astronomico di Padova (Italy); Massimo Cecconi, Fundación Galileo Galilei - INAF (Spain); Luca Fini, INAF - Osservatorio Astrofisico di Arcetri (Italy); Adriano Ghedina, Francesca Ghinassi Luschi, Manuel Gonzalez, Fundación Galileo Galilei - INAF (Spain); Raffaele G. Gratton, INAF - Osservatorio Astronomico di

Padova (Italy); Jose Guerra Sr., Avet Harutyunyan, Nauzet Hernandez, Fundación Galileo Galilei - INAF (Spain); Marcello Lodi, Fundación Galileo Galilei - INAF (Spain); Marcella Iuzzolino, INAF - Osservatorio Astrofisico di Arcetri (Italy); Luca Malavolta, Univ. degli Studi di Padova (Italy); Jesus Maldonado, Giuseppina Micela, INAF - Osservatorio Astronomico di Palermo Giuseppe S. Vaiana (Italy); Emilio Molinari, Fundación Galileo Galilei - INAF (Spain); Ernersto Oliva, Nicoletta Sanna, INAF - Osservatorio Astrofisico di Arcetri (Italy); José San Juan Gómez, Fundación Galileo Galilei - INAF (Spain); Salvatore Scuderi, INAF - Osservatorio Astrofisico di Catania (Italy); Alessandro Sozzetti, INAF - Osservatorio Astrofisico di Torino (Italy); Andrea Tozzi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Héctor Pérez Ventura, Marcos Hernandez Diaz, Alberto Galli, Manuel Gonzalez, Luis Riverol, Carlos Riverol, Fundación Galileo Galilei - INAF (Spain)

GIARPS (GIAno & haRPS) is a project devoted to have on the same focal station of the Telescopio Nazionale Galileo (TNG) both the high resolution spectrographs HARPS-N (VIS) and GIANO (NIR) working simultaneously. This could be considered the first and unique worldwide instrument providing cross-dispersed echelle spectroscopy at a resolution of 50,000 and over in a wide spectral range (0.383 - 2.45 μm) in a single exposure. The science case is very broad, given the versatility of such an instrument and the large wavelength range. A number of outstanding science cases encompassing mainly extra-solar planet science starting from rocky planet search and hot Jupiters, atmosphere characterization can be considered. Furthermore both instrument can measure high precision radial velocity by means the simultaneous thorium technique (HARPS - N) and absorbing cell technique (GIANO) in a single exposure. Other science cases are also possible. Young stars and proto-planetary disks, cool stars and stellar populations, moving minor bodies in the solar system, bursting young stellar objects, cataclysmic variables and X-ray binary transients in our Galaxy, supernovae up to gamma-ray bursts in the very distant and young Universe, can take advantage of the unicity of this facility both in terms of contemporaneous wide wavelength range and high resolution spectroscopy.

9908-48, Session 10

Precision radial velocities with inexpensive compact spectrographs

Christopher H. Betters, Alex Murray, Joss Bland-Hawthorn, Sergio G. Leon-Saval, The Univ. of Sydney (Australia)

The high-precision astronomical spectrographs routinely employed to detect planets via the radial velocity method are generally large expensive instruments. We present our progress developing a comparable compact spectrograph using commercial 'off-the-shelf' components that can achieve similar precision at a fraction of the cost and complexity.

The spectrograph, PIMMS Visible, has an effective resolving power of R-50,000 and is capable of operating from 550nm to 750nm. The spectrograph is fed by a single length of a 19 multi-core fibre (MCF). One end of the fibre has been fused into a Photonic Lantern, a multi-mode to single-mode converter, whilst the other is used directly as the single-mode spectrograph slit (TIGER mode hexagonal grid). The multi-mode end is then either attached to a conventional telescope injection system for stellar observations or to a Thorlabs CCSA2 cosine corrector for solar observations (the later method allows for a 'full-disk' spectrum of the Sun whilst also limiting the amount of light collected).

We use a Rb locked single-mode (SMF) Fabry-Perot etalon as a simultaneous calibration source. The etalon spectrum calibration source is introduced into the MCF fibre via a novel side coupled tapered SMF, and thus superimposed on the object spectrum. This is achieved by tapering the output fibre of the etalon such that it ceases to guide light. The tapered etalon fibre is then wrapped around a portion of the MCF which has had its cladding removed, thus allowing the etalon frequency combs light to be coupled to the cores of the MCF.

With this setup we obtain an RMS velocity precision of 1m/s when calibrating with the fibre etalon (which is stabilised to less than a few 10's cm/s). We demonstrate the power and stability of our approach through high cadence spectroscopy of the Sun. With a few hours of continuous observations, we detect the solar p-mode oscillations (also known as the 5-minute oscillations). We will also present a series of observations re-detecting exoplanets with known radial velocities.

9908-39, Session PS4

Stability of the FOCES spectrograph using an astro-frequency comb as calibrator

Anna Brucalassi, Hanna Kellermann, Liang Wang, Max-Planck-Institut für extraterrestrische Physik (Germany); Florian Lang-Bardl, Ulrich Hopp, Frank U. Grupp, Univ.-Sternwarte München (Germany); Ralf Bender, Max-Planck-Institut für extraterrestrische Physik (Germany)

Over the past decades, the discovery and characterization of exoplanets has progressed extraordinarily.

In particolar, searches for extrasolar planets using the periodic Doppler shift of stellar spectral lines resulting from the motion of the host star around the barycenter of an exo-solar system, have achieved a precision of ~50 cm/s, sufficient to find Super-Earth-mass planets. However, the detection of Earth-mass planets in the habitable zone around Sun-like stars, will require an order-of-magnitude improvement in RV measurement sensitivity to below 10 cm/s.

Key limitations of RV measurements are extreme precision spectrographs, stable over timescales of years, and ultra-precise and stable wavelength calibration of the astrophysical spectrographs. The astro-frequency comb is becoming the promising candidate for a revolutionary ideal wavelength calibrator providing high density of bright, regularly-spaced optical lines and nearly perfect long-term stability with a improved precision as high as 1 cm/s in astronomical radial velocity measurements.

We present here the results of a series of measurements conducted using the echelle spectrograph FOCES intended to be operated at the 2.0 m Fraunhofer Telescope at the Wendelstein Observatory and an Astro Frequency Comb as calibrator. Different analysis techniques have been applied to investigate the calibration precision and the medium-long term stability of the system in term of changes in stellar radial velocity.

9908-224, Session PS4

Dramatic robustness of a multiple delay dispersed interferometer to spectrograph errors: how mixing delays reduces or cancels wavelength drift

David J. Erskine, Lawrence Livermore National Lab. (United States); Eric V. Linder, Lawrence Berkeley National Lab. (United States); Edward H. Wishnow, Jerry Edelstein, Martin M. Sirk, Space Sciences Lab. (United States); Philip S. Muirhead, Boston Univ. (United States); James P. Lloyd, Cornell Univ. (United States); Alex G. Kim, Lawrence Berkeley National Lab. (United States)

Externally dispersed interferometry (EDI) with a multiple delays has been used to measure high resolution NIR stellar spectra at the 200 inch Hale telescope having a resolution 6x-10x larger than the native spectrograph (TripleSpec, 950 — 2450 nm). This produced a resolving power of 19,000 from a 2,700 disperser over the full bandwidth of the native spectrograph. Secondly, and the focus of this talk, the robustness of the output high resolution spectrum to lineshape (LSF) drifts and distortions of the native spectrograph was also increased 20x. This is due to the interferometer being crossed with the disperser, so that the former not the latter provides the high frequency information. The amount of observed drifts in TripleSpec native spectrograph was severe and would normally preclude the achieved high resolution. This robustness boost is significant for the community since LSF drifts and distortions are often the limiting factor in achieving m/s scale Doppler radial velocity precisions in astronomical spectrographs. We describe the theoretical basis for the EDI robustness, and the advantages of using multiple rather than single delay. Thirdly, the EDI has demonstrated to also be extremely robust to fixed pattern errors produced by bad detector pixels which pollute the native spectrum. Fourthly, the extremely high dynamic range of EDI has allowed us to measure line height differences between our ThAr lamp and the literature spectrum for weak features (~0.001 height of nearest strong line). Accurate knowledge of a reference spectrum is essential for precision radial velocimetry. Prepared by LLNL under Contract DE-AC52-07NA27344.

9908-225, Session PS4

High-sensitivity, wide coverage, and high-resolution NIR non-cryogenic spectrograph: WINERED

Yuji Ikeda, Photocoding (Japan); Naoto Kobayashi, The Univ. of Tokyo (Japan); Sohei Kondo, Shogo Ootsubo, Satoshi Hamano, Kyoto Sangyo Univ. (Japan); Hiroaki Sameshima, Kyoto Sangyo Univ (Japan); Tomoshiro Yoshikawa, Edecs (Japan); Kenshi Nakanishi, Tetsuya Nakaoka, Takahumi Kawanishi, Akira Asano, Ayaka Watase, Keiichi Takenaka, Kyoto Sangyo Univ. (Japan); Kei Fukue, Hiroyuki Mito, Chikako Yasui, Atsushi Minami, Noriyuki Matsunaga, The Univ. of Tokyo (Japan); Hideyo Kawakita, Ayaka Kitano, Masaomi Kinoshita, Kyoto Sangyo Univ. (Japan); Ryo Yamamoto, Misaki Mizumoto, Natsuko Izumu, Univ. of Tokyo (Japan); Takayuki Arasaki, Kyoto Sangyo Univ. (Japan)

WINERED is a near-infrared (NIR) high-resolution spectrograph, which is currently mounted on 1.3m Araki telescope of Koyama Astronomical Observatory in Kyoto-Sangyo University, Japan. WINERED is a PI-type instrument,which can be attached to various telescopes with a Nasmyth focus. It covers a wide wavelength range from 0.90 to 1.35μm (z, Y, J-bands) with the spectral resolution of R = 30,000 with 1.5 arcsec slit (for 1.3m telescope with f/10).The main concept of WINERED is to obtain high-resolution infrared spectra of high signal-to-noise and high-quality, which has been achieved with the state-of-the-art optical echelle spectrographs. To realize this concept, WINERED has three distinctive features: (i) optics with no cold stop, (ii) wide spectral coverage, and (iii) high sensitivity. Owing to the first feature, we succeeded in reducing the time for development, alignment, maintenance, and the total cost compared to the usual entirely-cooled NIR spectrographs. Second feature is realized with the spectral coverage of Delta_lambda / lambda ~ 1/6 in a single exposure, which is better than those of all the NIR high-resolution spectrographs attached to 8-10m telescopes (the best number is 1/10 for Subaru/IRCS). This wide coverage is enabled by the combination of decent optical design with cross-dispersed echelle and a large format array (2k x 2k HAWAII2-RG). Third feature makes WINERED as the most sensitive spectrograph among all commissioned/planned NIR high-resolution spectrographs in the world. If attached to 8-10 m telescopes, the limiting magnitudes of WINERED achieving S/N=30 with 1800 sec exposure are expected to be J=19.8 with AO and J=18.0 without AO. Such high sensitivity is achieved by the high-throughput optics (> 0.5) and the very low noise of the system. The major factors of high throughput is the echelle grating and VPH cross-disperser with high diffraction efficiencies of ~0.83 and ~0.86, respectively, and the high Q.E. of HAWAII2-RG (0.83 at 1.23 um). The readout noise of the electronics is 5.3 e- for NDR=32. The ambient thermal background radiation at longer wavelengths than that of WINERED is significantly reduced by two custom-made cold thermal blockers installed in front of the array and also by the short-wavelength cut-off (1.7um) of the array. The thermal background is measured as < 0.02 e-/sec/pix at 273K, which results in the thermal noise less than the typical read noise or the dark noise of the array even with 1800 sec exposure. Since the first-light in 2013, WINERED has been producing fruitful scientific results through a variety of fields from solar system objects, stars, to interstellar medium. The scientific topics include isotope ratios of C and N in comets, a spectral library of stars covering all spectral types and luminosity classes in this relatively uncultivated wavelength range, near-infrared diffuse interstellar bands, and so on. In this paper, we present the summary of design and final performances of WINERED along with the first scientific results. In addition, we briefly introduce a newly-installed high-resolution mode (R~80,000) with a high-blazed echelle grating (refer to Ootsubo et al. in this conference).

9908-226, Session PS4

Thermal stability improvements to the ESPaDOnS spectrograph with the addition of a thermal enclosure

Gregory Barrick, Tom Benedict, Claire Moutou, Lison Malo, Canada-France-Hawaii Telescope (United States); John K. White, André-Nicolas Chene, Gemini Observatory (United States)

As part of the GRACES (Gemini Remote Access to CFHT ESPaDOnS Spectrograph) project, a project to link the Gemini-North telescope to the ESPaDOnS (Echelle Polarimetric Device for the Observation of Stars) spectrograph at CFHT (Canada-France-Hawaii Telescope), the original thermal enclosure of the spectrograph needed to be modified. Although the modifications were slight, there was a significant possibility that the thermal stability of ESPaDOnS would be somewhat compromised. To eliminate this risk, a walk-in thermal enclosure was purchased and installed around the ESPaDOnS spectrograph as part of the GRACES project. The thermal impact of these modifications to the ESPaDOnS environment will be analyzed and the effect of the changes on the amplitude and behavior of the spectral drift for the ESPaDOnS and GRACES instruments will be examined.

9908-227, Session PS4

Performance characteristics of two volume phase holographic grisms produced for the ESPRESSO spectrograph

James Arns, Kaiser Optical Systems, Inc. (United States)

The ESPRESSO spectrograph requires two volume phase holographic (VPH) grisms as part of its optical design. The two grisms operate as cross-dispersing elements within the spectrographs with each working over a section of the overall spectral range. The grisms are relatively large in size with a working aperture of 185 mm x 185 mm for the blue grism and 215 x 185 mm for the red. This paper describes the specifications of the two grating types, gives the expected theoretical performances of diffraction efficiency for the production designs and presents the actual measured performances of the production grisms.

The blue grism covers the range from 375 nm to 520 nm with a dispersion of 0.88 degrees/nm at the central wavelength. The blue grism operates from 535 nm to 780 nm with a dispersion of 0.47 degrees /nm at 654.8 nm. Both designs use a single input prism to enhance the dispersion of the grism assembly. This paper shows the RCWA theoretical predictions for each of the designs and presents the test data for each of the gratings built.

9908-228, Session PS4

A system to provide sub-milliKelvin temperature control at T~300K for extreme precision optical radial velocimetry

Paul M. Robertson, Frederick R. Hearty, Tyler B. Anderson, Gudmundur K. Stefánsson, Eric I. Levi, Chad F. Bender, Suvrath Mahadevan, Samuel P. Halverson, Andrew J. Monson, Lawrence W. Ramsey, Arpita Roy, The Pennsylvania State Univ. (United States); Christian Schwab, Macquarie Univ. (Australia); Ryan C. Terrien, The Pennsylvania State Univ. (United States); Matthew J. Nelson, Univ. of Virginia (United States); Basil Blank, PulseRay (United States)

We present the design and preliminary results for the temperature monitoring and control (TMC) system from our instrument concept for NASA's Extreme Precision Doppler Spectrograph (EPDS). Exquisite temperature control is a requirement for high-precision spectrographs, such as this instrument being designed for the 3.5m WIYN telescope. We demonstrate sub-mk temperature stability over more than a week, and 0.14mK stability over a day in full scale model tests of our EPDS concept, called NEID.

Our TMC system is adapted from that of the Habitable Zone Planet Finder (HPF) instrument, operating temperature 180K. This stability is achieved by enclosing the entire optical train in a high quality (P < 10-7 Torr) vacuum, thereby eliminating convective and molecular heat transport. We have designed and implemented custom electronics—common to HPF and NEID—to measure and control the spectrograph temperature at the sub-mK level.

Our operational concept for NEID involves raising the temperature within the thermal shield to 10-15K above room temperature, and using the ambient environment as a uniform radiative heat sink. The thermal shield is adapted to warm operation with thicker aluminum walls and double the number of heaters, with with even distribution of area served per heater.

We have demonstrated the effectiveness of the NEID temperature control concept via a full-scale warm test of the HPF vacuum chamber. We show that, even when optimized for operation at 180K, the system maintains sub-mK stability at T~300K on the optical bench over more than a week. The ability to measure and control to such high precision unveils a plethora of physical effects that matter at the sub-mK level. We discuss these effects, as well as how they will be further mitigated in the NEID design.

9908-229, Session PS4

Multi-fiber coupling through a miniature lens system into the FOCES spectrograph

Hanna Kellermann, Anna Brucalassi, Max-Planck-Institut für extraterrestrische Physik (Germany); Florian Lang-Bardl, Ulrich Hopp, Frank U. Grupp, Univ.-Sternwarte München (Germany); Ralf Bender, Max-Planck-Institut für extraterrestrische Physik (Germany)

For the future goals of stable long term measurements with the upgraded version of the FOCES at Wendelstein Observatory the light injection into spectrograph was raised to a higher standard. We will present our concept and first results of the light injection consisting of several components namely a 4-fiber slit, the new micro optic system to reimage the light leaving the fiber onto the slit, as well as the new slit mask. The former adjustable slit will be replaced by slit mask glued to the last lens of the micro optic system to further eliminate sources of instabilities.

9908-230, Session PS4

Relative stability of two laser frequency combs for routine operation on HARPS and FOCES

Rafael A. Probst, Max-Planck-Institut für Quantenoptik (Germany); Gaspare Lo Curto, Gerardo Ávila, European Southern Observatory (Germany); Anna Brucalassi, Univ.-Sternwarte München (Germany); Bruno L. Canto Martins, Izan de Castro Leão, Univ. Federal do Rio Grande de Norte (Brazil); Massimiliano Esposito, Jonay I. González Hernández, Instituto de Astrofísica de Canarias (Spain); Frank U. Grupp, Univ.-Sternwarte München (Germany); Theodor W. Hänsch, Max-Planck-Institut für Quantenoptik (Germany); Ronald Holzwarth, Menlo Systems GmbH (Germany) and Max-Planck-Institut für Quantenoptik (Germany); Hanna Kellermann, Univ.-Sternwarte München (Germany); Florian Kerber, European Southern Observatory (Germany); Olaf Mandel, Menlo Systems GmbH (Germany); Antonio Manescau Hernandez, Luca Pasquini, Eszter Pozna, European Southern Observatory (Germany); Rafael Rebolo-López, Instituto de Astrofísica de Canarias (Spain); José Renan de Medeiros, Univ. Federal do Rio Grande de Norte (Brazil); Sebastian P. Stark, Tilo Steinmetz, Menlo Systems GmbH (Germany); Alejandro Suárez Mascareño, Instituto de Astrofísica de Canarias (Spain); Thomas Udem, Max-Planck-Institut für Quantenoptik (Germany); Josefina Urrutia Del Rio, European Southern Observatory (Germany); Yuanjie Wu, Max-Planck-Institut für Quantenoptik (Germany)

Astronomical spectrographs have been lacking calibration sources with sufficient precision for the detection of Earth analogues, which requires measuring radial-velocity amplitudes of about 9 cm/s. Laser frequency combs (LFCs) promise to overcome this limitation by offering a regular pattern of spectral lines that is referenced to an atomic clock. We report on the installation and test of an LFC at the two-channel fiber-fed spectrograph HARPS, located at ESO's La Silla Observatory in Chile. The test was conducted in conjunction with a second LFC owned by the University Observatory Munich that was in preparation for its installation at the Wendelstein Observatory as a calibrator for the FOCES spectrograph. This allowed us for the first time to probe the relative stability of two independent astronomical LFCs over an extended wavelength range. Both LFCs covered the spectral range of HARPS to at least 74 % from 460 to 690 nm. After optimization of the light delivery in optical fibers to HARPS to suppress modal noise, a relative stability of the two LFCs in the low cm/s range was obtained. In combination with the data from our four earlier LFC test campaigns on HARPS, the available data now cover a time span of more than six years. This is of great value for judging the long-term stability of an LFC-calibrated spectrograph, the importance of

understanding systematic errors, and the prospects of detecting long-term phenomena such as long-period exoplanets or the acceleration of cosmic objects. After our in-field tests, the LFC for FOCES was transported back to Germany, while the LFC for HARPS remained on the site in preparation for its service as a routine calibration device.

CARMENES: the VIS channel spectrograph

Walter Seifert, Landessternwarte Heidelberg (Germany); Wenli Xu, Wenli Xu Optical System Engineering (Germany); Gerardo Veredas, Otmar Stahl, Landessternwarte Heidelberg (Germany); Hans-Juergen Hagen, Hamburger Sternwarte (Germany); Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain); Stefan Dreizler, Georg-August-Univ. Göttingen (Germany); Carmen Feiz, Karl Wagner, Landessternwarte Heidelberg (Germany); Jens Helmling, Luis Hernandez, Ctr. Astronómico Hispano-Alemán (Spain); Simon M. Tulloch, FRACTAL S.L.N.E (Spain); Eike Guenther, Thüringer Landessternwarte Tautenburg (Germany); Andreas Quirrenbach, Holger G. Mandel, Landessternwarte Heidelberg (Germany)

CARMENES (Calar Alto high-Resolution search for M dwarfs with Exoearths with Near-infrared and optical Echelle Spectrographs) is a high resolution spectrograph built for the 3.5m telescope at the Calar Alto Observatory (Almeria, Spain), which is operated jointly by the Max-Planck-Society (MPG) and the Spanish National Research Council (CSIC). CARMENES consists of two separated highly stabilized spectrographs covering both the visible (0.55 to 1.0 μm) and the NIR (0.95 to 1.7 μm) wavelength ranges. A spectral resolution of R=82,000 combined with excellent long term stability provide high-accuracy radial-velocity measurements (?1 m/s).

CARMENES has been built by a consortium formed by five German institutions, five Spanish institutions and the Calar Alto Observatory itself. The instrument first light took place on November 2015 and will start operations on January 2016.

An overview of the design and expected performance of the VIS spectrograph system will be given, concentrating on the optical and mechanical design, the realization of the vacuum tank and thermal control to stabilize the spectrograph, and the exposure meter.

The integration phase at Calar Alto Observatory, giving details on the usual issues one is faced if an instrument is first time completely assembled at the observatory and the final implementation of the VIS channel is described as well as the fine tuning performed during the following test and first (technical) commissioning phase. There were - as expected - lessons to be learned.

The technical performance data, especially the achieved resolution, throughput and thermal stability and the resulting radial-velocity accuracy, as measured during the commissioning runs and the first months of science operation of the VIS channel will be shown and compared to the design values.

9908-232, Session PS4

An ultra-stable cryostat for the detectors of ESPRESSO

Jean-Louis Lizon, Olaf Iwert, Sebastian Deiries, Renate Hinterschuster, Johannes K. Dekker, European Southern Observatory (Germany); Eric Mueller, European Southern Obsevatory (Germany)

ESPRESSO The Echelle SPectrograph for Rocky Exoplanet and Stable Spectroscopic Observations, is a super-stable Optical High Resolution Spectrograph for the combined coude focus of the VLT. It can be operated by either one of the UTs or collecting the light from up to 4 UTs simultaneously. Given the wide spectral range, the optical path is split into two channels, two large 90 mm x 90 mm CCDs are used to record the full spectrum.

In order to achieve the extremely high stability, ESPRESSO has a fixed optical layout; no moving parts are foreseen inside the spectrograph to maximize the stability and repeatability of the instrument performance and to avoid any thermal load generated inside the spectrograph itself. The optical bench is placed in a vacuum vessel hosted in a three level enclosures system able to guarantee temperature stability of the order of 0.001 K and in a vacuum environment. We aim for a stability of the spectral line on the detector pixel matrix in the order of a few nanometer.

The paper gives a detailed description of the cryostat with the flexible de-coupling of the dewar between the vacuum vessel and optical bench. The design including the measures taken in order to provide an optimal thermal connection and a very accurate mechanical referencing of the large chip. We are going to describe the specific experiment which has been setup in order to verify and physically measure the real stability of the detector “pixels” relative to the rest of the world. We will also present the results obtained with the similar setup measuring the stability of the HARPS detector (the precursor of ESPRESSO) and the preliminary results of the stability of the final ESPRESSO detector system.

9908-233, Session PS4

The Leiden EXoplanet Instrument (LEXI): a high-contrast high-dispersion spectrograph

Sebastiaan Haffert, Christoph U. Keller, Ignas A. G. Snellen, Leiden Univ. (Netherlands)

The Leiden Exoplanet Instrument (LEXI) will be a new visitor instrument for the William Herschel Telescope. It will be the first instrument specifically designed for high contrast high dispersion spectroscopy at optical wavelengths. The combination of high contrast imaging (HCI) techniques together with the high dispersion spectroscopy (HDS) will be able to reach optical contrast levels of ~10-7. This enables us to characterize young hot gas giants, and uniquely map velocity fields of proto-planetary dust around young stars. LEXI will be a bench-mounted, high dispersion integral field spectrograph that will record spectra on a small area around the star with high spatial resolution and high dynamic range. A prototype is being setup to test the combination of HCI+HDS and its first light is expected in 2016.

9908-234, Session PS4

A calibration unit for the near-infrared spectropolarimeter SPIRou

Isabelle Boisse, Lab. d’Astrophysique de Marseille (France); Sandrine Perruchot, Observatoire de Haute-Provence (France); François Bouchy, Lab. d’Astrophysique de Marseille (France); François Dolon, François Moreau, Rico Sottile, Observatoire de Haute-Provence (France); François Wildi, Observatoire de Genève (Switzerland)

SPIRou is a near-infrared spectropolarimeter and high precision radial velocity instrument, to be offered to the CFHT community from 2018. It focuses on two main scientific objectives: (i) the search for Earth-like planets around M dwarfs (especially in their habitable zone) and (ii) the study of stellar and planetary formation in the presence of stellar magnetic field. ?Essential to the short- and long-term precision (1 m/s) are the

calibration and super-stable radial-velocity reference module, fiber linked to the spectrograph.

In this paper, we highlight the main differences in the calibration techniques referring to HARPS@ESO or SOPHIE@OHP: calibration lamps and optics adapted to the Spirou domain (domain 0.98µm-2.35µm), data reduction adapted to the use of a CMOS detector, calibration following star path after telescope and direct to the spectrograph, control of the thermal background contribution.

We also describe the calibration unit architecture, its design and production, including the fluoride fiber links, the Fabry-Perot radial velocity reference unit and the cold source module needed for simultaneous calibration because of K-Band contamination.

9908-235, Session PS4

TARdYS: a high-resolution near-infrared spectrograph for TAO

Leonardo Vanzi, Pontificia Univ. Católica de Chile (Chile); Kentaro Motohara, Yuzuru Yoshii, The Univ. of Tokyo (Japan); Christian Schwab, Macquarie Univ. (Australia); Surangkhana Rukdee, Abner Zapata, Mauricio Flores, Mathias Jones, Pontificia Univ. Católica de Chile (Chile); Marcelo Said Tala Pinto, Zentrum für Astronomie der Univ. Heidelberg (Germany)

TARdYS - the Tao-Aiuc-high-Resolution-Yband Spectrograph - is an instrument concept developed by the Center of Astro Engineering UC and the University of Tokyo for the Tokyo Atacama Observatory - TAO. The observatory will host a 6.5 m IR telescope installed at the summit of Cerro Chanjnantor at an altitude of 5640 m in northern Chile. The instrument being developed and presented here aims at precise RV measurement of M type stars and to give access to a number of additional science cases for the study and monitoring of cool stars. The optical design of the spectrograph is based on a classic white pupil configuration and an R6 echelle grating, which allows to reach relatively high spectral resolution (R > 50,000) with a compact setup. Fibre feeding, simultaneous wavelength calibration and thermal control will guarantee high stability. We present the opto-mechanical design and preliminary results.

9908-236, Session PS4

Advances on FIDEOS the high-resolution spectrograph for the ESO 1m telescope at La Silla

Leonardo Vanzi, Pontificia Univ. Católica de Chile (Chile); Marcelo Said Tala Pinto, Ruprecht-Karls-Univ. Heidelberg (Germany); Matias Jones, Samuel Ropert, Abner Zapata, Mauricio Flores, Holger Drass, Rafael Brahm, Nestor Espinoza, Pontificia Univ. Católica de Chile (Chile)

We present the last advances in the FIDEOS project. FIDEOS is the high resolution spectrograph developed at the Center of Astro Engineering UC for the ESO 1m telescope of La Silla. The spectrograph is based on a classic echelle optical configuration and covers the optical spectral range from 400 to 700 nm with a spectral resolution of about 42,000. Light is fed into the instrument with an optical fibre to guarantee optimal stability. Simultaneous wavelength calibration with a ThAr lamp and thermal control also contribute to make this instrument ideal for precise RV measurement of bright stars.

9908-237, Session PS4

CARMENES: interlocks or the importance of process visualization and system diagnostics in complex astronomical instruments

Jens Helmling, Ctr. Astronómico Hispano-Alemán (Spain); Karl Wagner, Zentrum für Astronomie der Univ. Heidelberg (Germany); Luis Hernandez, Francisco Hernandez, Juan Francisco Lopez, Ctr. Astronómico Hispano-Alemán (Spain); Hector Magan, Instituto de Astrofísica de Andalucía (Spain); Julio Marin, Jose Ignacio Vico, Ctr. Astronómico Hispano-Alemán (Spain); Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain); Jose Antonio Caballero Hernandez, Consejo Superior de Investigaciones Científicas (Spain); Walter Seifert, Andreas Quirrenbach, Zentrum für Astronomie der Univ. Heidelberg (Germany); Pedro J. Amado González, Instituto de Astrofísica de Andalucía (Spain); Ignasi Ribas, Institut de Ciències de l'Espai (Spain) and Institut d'Estudis Espacials de Catalunya (Spain); Ansgar Reiners, Georg-August-Univ. Göttingen (Germany); Daniel Benitez, Ctr. Astronómico Hispano-Alemán (Spain)

With the steadily increasing complexity of scientific instruments, there is an ever-growing demand for improved control electronics. This is especially important in infrared instruments, where the low pressure and challenging cryogenic systems increase the requirements of the overall control system.

CARMENES (Calar Alto high Resolution search for M dwarfs with Exo-earths with a visible and Near-infrared Echelle Spectrograph) is a combination of two spectrographs, one equipped with a CCD for the range 0.55 – 0.95?m, and one with HgCdTe detectors for the range 0.95 –1.7?m. Both spectrographs are coupled to the Calar Alto 3.5 m telescope with optical fibers.

Guiding is performed with a separate camera. Additional fibers are available for simultaneous injection of light from emission line lamps for RV calibration, or, alternatively, from the sky.

The two spectrographs are mounted on benches inside vacuum tanks, which are located in climate controlled chambers inside the air-conditioned coudè laboratory of the 3.5 m dome. Each detector is mounted in a small temperature stabilization system, a Continuous Flow Cryostat which is adapted to the vacuum tank.

That means the control electronics must monitor and adjust many different subsystems in different physical places, mounted at the telescope or placed inside the telescope building, these include:

- The "frontend" mounted at the cassegrain focus of the telescope including the autoguider and the exposuremeter

- The calibration units with the different calibration sources placed in a separate room

- The VIS vacuum tank including the optical bench and the Continuous Flow Cryostat placed inside the temperature chamber build in the coudé room area

- The NIR vacuum tank including the optical bench and the Continuous Flow Cryostat placed inside the temperature chamber build in the coudé room area

- The instrument control electronics and the different pre-vacuum and turbo-molecular pumps in the area between the temperature chambers inside the coudé laboratory

Measurement and control of different physical values like vacuum pressure, temperature, oxygen content, the quality of vacuum, flowrate of cooling

water or voltage and current have to be monitored and controlled by an overall system.

Processes within the vacuum tanks, like evacuation, cooling, warming or flooding with nitrogen gas have to be protected from operator error.

For safety reasons it is essential to have an intelligent Interlock system which will inform the operator in case of malfunction in any part in the instrument. Warnings and Alarms are generated and can even react in autonomous mode starting vacuum pumps and opening or closing valves automatically.

In addition to monitoring safety issues, the process visualization and powerful diagnostic of the Interlock system is able to make all necessary information available in a clear graphical way. This is especially important for the Assembly, Integration and Verification (AIV) phase and to understand the interaction of all sub-systems and see the healthiness and the history of the whole technical instrument processes.

To implement these different demands a comprehensive Interlock system with process visualisation and powerful diagnostics has been developed at the Calar Alto Observatory and the Zentrum für Astronomie Heidelberg (LSW).

9908-238, Session PS4

GIANO and HARPS-N together: towards an Earth-mass detection instrument

Andrea Tozzi, Ernesto Oliva, Marcella Iuzzolino, Luca Fini, Alfio T. Puglisi, Mauro Sozzi, Gilberto Falcini, Luca Carbonaro, INAF - Osservatorio Astrofisico di Arcetri (Italy); Adriano Ghedina, Fundación Galileo Galilei - INAF (Spain); Riccardo U. Claudi, INAF - Osservatorio Astronomico di Padova (Italy)

This article describes the works we are doing for modifying the interface between the high resolution infrared spectrograph GIANO (0.97-2.4 micron) and the TNG telescope, passing from a fiber feed configuration to the original design of a direct light-feeding from the telescope to the spectrograph. So doing the IR spectrograph, GIANO, will work in parallel to HARPS-N spectrometer (0.38-0.70 micron), the visible high resolution spectrograph, thanks to a new telescope interface based on a dichroic window that simultaneously feeds the two instrumentes: this is GIARPS (GIAno & haRPS).

The scientific aims of this project are to improve the radial velocity accuracy achievable with GIANO, down to a goal of 1 m/s, the value necessary to detect Earth-mass planets on habitable orbits around late-M stars, to implement simultaneous observations with Harps-N and GIANO optimizing the study of planets around cool stars. The very broad wavelengths range is particularly important to discriminate false radial velocity signals caused by stellar activity. We therefore include several absorption cells with different mixtures of gases and a stabilized Fabry Perot cavity, necessary to have absorption lines over the 0.97–2.4 microns range covered by GIANO.

9908-240, Session PS4

Development of illumination optics in optical scheme of high-resolution fiber-fed echelle-spectrograph for the Big Telescope Alt-azimuth (BTA)

Dmitrii Kukushkin, Dmitrii Sazonenko, Alexey V. Bakholdin, ITMO Univ. (Russian Federation); Gennady G. Valyavin, Special Astrophysical Observatory (Russian Federation)

The report describes the development and optimization of optical scheme of the illumination optics of the entrance slit for the high-resolution fiber-fed echelle-spectrograph. The optical system of the illuminator provides the necessary agreement of the numerical apertures of the fiber and spectrograph, as well as it allows to install the necessary equipment to obtain the required structure of the image.

The entrance slit of the spectrograph is illuminated by a lens illumination system, which forms the image of the output ends of the two optical fibers on the slit of the spectrograph. The operating wavelength region spans from 400 to 750 nm. Since the light beam from the output ends of the optical fibers goes under a certain angle and has a numerical aperture NA=0,22 (F/2.217), it is necessary to convert this beam to the input numerical aperture of the spectrograph NA=0,043 (F/11.6). According to the tasks of the spectrograph in the illuminator we are planning to install a slicer to divide the intermediate image of the fiber cores at the two images forming the output uniformly illuminated rectangular slit. To install the slicer the optical system was designed, with the intermediate image plane (F/30) for placement the slicer in it. The slicer divides each image of output end of the fiber (the core of the fiber) on two parts, arranged one above the other. The structure of the image is the following: all four parts are located one above the other – the two parts form a channel of one optical fiber, two other parts form the other channel, the parts, separated by a dark interval, inside each of the channels should be arranged without considerable gap. Thus, there are the four images at the exit of the illuminator. These images form the entrance slit of the spectrograph. As a result of the designing a five-component, seven-lens illumination system was obtained. The analysis of this optical illumination scheme of the illuminator has shown its efficiency within the entire system of the spectrograph. The main disadvantage of this system is the large number of lenses, affecting the light transmission of the system.

Also we considered the optical system of the illuminator without the slicer. Due to the fact that the slicer is not used in this optical scheme, the system does not require the plane of the intermediate image. This feature has helped to simplify the whole scheme. The obtained system consists of two components and outputs the image of the two cores of optical fibers by performing the necessary conversion of numerical apertures. Because there are fewer lenses in this system, the system has a significantly better transmission in a defined spectral range and lower cost. This illumination system is more technological and simpler to manufacture. However, due to the lack of slicer and the round shape of the image given by the illuminator, the spectral resolution of the spectrograph is lowered.

This research provides a good instrument for performing modern researches for the astronomy.

9908-241, Session PS4

Achieving the resolution of the spectrograph of the 6m Large Azimuthal Telescope

Dmitrii Sazonenko, Dmitrii Kukushkin, Alexey V. Bakholdin, ITMO Univ. (Russian Federation); Gennady G. Valyavin, Special Astrophysical Observatory (Russian Federation)

The basis of any spectral device is the spectral element which disperses the light by wavelength. The spectral resolution requirements for instruments, used for space application, are growing from year to year. Nowadays, the spectral resolution that can give one dispersing element is insufficient. For this reason, modern astronomical spectral instruments use more than one dispersive element. This allows achieving a high spectral resolution with the best distribution of energy over the spectrum.

In the Special Astrophysical Observatory of Russian Academy of Sciences (SAO RAS) creates a spectrograph with a high spectral resolution for 6-meter telescope. The spectrograph consists of a mobile part, located at the focus of the main mirror of the telescope, the stationary part located

under the telescope, and optical fibers, which transmits light from the mobile part to the stationary part. The mobile part provides various operating modes of the spectrograph. The stationary part converts the light to the spectrum for further analysis. The spectral resolution of the stationary part should be R=100000. To achieve such value, the scheme has two spectral elements, with cross-dispersion. The main spectral element is an echelle-grating. This element works in spectral orders from 68 to 127 . The second spectral element is a prism with a diffraction grating on one face. Such an element is called grism. The dispersion of the prism is perpendicular to the dispersion of the echelle-grating. The result is a structure of lines from different spectral orders. Orders are arranged so that the last wavelength of the one order is the first wavelength of the next order. Obtaining such an image on a CCD detector is 4000 by 4000 pixels, with a pixel size of 15 ?m, allows to achieve a spectral resolution of R=100000.

Optical scheme of the spectrograph was designed for operating with the standard echelle-grating. The main task was to design the grism that is to choose the parameters of the grism: optical material, the grism vertex angle, grating frequency. The grism material affects the uniformity of the spectral orders distribution at the detector. It is also an important parameter is the transmittance of the glass over the spectral range of 400-750 nm. Many glasses from different manufacturers were analyzed to choose the optimal variant. The grizm's vertex angle and grating's frequency determine deviation and beam width after the grism. After analyzing all parameters, the optimal grism configuration was found.

An important parameter to achieve the spectral resolution is the size of the slit. The spectral resolution is determined by the width of the slit's image at a certain wavelength. Than the size smaller, the higher resolution can be achieved. To achieve a spectral resolution of 100000, the width of the slit's image at one wavelength should not exceed 2 pixels, i.e. 30 ?m. In this case, the entrance slit width must not exceed 186 ?m. As the entrance slit for the spectrograph is planned to use the actual image of the ends of optical fibers.

9908-242, Session PS4

HARPS3 for a roboticized Isaac Newton telescope

Samantha J. Thompson, Univ. of Cambridge (United Kingdom); Samuel Santana Tschudi, Instituto de Astrofísica de Canarias (Spain); Eugene Seneta, Univ. of Cambridge (United Kingdom); David Sing, Martyn Brake, Univ. of Exeter (United Kingdom); Jan Kragt, ASTRON (Netherlands); Francesco Pepe, Observatoire de Genève (Switzerland); Nikolai A. Piskunov, Uppsala Univ. (Sweden); Julien F. P. Spronck, Leiden Univ. (Netherlands); Michel Fleury, Observatoire de Genève (Switzerland); Frans Snik, Leiden Univ. (Netherlands) and ASTRON (Netherlands); Didier Queloz, Univ. of Cambridge (United Kingdom) and Observatoire de Genève (Switzerland); Richard Hall, Martin Fisher, Univ. of Cambridge (United Kingdom); Tim Naylor, Univ. of Exeter (United Kingdom); Damien Ségransan, Observatoire de Genève (Switzerland); Xiaowei Sun, Univ. of Cambridge (United Kingdom); Ramón Navarro, ASTRON (Netherlands); Rafael Rebolo-López, Jonai I. González Hernández, Instituto de Astrofísica de Canarias (Spain); Ignas A. G. Snellen, Leiden Univ. (Netherlands); Rik ter Horst, ASTRON (Netherlands); Isabelle Baraffe, Univ. of Exeter (United Kingdom); John S. Young, Univ. of Cambridge (United Kingdom)

We present a description of a new instrument development, HARPS3, planned to be installed on an upgraded and roboticized Isaac Newton Telescope by end-2018. HARPS3 will be a high resolution (R ~ 115,000) echelle spectrograph with a wavelength range from 380-690nm. It is being built as part of the Terra Hunting Experiment – a future planned 10 year radial velocity measurement programme to discover Earth-like exoplanets. The instrument design is based on the successful HARPS spectrograph on the 3.6m ESO telescope and HARPS-N on the TNG telescope. The main changes to the design in HARPS3 will be: a customised fibre adapter at the Cassegrain focus providing a stabilised beam feed and on-sky fibre diameter ~ 1.4 arcsec, the implementation of a new continuous flow cryostat to keep the CCD temperature very stable, characterisation of the HARPS3 CCD to map the effective pixel positions and thus provide an improved accuracy wavelength solution, an optimised integrated polarimeter and the instrument integrated into a robotic operation. The robotic operation will optimise our programme which requires our target stars to be measured on a daily basis. We present an overview of the entire project, including a description of our anticipated robotic operation.

9908-243, Session PS4

CARMENES: NIR channel spectrograph, optical, and opto-mechanical as-built design II

María Concepción Cárdenas Vázquez, Santiago Becerril Jarque, Instituto de Astrofísica de Andalucía (Spain); Ernesto Sánchez-Blanco, Instituto de Astrofísica de Andalucía (Spain) and Optical Development (Spain); Pedro J. Amado González, Irene M. Ferro Rodríguez, David Pérez-Medialdea, Instituto de Astrofísica de Andalucía (Spain)

CARMENES is a next-generation radial-velocity instrument. It is the new high resolution high stability spectrograph built for the 3.5m telescope at the Calar Alto Observatory (CAHA, Almería, Spain) by a consortium formed by German and Spanish institutions. This spectrograph is composed by two separated echelle spectrographs, VIS channel (550-1050 nm) and NIR channel (950-1700 nm) at a spectral resolution of R = 82,000. Each channel is fed by two optical fibers from the Cassegrain focus of the telescope, one for the target, and the other for calibration light. Fibers with octagonal cross-section are employed to ensure good stability of the output.

The CARMENES instrument passed its Final Design Review (FDR) in February 2013. The NIR channel has been manufactured, assembled, integrated and verified (MAIV) in the last two years. It was delivered to the observatory in fall 2015, and the commissioning phase on-sky has been accomplished in December 2015. The expected performances comply with the scientific requirements and its science verification started.

This paper covers the NIR channel final as-built optical and opto-mechanical design; from the FDR until make the different subsystems feasible, real and meeting the tolerances. We talk about the different subsystems, the Fiber Exit Unit (which feeds the spectrograph, including the Imager Slicer), the off-axis collimator (used in three bounces), the high dispersion echelle, the cross disperser grism and the 5 lenses camera. The detector is a mosaic of two 2k?2k HAWAII-2RG, giving 4096?2048 pixels with a 2.5 μm cut-off. The optics includes a special cut-off filter for wavelength from 1.7 to 2.5 μm in order to reduce the thermal contribution of that wavelengths range to be within requirements.

The optical design has been optimized for the operation temperature (140 K) but the mechanical design, manufacturing and assembly have been done at room temperature (300 K). The mounts of the optical elements have been designed to ensure survival when temperature changes between 300K and 140K and also to position the elements at the right distances at operation temperature.

The spectrograph is mounted on an optical bench which is housed in

a vacuum tank located in the Coudé laboratory of the 3.5m dome. The instrument works at about 140 K, except for the detector, that works at 82 K. The tank is equipped with a temperature stabilization system capable of keeping the temperature constant to within ± 0.01ºC over 24 hours. The temperature-stabilized environment is necessary to enable a 1 m/s radial velocity precision employing a simultaneous calibration with an emission-line lamp or with a Fabry-Perot etalon.

The MAIV of the channel has been schedule driven since we had with a fixed project deadline. The process of manufacturing and final definition for most of the subsystems have taken place at the same time, and simultaneously with other subsystems being integrated and verified at laboratory, along the complete crazy AIV phase.

9908-244, Session PS4

CARMENES: NIR channel spectrograph, optical AIV plan overview

María Concepción Cárdenas Vázquez, Irene M. Ferro Rodríguez, David Pérez-Medialdea, Instituto de Astrofísica de Andalucía (Spain); Ernesto Sánchez-Blanco, Instituto de Astrofísica de Andalucía (Spain) and Optical Development (Spain); Santiago Becerril Jarque, Instituto de Astrofísica de Andalucía (Spain)

CARMENES is a next-generation radial-velocity instrument. It is the new high resolution high stability spectrograph built for the 3.5m telescope at the Calar Alto Observatory (CAHA, Almería, Spain). This spectrograph is composed by two separated echelle spectrographs, VIS channel (550-1050 nm) and NIR channel (950-1700 nm) at a spectral resolution of R = 82,000. Each channel is fed by two optical fibers from the Cassegrain focus of the telescope, one for the target, and the other for calibration light.

The CARMENES instrument passed its Final Design Review (FDR) in February 2013. The NIR channel has been manufactured, assembled, integrated and verified (MAIV) in the last two years. It was delivered to the observatory in fall 2015, and the commissioning phase on-sky has been accomplished in December 2015. The expected performances comply with the scientific requirements and its science verification started.

The MAIV of the channel has been schedule driven since we had with a fixed project deadline. The process of manufacturing and final definition for most of the subsystems have taken place at the same time, and simultaneously with other subsystems being integrated and verified at laboratory, along the complete crazy AIV phase.

This paper goes through the AIV process and the final laboratory tests.

Concerning the AIV process, we describe how the subsystems have been verified individually before their integration in the spectrograph. When the subsystem is composed by more than one optical element, such as the Fiber Exit Unit (FEU, which feeds the spectrograph, including the Imager Slicer), then the subsystem was aligned at warm and verified at cold as a unit in a testing cryostat, before its integration in the complete instrument. How the system has been aligned at room temperature (300K), taking the off-axis collimator mirror (used in three bounces) of the instrument at the starting point of reference for the complete opto-mechanical alignment. Then we go through the optical path, with the folding mirror alignment, the camera barrel integration and alignment, the echelle grating integration and alignment and the cross disperser grims integration. We also describe how the Exposure Meter, which is feed by the cero order of the echelle, was aligned. Once the optical bench was completely populated and aligned at warm, we applied the calculated off-sets to some elements (FEU, Folding Mirror, EM-FiberExitUnit) in order to have the system aligned at the operation temperature of 140K. Finally we describe the laboratory tests performed along several cryogenic cycles of the complete instrument in order to final adjust and align the complete spectrograph to be within requirements.

We describe how these activities were carried out in order to have the cryogenic channel fully operational and complying with the scientific requirements at the required date. Every subsystem had been in the "critical path" at least one. We had to take some critical and risky technical decisions in order to be on time.

The laboratory final test confirmed the expected NIR channel spectrograph performances, complying with the scientific requirements.

9908-245, Session PS4

CARMENES: NIR channel spectrograph instrument requirements versus performance at telescope

Irene M. Ferro Rodriguez, María Concepción Cárdenas Vazquez, David Perez Medialdea, Instituto de Astrofísica de Andalucía (Spain); Ernesto Sánchez-Blanco, Optical Development (Spain); Alejandro Ramón Ballesta, Pedro J. Amado González, Instituto de Astrofísica de Andalucía (Spain)

CARMENES (Calar Alto high-Resolution search for M dwarfs with Exoearths with Near-infrared and optical Échelle Spectrographs) is the new high resolution high stability spectrograph built for the 3.5m telescope at the Calar Alto Observatory (CAHA, Almería, Spain) by a consortium formed by German and Spanish institutions and the CAHA observatory itself. This spectrograph is composed by two separated spectrographs, VIS channel (550-1050 nm) and NIR channel (900-1700 nm). The NIR channel has been manufactured, assembled, integrated and verified in the last two years. Operation starts by January 2016.

The NIR channel main difficult lays in the thermo-stabilization of the instrument at cryo-vacuum conditions. An innovative cooling system keeps the spectrograph within the required operation temperature (138.36 K). Therefore, a set of specifications at both system and subsystem levels are stablished. Furthermore, there is an added difficulty: accomplish all requirements in a very short time for this complex instrument (two years for manufacture, integration, acceptance tests and fulfil all requirements).

A complete optical design is optimized not only for room temperature, but also for operation temperature. With this model, the evolution of the optical alignment can be tested in three points during the assembly, verification and integration stage (WARM, WARM-AIV and COLD). In WARM stage, the system is at room temperature. WARM-AIV is the phase where several offsets should be applied at subsystem level in order to correct the aluminium shrinks during cooling down. Finally, the optical model can describe the alignment of the system at operation temperature. On the other hand, the mechanical design, manufacturing and assembly present a temperature of reference for all the dimensions and tolerances of 293 K (20ºC). Mounts, supports and holders of optical elements have been designed to ensure survival when the spectrograph shifts from reference temperature toward NIR channel operation temperature. Note that the detector works at 85K.

This paper shows a comparison between scientific requirements, as-built model of the whole instrument and final performances at telescope. Although, the instrument was delivered to the observatory in fall 2015, and commissioned in December 2015.

The final test on the telescope confirms that the expected NIR channel performances comply with the scientific requirements, and also some improvements are achieved.

9908-246, Session PS4

On-sky Doppler performance of TOU optical very high-resolution spectrograph for detecting low-mass planets

Jian Ge, Bo Ma, Scott Powell, Frank Varosi, Michael

A. Singer, Univ. of Florida (United States); Michael H. Williamson, Matthew W. Muterspaugh, Tennessee State Univ. (United States); Bo Zhao, Sidney L. Schofield, Jian Liu, Sirinrat Sithajan, Nolan S. S. Grieves, Anthony Cassette, Univ. of Florida (United States)

The TOU robotic, compact very high resolution optical spectrograph (R=100,000, 0.38-0.9 microns) has been fully characterized at the 2 meter Automatic Spectroscopy Telescope (AST) at Fairborn Observatory in Arizona during its pilot survey of 25 bright FGKM dwarfs in 2014-2015. This instrument has delivered sub m/s Doppler precision for bright reference stars with 5-30 min exposures and 0.7 m/s long-term instrument stability, which is the best performance among all of the known Doppler spectrographs to our knowledge. This performance was achieved by maintaining the instrument in a very high vacuum of 1 micron torr and about 0.5 mK (RMS) long-term temperature stability through an innovative close-loop instrument bench temperature control. It has discovered a 21 Earth-mass planet (P=42days) around a bright K dwarf and confirmed three super-Earth planetary systems, HD 1461, 190360 and HD 219314. This instrument will be used to conduct the Dharma Planet Survey (DPS) in 2016-2018 to monitor ~100 nearby very bright FGKM dwarfs (most of them brighter than V=8) at the dedicated 50-inch Robotic Telescope on Mt. Lemmon. With very high RV precision and high cadence (~100 observations per target randomly spread over 450 days), a large number of rocky planets, including possible habitable ones, are expected to be detected. The survey also provides the largest single homogenous high precision RV sample of nearby stars for studying low mass planet populations and constraining various planet formation models. Instrument performance and science results will be presented.

9908-247, Session PS4

Optical design of the NASA-NSF extreme precision Doppler spectrograph concept "wisdom"

Stuart I. Barnes, Stuart Barnes Optical Design (Germany); Gábor Furész, Robert A. Simcoe, MIT Kavli Institute for Astrophysics and Space Research (United States); Stephen A. Shectman, Carnegie Observatories (United States); Deborah F. Woods, MIT Lincoln Lab. (United States)

The WISDOM instrument is being developed as part of a NASA-NSF funded study to equip the 3.5m WIYN telescope with an extremely precise radial velocity spectrometer. A general overview of the instrument is presented elsewhere in these proceedings. WISDOM is fed from the telescope using a combination of octagonal and rectangular core fibres, together with an optical double scrambler. The fibre feed includes an ADC and tip-tilt mirror for maximising throughput, as well as a novel pupil slicer. Detailed descriptions of these aspects of the instrument are also presented elsewhere in these proceedings. This paper will concentrate on the spectrograph optical design.

The WISDOM spectrograph is split into "short" (380 to 750nm) and "long" (750 to 1300nm) wavelength channels. Both channels use an asymmetric white pupil optical design, where the echelle gratings and beam sizes are R3.75/125mm and R6/80mm in the short and long channels respectively. Together with the pupil slicer, and octagonal to rectangular fibre coupling, this permits resolving powers over R=110,000 with a 1.2" fibre on the sky. The focal length of the main collimator OAP is 1000mm and the transfer collimator is exactly half this focal length. This greatly reduces the size of the "white pupil" ahead of the cross-dispersers and cameras thereby ensuring a very compact instrument. A dichroic is placed in this collimated beam to split the wavelength coverage again in each channel. The white pupil relay includes a Mangin mirror very close to the intermediate focus which is used to correct the white pupil relay Petzval curvature before it is swept into a cylinder by the cross-dispersers. This mirror, which is a simple off-axis section of a concave/convex singlet lens, is carefully designed in order avoid any potential ghosts. This design decision allows each of the dioptric cameras to be fully optimised and tested independently of the rest of the spectrograph. In each of the final four channels slightly anamorphic VPH grisms are used for cross-dispersion. The orientation and dispersive properties of these gratings have been tuned in order to permit a symmetrical short/long design, to allow the camera optical axes to be exactly parallel to the M1 collimator optical axis, to avoid VPH recombination ghosts, and also to ensure that the quasi-Littrow slit tilt can be removed by rotating the slit. This arrangement also allows the four channel instrument to fit inside a single vacuum tank approximately 850mm in diameter and around 1.8m in length. The spectral footprints cover 4k x 4k and 6k x 6k CCDs with 15um pixels in the short "blue" and "green" wavelength channels respectively. All-spherical dioptric cameras with 425mm focal lengths give 3.5 pixel sampling of a 120k resolution element. A 4k x 4k CCD with 15um pixels is used in the long "red" channel, with a HgCdTe 1.7um cutoff 4k x 4k detector with 10um pixels is to be used in the long "NIR" channel. Again, in each case the focal lengths (258 and 172mm) of the dioptric cameras ensure 3.5 pixel sampling of the same 120k resolution element. The baseline design for the cameras ensures that the highest possible (near diffraction limited) image quality is achieved across all wavelengths, while also ensuring insensitivity of spot centroids to any variation in the pupil illumination. Fully ray-traced simulations of the spectral formats are used to demonstrate the optical performance, as well as to provide pre- first-light spectra that can be used for optimisation of the data reduction.

9908-248, Session PS4

Performance and future developments of the RHEA single-mode spectrograph

Tobias Feger, Macquarie Univ. (Australia); Joao Bento, Michael J. Ireland, Adam D. Rains, The Australian National Univ. (Australia); Alexander Arriola Martiarena, Christian Schwab, David W. Coutts, Macquarie Univ. (Australia)

The Replicable High-resolution Exoplanet and Asteroseismology (RHEA) spectrograph is being developed to serve as a basis for multiple copies across a network of small robotic telescopes. The spectrograph operates at the diffraction-limit by using a single-mode fiber input, resulting in a compact and modal-noise-free unit. The optical design is mainly based on off-the-shelf available components and comprises a near-Littrow configuration with prism cross-disperser. The echelle format covers a wavelength range of 430-650 nm at R~75,000 spectral resolution. In this paper we briefly summarize the current status of the instrument and present preliminary results from the first on-sky demonstration of the prototype using a fully automated 0.4 m telescope, where we observe stable and semi-variable stars up to V=3.5 magnitude. Future steps to enhance the efficiency and passive stability of RHEA are discussed in detail. For example, we show the concept of using a multi-fiber injection unit (e.g. Photonic Lantern) which not only enables increased throughput but also offers simultaneous wavelength calibration. To further improve the intrinsic precision we outline a cost-effective way of housing the complete instrument in a vacuum chamber. This will eliminate residual low amplitude temperature and pressure oscillations over long time scales, necessary to perform long-baseline precision RV observations.

9908-249, Session PS4

A new fiber link for the HERMES spectrograph: throughput, scrambling, and modal noise issues

Gert Raskin, KU Leuven (Belgium); Gerardo Ávila, European Southern Observatory (Germany); Hans Van Winckel, KU Leuven (Belgium)

HERMES, a fiber-fed high-resolution spectrograph, is the workhorse instrument of the Mercator Telescope at the Roque De Los Muchachos Observatory on La Palma (Spain). It is in operation since 2009 and producing very satisfying results. To further improve the spectrograph performance, we are now planning to upgrade the fiber link. This upgrade targets several goals: improved scrambling through the use of an octagonal fiber, reduction of fiber modal noise to enable very high signal-to-noise spectroscopy, increasing the fiber link throughput, and finally, the addition of a simultaneous wavelength reference spectrum to the high-resolution mode of the spectrograph in order to achieve an increased radial velocity accuracy. The high-resolution mode of HERMES makes use of a double-image image slicer, leading to a wide cross-order profile. As a consequence, the inter-order space that is available for interlacing a reference spectrum with the spectrum of the science target, is extremely limited. For this reason, we have to limit the diameter of the wavelength reference fiber to only 25 micron. Such a narrow fiber introduces the same type of modal noise problems in the optical domain as faced by the new generation of radial velocity spectrographs operating in the near-infrared spectral range. In this contribution we discuss the design of the new fiber link, paying special attention to the issue of modal noise mitigation. We also present the results of laboratory measurements of focal-ratio-degradation and scrambling performance of the new 72-micron octagonal science fiber, and compare this with the performance of the original 80-micron circular fiber.

9908-251, Session PS4

NEWS: the near-infrared Echelle for wideband spectroscopy

Mark Veyette, Philip S. Muirhead, Zachary Hall, Brian Taylor, Boston Univ. (United States); Jimmy Ye, College of the Holy Cross (United States)

We present an updated optical and mechanical design of NEWS: the Near-infrared Echelle for Wide-band Spectroscopy (formerly called HiJaK: the High-resolution J, H and K spectrometer), a compact, high-resolution, near-infrared spectrometer for 5-meter class telescopes. NEWS achieves a resolution of 60,000 over 0.8-2.5 microns via a high blaze angle, R6 echelle grating with coarsely spaced rulings. The coarse ruling reduces the free spectral range of the orders, allowing them to be well sampled by a detector with only 2048 pixels in the dispersion direction. With a 0.5 arcsecond by 5 arcsecond slit, the full 0.8-2.5 micron range can be acquired in 5 modes via a filter wheel to select different orders of the cross-dispersing grating.

A single parabolic mirror, used off-axis, collimates the 4 cm beam onto both the echelle and cross-dispersing gratings. The echelle is tilted 1.5 degrees out-of-plane to separate the dispersed beam from the incoming beam at the intermediate image plane. To reduce aberrations introduced by dispersing onto the collimator, NEWS employs a Mangin fold mirror consisting of a CaF2 lens with a reflective coating on one surface. The fold mirror redirects the beam to the opposite side of the parabolic mirror for collimation onto the cross-disperser. An 8-element, all-spherical camera images the spectrum onto a 2048x2048 pixel detector and achieves RMS spot sizes smaller than the 18 micron pixel size.

NEWS has been designed to mount to the instrument cube at the Cassegrain focus of the the new 4.3-meter Discovery Channel Telescope in Happy Jack, Arizona. To meet the strict weight and size requirements for mounting to the Cassegrain, we designed NEWS to be highly space-efficient without sacrificing performance or capability. All optics mount to a honey-combed and light-weighted optical bench to be milled from a single piece of aluminium. The instrument is designed to fit within a 100x65x30 cm volume and weigh less than 200 kg.

9908-252, Session PS4

Commissioning the dual etalon Fabry-Perot modes of the Robert Stobie spectrograph on the Southern African Large Telescope

Theodore B. Williams, Encarnacion Romero Colmenero, Petri Vaisanen, South African Astronomical Observatory (South Africa); Keith R. J. Browne, Thabelo Makananise, Southern African Large Telescope (South Africa); Anthony R. Koeslag, Christian Hettlage, South African Astronomical Observatory (South Africa); Eben Wiid, Etienne Simon, Southern African Large Telescope (South Africa); Michael P. Smith, Univ. of Wisconsin-Madison (United States); Krzysztof A. R. B. Pietraszewski, IC Optical Systems Ltd. (United Kingdom)

The Robert Stobie Spectrograph (RSS) is the prime focus main workhorse instrument on the Southern African Large Telescope (SALT). It was designed to have a wide range of capabilities and observing modes, each one rapidly reconfigurable under software control: imaging, long-slit spectroscopy, multi-object spectroscopy, Fabry-Pérot imaging spectroscopy, and polarimetry in combination with any of the other modes. The SALT RSS Fabry-Pérot system provides spectroscopic imaging over the entire 8 arcminute diameter RSS science field of view, in the wavelength range 430-860 nm, with spectral resolutions ranging from 300 to10,000.

The system consists of three etalons with gap spacings of ~0.6 nm, ~2.8 nm, and ~13.6 nm, referred to as the low resolution (LR), medium resolution (MR), and high resolution (HR) etalons, respectively. The gap and parallelism of the etalons are adjusted with piezoelectric spacers, and are measured with capacitive sensors in a servo control system. The range of gap spacing of the LR etalon is sufficient to provide two spectral resolution modes, low resolution (LR) and tunable filter (TF), with spectral resolution 600 and 300, respectively. The desired interference order of the LR etalon is selected with one of 40 interference filters. In order to limit the number of order-selecting filters required, the MR and HR etalons are designed to be used in conjunction with the LR etalon in dual-etalon configuration (also including one of the interference filters).

During commissioning of the dual etalon modes, a serious reflection problem between the two etalons was discovered. Multiple reflections between the etalons introduce a series of strong ghost images, significantly degrading image quality and precluding useful observations. Flexure in the original etalon mountings made it impossible to keep the etalons aligned sufficiently well to eliminate these ghosts. The MR etalon has been successfully used in single etalon mode since 2012 (but with three adjacent interference orders transmitted), but single etalon mode is not feasible for the HR etalon with the existing filters.

An improved mounting design for the etalons that provides the necessary mechanical robustness was implemented in 2015. Temporal drifts in parallelism of each etalon also introduce misalignments, requiring an efficient way of optimizing the parallelism on a nightly basis. The new dual etalon system was commissioned in late 2015 and is now producing useful scientific observations.

In this paper, we present the details of the improved mechanical design, a new method for rapidly measuring and adjusting etalon parallelism in-situ, a way to use dual etalon measurements to determine the transmission of the individual etalons, other lessons learned from the implementation of dual etalon mode, and the first science verification results.

9908-253, Session PS4

A high-resolution spectrograph for the 72cm Waltz Telescope at Landessternwarte, Heidelberg

Marcelo Said Tala Pinto, Paul Heeren, Marcus Grill, Robert J. Harris, Zentrum für Astronomie der Univ. Heidelberg (Germany); Julian Stürmer, The Univ. of Chicago (United States); Christian Schwab, Macquarie Univ. (Australia); Thales A. Gutcke, Max-Planck-Institut für Astronomie (Germany); Sabine Reffert, Andreas Quirrenbach, Walter Seifert, Holger G. Mandel, Lutz Geuer, Ludwig Schäffner, Landessternwarte Heidelberg (Germany); Guido Thimm, Astronomisches Rechen-Institut (Germany); Ulf Seeman, Georg-August-Univ. Göttingen (Germany)

The Waltz Spectrograph is a fibre-fed bench-mounted high-resolution cross-dispersed echelle spectrograph for the 72 cm Waltz telescope at the Landessternwarte, Heidelberg. It is based on an 31.6 lines/mm 63.5° blaze angle echelle grating in white-pupil configuration, providing a spectral resolution of R ~ 66,000 covering the spectral range between 420nm-750nm in one single CCD exposure. An equilateral prism is used for cross-dispersing the echelle orders. The spectrum is focused by an F/5 apochromat objective camera with 530mm of focal length , onto a 2k x 2k array detector with 13.5 um per pixel. The spectrograph will be fed by one rectangular fibre with 25 um x 100 um size, providing a 2.6 pix spectral sampling on the detector centre. An exposure meter will be included into the spectrograph, to provide a precise photon-weighted midpoint of the exposure, to be used as the time for which the barycentric correction is computed.

An iodine cell will be used for wavelength calibration for high precision radial velocities. In addition, a ThAr lamp can be used when not working in the high precision RV regime.

The Waltz spectrograph instrument consist on three different modules: the telescope front-end, the calibration unit and the spectrograph. The telescope will be connected to the spectrograph via the front end module which allows us to feed the instrument with starlight, inject the light from the calibration unit to the spectrograph and place in and out the I2 cell on the telescope optical axis. A Bowen-Walraven image slicer will be placed at the focal plane of the telescope, to reformat the image of the star into a slit, to couple efficiently the light of the star into the rectangular fibre. The fibre will be fed with an input beam of F/5.5, to minimize focal ratio degradation.

The instrument will be used both for student education as well as for science. The main scientific project is the continuation of our Doppler survey of K-giants which had been carried out at Lick Observatory from 1999 to 2011. The giant stars are all rather bright (V < 6), so that it should be possible to achieve S/N of about 100 in half an hour integration.

Our goal is to reach a radial velocity precision of 5 m/s, providing an instrument for exoplanetary Doppler detection. We describe the design and first results of the spectrograph. Commissioning of the Waltz spectrograph is scheduled for 2016.

9908-254, Session PS4

A comprehensive radial velocity error budget for next generation Doppler spectrometers

Samuel P. Halverson, The Pennsylvania State Univ. (United States); Ryan C. Terrien, National Institute of Standards and Technology (United States); Suvrath Mahadevan, Chad F. Bender, Arpita Roy, Gudmundur K. Stefansson, Andrew J. Monson, Eric I. Levi, Frederick R. Hearty, The Pennsylvania State Univ. (United States); Cullen H. Blake, Univ. of Pennsylvania (United States); Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States); Christian Schwab, Macquarie Univ. (Australia); Lawrence W. Ramsey, Sharon X. Wang, Jason T. Wright, The Pennsylvania State Univ. (United States); Qian Gong, NASA Goddard Space Flight Ctr. (United States)

We present a comprehensive and rigorous radial velocity (RV) error budget for the next generation Extreme Precision Doppler Spectrometer (EPDS) on the 3.5-meter WIYN telescope. This RV error budget is largely based on the systems engineering approach of Podgorski et al. (2014), though includes many additional error sources for WIYN/EPDS. We consider RV error contributions from the EPDS spectrometer optomechanics, instrument environment, wavelength calibration sources, detector effects, telescope illumination, fiber injection system, data reduction pipelines, telluric contamination, and atmospheric variations. Many of these error terms are traced by the instrument calibration fiber, while others are not. We separate error sources that are 'calibratable', and combine these in quadrature with contributions from 'uncalibratable' terms assuming reasonable levels of calibration accuracy. For each term, we justify the RV magnitude with detailed physical models or reasonable estimations to derive a single expected instrumental error estimate. This comprehensive error analysis is not only essential for achieving a desired measurement precision, but also to identify the technological path towards 10 cm/s precision.

9908-255, Session PS4

Espresso APSU integration and performance verification

Manuele Moschetti, Marco Riva, Matteo Aliverti, Luca Oggioni, Marco Landoni, Giorgio Pariani, INAF - Osservatorio Astronomico di Brera (Italy); Denis Mégevand, Francesco Pepe, Observatoire de Genève (Switzerland); Matteo Genoni, INAF - Osservatorio Astronomico di Brera (Italy); Stefano Cristiani, INAF - Osservatorio Astronomico di Trieste (Italy)

ESPRESSO is a new generation spectrograph for ESO's Very Large Telescope, whose purpose is to search for rocky extrasolar planets and determine possible variability of physical constants. This paper describes the functionalities of the Anamorphic Pupil Slicer Unit (APSU), one of the most critical optomechanical system of the ESPRESSO instrument. The key component - the slicer - is used to increase the resolving power by decreasing the slit width, based on simplified optical component that introduces large anamorphism while keeping low aberrations. At the focal plane, 12 miniprisms are necessary to differently fold each field to correctly illuminate the echelle. The positioning process of these crucial devices has been defined and tested, including the glue injection control mechanism. It is described the metrology procedure adopted, starting from CMM measurements of each single component, the alignment technique and the testing activities for the whole assembly.

9908-256, Session PS4

Precision velocimetry planet hunting with PARAS: current performance and lessons to inform future extreme precision radial velocity instruments

Arpita Roy, The Pennsylvania State Univ. (United States);

Abhijit G. Chakraborty, Physical Research Lab. (India); Suvrath Mahadevan, The Pennsylvania State Univ. (United States); Vishal M. Shah, Fazalahmed M. Pathan, Priyanka Chaturvedi, Boddapati G. Anandarao, Physical Research Lab. (India)

The PRL Advanced Radial-velocity Abu-sky Search (PARAS) instrument is a fiber-fed stabilized high-resolution cross-dispersed echelle spectrograph, located on the 1.2m telescope in Mt. Abu India. Designed for exoplanet detection, PARAS is capable of single-shot spectral coverage of 3800–9500 Å, and currently achieving radial velocity (RV) precisions approaching ~1m/s over several months using simultaneous ThAr calibration. As such, it is one of the few dedicated stabilized fiber-fed spectrographs on small (1-2) telescopes that are able to fill an important niche in RV follow-up and stellar characterization. The success of ground-based RV surveys is also motivating the push into extreme precisions, with goals of ~10cm/s in the optical and <1m/s in the near-infrared. Lessons from existing instruments like PARAS are invaluable in informing hardware design, providing pipeline prototypes, and guiding scientific surveys. Here we present our current precision estimates of PARAS based on observations of bright RV standard stars, and describe the evolution of the data reduction and RV analysis pipeline as we gather longer baselines of data and instrument characterization progresses. Secondly, we discuss how our experience with PARAS is a critical component in the development of future cutting edge instruments like (1) the Habitable Zone Planet Finder (HPF), a near-infrared spectrograph optimized to look for planets around M dwarfs, scheduled to be commissioned on the Hobby Eberly Telescope in Fall 2016, and (2) the NEID optical spectrograph, designed in response to NASA's call for an extreme precision Doppler spectrometer (EPDS) for the WIYN telescope. In anticipation of instruments like TESS and GAIA, the ground-based RV support system is being reinforced. We emphasize that instruments like PARAS will play an intrinsic role in providing both complementary follow-up and battlefront experience for these next generation of precision velocimeters.

9908-257, Session PS4

CARMENES: NIR channel spectrograph, optical AIV main challenges and highlights

David Pérez-Medialdea, Instituto de Astrofísica de Andalucía (Spain)

CARMENES is the new high resolution high stability spectrograph built for the 3.5m telescope at the Calar Alto Observatory (CAHA, Almeria, Spain) by a consortium formed by German and Spanish institutions. This spectrograph is composed by two separated spectrographs, VIS channel (550-1050 nm) and NIR channel (900-1700 nm), wavelengths ranges with spectral resolution of R=82,000. The NIR channel has been manufactured, assembled, integrated and verified in the last two years. It was delivered to the observatory in fall 2015, and commissioned in December 2015. The expected performances comply with the scientific requirements and its science verification started.

In this paper is the main challenges and highlights during the optical assembly, verification and integration (AIV) stage are shown.

The main challenge at system level is the alignment of several subsystems which shift during the cooling-down towards the operation temperature (138.36 K) because the aluminum optical bench shrinks. To solve this problem there are established three reference systems. WARM, WARM-AIV and COLD. In WARM, i.e. at room temperature, all the subsystem should be well aligned. In WARM-AIV, an offset should be applied to almost all the subsystems. Those offset will correct the aluminum shrinking when the instrument is cooling-down towards the COLD stage. The well alignment depends on these values.

For a complete system test, several cryo-vacuum cycles (CVCs) are carried out. Due to timing issues, the number of cycles was reduced. This implies risky decisions like align at WARM stage, applied offsets (WARM-AIV) and check the system at COLD stage with science detector.

The subsystems which integrate the main optical layout are: Fiber Exit Unit (FEU), collimator (off-Axis parabolic mirror), Echèlle grating, folding mirror (FM), cross-disperser (CD) and camera barrel (CB). In addition, there is an extra subsystem, called Exposure Meter (EM), in charge of photon counting.

The collimator is the reference system of the opto-mechanical alignment; therefore, its positioning is quite delicate. The FEU output is the system optical object. So this is the most critical subsystem. Before FEU integration, it was tested under cryo-vacuum conditions. For that purpose, a complex set-up was created. The Echèlle grating structure determines the efficiency peak. When the spectrograph is cooling down, this structure is slightly affected shifting this efficiency peak. To correct it a fine tuning is required using image analysis.

For a fine position of the spectrum over the detector, the CB should be adjusted carefully. On the other hand the detector should reach the optimum focus in tilt and position. The checkup consists in the analysis of the full width half maximum (FWHM) of lines at flat field images in the spatial direction. The lower the FWHM, the better focus position along the complete focal plane.

EM measures the flux coming from the science light. The main challenge of the EM AIV was the optical alignment. The need for large offsets to compensate the aluminum shrink adds a new complexity for the alignment. Measuring the flux during the cooling-down gives information about how stable the alignment is.

9908-258, Session PS4

EXPRES: a next generation RV spectrograph in the search for earth-like worlds

Colby A. Jurgenson, Debra A. Fischer, Tyler M. McCracken, David G. Sawyer, Andrew E. Szymkowiak, Yale Univ. (United States); Gary P. Muller, Fernando G. Santoro, ASTRO Electro-Mechanical Engineering, LLC (United States)

The EXtreme PREcision Spectrograph (EXPRES) is an optical fiber fed echelle being designed and built at the Yale Exoplanet Laboratory to be installed on the 4.3 meter Discovery Channel Telescope operated by Lowell Observatory. The primary science driver for EXPRES is to detect Earth-like worlds around Sun-like stars. With this in mind, we are designing the spectrograph to have an instrumental precision of 0.1 m/s so that the on-sky measurement precision (that includes modeling for RV noise from the star) can reach at least 0.5 m/s. This goal places challenging requirements on every aspect of the instrument development, including optomechanical design, environmental control, image stabilization, fiber coupling, and wavelength calibration. In this paper we describe our detailed error budget, our preliminary design for the instrument, and the use of integrated structural, thermal, and optical analysis (STOP) to verify the system requirements can be met.

There are three optomechanical subsystems that make up EXPRES; the front-end module, spectrograph, and wavelength calibration unit. The three subsystems operate from 380 to 680 nm, and are connected via optical fibers. The front-end interfaces to an instrument cube at the telescope Cassegrain focus. It provides atmospheric dispersion compensation down to a Zenith angle of 65 degrees, fast tip-tilt guiding using a high-speed EMCCD camera, reimaging optics for injection into an octagonal science fiber, and interface optics to inject calibration light into the science fiber. The science fiber then transports the telescope light from the front-end module to a climate controlled room that houses the spectrograph and wavelength calibration unit. Prior to entering the spectrograph, the science fiber is sliced to achieve higher resolution and double scrambled to mitigate modal noise. The slicer converts the octagonal fiber into a 1 x

4 rectangular fiber which serves as the "entrance slit" to the spectrograph. The spectrograph is an asymmetric white-pupil design with a resolution of 150,000. The wavelength calibration unit can inject light from a laser frequency comb, Th-Ar lamp, or quartz lamp, either directly into the spectrograph, or out into the front-end for injection into the science fiber.

EXPRES is funded by the National Science Foundation Major Research Instrumentation Program.

9908-259, Session PS4

CARMENES-NIR channel spectrograph: optical and opto-mechanical as-built design I

Santiago Becerril Jarque, Instituto de Astrofísica de Andalucía - CSIC (Spain)

CARMENES is the new high-resolution high-stability spectrograph built for the 3.5m telescope at the Calar Alto Observatory (CAHA, Almería, Spain) by a consortium formed by German and Spanish institutions. This instrument is composed by two separated spectrographs: VIS channel (550-1050 nm) and NIR channel (900-1700 nm). The NIR-channel spectrograph's responsible is the Instituto de Astrofísica de Andalucía, IAA-CSIC. The channel has been manufactured, assembled, integrated and verified in the last two years. It was delivered to the observatory in fall 2015, and commissioned in December 2015. The expected performances comply with the scientific requirements and its science verification started.

This paper covers the NIR channel final as-built design of the piece of mechanics affecting the opto-mechanical and structural behavior of the optics included in the NIR-channel. This includes of course all the opto-mechanical mounts and the bench where all of them are attached to.

All the mechanics here involved has been thought to behave extremely stable. Indeed, the overall stability of the CARMENEs-NIR spectrograph is one the factor to achieve high radial-velocity accuracy, the mechanical stability being one important contribution to it. This notion of stability has driven the main design guidelines leading to low-stress components compliant with the temperature travel required to reach working conditions (138K) from ambient conditions.

Special role has played in the present design kinematic and quasi-kinematic mounts, as well as other ways to decouple effects coming from the dimensional shrinkage due to the temperature travel. Additionally, this notion to maximize mechanical stability has led us to include additional, customized ageing treatments for all the mechanical components involved.

In particular, the present work describes the final design of the following subsystems. The FEU (Fiber Exit Unit) delivers the light to the spectrograph by means of two fibers as well as accommodate the #f and implement the slicing of the beams. Next, the Collimator mirror Mount, this being the most massive element, receives the beam from the FEU and redirects to the Échelle Mount, one of the biggest component of its class worldwide, which is in charge of providing the long dispersion of the light. After that, the beam goes again to the Collimator being redirected to a narrow Folding Mirror, which, in turn, returns the beam to the Collimator (3rd pass). Finally the beam takes its collimating path to the Cross Disperser and the Camera Barrel behind, just before to come into the Detector Cryostat.

In addition, two more opto-mechanical mounts are described as they belong to the Exposure Meter, which is an additional subsystem in charge of providing the exposure mean reference according to the photon count measured. Finally, the optical bench plays a key role to not even slightly stress the opto-mechanical mounts and decouple them from any undesired effect outside.

9908-260, Session PS4

Demonstrated precision environmental control techniques: a blueprint for a broad range of precision RV instruments

Frederick R. Hearty, Suvrath Mahadevan, Eric I. Levi, Paul M. Robertson, Gudmundur Kári K. Stefánsson, Tyler B. Anderson, Chad F. Bender, The Pennsylvania State Univ. (United States); Matthew J. Nelson, Univ. of Virginia (United States); Arpita Roy, Samuel P. Halverson, Ryan C. Terrien, Lawrence W. Ramsey, The Pennsylvania State Univ. (United States)

A principal requirement for a precision Doppler instrument is thermal and opto-mechanical stability of the full optical train. It is now standard practice to fiber-feed these instruments and to enclose the optics in a vacuum chamber. While vacuum environments eliminate convection and minimize coupling to the ambient environment, thermal stability remains the primary cause of environmentally induced RV errors. Through novel enhancements of control techniques originally developed for cryogenic instruments like HPF, we have demonstrated exquisite thermal (< 1milliKelvin) and vacuum (<1.d-7 Torr) stability – essentially eliminating environmentally induced RV errors. This report describes the basic concept and implementation of this technique, and enables broad applicability to a range of precision RV instruments.

9908-261, Session PS4

The VLT/CRIRES+ calibration unit: design, integration, and test results including a novel Fabry-Perot etalon for wavelength calibration from 1-5um

Ulf Seemann, Heiko M. Anwand-Heerwart, Georg-August-Univ. Göttingen (Germany); Paul Bristow, Claudio Cumani, Reinhold J. Dorn, European Southern Observatory (Germany); Roman Follert, Thüringer Landessternwarte Tautenburg (Germany); Jason Grunhut, European Southern Observatory (Germany); Artie P. Hatzes, Thüringer Landessternwarte Tautenburg (Germany); Ulrike Heiter, Uppsala Univ. (Sweden); Derek J. Ives, Yves Jung, Hans-Ulrich Käufl, Barbara Klein, European Southern Observatory (Germany); Alexis Lavail, Uppsala Univ. (Sweden); Jean-Louis Lizon, European Southern Observatory (Germany); Tom Löwinger, Thüringer Landessternwarte Tautenburg (Germany); Thomas Marquart, Uppsala Univ. (Sweden); Ignacio Molina-Conde, European Southern Observatory (Germany); Ernesto Oliva, INAF - Osservatorio Astrofisico di Arcetri (Italy); Jérôme Paufique, European Southern Observatory (Germany); Nikolai A. Piskunov, Uppsala Univ. (Sweden); Ansgar Reiners, Georg-August-Univ. Göttingen (Germany); Eric Stempels, Uppsala Univ. (Sweden)

The VLT/CRIRES+ instrument will be the premier high-resolution, infra-red spectrograph at ESO's Very Large Telescope in early 2018. The ambitious instrument upgrade project has recently entered its assembly and integration phase, implementing a set of new capabilities such as cross-dispersion, a new detector system, spectro-polarimetry, and a set of newly developed, tailored wavelength calibration sources.

In this paper, we discuss the design of the complete calibration unit, and describe the strategy and its implementation featuring high-precision infra-red absorption gas-cells for RV studies, a next-generation Uranium-Neon emission lamp, an enhanced metrology system for long-term instrumental stability, and the workhorse wavelength calibration tool: a broad-band infra-red Fabry-Perot etalon system. The stabilized etalon unit is a new challenging addition to CRIRES+ and serves as the new precision calibrator in all modes, including the spectro-polarimeter. Its optical design and the challenges to overcome are detailed, and we also present first results of the prototype etalon system on CRIRES and demonstrate its performance.

9908-262, Session PS4

NRES: the network of robotic Echelle spectrographs

Robert Siverd, Las Cumbres Observatory Global Telescope Network (United States)

Las Cumbres Observatory Global Network (LCOGT) is building the Network of Robotic Echelle Spectrographs (NRES), which will consist of six identical, optical (390 - 860 nm) high-precision spectrographs, each fiber-fed simultaneously by up to two 1-meter telescopes and a thorium argon calibration source. We plan to install one at up to 6 observatory sites in the Northern and Southern hemispheres, creating a single, globally-distributed, autonomous spectrograph facility using up to twelve 1-m telescopes. Simulations suggest we will achieve long-term radial velocity precision of 3 m/s in less than an hour for stars brighter than V = 12. We have been funded with NSF MRI and ATI grants, and expect our first spectrograph to be deployed in mid 2016, with the full network operation of 5 or 6 units beginning in 2017. We will briefly overview the NRES design, goals, robotic operation, and status. In addition, we will discuss early results from our prototype spectrograph, the laboratory and on-sky performance of our first production unit, and the ongoing software development effort to bring this resource online.

9908-263, Session PS4

PFES2: new primary focus Echelle spectrograph for Russian 6-m telescope

Vladimir E. Panchuk, Special Astrophysical Observatory (Russian Federation) and ITMO Univ. (Russian Federation); Maxim Yushkin, Valentina G. Klochkova, Special Astrophysical Observatory (Russian Federation); Mikhail Sachkov, Institute of Astronomy (Russian Federation)

In the primary focus of the Russian 6-m telescope large dimention spectrographs can be installed (up to 160 sm). In late 90-es we crated the echelle spectrograph PFES with collimated beam of 50 mm for moderate spectral resolution (R=15000) spectroscopy as well as for stellar spectropolarimetry. We used small CCD so observations in blue and red optical sub-regions can be obtained by using changed cross-dispertion difraction gratins. Now we are presenting the new optical design of the new instrument PFES2 for faint stellar spectroscopy and spectropolarimetry. Parameters are: linse collimator 1:4; collimated beam diameter d=70 mm, echelle grove density is 37.5 grv/mm; camera 1:1.8 with focus F=200 mm ; detector 2??2?. In contrast to PFES optical layout (mirror collimator - echelle- cross disperse grating - linse camera) we propose prism+grating cross dispertion unit for PFES2 that allows to observe in one of two wavelength regions: 380-810 nm or 440-1000 nm. For slit of 0.5 arcsec spectral resolution is about R=30000. Observations can be obtained in spectropolatimetric mode in all 4 Stocks parameters with spectral resolution about R=21000. PFES2 instrument is now at assambly stage.

9908-264, Session PS4

Spectrograph sensitivity analysis: an efficient tool for different design phases

Matteo Genoni, INAF - Osservatorio Astronomico di Brera (Italy) and Univ. degli Studi dell'Insubria (Italy); Marco Riva, Giorgio Pariani, INAF - Osservatorio Astronomico di Brera (Italy)

In this paper we present an efficient tool developed to perform opto-mechanical tolerance and sensitivity analysis both for the preliminary and final design phases of a spectrograph. With this tool it will be possible to evaluate the effect of mechanical perturbation of each single spectrograph optical element in terms of image stability, i.e the motion of the echellogram on the spectrograph focal plane, and of image quality, i.e. the spot size of the different echellogram wavelengths. We present the Matlab-Zemax script architecture of the tool. In addition we present the detailed results concerning its application to the sensitivity analysis of the ESPRESSO spectrograph (the Echelle SPectrograph for Rocky Exoplanets and Stable Spectroscopic Observations which will be soon installed on ESO's Very Large Telescope) in the framework of the incoming assembly, alignment and integration phases.

9908-265, Session PS4

SHREK: stable high-resolution Echelle for Keck

Steven R. Gibson, Univ. of California, Berkeley (United States) and Space Sciences Lab. (United States); Andrew W. Howard, Univ. of Hawai'i (United States) and Institute for Astronomy (United States); Geoffrey W. Marcy, Univ. of California, Berkeley (United States); Jerry Edelstein, Claire L. Poppett, Edward H. Wishnow, Univ. of California, Berkeley (United States) and Space Sciences Lab. (United States)

SHREK is a fiber-fed, high-resolution, high-stability spectrometer in development at the UC Berkeley Space Sciences Laboratory for the W.M. Keck Observatory. The instrument will be used to characterize exoplanets via Doppler spectroscopy with a single measurement precision of 0.5 m/s or better. SHREK will have a 200mm collimated beam diameter and a resolving power of >80,000. The design includes a green channel (440nm to 590nm) and red channel (590nm to 850nm). A novel design aspect of SHREK is the use of a Zerodur optical bench, and Zerodur optics with integral mounts, to provide stability against thermal expansion and contraction effects.

9908-266, Session PS4

Ultra-stable temperature and pressure control for the Habitable-zone Planet Finder spectrograph

Gudmundur Kári K. Stefánsson, Frederick R. Hearty, Paul M. Robertson, Eric I. Levi, Suvrath Mahadevan, Tyler B. Anderson, Andrew J. Monson, Chad F. Bender, Samuel P. Halverson, Yiting Li, Lawrence W. Ramsey, Arpita Roy, The Pennsylvania State Univ. (United States); Christian Schwab, Macquarie Univ. (Australia); Ryan C. Terrien, National Institute of Standards and Technology (United States); Matthew J. Nelson, Univ. of Virginia (United

States); Basil Blank, PulseRay (United States)

We present the design and the long-term stability results of the Environmental Control System (ECS) for the Habitable Zone Planet Finder (HPF), a near infrared (NIR) ultra-stable spectrograph for the 10m class Hobby-Eberly Telescope. Exquisite temperature and pressure stability is required for high precision (<1m/s) radial velocity spectrographs, as temperature and pressure variations inside the instrument can easily induce systematic Doppler drifts of several tens to hundreds of meters per second.

The HPF ECS minimizes these errors by enclosing the full optical train in a thermally stabilized high-vacuum environment (<10-7 Torr), eliminating convective heat transport. This ensures the optics are only coupled to the surroundings via radiation. High efficiency Multi-Layer Insulation blankets, and a passive external thermal enclosure further isolate the optics from ambient perturbations. An actively controlled radiation shield, outfitted with high-fidelity custom feedback electronics, compensates for the dampened temperature fluctuations. The radiation shield is maintained at a 180K operating temperature, motivated by the choice of a Teledyne Hawaii-2RG NIR detector with a 1.7micron cutoff. A large internal LN2 tank acts as a heat sink for the detector array and radiation shield. Long-term high-quality vacuum is achieved with activated charcoal getters directly mounted to the LN2 tank and a commercially available NEXTorr pump from SAES getters.

This environmental control approach is simple, robust, and easily adaptable to stabilize large-scale instruments at the sub-mK level for a wide range of operating temperatures. Preliminary tests of the HPF ECS system at room temperature have already demonstrated sub-mK stability over more than one week. Here we present the latest stability results from full-scale operation at 180K.

9908-267, Session PS4

Integration of the multi mini prism device for the ESPRESSO APSU

Luca Oggioni, Manuele Moschetti, Marco Riva, Giorgio Pariani, Matteo Genoni, Matteo Aliverti, Marco Landoni, INAF - Osservatorio Astronomico di Brera (Italy)

ESPRESSO is a new generation spectrograph for ESO's Very Large Telescope, whose purpose is to search for rocky extrasolar planets and determine possible variability of physical constants. At the spectrograph focal plane, 12 miniprisms are necessary to differently fold each field to correctly illuminate the echelle. This paper describes the procedure used to assembly the multiminiprism system, monitoring the critical aspects such us the definition of the xy zero, the parallelism of the gluing interfaces and the control of the glue thickness.

9908-268, Session PS4

The iLocater cryostat: design and thermal control strategy for precision radial velocity measurements

Jonathan Crass, Univ. of Notre Dame (United States); Louis G. Fantano, NASA Goddard Space Flight Ctr. (United States); Justin R. Crepp, Univ. of Notre Dame (United States); Frederick R. Hearty, The Pennsylvania State Univ. (United States); Matthew J. Nelson, Univ. of Virginia (United States); Sheila M. Wall, NASA Goddard Space Flight Ctr. (United States); David A. Cavalieri, Univ. of Notre Dame (United States); Corina Koca, NASA Goddard Space Flight Ctr. (United States); David M. P. King, Univ. of Cambridge (United Kingdom); Robert O. Reynolds, Large Binocular Telescope Observatory (United States); Karl R. Stapelfeldt, NASA Goddard Space Flight Ctr. (United States)

The current generation of precision radial velocity (RV) instrument are seeing-limited in design. In order to achieve high spectral resolution on 8m class telescopes, instruments require large optics and in turn, large instrument volumes. Achieving milli-Kelvin thermal stability for these systems is challenging but is vital to achieve a single measurement RV precision of better than 1m/s. This precision is crucial in the search for Earth-like exoplanets.

iLocater, a next generation RV instrument being developed for the Large Binocular Telescope (LBT), uses the LBT adaptive optics (AO) system to inject a diffraction-limited beam into single-mode fibers. These fibers illuminate the instrument spectrograph, facilitating a diffraction-limited design and a significantly smaller instrument volume compared to instruments today. This enables intrinsic instrument stability and precision thermal control.

We present the current design of the iLocater cryostat which houses the instrument spectrograph. The spectrograph is situated within two radiation shields inside the MLI lined instrument vacuum chamber. The outer shield is actively controlled to maintain instrument stability and minimize the effects of thermal changes from the external environment.

The instrument is cooled to an operating temperature of 60K using two pulse-tube cryocoolers from Cryomech which are vibrationally isolated from the internal vacuum structure. To improve the intrinsic stability of the instrument, the optical board and mounts for the spectrograph optics are made from Invar which offers a CTE value an order of magnitude better than aluminum. Combined, the small footprint of the instrument spectrograph, the use of Invar and a precision thermal control strategy will allow long-term milli-Kelvin stability of the instrument to be achieved.

9908-269, Session PS4

CRIGGLEX: a novel long-path infrared gas-absorption cell for VLT/CRIRES+

Ulf Seemann, Heiko M. Anwand-Heerwart, Georg-August-Univ. Göttingen (Germany); Tom Löwinger, Thüringer Landessternwarte Tautenburg (Germany); Christof Schmidt, Georg-August Univ. Göttingen (Germany); Ansgar Reiners, Georg-August-Univ. Göttingen (Germany)

We present the design of a newly developed gas-absorption cell with very long optical path-length for precision wavelength calibration. The CRIGGLEX project is an ambitious effort to extend the absorption-cell technique to the infra-red wavelength regime and enable high-precision IR radial velocity experiments in regimes where traditional short-path cells are no longer feasible, and on spectrographs with extreme space limitations in the optical train. Our purely reflective optical design allows for an active path-length of over 3m in the spectroscopic reference medium, while at the same time only a small pick-off unit is inserted into the telescope beam in front of the spectrograph. The design is flexible to adapt to a range of telescope/instrument requirements, and is particularly optimised for the upcoming CRIRES+ spectrograph at the VLT, supporting the full instrumental field of view and the adaptive optics capabilities, while maintaining the telescope beam properties.

We discuss the optical design, the mechanical implementation, and demonstrate the system performance of a fully integrated prototype unit, including the challenges and lessons learnt on the system's complex opto-mechanical alignment.

9908-270, Session PS4

VINROUGE: a very compact 2-5um high-resolution spectrograph with germanium immersion grating

Takayuki Arasaki, Kyoto Sangyo Univ. (Japan); Naoto Kobayashi, The Univ. of Tokyo (Japan); Yuji Ikeda, Kyoto Sangyo Univ. (Japan) and Photocoding (Japan); Shohei Kondo, Kyoto Sangyo Univ. (Japan); Yuki Sarugaku, The Univ. of Tokyo (Japan); Sayumi Kaji, Hideyo Kawakita, Kyoto Sangyo Univ. (Japan)

The 2-5 um wavelength region is an essential window to access to the molecules of astrophysical interest through their stretching vibration transitions (e.g., C-H, N-H, O-H, C-O, and C-N) even for symmetric molecules (e.g., H3+ and CH3+ which have never been detected in the radio region because of zero permanent electric dipole moment). The ro-vibrational spectra of those molecules are diagnostic not only for chemical abundance but also for temperature, number density and kinetics of the gas in the relatively low-temperature environments like molecular clouds, proto-planetary disks, circumstellar envelopes and low-temperature stars. The high-resolution spectroscopy which simultaneously covers is necessary to resolve the rotational structure of vibrational spectrum for the various molecular species.

VINROUGE is a high-efficiency and high-resolution spectrograph to study these astronomical molecules in K, L, and M bands. This instrument is being developed by Laboratory of Infrared High-resolution spectroscopy (LiH) of Koyama Astronomical Observatory in Kyoto Sangyo University, Japan. VINROUGE is designed to be compact (600mmL x 600mmW x 500mmH) despite the high resolution (R = 80,000) by making use of an Germainium (n = 4) immersion grating, so that it can be flexibly installed at the Cassegrain focus of any 3-8 m telescopes.

VINROUGE employs a white pupil type echelle spectrograph that can reduces the beam size, resulting in the small size of the instrument. The total throughput of VINROUGE reaches greater than 25%, which is achieved by the combination of optical elements with high throughput: specially-designed immersion grating and cross-dispersers, an optics consisting of reflective mirrors, and a large format and high Q.E. infrared array. The immersion grating is designed to have the blaze angle of 75 degree, the groove pitch of 57.1 um, and the apex angle of 86 degree. The apex angle smaller than the right angle and the Au reflective coating on the grating surface maximize the diffraction efficiency up to 70% (see Sarugaku et al. in this conference). VINROUGE uses four reflective gratings as cross-disperser (one is for K-band, two are for L-band, and one is for M-band), for which diffraction efficiencies are optimized for each band. All optics of VINROUGE (the collimator, the relay, and the camera) are reflective optics with high-reflective Au or Ag coating in IR, based on three mirror anastigmat (TMA) configuration. We adapt the 5.3 um cutoff HWAII-2RG as the detector, which shows the Q.E. of > 80%. The optics is athermal with all the optics including reflective mirrors, mirror holders and optical bench are made of the same extremely-low expansion material, SiC or Cordierite, with the TEC < 10-7 K-1. As a result, we can easily align the off-axis optics with the visible light and the CCD camera under the room temperature environment, which significantly reduces the cost and time for development.

The first light of VINROUGE is expected in 2018. In this paper, we introduce science cases, conceptual design, and future plan of VINROUGE. See Sarugaku et al. and Kaji et al. for the detail of the Ge-immersion grating.

9908-271, Session PS4

Precision single mode fibre integral field spectroscopy with the RHEA spectrograph

Adam D. Rains, Michael J. Ireland, The Australian National Univ. (Australia); Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Joao Bento, The Australian National Univ. (Australia); Tobias Feger, Macquarie Univ. (Australia)

The RHEA Spectrograph is a single-mode echelle spectrograph designed to be a replicable and cost effective method of undertaking precision radial velocity measurements. Two versions of RHEA currently exist, one located at the Australian National University (ANU) in Canberra, Australia (450 – 600nm wavelength range), and another located at the Subaru Telescope in Hawaii, USA (600 – 800 nm wavelength range). Both instruments have a novel fibre feed consisting of an integral field unit injecting light into a 2 dimensional grid of single mode fibres. This 2D grid of fibres is then reformatted into a 1D array at the input of the spectrograph (consisting of the science fibres and a reference fibre capable of receiving a white-light or xenon reference source for simultaneous calibration). The use of single mode fibres frees RHEA from the issue of modal noise and significantly reduces the size of the optics used. In addition to increasing the overall light throughput of the system, the integral field unit allows for cutting edge science goals to be achieved when operating behind the 8.3 m Subaru Telescope and the SCExAO adaptive optics system. These include, but are not limited to: resolved stellar photospheres; resolved protoplanetary disk structures; resolved Mira shocks, dust and winds; and sub-arcsecond companions. We present details and results of early tests of RHEA@Subaru and progress towards the stated science goals.

9908-272, Session PS4

Investigating the stability limitations and improving the design of iodine gas-absorption cells for exoplanet radial velocimetry

Ulf Seemann, Julia Bienert, Wilfried Steinhof, Peter Jeep, Ansgar Reiners, Georg-August-Univ. Göttingen (Germany)

We revisit the design, construction, and performance of iodine absorption cells frequently in use for precision radial velocity monitoring targeted to detect and characterize extra-solar planets. The project aims to investigate the stability and performance limitations of the well established yet poorly studied iodine gas-absorption cells, and to improve the design and manufacturing of contemporaneous iodine calibration cells, offering a cost-effective, high-precision simultaneous wavelength reference for optical high-resolution spectrographs.

We present the scope of the project and discuss our stability measurements as well as an improved cell design. We also demonstrate the performance of protoypes already manufactured and tested.

9908-273, Session PS4

Next generation multi-order reflective spatial heterodyne spectroscopy for broadband high resolving power spectroscopy of diffused emission line sources

Walter M. Harris, Jason B. Corliss, The Univ. of Arizona (United States)

Spectral observations of the intensity and distribution of UV-Visible emission/absorption features is a staple technique for the remote sensing of comets, planetary upper atmospheres and near space environments, thin satellite atmospheres, and interactions of all of these with the solar wind and high-energy radiation field. Bandpass imaging and low resolving power spectroscopic measurements are adequate for identifying basic composition, spatial structure, and total energy input of these features. However, these measurements miss the useful information available from line shapes and ratios, including velocity distributions, thermal properties, turbulence, energetic neutral/ion populations, radiative transfer effects, isotopic ratios and contributions from multiple sources. Unfortunately, gaining access to this information is complicated by the fact that the sources under study are relatively low in energy from an astrophysical perspective and are low in surface brightness and angularly extended, particularly from the close perspective of a remote probe.

The most commonly utilized approaches for high resolving power spectroscopy, such as the cross dispersed echelle spectrometer, are typically limited in their field of view (FOV) such that they undersample extended features. As a result, their étendue relies on the input aperture of a telescope. One alternative to this is to employ an interferometric technique such as a reflective spatial heterodyne spectrometer (SHS). Reflective SHS instruments are common-path Fourier Transform Spectrometers that use a diffraction grating to split incoming light into two beams that are then interfered to obtain high resolving power spectra. Their chief advantage comes from their large relative FOV compared with other instruments that allows their use at small aperture telescopes. Their chief disadvantage comes from their limited sampling bandpass (1-10 nm).

We describe here the first results from a new SHS design that employs a high order grating to simultaneously sample a very broad spectral range (300-650 nm) with a single instrumental alignment. The instrument was constructed and tested at the McMath-Pierce solar observatory where it was used to observe several extended astronomical targets. In this report we describe the instrumental design, efficiency, and optical performance of the instrument and evaluate the multi-order technique as a potential tool for remote sensing at small aperture telescopes and space based remote probes.

9908-274, Session PS4

First high-efficiency and high-resolution NIR spectroscopy with high-blazed Echelle grating: WINERED HIRES-mode w/R80,000 commissioned

Shogo Otsubo, Yuji Ikeda, Kyoto Sangyo Univ. (Japan); Naoto Kobayashi, The Univ. of Tokyo (Japan); Takashi Sukegawa, Canon Inc. (Japan); Sohei Kondo, Satoshi Hamano, Hiroaki Sameshima, Tomohiro Yoshikawa, Kenshi Nakanishi, Ayaka Watase, Keiichi Takenaka, Akira Asano, Kyoto Sangyo Univ. (Japan); Chikako Yasui, Kei Fukue, Noriyuki Matsunaga, The Univ. of Tokyo (Japan); Hideyo Kawakita, Kyoto Sangyo Univ. (Japan)

WINERED is a PI-type NIR high-resolution and high-sensitive spectrograph. It was commissioned by Laboratory of Infrared High-resolution spectroscopy (LiH) at Koyama Astronomical Observatory in Kyoto Sangyo University, Japan, and it is currently mounted on the 1.3 m Araki Telescope located in the university campus. WINERED has the "WIDE mode" that simultaneously obtains 0.90-1.35 um spectra with the spectral resolution of 30,000 and the throughput of > 50 % (including the Q.E. of the array detector). This mode has been already completed and producing fruitful scientific results for various astronomical objects, such as comets, planets, stars, and interstellar medium (see Ikeda et al. in this conference for more details). At present, we have been developing a new mode that provides much higher spectral resolution of R ~80,000 (=HIRES mode). In general, there are two choices to achieve such high spectral resolution with grating: immersion grating and high-blazed echelle grating. We selected the latter because the fabrication is easier than immersion grating due to the looser tolerances on surface irregularity, surface roughness, and groove pitch error, although the ideal maximum diffraction efficiency is often degraded compared to that of immersion grating by about 10 %. Custom high-brazed gratings were fabricated by CANON Inc., Japan. The designed groove pitch, blaze angle, and the apex angle are 90.38 um, 79.32 deg, and 88 deg, respectively. The protected Ag is adopted for the reflective coating on the grating surface and the apex angle is set to 88 deg to compensate the unavoidable degradation of diffraction efficiency for high-blazed echelle grating due to the shadow effect. A mosaic of two gratings with the 200 mm x 60 mm ruled area is set on the pupil. The total throughput of WINERED with this grating is expected to be ~40 %. The accurate alignment of two gratings is technically challenging because the alignment tolerances are extremely tight. In particular, the parallelism of 100nm is required for the monochromatic slit-images diffracted from two gratings to be focused with the positional difference of < 1/10 pixels (the roll-angle error and the pitch-angle error between grating surfaces are 1 arcsec and 0.5 arcsec, respectively). To meet with this tight requirement, we designed a special grating holder made of an extremely low CTE material such as low expansion ceramic with an ultra-precise alignment mechanism. Since the high-blazed echelle gratings are used in the quasi-Littrow condition with the gamma angle of 6 deg, the monochromatic slit image is considerably tilted on the detector, which may result in degraded spectral resolution due to pixelization effect in the diagonal direction of the pixel. We investigate the influence and appropriate reduction methods for keeping the spectral resolution determined by optics. In this paper, we present the designed and optical performances of this HIRES mode, the reduction procedure of images obtained by this mode, and preliminary astronomical results by engineering observations.

9908-275, Session PS4

The precision radial velocity error budget for the Gemini High-resolution Optical SpecTrograph (GHOST)

Michael J. Ireland, The Australian National Univ. (Australia); Étienne Artigau, Univ. de Montréal (Canada); Gregory S. Burley, NRC - Herzberg Astronomy & Astrophysics (Canada); Michael Edgar, Richard M. McDermid, Australian Astronomical Observatory (Australia); Steven Margheim, Gemini Observatory (Chile); Gordon Robertson, Australian Astronomical Observatory (Australia); John Pazder, NRC - Herzberg Astronomy & Astrophysics (Canada); Andrew I. Sheinis, Australian Astronomical Observatory (Australia)

The Gemini High-resolution Optical SpecTrograph (GHOST) is a fiber fed spectrograph primarily designed for high efficiency and broad wavelength coverage (363-1000nm), with an anticipated commissioning early in 2018. The primary scientific goal of the Precision Radial Velocity (PRV) mode will be follow-up of relatively faint (R>12) transiting exoplanet targets, especially from the TESS mission. The high predicted efficiency

of GHOST will mean that it is competitive with other southern PRV instruments, especially for faint, cool stars. In the PRV mode, the 1.2 arcsec diameter stellar image will be split 19 ways, combined in a single slit with a simultaneous Th/Xe reference source, dispersed at a resolving power of ~80,000 and imaged onto two detectors. The spectrograph will be thermally stabilised in the Gemini pier laboratory, and modal noise will be ameliorated through the use of a fiber agitator. Unlike other precision high resolution spectrographs, GHOST will not be pressure controlled (although pressure will be monitored precisely), and there will be no double scrambler or shaped (e.g. octagonal) fibers. Instead, GHOST will have to rely on simultaneous imaging of the slit and simultaneous Th/Xe fiber in two filters to correct for variable fiber illumination and focal-ratio degradation. This configuration presents unique challenges in estimating a PRV error budget. We will describe all terms in this error budget, which in the most optimistic (goal) error budget are dominated by slit profile measurement errors and time-variable spectrograph aberrations. We will verify the error budget terms with simplified end-to-end simulations which include terms such as seeing variations, micro-optic fabrication uncertainties, variable focal-ratio degradation and atmospheric pressure changes. We will show that the spectrograph requirement of 10m/s PRV uncertainty is justified, and that the goal of 1m/s is plausibly within reach.

9908-276, Session PS4

Integration, alignment, and verification of the ESPRESSO front-end

Giorgio Pariani, Matteo Aliverti, Marco Landoni, Marco Riva, Filippo Maria Zerbi, INAF - Osservatorio Astronomico di Brera (Italy); Denis Mégevand, Observatoire de Genève (Switzerland); Stefano Cristiani, INAF - Osservatorio Astronomico di Trieste (Italy); Francesco Pepe, Observatoire de Genève (Switzerland)

ESPRESSO, Echelle SPectrograph for Rocky Exoplanets and Stable Spectroscopic Observations, will be installed soon on ESO's VLT. The Front End modular subsystems collect the light from the CoudÃ©e Trains of all the four Telescope Units (UT), provide field and pupil stabilization via piezoelectric tip tilt driven by a reimaging system, and inject the beam into the Spectrograph fibre. The Front End will also inject the calibration light coming from the calibration unit. A toggling system is provided to switch between the different observation modes, using single or multiple UTs.

The presence of different modes shared between the four Front End Units drove the design of the system and the alignment workflow. The strategy followed to define the convergence point and the optical paths linking the Coudé trains to the six fibres are described. Once defined the reference system, all the mechanical and optomechanical components are aligned. The different procedures and methods used to align the ground plates, the main structure, the mode selector, the fibres and the Front End Units will be presented.

Finally, we evaluate the performances of the system in terms of image quality both on the Fiber Link focal plane and on TCCD used for pupil and field stabilisation, and in terms of encircled energy in the observed point spread function (PSF, fitted by a two-dimensional gaussian profile), which is directly linked with the efficiency of the light collection at the fibre plane.

9908-277, Session PS4

Integration and alignment through mechanical measurements: the example of the ESPRESSO front-end units

Matteo Aliverti, Giorgio Pariani, Manuele Moschetti, Marco Riva, INAF - Osservatorio Astronomico di Brera (Italy)

Traditional techniques usually relies on optical feedback to align optical elements over all the degrees of freedom needed. This strongly iterative process imply the use of bulky and/or flexible adjustable mountings.

Another solution under study consists in the characterization of every optomechanical elements and the integration of the parts without any optical feedback. The characterization can be performed using different 3D Coordinate Measuring Machines like Laser Tracker, Articulated Arms and Cartesian ones) and referencing different parts like the optomechanical mounts or the optical surfaces. The alignment of the system is done adjusting the six degrees of freedom of every element with metallic shims. Those calibrated element are used to correct the interfaces position of the semi-kinematic system composed by 3 screws and 3 pins.

In this paper, the integration and alignment of the ESPRESSO Front End Units (FEUs) will be used as pathfinder to test different alignment methods and evaluate their performances. The FEUs are five identical system used to stabilize and inject the light of the four Unit Telescopes composing the VLT into a number of fibres. This lead to strong requirements in term of accuracy and repeatability of the alignment proving them as the perfect candidate for this study.

The alignment is done mounting any single unit on a fixed kinematic mount system and placing all the optomechanical elements in the correct position with an Articulated Arm Coordinate Measuring Machine and calibrated stainless steel shims, to reach the 50 micrometer positioning precision. The characterization of the mechanical mountings is performed with a Cartesian Coordinate Measuring Machine. The alignment is then verified and eventually refined by means of a Telescope Simulator, producing the image of the telescope field and pupil in the proper position of the FE. Encircled energy on the fibre plane and image quality of the guiding system will be presented and discussed as verification of the alignment quality.

9908-278, Session PS4

Developing and deploying an externally dispersed interferometer-test bed for visual-band, high-resolution spectroscopy on 2.0-m class telescopes

James Maxwell, Matthew W. Muterspaugh, Michael H. Williamson, Tennessee State Univ. (United States); Edward H. Wishnow, Space Sciences Lab. (United States) and Univ. of California, Berkeley (United States); Chelsea N. Harrison, Aarin Whitehurst, Tennessee State Univ. (United States); Jerry Edelstein, Space Sciences Lab. (United States) and Univ. of California, Berkeley (United States); David J. Erskine, Lawrence Livermore National Lab. (United States); Dan Fishler, Tennessee State Univ. (United States); Forrest Hoff, Tenesee State Univ. (United States); Samuel Swihart, Univ. of Michigan (United States)

The Externally-Dispersed Spectrograph (EDI) Testbed was developed and constructed at Tennessee State University in conjunction with the University of California, Berkley. EDI Technology has been shown to boost the effective resolution of spectrographs by a factor 10. Unlike previous installments of EDI technology, this instrument is optimized for use in the visible wavelengths, 480-620 nm. The system is a fiber-fed Michelson-type interferometer, whose outputs are then fed to an echelle spectrograph of R~4000. Data pipeline processing software has been developed to produce the desired data product from a properly constructed set of EDI images. It has been designed to be portable, cost-effective and robotically operated. Constructed using mostly off the shelf parts with a budget under 100,000 USD, this technology is easily attainable by institutions using 2.0-m class telescopes. As a testbed instrument, it has been designed to be flexible in order to test a range of configurations and so mature the EDI technology

itself. The flexibility of the system also allows for its use observing a large range of astronomical objects in addition to its intended purpose of detecting exoplanets by measuring the small Doppler shifts of their host stars caused by their orbits. The EDI-Testbed can also be used to produce high resolution spectroscopy using methods developed on previous EDI instruments (see Erskine et al 2015, http://spectralfringe.org/EDI/MyPubs3/TediTenx38twocol.pdf). The alignment and the delay of the interferometer arms are adjustable with computer controlled stages and optical mounts. Alignment maintenance can be accomplished remotely and automatically, a requirement for use on TSU's 2.0-m telescope at Fairborn Observatory. It is housed in a special built instrument room that is temperature controlled to less than 1 degree Celsius. This room has been built to house this and other instruments connected by fiber to TSU's 2.0-m Telescope. Spots are available for housing new fiber-fed guest instruments for interested institutions.

The astro-comb on Chinese 216 Telescope

Dong Xiao, Huiqi Ye, Jian Han, Yuanjie Wu, Nanjing Institute of Astronomical Optics & Technology (China)

The radial velocity method, based on the Doppler effect, plays an important role in the extrasolar planets searching. The astronomical spectrographs have been lacking calibration sources when searching for the twin earth. The astro-comb is emerging as a promising calibration source with significant performances leaping. After installing a GPS referenced 25GHz astro-comb from Menlosystem in Xinlong, China, We couple the output from the astro-comb into a mode scrambler employing polygon fiber and mechanical shaker. Then, the beam is relayed to the high resolution astronomical spectrograph of Chinese 2.16-m telescope. We will present our test run results.

9908-280, Session PS4

The Gemini High-Resolution Optical SpecTrograph (GHOST) bench spectrograph optical design

John Pazder, NRC - Herzberg Astronomy & Astrophysics (Canada)

The instrument group of the NRC Herzberg Astronomy and Astrophysics has been subcontracted by the Australian Astronomical Observatory to design and build the bench spectrograph for Gemini High-Resolution Optical SpecTrograph (GHOST) instrument. GHOST is the newest instrument being developed for the Gemini telescope and is a collaboration between the Australian Astronomical Observatory, the NRC Herzberg Astronomy and Astrophysics in Canada and the Australian National University (ANU). The instrument is a fiber feed spectrograph with R>50,000 in two-object mode and R>75,000 in single object mode. This paper outlines the optical design of the bench-mounted spectrograph and the predicted spectrograph resolution and efficiency for the spectrograph.

9908-281, Session PS4

Fiber link design for the NASA-NSF extreme precision Doppler spectrograph concept "WISDOM"

Gábor F?rész, MIT Kavli Institute for Astrophysics and Space Research (United States); Rafal Pawluczyk, Paul Fournier, Fibertech Optica Inc. (Canada)

We describe designs for the fiber-optic coupling and light transfer system of the WISDOM (WIYN Spectrograph for DOppler Monitoring) instrument. As a next-generation Precision Radial Velocity (PRV) spectometer, WISDOM incorporates lessons learned from HARPS about thermal, pressure, and gravity control, but also takes new measures to stabilize the spectrograph illumination, a subject that has been overlooked until recently. While fiber optic links provide more even illumination than a conventional slit, careful engineering of the interface is required to realize their full potential. Conventional round fiber core geometries have been used successfully in conjunction with optical double scramblers, but such systems still retain a memory of the input illumination that is visible in systems seeking sub-m/s PRV precision. Non-circular fibers, along with advanced optical scramblers, and careful optimization of the spectrograph optical system itself are therefore necessary to study Earth-sized planets. For WISDOM, we have developed such a state-of-the-art fiber link concept. Its design is driven primarily by PRV requirements, but it also manages to preserve high overall throughput.

Light from the telescope is coupled into a set of six, 32 micron diameter octagonal core fibers, as high resolution is achieved via pupil slicing. The low-OH, step index, fused silica, FBPI-type fibers are custom designed for their numerical aperture that matches the convergence of the feeding beam and thus minimizes focal ratio degradation at the output. Given the demanding environment at the telescope the fiber end tips are mounted in a custom fused silica holder, providing a perfect thermal match. We used a novel process, chemically assisted photo etching, to manufacture this glass fiber.

A single ball-lens scrambler is inserted into the 25m long fibers. Employing an anti-reflection (AR) coated, high index, cubic-zirconia ball lens the alignment of the scrambler components are straightforward, as the fiber end tips (also AR coated) by design touch the ball lens and thus eliminate spacing tolerances. A clever and simple opto-mechanical design and assembly process assures micron-level self-alignment, yielding a ~87% throughput and a scrambling gain of >20,000.

To mitigate modal noise the individual fibers then subsequently combined into a pair of rectangular fibers, providing a much larger modal area thanks to the 34x106 micron diameter. To minimize slit height, and thus better utilize detector area, the octagonal cores are brought very close together in this transition. The two outer fibers are side polished at one side, into a D-shaped cladding, while the central fiber has a dual side polish. These tapered, side-flattening operations are executed with precise alignment to the octagonal core. Thus the cores of the 3 fibers are brought together and aligned within few microns of each other before spliced into the rectangular fiber.

Overall throughput kept high and FRD at bay by careful management of fiber mounting, vacuum feed-through, application of efficient AR coatings, and implementation of thermal breaks that allow for independent expansion of the fibers and the protective tubing.

9908-282, Session PS4

Optical design for NEID, a proposed spectrometer for NASA's WIYN extreme precision Doppler spectrometer

Christian Schwab, Macquarie Univ. (Australia) and Australian Astronomical Observatory (Australia); Andrew P. Rakich, GMTO Corp. (United States); Suvrath Mahadevan, Samuel P. Halverson, The Pennsylvania State Univ. (United States); Qian Gong, NASA Goddard Space Flight Ctr. (United States); Julian Stürmer, The Univ. of Chicago (United States); Yulia V. Gurevich, Landessternwarte Heidelberg (Germany); Eric I. Levi, Frederick R. Hearty, Ryan C. Terrien, Paul M. Robertson, Andrew J. Monson, Jason T. Wright, The Pennsylvania State Univ. (United States); Michael W. McElwain, NASA

Goddard Space Flight Ctr. (United States); Chad F. Bender, The Pennsylvania State Univ. (United States); Cullen H. Blake, Univ. of Pennsylvania (United States); Abhijit G. Chakraborty, Physical Research Lab. (United States); Lawrence W. Ramsey, The Pennsylvania State Univ. (United States)

We have developed an optical design for a high resolution spectrograph in response to NASA's call for an extreme precision Doppler spectrometer (EPDS) for the WIYN telescope. Our instrument covers a wavelength range of 380 to 930nm on a single detector, with a resolution more than 100,000. To deliver the most stable spectrum, we avoid the use of an image slicer, in favour of a large ~190mm diameter beam footprint on a 1x2 mosaic R4 Echelle grating. The optical design is based on a classic white pupil layout, with a single parabolic mirror, used as main as well as transfer collimator. Cross-dispersion is delivered by a single large PBM2Y glass prism. The refractive camera is comprised of only four rotationally symmetric lenses of i-Line glass, yet delivers very high image quality over the full spectral bandpass. We present the optical design of the main spectrograph bench and discuss the design trade-offs and expected performance that enable simultaneous science, sky, and calibration fibers to be recorded on the large format CCD.

9908-283, Session PS4

Scrambling gain of non-circular core fibers being tested for use in the Stable High Resolution Echelle for Keck (SHREK) instrument

Claire L. Poppett, Edward H. Wishnow, Space Sciences Lab. (United States); Daniel Finstead, Univ. of California, Berkeley (United States); Jerry Edelstein, Steven R. Gibson, Space Sciences Lab. (United States)

The SHREK collaboration has been testing octagonal fibers for a new high resolution Doppler shift spectrometer. The fibers serve a number of purposes: transporting light from the telescope focus to the temperature controlled spectrometer in the basement, and scrambling the light so that guiding errors do not cause spectral line distortions or shifts. We present tests of focal ratio degradation, near and far-field fiber output patterns, and efficiencies for non-circular core fibers coupled to double scramblers and agitators.

9908-284, Session PS4

ESPRESSO AIT: a critical step toward the science

Marco Riva, INAF - Osservatorio Astronomico di Brera (Italy); Denis Mégevand, Ian Huges, Observatoire de Genève (Switzerland); Filippo Maria Zerbi, INAF - Osservatorio Astronomico di Brera (Italy); Alexandre Cabral, Instituto de Astrofísica e Ciências do Espaço (Portugal); Paolo Di Marcantonio, INAF - Osservatorio Astronomico di Trieste (Italy); Manuel Abreu, Instituto de Astrofísica e Ciências do Espaço (Portugal); Giorgio Pariani, INAF - Osservatorio Astronomico di Brera (Italy); Francesco Pepe, Observatoire de Genève (Switzerland); Johannes K. Dekker, European Southern Observatory (Germany); Stefano Cristiani, INAF - Osservatorio Astronomico di Trieste (Italy); Nuno C. Santos, Instituto de Astrofísica e Ciências do Espaço (Portugal); Rafael Rebolo-López, Instituto de Astrofísica de Canarias (Spain)

ESPRESSO, the Echelle SPectrograph for Rocky Exoplanet and Stable Spectroscopic Observations of the ESO - Very Large Telescope site, is now in its integration phase.

The assembly, integration and verification phase of ESPRESSO, due to its distributed nature and different geographical locations of the consortium partners, is quite challenging.

This paper will describe the AIT strategies of the subsystems into the complete Espresso. The activities performed and their results will be described here focusing the attention onto the experience gained and the lessons learned in the last project's phases. Preliminary performances are also presented.

9908-285, Session PS4

The HARPS-North@TNG polarimeter

Francesco Leone, Univ. degli Studi di Catania (Italy); Massimo Cecconi, Rosario Cosentino, Adriano Ghedina, Fundación Galileo Galilei - INAF (Spain); Marina Giarrusso, Univ. degli Studi di Catania (Italy); Marcos Hernandez Diaz, Manuel Gonzalez, Fundación Galileo Galilei - INAF (Spain); Matteo Munari, INAF - Osservatorio Astrofisico di Catania (Italy); Héctor Pérez Ventura, Luis Riverol, José San Juan Gómez, Fundación Galileo Galilei - INAF (Spain); Salvatore Scuderi, INAF - Osservatorio Astrofisico di Catania (Italy)

A new spectro-polarimetric unit for the High Accuracy Radial velocity Planet Searcher of North emisphere (HARPS-N) of the Telescopio Nazionale Galileo has been installed.

Electro-opto-mechanical solutions adopted to link the dual-beam spectro-polarimeter located at a Nasmyth focus to the fiber-fed spectrograph and, at the same time, able to guarantee a correct orientation of optical axes in the celestial equatorial system are described. First results of science verification are reported.

9908-286, Session PS4

First results from the MINERVA precision RV spectrograph

Jason D. Eastman, Samson Johnson, John A. Johnson, Harvard-Smithsonian Ctr. for Astrophysics (United States); Nate McCrady, The Univ. of Montana (United States); Robert Wittenmyer, The Univ. of New South Wales (Australia); Jason T. Wright, Sharon X. Wang, The Pennsylvania State Univ. (United States); Peter P. Plavchan, Missouri State Univ. (United States); Adam Bolton, National Optical Astronomy Observatory (United States); Thomas G. Beatty, The Pennsylvania State Univ. (United States); Matthew Cornachione, The Univ. of Utah (United States); Michael Bottom, California Institute of Technology (United States); Cullen H. Blake, David H. Sliski, Univ. of Pennsylvania (United States); Stuart I. Barnes, Leibniz-Institut für Astrophysik Potsdam (Germany)

The MINiature Exoplanet Radial Velocity Array (MINERVA) is a dedicated

observatory for exoplanet detection that consists of four robotic 0.7-meter telescopes located at Whipple Observatory on Mt Hopkins, Arizona. We have been doing robotic photometry, primarily of transits and microlensing, since December 2014. At the end of December 2015, we installed a purpose-built, environmentally-stabilized, high-precision iodine cell spectrometer built by Callaghan Innovations that is fiber fed simultaneously from all four telescopes to conduct a survey for small planets around the brightest RV-quiet GKM stars. The four smaller telescopes have the same collecting area as a 1.4 meter telescope at a fifth of the cost and allow greater understanding of guiding and telescope induced systematic errors. We will discuss the first results from the commissioning effort since the installation. MINERVA is a collaboration among Harvard University, Penn State University, University of Montana, and University of New South Wales.

9908-387, Session PS4

First light of a laser frequency comb at SALT

Éric Depagne, Southern African Large Telescope (South Africa) and South African Astronomical Observatory (South Africa); Richard A. McCracken, Derryck T. Reid, Heriot-Watt Univ. (United Kingdom); Rudi B Kuhn, Nicolas A Erasmus, Lisa Ann Crause, South African Astronomical Observatory (South Africa)

The High Resolution Spectrograph (HRS) on the Southern African Large Telescope (SALT) is a dual beam, fiber-fed echelle spectrograph providing high resolution capabilities to the SALT observing community. Its High Stability mode has a resolution of 65000, and its standard calibration sources are a ThAr lamp and an Iodine cell. The ThAr lamp's emission lines cover two thirds of HRS' red channel wavelength range, but with sparse and severely uneven spectral line spacing. The line intensity also ranges from only a few counts above the background noise to close to saturation. The Iodine Cell provides narrower wavelength coverage: from 500 to 620 nm (roughly a third of the red channel range), but with improved line spacing and greater homogeneity in line intensity.

Here we report on a Laser Frequency Comb (LFC) which provides complete coverage of the red channel, with comb lines uniformly separated in frequency space, with good intensity homogeneity and offering unprecedented line occurrence (20 000 lines vs 400 ThAr lamp lines). The LFC is powered by a Nd:YVO4 laser centred at 1064 nm, which is frequency doubled to 532 nm. A mode-locked Ti:Sapphire laser oscillator, pumped by the Nd:YVO4 laser, generates sub-30 femtosecond laser pulses at a 1 GHz repetition rate and centred at 800 nm. The near-infrared pulses are then spectrally broadened into a super-continuum in the 2.7 micron core of a 50 cm long Photonic Crystal Fibre, yielding wavelength coverage from 550 to beyond 1000 nm. A Fabry-Pérot cavity then filters the laser modes such that the individual lines are 15 GHz apart, corresponding to ~10 pixels between successive comb lines on the HRS's red detector. A narrow linewidth diode laser is stabilised to an atomic transition in a Rb gas cell (at a wavelength of 780.24nm) and co-coupled into the spectrograph with the frequency comb to provide an absolute fiducial point for wavelength calibration.

The output beam of the frequency comb is fed into a 10 m transport fibre and directed into the HRS. This optical injection setup makes provision for effortlessly alternating between calibration sources: the ThAr lamp, the frequency comb, or both at the same time. The first on-sky observations were made 5 days after arrival at the telescope. Results obtained during a week of operation include refinement of the wavelength calibration established using only the ThAr lamp, and a revised determination of the High-Stability mode's resolution: 67000 rather than 65000. Expected results include: full calibration of the ThAr spectrum due to the possibility of obtaining frames that afford simultaneous detection of lines from the ThAr arc lamp and the LFC, improved understanding of the HRS stability and resultant radial velocity precision, and (from an engineering point of view) practical operational requirements for a LFC on a large telescope.

9908-49, Session 11

Galactic archeology with the high-efficiency and resolution multi-element spectrograph, HERMES at the AAT *(Invited Paper)*

Andrew I. Sheinis, Australian Astronomical Observatory (Australia)

The High Efficiency and Resolution Multi Element Spectrograph, HERMES is a facility-class optical spectrograph for the AAT. It is designed primarily for Galactic Archeology, the first major attempt to create a detailed understanding of galaxy formation and evolution by studying the history of our own galaxy, the Milky Way. The goal of the Galactic Archeology with Hermes (GALAH) survey is to reconstruct the mass assembly history of the Milky Way, through a detailed spatially tagged abundance study of one million stars. The spectrograph is based at the Anglo Australian Telescope (AAT) and is fed by the existing 2dF robotic fiber positioning system. The spectrograph uses VPH-gratings to achieve a spectral resolving power of 28,000 in standard mode and also provides a high-resolution mode ranging between 40,000 to 50,000 using a slit mask. The GALAH survey requires a SNR greater than 100 for a star brightness of V=14. The total spectral coverage of the four channels is about 100nm between 370 and 1000nm for up to 392 simultaneous targets within the 2-degree field of view. Hermes was commissioned in late 2013, with the GALAH Pilot starting in parallel with the commissioning, The GALAH survey started in early 2014 is currently about 25% complete. We present a description of the motivating science; an overview the instrument; and a status report on GALAH Survey.

9908-50, Session 11

DESI: design considerations for a massive redshift survey

David J. Schlegel, Lawrence Berkeley National Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs.

DESI will measure redshifts for 35 million galaxies and 2.5 million quasars over a survey footprint of 14,000 square degrees. The focal plane is required to cover 8 square degrees in each exposure in order to map the full survey footprint.

5000 fiber positioners are required for multiplexing a sufficient number of targets in each DESI exposure. Each of 10 spectrographs split the light into 3 cameras to retain high throughput over a wavelength range spanning 360 nm to 980 nm. The blue wavelengths are designed to provide mapping of the Lyman-alpha forest at redshifts at z>2, and the red wavelengths are designed to obtain galaxy redshift to z=1.6. A resolving power of 2000 in the blue extracts most of the information from the Lyman-alpha forest. A resolving power of 5000 in the red is required to measure emission lines from galaxies between the much brighter terrestrial sky lines. This broad wavelength coverage is also required for high redshift success rates with minimal contamination of the maps with incorrect redshifts. The wide field of view, 5000-fiber multiplexing, high throughput, and an instrument reconfiguration time of one minute will allow the key project to complete in 5 years.

DESI will provide an order of magnitude improvement over previous redshift surveys in both the number of galaxies and the volume of space that is probed. This will significantly advance our understanding of the expansion history of the Universe and the effects of Dark Energy.

9908-51, Session 11

Design of the DESI focal plane system

Joseph H. Silber, Lawrence Berkeley National Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We describe here the Focal Plane System, which contains the 5000 robotic fiber positioners, 6 guide cameras, 4 wavefront cameras, 120 fiducial point sources, and a metrology camera, mounted at the primary mirror, which surveys the precise positions of these items for every observation. The system has 365,135 moving parts, and 778,709 parts total. The density of the instrument is such that 99.96% of these parts are contained within an envelope volume of only 0.4 m?. We explain here the overall architecture, the functions and interfaces of each of the subcomponents, and integration and operation of the system. The instrument will be constructed in 2017, and commissioned in 2018.

9908-52, Session 11

Hector: a massive new IFU instrument for the Anglo-Australian Telescope

Julia J. Bryant, The Univ. of Sydney (Australia) and Australian Astronomical Observatory (Australia); Joss Bland-Hawthorn, The Univ. of Sydney (Australia); Jonathan S. Lawrence, Warrick Couch, Australian Astronomical Observatory (Australia); Scott Croom, The Univ. of Sydney (Australia); Will Saunders, Robert Content, Julia Tims, Nicholas F. Staszak, Sudharshan Venkatesan, Australian Astronomical Observatory (Australia); Jesse van de Sande, The Univ. of Sydney (Australia); Ross Zhelem, Australian Astronomical Observatory (Australia)

Hector will be the new massively-multiplexed integral field instrument for the Anglo-Australian Observatory in Australia and the next main dark-time instrument for the observatory. Based on the success of the SAMI instrument, which is undertaking a large 3400-galaxy survey, the IFU imaging fibre bundle (hexabundle) technology under-pinning SAMI is being improved to a new innovative design. The distribution of hexabundle angular sizes is matched to the galaxy survey properties in order to image 90% of galaxies out to 2 effective radii. 50-100 of these IFU imaging bundles will be positioned by `Starbug' robots across a new 3-degree field top end to be purpose-built for the AAT. Many thousand fibres will then be fed into new replicable spectrographs.

Fundamentally new science will be achieved compared to existing instruments due to Hector's wider field of view (3 degrees), high positioning efficiency using starbugs, higher spectroscopic resolution (R=3000-5500 from 3727-7761 Angstroms, with a possible redder extension later) and large IFUs (up to 30" diameter with 61-217 fibre cores).

Hector will decipher the diversity of galaxies through understanding their individuality.

A 100,000 galaxy IFU survey will decrypt how the accretion and merger history and large-scale environment made every galaxy different in its morphology and star formation history.

The high resolution, particularly in the blue, will make Hector the only instrument to be able to measure higher-order kinematics for galaxies down to much lower velocity dispersion than in current large IFU galaxy surveys, opening up a wealth of new nearby galaxy science.

The science requirements are complete and both the spectrograph design and the 3 degree field top end optical and mechanical design have reached concept design review stage. The adaptation of single-fibre starbugs to now hold a larger fibre bundle is also underway. Hector is targeted for completion in ~2020.

9908-53, Session 11

Final design and progress of WEAVE: the next generation wide-field spectroscopy facility for the William Herschel Telescope

Gavin B. Dalton, Univ. of Oxford (United Kingdom) and STFC Rutherford Appleton Lab. (United Kingdom); Scott C. Trager, Univ. of Groningen (Netherlands); Jose Alphonso López Aguerri, Instituto de Astrofísica de Canarias (Spain); Piercarlo Bonifacio, Observatoire de Paris à Meudon (France); Antonella Vallenari, INAF - Osservatorio Astronomico di Padova (Italy); Don Carlos Abrams, Isaac Newton Group of Telescopes (Spain); Kevin F. MIddleton, STFC Rutherford Appleton Lab. (United Kingdom); Esperanza E. Carrasco-Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Chris R. Benn, Isaac Newton Group of Telescopes (Spain); Kevin Dee, Isaac Newton Group of Telescopes (Spain) and Univ. of Oxford (United Kingdom); Frédéric N. Sayède, Observatoire de Paris à Meudon (France); Ian J. Lewis, Univ. of Oxford (United Kingdom); Johan H. Pragt, NOVA Optical Infrared Instrumentation Group (Netherlands); Sergio Picó Rueda, Isaac Newton Group of Telescopes (Spain); Nicholas A. Walton, Univ. of Cambridge (United Kingdom); Jeurg Rey, Isaac Newton Group of Telescopes (Spain); Carlos Allende Prieto, Instituto de Astrofísica de Canarias (Spain); Émilie Lhome, Isaac Newton Group of Telescopes (Spain); Tibor Agócs, ASTRON (Netherlands); David L. Terrett, STFC Rutherford Appleton Lab. (United Kingdom); Matthew Brock, James Gilbert, Univ. of Oxford (United Kingdom); Andrew W. Ridings, Isaac Newton Group of Telescopes (Spain); Mark A. W. Verheijen, Univ. of Groningen (Netherlands); Ian A. J. Tosh, Kevin Rogers, STFC Rutherford Appleton Lab. (United Kingdom); Iain A. Steele, Liverpool John Moores Univ. (United Kingdom); Sun-Jeong Ham, Univ. of Oxford (United Kingdom); Remko Stuik, Gabby Aitink-Kroes, ASTRON (Netherlands); Niels Tromp, NOVA Optical Infrared Instrumentation Group (Netherlands); Attila Jaskó, Konkoly Observatory (Hungary); Jan W. Kragt, ASTRON (Netherlands); Dirk Lesman, NOVA Optical Infrared Instrumentation Group (Netherlands); Christopher J. Mottram, Stuart D. Bates, Liverpool John Moores Univ. (United Kingdom); Frank James H. Gribbin, Isaac Newton Group of Telescopes (Spain); José Peñate Castro, José Alonso Burgal, José Miguel Herreros Linares, Jose Miguel Delgado Hernandez, José Vicente Gigante, Instituto de Astrofísica de Canarias (Spain); Carlos Martín, Diego Cano Infantes, Isaac Newton Group of Telescopes (Spain); Ramón Navarro, NOVA Optical Infrared Instrumentation

Group (Netherlands); Michael J. Irwin, James R. Lewis, Eduardo Gonzalez-Solares, Univ. of Cambridge (United Kingdom); Neil O'Mahoney, Isaac Newton Group of Telescopes (Spain); Andrea Bianco, INAF - Osservatorio Astronomico di Brera (Italy); Christina Zurita, Instituto de Astrofísica de Canarias (Spain); Rik ter Horst, ASTRON (Netherlands); Emilio Molinari, Jose Guerra Sr., Marcello Lodi, Telescopio Nazionale Galileo (Spain); Bernardo Salasnich, INAF - Osservatorio Astronomico di Padova (Italy); Hiddo Hannenburg, Eddy Elswijk, Menno de Haan, ASTRON (Netherlands); Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Szigfrid Farkas, Konkoly Observatory (Hungary); Ellen Schallig, Univ. of Oxford (United Kingdom); Lilian Domínquez Palmero, Ceclila Fariña, Isaac Newton Group of Telescopes (Spain); Vanessa Hill, Observatoire de la Côte d'Azur (France); Dan Smith, Janet Drew, Univ. of Hertfordshire (United Kingdom); Mat Pieri, Lab. d'Astrophysique de Marseille (France); Bianca Poggianti, INAF - Osservatorio Astronomico di Padova (Italy); Shoko Jin, Univ. of Groningen (Netherlands)

We present the Final Design of the WEAVE next-generation spectroscopy facility for the William Herschel Telescope (WHT), together with a status update on the details of manufacturing, integration and the overall project schedule now that all the major fabrication contracts are in place. We also present a summary of the current planning behind the 5-year initial phase of survey operations. WEAVE will provide optical ground-based follow up of ground-based (LOFAR) and space-based (Gaia) surveys. WEAVE is a multi-object and multi-IFU facility utilizing a new 2-degree prime focus field of view at the WHT, with a buffered pick-and-place positioner system hosting 1000 multi-object (MOS) fibres, 20 integral field units, or a single large IFU for each observation. The fibres are fed to a single (dual-beam) spectrograph, with total of 16k spectral pixels, located within the WHT GHRIL enclosure on the telescope Nasmyth platform, supporting observations at R~5000 over the full 370-1000nm wavelength range in a single exposure, or a high resolution mode with limited coverage in each arm at R~20000. The project is now in the manufacturing and integration phase with first light expected for the end of 2017.

9908-54, Session 12

VIRUS: first deployment of the massively replicated fiber integral field spectrograph for the upgraded Hobby-Eberly Telescope

Gary J. Hill, Sarah E. Tuttle, Brian L. Vattiat, Hanshin Lee, Niv Drory, The Univ. of Texas at Austin (United States); Andreas Kelz, Leibniz-Institut für Astrophysik Potsdam (Germany); Jason Ramsey, The Univ. of Texas at Austin (United States); Darren L. DePoy, Jennifer L. Marshall, Texas A&M Univ. (United States); Karl Gebhardt, Taylor S. Chonis, The Univ. of Texas at Austin (United States); Gavin B. Dalton, Univ. of Oxford (United Kingdom); Daniel Farrow, Max-Planck-Institut für extraterrestrische Physik (Germany); John M. Good, The Univ. of Texas at Austin (United States); Dionne M. Haynes, Leibniz-Institut für Astrophysik Potsdam (Germany); Briana L. Indahl, The Univ. of Texas at Austin (United States); Thomas Jahn, Leibniz-Institut für Astrophysik Potsdam (Germany); Hermanus Kriel, The Univ. of Texas at Austin (United States); Francesco Montesano, Max-Planck-Institut für extraterrestrische Physik (Germany); Harald Nicklas, Georg-August-Univ. Göttingen (Germany); Eva Noyola, The Univ. of Texas at Austin (United States); Travis Prochaska, Richard D. Allen, Texas A&M Univ. (United States); Guillermo Blanc, Carnegie Observatories (United States); Maximilian H. Fabricius, Max-Planck-Institut für extraterrestrische Physik (Germany); Martin Landriau, Phillip J. MacQueen, The Univ. of Texas at Austin (United States); Martin M. Roth, Leibniz-Institut für Astrophysik Potsdam (Germany); Richard Savage, The Univ. of Texas at Austin (United States); Jan M. Snigula, Max-Planck-Institut für extraterrestrische Physik (Germany)

The Visible Integral-field Replicable Unit Spectrograph (VIRUS) consists of 156 identical spectrographs (arrayed as 78 pairs) fed by 35,000 fibers, each 1.5 arcsec diameter, at the focus of the upgraded 10 m Hobby-Eberly Telescope (HET). VIRUS has a fixed bandpass of 350-550 nm and resolving power R~700. VIRUS is the first example of industrial-scale replication applied to optical astronomy and is capable of surveying large areas of sky, spectrally. The VIRUS concept offers significant savings of engineering effort, cost, and schedule when compared to traditional instruments.

The main motivator for VIRUS is to map the evolution of dark energy for the Hobby-Eberly Telescope Dark Energy Experiment (HETDEX), using 0.8M Lyman-alpha emitting galaxies as tracers. The VIRUS array is undergoing staged deployment during 2016. It will provide a powerful new facility instrument for the HET, well suited to the survey niche of the telescope, and will open up large spectroscopic surveys of the emission line universe for the first time. We will review the production, lessons learned in reaching volume production, characterization and first deployment of this massive instrument.

9908-55, Session 12

VIRUS early installation and commissioning

Gary J. Hill, Brian L. Vattiat, Hanshin Lee, Niv Drory, Sarah E. Tuttle, The Univ. of Texas at Austin (United States); Andreas Kelz, Leibniz-Institut für Astrophysik Potsdam (Germany); Jason Ramsey, Trent W. Peterson, The Univ. of Texas at Austin (United States); Eva Noyola, The Univ. of Texas as Austin (United States); Darren L. DePoy, Jennifer L. Marshall, Texas A&M Univ. (United States); Taylor S. Chonis, The Univ. of Texas at Austin (United States); Gavin B. Dalton, Univ. of Oxford (United Kingdom); Maximilian H. Fabricius, Max-Planck Institut fur Extraterrestrische Physik (Germany); Daniel Farrow, Max-Planck Institut fur Extraterrestrische Physik (Germany); John M. Good, The Univ. of Texas at Austin (United States); Dionne M. Haynes, Leibniz-Institut für Astrophysik Potsdam (Germany); Briana L. Indahl, The Univ. of Texas at Austin (United States); Thomas Jahn, Leibniz-Institut für Astrophysik Potsdam (Germany); Hermanus Kriel, The Univ. of Texas at Austin (United States); Harald Nicklas, Georg-August-Univ. Göttingen (Germany); Francesco Montesano, Max-Planck Institut fur Extraterrestrische Physik (Germany); Travis Prochaska, Richard D. Allen, Texas A&M Univ. (United States); Martin Landriau, Phillip J. MacQueen, The Univ. of Texas at Austin (United States);

Martin M. Roth, Leibniz-Institut für Astrophysik Potsdam (Germany); Richard Savage, The Univ. of Texas at Austin (United States); Jan M. Snigula, Max-Planck-Institut für extraterrestrische Physik (Germany)

VIRUS is a massively replicated spectrograph built for HETDEX, the Hobby Eberly Telescope Dark Energy Experiment. It consists of 156 channels within 78 units fed by 34944 fibers over the 22 arcminute field of the upgraded HET. VIRUS covers a relatively narrow bandpass (350-550nm) at low resolution (R~700) to target the emission of Lyman-alpha emitters (LAEs) for HETDEX. VIRUS is a first demonstration of industrial style large scale assembly line replication in optical astronomy.

Installation and testing of VIRUS units began in November of 2015. This winter we celebrated the first on sky instrument activity of the upgraded HET, using a VIRUS unit and LRS2-R (the upgraded facility Low Resolution Spectrograph for the HET). Here we describe progress in VIRUS installation and commissioning through June 2016. We walk through achievements of each installation batch, including integration and testing of the VIRUS enclosures via long-term vacuum and temperature performance. We include early sky data obtained to characterize spectrograph performance and on sky performance of the newly upgraded HET. As part of the instrumentation for first science light at the HET, the IFU fed spectrographs were used to test a full range of telescope system functionality including the field calibration unit (FCU). We also use placement of strategic IFUs to map the new HET field to the fiber placement, and demonstrate actuation of the dithering mechanism key to HETDEX observations.

9908-56, Session 12

EMIR at the GTC: results on the commissioning at the telescope

Francisco Garzón López, Instituto de Astrofísica de Canarias (Spain) and Univ. de La Laguna (Spain); Maria Barreto, Miguel Núñez Cagigal, Nieves Castro-Rodríguez, Patricia Fernández Izquierdo, Maider Insausti, Pablo L. López, Elena Manjavacas, Angel Mato, Matteo Miluzio, Heidy Moreno Arce, Jesús Patrón Recio, Josefina Rosich Minguell, Instituto de Astrofísica de Canarias (Spain); Jordi Molgó Sendra, Gran Telescopio de Canarias, S.A. (Spain); Peter Hammersley, European Southern Observatory (Germany); Sergio Pascual Ramirez, Nicolás Cardiel, Univ. Complutense de Madrid (Spain)

We report the results on the EMIR performances after the commissioning period of the instrument at the GTC. EMIR is one of the first common user instruments for the GTC, the 10 meter telescope operating at the Roque de los Muchachos Observatory (La Palma, Canary Islands, Spain). EMIR is being built by a Consortium of Spanish and French institutes led by the Instituto de Astrofi?sica de Canarias (IAC). EMIR is primarily designed to be operated as a MOS in the K band, but offers a wide range of observing modes, including imaging and spectroscopy, both long slit and multiobject, in the wavelength range 0.9 to 2.5 ?m. The development and fabrication of EMIR is funded by GRANTECAN and the Plan Nacional de Astronomi?a y Astrofi?sica (National Plan for Astronomy and Astrophysics, Spain).

After an extensive and intensive period of system verification at the IAC, EMIR is shipped to the GTC for its integration at the Nasmyth platform. Once in the observatory, many tests are being conducted to ensure the functionality of EMIR at the telescope, in particular that of the ECS (EMIR Control System) which has to be fully embedded into the GCS (GTC Control System) so as to become an integral part of it. During the commissioning, the main capabilities of EMIR and its combined operation with the GTC are tested and the ECS are modified to its final form. This contribution reports on the details of the EMIR operation at the GTC obtained so far.

9908-57, Session 12

MEGARA, the new intermediate-resolution optical IFU and MOS for GTC: getting ready for the telescope

Armando Gil de Paz, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain); Francisco Manuel Sánchez-Moreno, Univ. Politécnica de Madrid (Spain); María Luisa García Vargas, FRACTAL S.L.N.E (Spain); Xabier Arrillaga Echaniz, AVS Added Value Industrial Engineering Solution S.L.U. (Spain); José Luis Avilés Urbiola, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Nicolás Cardiel, Univ. Complutense de Madrid (Spain); Miguel Ángel Carrera Astigarraga, AVS Added Value Industrial Engineering Solution S.L.U. (Spain); Edgar Castillo-Domínguez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); África Castillo Morales, Univ. Complutense de Madrid (Spain); Raquel Cedazo, Univ. Politécnica de Madrid (Spain); Jesús Manuel de la Cruz García, Segundo Esteban San Román, Univ. Complutense de Madrid (Spain); Daniel Ferrusca Rodriguez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Pedro Gómez-Álvarez, FRACTAL S.L.N.E (Spain); Rafael Izazaga-Pérez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Bertrand B. L. Lefort, FRACTAL S.L.N.E (Spain); José Antonio López Orozco, Univ. Complutense de Madrid (Spain); Manuel Maldonado Medina, Ismael Martínez Delgado, FRACTAL S.L.N.E (Spain); Isaac Morales Durán, Instituto de Astrofísica de Andalucía (Spain); Emma Mujica-Alvarez, FRACTAL S.L.N.E (Spain); Gonzalo Páez, Ctr. de Investigaciones en Óptica, A.C. (Spain); Sergio Pascual Ramirez, Univ. Complutense de Madrid (Spain); Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain); Pablo Picazo, Ainhoa Sánchez-Penim, Univ. Complutense de Madrid (Spain); Ernesto Sánchez-Blanco, Simon M. Tulloch, FRACTAL S.L.N.E (Spain); Miguel Velázquez de la Rosa, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); José M. Vílchez, Instituto de Astrofísica de Andalucía (Spain); Jaime Zamorano Calvo, Univ. Complutense de Madrid (Spain)

MEGARA is the new optical spectrograph for the 10.4m GTC telescope that will soon offer to the community Integral-Field Unit (IFU) and Multi-Object Spectroscopy (MOS) capabilities within the entire optical window (360nm-970nm) with resolutions ranging from R=6000 to R=20000. MEGARA will be installed at GTC before the end of 2016.

The MEGARA IFU (also called the Large Compact Bundle) fully covers an area of 12.5 x 11.3 arcsec^2 with hexagonal spaxels of 0.62" arcsec in diameter while the MOS is composed by a total of 92 robotic positioners (with each positioner equipped with a 7-spaxel mini-IFU) that move independently within overlapping patrol areas that all together cover an area of 3.5 x 3.5 arcmin^2, i.e. the flat and non-vignetted Field-of-View of the GTC Folded-Cass focus. The light is conducted by means of optical fibers to the MEGARA spectrograph that is kept static on the Nasmyth platform of GTC. Thanks to the use of high-efficiency optical fibers, state-

of-the-art VPH gratings and detector and to the large(st) collecting area of GTC, MEGARA will be unique for carrying out chemo-dynamical studies of very faint targets, both point-like and extended. The instrument is now in AIV phase at the LICA laboratory of the Universidad Complutense de Madrid and it will be shipped to GTC this upcoming November.

MEGARA is being developed by a Consortium of institutions led by the Universidad Complutense de Madrid (UCM) but also includes the Instituto Nacional de Astrofísica, Óptica y Electrónica (INAOE, Mexico), the Instituto de Astrofísica de Andalucía (IAA-CSIC, Spain) and the Universidad Politécnica de Madrid (UPM, Spain). The instrument is financed by GRANTECAN S.A. (the public company in charge of the operation of GTC) and by the Consortium institutions.

In this talk I will present the main characteristics of the instrument and provide details on the status and results of the AIV phase, both at subsystem and already at system level. Laboratory acceptance is scheduled for September 2016.

9908-58, Session 12

MIRADAS for the Gran Telescopio Canarias: overview

Stephen S. Eikenberry, Steven Nicholas Raines, Richard Deno Stelter, Alan Garner, Yigit Dallilar, Kendall Ackley, John G. Bennett, Charles H. Murphey, Paola Miller, David Tooke, Luke Williams, Brian Chinn, Scott A. Mullin, Sidney L. Schofield, Craig D. Warner, Frank Varosi, Bo Zhao, Sophia A. Eikenberry, Claudia Vega, Hipatia Veronica Donoso, Univ. of Florida (United States); Josep Sabater, José María Gómez, Jordi Torra, Univ. de Barcelona (Spain); Josefina Rosich Minguell, Francisco Garzón López, Instituto de Astrofísica de Canarias (Spain); Nicolás Cardiel, Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Antonio Marín-Franch, Ctr. de Estudios de Física del Cosmos de Aragón (Spain); Julio Galipienzo, Miguel Ángel Carrera Astigarraga, AVS Added Value Industrial Engineering Solution S.L.U. (Spain); Greg J. Fitzgerald, Ian Prees, Todd M. Stolberg, Peter A. Kornik, New England Optical Systems (United States); Anamparambu N. Ramaprakash, Mahesh P. Burse, Sujit P. Punnadi, Inter-Univ. Ctr. for Astronomy and Astrophysics (India)

MIRADAS (Mid-resolution InfRAreD Astronomical Spectrograph) is the facility near-infrared multi-object echelle spectrograph for the Gran Telescopio Canarias (GTC) 10.4-meter telescope. MIRADAS operates at spectral resolution R=20,000 over the 1-2.5μm bandpass), and provides multiplexing (up to N=12 targets) and spectro-polarimetry. The MIRADAS consortium includes the University of Florida, Universidad de Barcelona, Universidad Complutense de Madrid, Instituto de Astrofísica de Canarias, Institut d'Estudis Espacials de Catalunya and Universidad Nacional Autonoma de Mexico, as well as partners at A-V-S (Spain), New England Optical Systems (USA), and IUCAA (India). MIRADAS completed its Final Design Review in 2015, and in this paper, we review the current status and overall system design for the instrument, with scheduled delivery in 2018. We particularly emphasize key developments in cryogenic robotic probe arms for multiplexing, a macro-slicer mini-IFU, an advanced cryogenic spectrograph optical system, and a SIDECAR-based array control system for the 1x2 HAWAII-2RG detector mosaic.

9908-59, Session 13

Prime Focus Spectrograph (PFS) for Subaru Telescope: overview, recent progresses, and future perspectives

Naoyuki Tamura, Kavli Institute for the Physics and Mathematics of the Universe (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Atsushi Shimono, Yuki Moritani, Kiyoto Yabe, Kavli Institute for the Physics and Mathematics of the Universe (Japan); Akitoshi Ueda, National Astronomical Observatory of Japan (Japan); Hitoshi Murayama, Kavli Institute for the Physics and Mathematics of the Universe (Japan) and Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. Murray, Durham Univ. (United Kingdom)

PFS (Prime Focus Spectrograph), a next generation facility instrumentis on the 8.2m Subaru Telescope, is a very wide-field, massively multiplexed, and optical & near-infrared (NIR) spectrograph.

Exploiting the Subaru prime focus, 2400 reconfigurable fibers will be distributed in the 1.3 deg field of view. The spectrograph has been designed to cover a wide range of wavelengths simultaneously from 380nm to 1260nm at one exposure.

On the Subaru Telescope, Hyper Suprime-Cam (HSC), a very wide-field imager on the prime focus, has already been in science operation and a 5-years survey program in the framework of Subaru Strategic Program (SSP) is on-going. PFS and HSC are in fact the instrumentation projects under the Subaru Measurement of Images and Redshifts (SuMIRe) project to conduct deep and wide sky surveys exploiting the unique capability of the Subaru Telescope. PFS is therefore expected to start in a timely manner subsequently after the HSC SSP survey. It should be emphasized that HSC and PFS enable deep imaging and spectroscopic surveys of the same patches of sky using the same 8.2m telescope, allowing one to have good understandings of various systematics that should be considered for physical interpretations of the data.

The PFS instrument consists of a few subsystems. The Prime Focus Instrument (PFI) will be installed in the same Prime Focus housing unit "POpt2" with the Wide Field Corrector (WFC) lens system mechanically integrated (i.e. WFC will be used for PFS as well as HSC). PFI accommodates the fiber posioner system which populates 2394 science fibers on the focal plane with the "Cobra" actuators. In the process of configuring fibers to science targets on sky, all the science fibers and fiducial fibers will be backlit and then the fiber tips will be imaged all at one exposure from the Cassegrain port by the Metrology Camera System

(MCS), which enables quick fiber configuration. The Spectrograph System (SpS) will receive the light tranmitted in the fiber system from the prime focus and deliver their spectral images on the detectors. SpS has four identical modules each of which will accept 600 fibers. Using the two dichroic mirrors, the beam from the pseudo fiber slit will be split into the blue, red, and NIR cameras. The fiber system is devided into three sections via the two sets of fiber connectors both are of contact type. While the middle section will permanently stay on the telescope, either side is a part of PFI or SpS.

The development of this instrument has been undertaken by the international collaboration at the initiative of Kavli IPMU. The project is now going into construction, integration and test aiming at starting system integration in 2017, engineering operations in 2018, and science operation from 2019. In parallel, detailed modeling of the instrument and output spectral images activities of instrument and data modeling are on-going in order to are on-going in order to characterize the instrument on-sky capabilities and accordingly mature the SSP survey design. In this contribution, an overview of the instrument, current project status and future perspectives will be presented.

9908-60, Session 13

MOONS: towards the VLT's next generation of multi-object spectrograph

When MOONS arrives at the VLT in a few years time it will provide the European community with a revolutionary new tool to tackle a wide range of Galactic, extragalactic and cosmological questions. This remarkable instrument will simultaneously deliver ~1000 optical and near infrared spectra from across the full 500 square arcmin field of view of the VLT. In its low resolution mode (R>4000) MOONS will provide almost complete spectral coverage from 0.65 - 1.8?m, while a high resolution mode will allow detailed abundance analysis of the CaT (R~9000) and in the H-band at R~18,000. The objects are coupled to the spectrograph through optical fibres, deployed with a host of individual small robotic positioners that will provide both excellent field coverage and very fast configuration times. This paper will provide an update on the instrument's current design, with all of its evolutions, challenges and successes.

9908-61, Session 13

4MOST: the 4-metre Multi-Object Spectroscopic Telescope project at preliminary design review

Olga Bellido-Tirado, Joar G. Brynnel, Steffen Frey, Domenico Giannone, Roger Haynes, Diana Johl, Daniel Phillips, Olivier Schnurr, Jakob C. Walcher, Roland Winkler, Roelof S. de Jong, Samuel C. Barden, Leibniz-Institut für Astrophysik Potsdam (Germany); Wolfgang R. Ansorge, RAMS-CON Management Consultants (Germany); Sofia Feltzing, Lund Univ. (Sweden); Richard G. McMahon, Univ. of Cambridge (United Kingdom); Gabriella Baker, Australian Astronomical Observatory (Australia); Patrick Caillier, Ctr. de Recherche Astrophysique de Lyon (France); Tom Dwelly, Max-Planck-Institut für extraterrestrische Physik (Germany); Wolfgang Gaessler, Max-Planck-Institut für Astronomie (Germany); Olaf Iwert, European Southern Observatory (Germany); Holger G. Mandel, Landessternwarte Heidelberg (Germany); Nikolai A. Piskunov, Uppsala Univ. (Sweden); Johan H. Pragt, ASTRON (Netherlands); Nikolas A. Walton, Univ. of Cambridge (United Kingdom); Thomas Bensby, Lund Univ. (Sweden); Maria Bergemann, Max-Planck-Institut für Astronomie (Germany); Cristina Chiappini, Leibniz-Institut für Astrophysik Potsdam (Germany); Norbert Christlieb, Ruprecht-Karls-Univ. Heidelberg (Germany); Maria-Rosa Cioni, Leibniz-Institut für Astrophysik Potsdam (Germany); Simon Driver, The Univ. of Western Australia (Australia); Amina Helmi, Univ. of Groningen (Netherlands); Michael J. Irwin, Univ. of Cambridge (United Kingdom); Francisco S. Kitaura, Leibniz-Institut für Astrophysik Potsdam (Germany); Jochen Liske, Univ. Hamburg (Germany); Andrea Merloni, Max-Planck-Institut für extraterrestrische Physik (Germany); Ivan Minchev, Leibniz-Institut für Astrophysik Potsdam (Germany); Johan Richard, Ctr. de Recherche Astrophysique de Lyon (France); Else Starkenburg, Leibniz-Institut für Astrophysik Potsdam (Germany)

We present an overview and status update of the 4MOST project as presented at the Preliminary Design Review. 4MOST is a major new wide-field, high-multiplex spectroscopic survey facility under development for the VISTA telescope at the Paranal Observatory of ESO. Starting in 2021, 4MOST will deploy 2436 optical fibres in a 4.1 square degree field-of-view using a fibre positioner based on the tilting spine principle. The fibres will feed one high-resolution (R~20,000) and two medium-resolution (R~5000) spectrographs that all have fixed configuration, 3-channel designs with identical 6k x 6k CCD detectors.

The 4MOST science goals are mostly driven by a number of large area, space-based observatories of prime European interest: Gaia and PLATO (Galactic Archeology and Stellar Physics), eROSITA (High-Energy Sky), and Euclid (Cosmology and Galaxy Evolution). These main science cases drive the nine Consortium Surveys covering a large fraction of the Southern sky, with bright time mostly devoted to the Milky Way disk and bulge areas and the Magellanic Clouds, and the dark/gray time essentially devoted to extra-galactic targets. In addition there will be a significant fraction of the fibre-hours devoted to ESO Community Surveys, making 4MOST a true general-purpose survey facility, capable of delivering spectra of samples of objects that are spread over a large fraction of the sky.

The 4MOST Facility Simulator was created to show the feasibility of the innovative operations scheme of 4MOST with all surveys operating in parallel. The simulator uses the mock catalogues created by the science teams, simulates the spectral throughput and detection of the objects, assigns the fibres at each telescope pointing, creates pointing distributions across the sky and simulates a 5-year survey (including overhead, calibration and weather losses), and finally does data quality analyses and computes the science Figure-of-Merits to assess the quality of science produced. The simulations prove the full feasibility of running different surveys in parallel.

9908-64, Session 13

Mauna Kea Spectrographic Explorer (MSE): conceptual design of multi-object high resolution spectrograph

Kai Zhang, Yongtian Zhu, Zhongwen Hu, Nanjing Institute of Astronomical Optics & Technology (China)

The Maunakea Spectroscopic Explorer (MSE) project will transform the CFHT 3.6m optical telescope into a 10m class dedicated multi-object spectroscopic facility, with an ability to simultaneously measure thousands of objects with a spectral resolution range spanning 2,000 to 40,000. MSE will develop two spectrographic facilities to meet the science requirements. These are, respectively, the Low/Medium Resolution spectrographs (LMRS) and High Resolution spectrographs (HRS). Multi-object high resolution spectrographs with total of 1156 fibers is big challenge, one that has never been attempted for a 10m class telescope. To date, most of spectral survey facilities over the world work in single order low/medium resolution mode, and only a few Wide Field Spectrographs (WFS) provide a cross-dispersion high resolution mode with a limited number of orders. Nanjing Institute of Astronomical Optics and Technology proposes a conceptual design with the use of novel image slicer arrays and single order immersed VPH grating for MSE HR Multi-Object Spectrographs (MOS). The conceptual scheme contains three identical fiber-link spectrographs, each of which simultaneously covers two restricted (about 20nm) bands in the optical regime, with a spectral resolution of 38000 – 42000. The details of the design will be given in this paper.

9908-65, Session 13

ULTIMATE: a deployable multiple integral field unit for Subaru

Simon Ellis, Andrew I. Sheinis, Ross Zhelem, David M. Brown, Christopher Lidman, Australian Astronomical Observatory (Australia); David Nataf, Andy Casey, The Australian National Univ. (Australia); Pascal Xavier, Julia Tims, Nicholas F. Staszak, Jonathan S. Lawrence, Australian Astronomical Observatory (Australia); Julia J. Bryant, Australian Astronomical Observatory (Australia) and The Univ. of Sydney (Australia); Robert Sharp, The Australian National Univ. (Australia); Peter R. Gillingham, Australian Astronomical Observatory (Australia)

ULTIMATE is an instrument concept under development for the Subaru Telescope, which will have the unique combination of ground layer adaptive optics feeding multiple deployable integral field units. This will give ULTIMATE a unique parameter space, in terms of number of IFUs and spatial resolution, enabling science cases such as the evolution of galaxies at z~0.5 to 1.5, and the dark matter content of the inner part of our Galaxy.

ULTIMATE will use Starbugs to position between 7 and 13 IFUs over a 14 x 8 arcmin field-of-view, provided by a new wide-field corrector. Each IFU will consist of a fore-optics feeding a 61 element hexagonally packed microlens array, providing a pupil image onto a fibre array. These components will be housed in a Starbug positioner, a semi autonomous robotic positioner, that moves over a field plate at the f/12 Cassegrain focus. All Starbugs can be positioned simultaneously, to an accuracy of better than 5 milli-arcsec within the typical slew-time of the telescope, allowing for very efficient re-configuration between observations. Each microlens will subtend 0.15 arcsec on the sky.

The IFUs will feed either the nuMOIRCS or the PFS spectrographs, or both. The fibres will form a pseudo-slit inside the spectrograph dewar, via a vacuum feed-through, to minimise thermal emission. The image from each fibre will be relayed onto the spectrograph slit proper. For the

NIR nuMOIRCS spectrograph we are investigating the possibility of using ZBLAN fibres to provide spectroscopy over the full J,H and K bands. In particular, ZrF4 fibres are now available which have better than 90% transmission over the full J, H and K bands for a 30m length, and 98% transmission at 2.5 microns, and FRD properties commensurable with silica fibres. The handling of such fibres, and end-face treatment, remain issues to be further investigated. Future possible upgrades include the possibilty of OH suppression using fibre Bragg gratings.

9908-184, Session 13

Feasibility study of GMOX: a next-generation instrument for Gemini

Massimo Robberto, Space Telescope Science Institute (United States) and Johns Hopkins Univ. (United States); Stephen A. Smee, Robert H. Barkhouser, Johns Hopkins Univ. (United States); Zoran Ninkov, Rochester Institute of Technology (United States); Mario Gennaro, Space Telescope Science Institute (United States); Timothy M. Heckman, Johns Hopkins Univ. (United States)

We present the feasibility study of GMOX, the Gemini Multi-Object eXtra-wide-band spectrograph, funded to help Gemini craft the requirements for the next facility instrument (Gen~4#3). We envision GMOX as a spectrograph covering the entire optical/near-IR wavelength range accessible from the ground (from 3500 A in the U-band up to 2.4 micron in the K-band) with nominal resolving power R~5,000, adequate to mitigate the effect of telluric airglow lines. Using existing Digital Micromirror Device (DMD) technology, GMOX can simultaneously acquire hundreds of spectra of faint sources in crowded fields with unparalleled spatial resolution. GMOX optimally adapts to both seeing-limited and diffraction-limited conditions provided by ALTAIR and GeMS at Gemini North and South, respectively. On a large fraction of nights, these systems deliver nearly diffraction-limited imaging in the near-IR (lambda/D=50 mas at 2micron) and exquisite, seeing-limited images across the visible. Fed by GeMS (f/33), GMOX can synthesize slits as small as 40mas (corresponding to a single HST/WFC3 CCD pixel) over its entire 85.2x45.2 arcsec field of view, reaching the ultimate sensitivity to point sources while resolving structures smaller than 300 pc across the observable Universe. Both the slit and field size double at the native f/16 focal ratio of Gemini. Leveraging on studies to bring DMD technology to fruition for future space missions, GMOX can deliver unique science and superior performance at a lower cost than any competing IFU or multi-slit spectrograph.

9908-62, Session PS5

Optical design of MEMS-based infrared multi-object spectrograph concept for the Gemini South Telescope

Shaojie Chen, Suresh Sivanandam, Dae-Sik Moon, Univ. of Toronto (Canada)

We discuss the optical design of an infrared multi-object spectrograph concept that is designed to take advantage of the multi-conjugate adaptive optics (MCAO) corrected field at the Gemini South telescope. This design employs a unique, cryogenic MEMS-based focal plane mask, a Micro-Shutter Array (MSA) that has been developed for the Near Infrared Spectrometer of the James Webb Space Telescope, to select target objects for spectroscopy. Our optical design is based on all spherical refractive optics, which serves both imaging and spectral modes across the wavelength range of 0.9-2.5 μm. The optical system consists of a reimaging system, the MSA, a collimator, volume phase holographic (VPH) grisms, and spectrograph camera optics. The VPH grisms, which are VPH gratings sandwiched between two prisms, provide high dispersing efficiencies, while a set of four different VPH grisms provide the broad spectral coverage at high throughputs. The imaging mode is implemented by removing the MSA and the dispersing unit out of the beam. We optimize both the spectrographic and imaging modes simultaneously, while paying special attention to the performance of the pupil imaging at the cold stop. Our current design provides a 1' ? 1' and a 0.5' ? 1' field of views for imaging and spectral modes, respectively, on a 2048 ? 2048 pixel HAWAII-2RG detector array. Its slit width and spectral resolving power are 0.18" and 3,000, respectively, and spectra of up to 100 objects can be obtained simultaneously. We present the results of simulated performance of this spectrograph's optical design.

9908-287, Session PS5

Performance characteristics of a suite of volume phase holographic gratings produced for the Subaru prime focus spectrograph

James Arns, Kaiser Optical Systems, Inc. (United States)

The Subaru Prime Focus Spectrograph requires a suite of volume phase holographic (VPH) gratings that parse the observational spectrum into three sub-spectral regions. In addition, the red region has second, a higher resolution design. This paper describes the specifications of the four grating types, gives the expected theoretical performances of diffraction efficiency for the production designs and presents the actual measured performances on the production gratings.

The three spectral regions cover the overall range from 380 nm (blue) into the near infrared at 1260 nm. Four gratings each of four different grating designs were manufactured for the Subaru PFS for a total of sixteen gratings. The lowest grating deigns operate from 380 to 650 nm, the next from 630 to 970 nm and the highest from 940 to 1260 nm. This paper shows the RCWA theoretical predictions for each of the designs and presents the test data for each of the gratings built.

9908-288, Session PS5

The Dark Energy Spectroscopic Instrument (DESI) instrument mechanism control systems

Carl T. Coker, Daniel P. Pappalardo, Richard W. Pogge, Paul Martini, Mark A. Derwent, Thomas P. O'Brien, Klaus Honscheid, The Ohio State Univ. (United States); Michael E. Levi, Lawrence Berkeley National Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14,000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5,000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the design details of the spectrograph mechanism control system. Each spectrograph has a stand-alone mechanism control system that operates the unit's four remotely-operated mechanisms (two shutters and two Hartmann doors), including an inflatable shutter seal and fiber illumination system, and provides a suite of temperature and humidity sensors. Each control system is highly modular, and is operated by a dedicated on-board Linux computer to provide all of the control and monitoring functions. We describe our solution for integrating a number of network-connected devices within each unit spectrograph, and describe the basic software architecture.

9908-289, Session PS5

Fusion splicing: a novel approach to fiber connections for the Dark Energy Spectroscopic Instrument

Parker Fagrelius, Lawrence Berkeley National Lab. (United States); Claire L. Poppett, Univ. of California, Berkeley (United States); Jerry Edelstein, Space Sciences Lab. (United States) and Univ. of California, Berkeley (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers will run 40 meters from the focal plane to the coude ? room where they feed ten broad-band spectrographs. The focal plane assembly will be integrated independently of the spectrograph slits and long fiber cables in order to ease integration flow, and the two subsystems will be connected before final integration on the telescope. In order to retain maximum throughput and minimize the focal ratio degradation (FRD) when connecting the fiber system, we are employing fusion splicing as opposed to mechanical connectorization. For the best splice performance, the optical fibers are stripped of their polyimide coating, precision cleaved, and then fused with a heating filament. We report results from the splicing process, measuring a collimated FRD increase of less than 0.5 degrees for a f/3.9 input beam compared to >1 degree increase for mechanical connectors. We also show that the near field performance is not degraded after splicing. These results represent the first of their kind for a fiber-fed astronomical instrument.

9908-290, Session PS5

The MOONS-VLT Spectrometer: toward the final design

Ernesto Oliva, INAF - Osservatorio Astrofisico di Arcetri (Italy); Bernard-Alexis Delabre, European Southern Observatory (Germany); Andrea Tozzi, Debora Ferruzzi, INAF - Osservatorio Astrofisico di Arcetri (Italy); David Lee, UK Astronomy Technology Ctr. (United Kingdom); Ian R. Parry, Univ. of Cambridge (United Kingdom); Philip Rees II, UK Astronomy Technology Ctr. (United Kingdom)

MOONS, the Multi-Object Optical and Near-infrared Spectrograph for the VLT, is entering into the final design phase.

This paper presents and discusses the latest proposed version of the optical design of the cryogenic spectrograph. The main developements and modifications were aimed at minimizing the overall size and mass of the cryogenic spectrometer. The most remarkable new feature is the design of an extremely fast (F/0.95), light and compact (40 kg in less than 80 dm^3) camera with superbe image quality (80% encircled energy within <20 microns) over a very large field of view (9 degrees on a collimated beam of 265 mm). The camera consists of only 3 optical elements: 2 lenses and 1 mirror. All elements are made of fused-silica. The optical performances are independent on the temperature, i.e. the camera can be fully characterized at room temperatures.

9908-291, Session PS5

Slit tests for FOCCoS, PFS, Subaru

Antonio C. de Oliveira Sr., Lab. Nacional de Astrofísica (Brazil); James E. Guin Sr., Princeton Univ. (United States); Lígia Souza de Oliveira, Lucas Souza Marrara, OIO - Oliveira Instrumentação Óptica Ltda. (Brazil); Leandro Henrique dos Santos, Décio Ferreira Sr., Jesulino Bispo dos Santos Sr., Lab. Nacional de Astrofísica (Brazil); Josimar A. Rosa, Lab. Nacional de Astrofisica (Brazil); Laerte Sodré Jr., Claudia L. M. de Oliveira, Univ. de São Paulo (Brazil); Graham J. Murray, Durham Univ. (United Kingdom); Naoyuki Tamura, Atsushi Shimono, Kavli Institute for the Physics and Mathematics of the Universe (Japan) and The Univ. of Tokyo (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Yuki Moritani, Kavli Institute for the Physics and Mathematics of the Universe (Japan) and The Univ. of Tokyo (Japan)

The Fiber Optical Cable and Connector System, "FOCCoS", subsystem of the Prime Focus Spectrograph, "PFS", for Subaru telescope, is responsible to feed four spectrographs with a set of optical fibers cables. The light injection for each spectrograph is assured by a convex curved slit with a linear array of 616 optical fibers. In this paper we show tests made with a different design of a slit that ensures the right direction of the fibers by using masks of micro holes. This kind of mask is made by a technique called electroforming, which is able to produce a nickel plate with holes in a linear sequence. The precision error is around 1-?m in the diameter and 1-?m in the positions of the holes. This nickel plate may be produced with a thickness between 50 and 200 microns, so it may be very flexible. This flexibility allows the mask to be bent into the shape necessary for a curved slit. The concept requires two masks, which we call Front Mask, and Rear Mask, separated by a gap that defines the thickness of the slit. The pitch and the diameter of the holes define the linear geometry of the slit; the curvature of each mask defines the angular geometry of the slit. Tests with the prototype include FRD analysis, Absolut Transmission of the fibers, and aiming fibers error, in room temperature and low temperature.

9908-292, Session PS5

The DESI shutter with integrated fiber illumination system

Mark A. Derwent, Thomas P. O'Brien, Daniel P. Pappalardo, Paul Martini, Carl T. Coker, Richard W. Pogge, The Ohio State Univ. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the unique shutter design that incorporates a fiber illumination system into its closed blade position. When activated, the fiber illumination system directs intense 430-480nm wavelength light at the instrument's fiber slit in order to back-illuminate the telescope's focal plane and verify the location of the robotic fiber optic positioners. The back-illumination is typically active during science exposure read-outs and therefore requires the shutter to attenuate light by a factor of at least 10^9. This paper describes how we have integrated the fiber illumination system into the shutter blade, as well as incorporated an inflatable seal around the shutter aperture to achieve the light attenuation requirement. We also present lab results that characterize the fiber illumination and shutter attenuation. Finally, we discuss the control scheme that distinguishes between exposure and fiber illumination modes, and meets the shutter timing requirements.

9908-293, Session PS5

Developments in fiber positioning technology for the WEAVE instrument at the William Herschel Telescope

Ian J. Lewis, James Gilbert, Ellen Schallig, Matthew Brock, Univ. of Oxford (United Kingdom); Gavin B. Dalton, Univ. of Oxford (United Kingdom) and STFC Rutherford Appleton Lab. (United Kingdom); David L. Terrett, Kevin F. Middleton, STFC Rutherford Appleton Lab. (United Kingdom); Don Carlos Abrams, Isaac Newton Group of Telescopes (Spain); Jose Alfonso López Aguerri, Instituto de Astrofísica de Canarias (Spain); Scott C. Trager, Univ. of Groningen (Netherlands); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Piercarlo Bonifacio, Observatoire de Paris à Meudon (France); Antonella Vallenari, INAF - Osservatorio Astronomico di Padova (Italy)

As the WEAVE project for the William Herschel Telescope completes the final design review phase the fibre positioner sub-system has completed is rapidly entering its procurement and manufacturing phase. Wee present an update of the final design decisions and report on the technological prototyping that has taken place. This includes fast, accurate centre finding algorithms for fibre images, improved pick and place sequencing and flexure compensation.

9908-294, Session PS5

4MOST low-resolution spectrograph: design and performances

Florence Laurent, Observatoire de Lyon (France); Samuel C. Barden, Olga Bellido-Tirado, Leibniz-Institut für Astrophysik Potsdam (Germany); Didier Boudon, Patrick Caillier, Eric Daguisé, Observatoire de Lyon (France); Steffen Frey, Leibniz-Institut für Astrophysik Potsdam (Germany); Johan Kosmalski, Jean-Emmanuel Migniau, Arlette Pécontal-Rousset, Johan Richard, Observatoire de Lyon (France); Allar Saviauk, Leibniz-Institut für Astrophysik Potsdam (Germany)

4MOST, the 4m Multi Object Spectroscopic Telescope, is an upcoming optical, fiber-fed, MOS facility for the VISTA telescope at ESO's Paranal Observatory in Chile. Its main science drivers are in the fields of galactic archeology, high-energy physics, galaxy evolution and cosmology. The preliminary design of 4MOST features 2436 fibers split into low-resolution (1624 fibers, 370-950 nm, R > 4000) and high-resolution spectrographs (812 fibers, three arms, ~44-69 nm coverage each, R > 18000) with a fiber positioner and covering an hexagonal field of view of ~4.1 deg?. The 4MOST consortium consists of several institutes in Europe and Australia under leadership of the Leibniz-Institut für Astrophysik, Potsdam (AIP). 4MOST is currently in its Preliminary Design Phase with an expected start of science operations in 2021.

The 1600 fibres go to two Low Resolution Spectrographs with three channels per spectrograph. Each low resolution spectrograph is composed of 812 scientific fibers using 85µm core fibers at f/3, a 200mm beam for an off-axis collimator associated to its Schmidt corrector, 3 arms with f/1.73 cameras and standard 6k x 6k 15µm pixel detectors. CRAL has the responsibility of the Low Resolution Spectrographs.

In this paper, the optical design and performances of 4MOST Low Resolution Spectrograph will be presented. Special emphasis will be put on the Low Resolution Spectrograph system budget and performance analysis.

9908-295, Session PS5

Integration and testing of DESI multi-object spectrograph

Sandrine Perruchot, Observatoire de Haute-Provence (France); Aurélia Secroun, Ctr. de Physique des Particules de Marseille (France) and Aix-Marseille Univ. (France); Pierre-Eric Blanc, Samuel Ronayette, Xavier Régal, Gérard Castagnoli, Auguste Le Van Suu, Observatoire de Haute-Provence (France); Anne Ealet, Ctr. de Physique des Particules de Marseille (France) and Aix-Marseille Univ. (France); Jean-Gabriel Cuby, Lab. d'Astrophysique de Marseille (France) and Aix-Marseille Univ. (France)

The DESI project (Dark Energy Spectroscopic Instrument), under LBNL leadership, is one of the main programs of observational cosmology, which aims at understanding the nature of the "dark energy" responsible for the acceleration of the expansion of the Universe. DESI will survey more than 20 millions of objects in the sky thanks to its multi-object spectrograph fed by 5,000 robotically controlled fiber-positioners covering 360 nm to 980 nm. The DESI spectrograph, actually consisting of 10 units with 3 arms each, will be installed on the 4-m Mayall telescope at Kitt Peak in 2018.

An Aix-Marseille University consortium, bringing together three CNRS laboratories from Marseille, France, namely LAM, OHP and CPPM, has committed to deliver a fully validated spectrograph prototype, the first of a series of 10 units, with a view to validating the integration of all its constituents and the instrumental performances before building the other nine spectrographs. This validation will take place at Winlight, who is in charge of the production of the optical spectrograph near Marseille, a close combination, which is certainly an advantageous approach in terms of risk reduction. In the integration phase, all integration procedures and interfaces between constituents will be validated. During the scientific qualification phase, many performance tests will be conducted, including focus adjustment procedure and verification, image quality, spectral resolution, spectra position and size, fiber separation, thermal performance of the whole system, cross-talk between the 3 arms and between adjacent spectra, straylight, second order contamination. Additional tests will also be possible to help scientists prepare the pipeline with the evaluation of the PSF and the throughput of the spectrograph. The experience gained from the first spectrograph will allow us to optimize the "integration and qualification" process for the other nine spectrographs.

For these purposes, a dedicated test equipment taking into account both the integration and qualification phases has been defined with a view to fulfill the compliance matrix and verify the design requirements. It has lead to the development of a multi-purpose and flexible test bench, which allows to feed the fiber test slit so as to perform all the required tests. It simulates the fiber inputs incoming from the telescope, offers continuum and line sources, and it allows to adjust the flux level and to choose to illuminate one or several fibers. It is fully automated and interfaced with the global ICS system. Dedicated analysis tools have also been developed, both initial monitoring to validate the quality of the data and more specific tools according to the DESI configuration. All these developments will be described in details and first results will be presented.

9908-296, Session PS5

ProtoDESI: risk reduction experiment for the Dark Energy Spectroscopic Instrument

Parker Fagrelius, Lawrence Berkeley National Lab. (United States); Charles Baltay, Yale Univ. (United States); Christopher J. Bebek, Lawrence Berkeley National Lab. (United States); Robert W. Besuner, Space Sciences Lab. (United States) and Univ. of California, Berkeley (United States); Francisco J. Castander, Institut de Ciències de l'Espai (Spain); Arjun Dey, National Optical Astronomy Observatory (United States); Elizabeth J. Buckley-Geer, Fermi National Accelerator Lab. (United States); Ann Elliott, The Ohio State Univ. (United States); William Emmet, Yale Univ. (United States); Brenna L. Flaugher, Fermi National Accelerator Lab. (United States); Irena Gershkovich, Univ. of Michigan (United States); Klaus Honscheid, The Ohio State Univ. (United States); Richard Joyce, National Optical Astronomy Observatory (United States); Stephen Kent, Fermi National Accelerator Lab. (United States); Robert Marshall, Ronald G. Probst, National Optical Astronomy Observatory (United States); David Rabinowitz, Yale Univ. (United States); Kevin A. Reil, SLAC National Accelerator Lab. (United States); David J. Schlegel, Lawrence Berkeley National Lab. (United States); Michael S. Schubnell, Univ. of Michigan (United States); Santiago Serrano, Institut de Ciències de l'Espai (Spain); Joseph H. Silber, Lawrence Berkeley National Lab. (United States); David Sprayberry, National Optical Astronomy Observatory (United States); Gregory Tarle, Univ. of Michigan (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We describe the ProtoDESI experiment, planned for installation and commissioning at the Mayall telescope in the fall of 2016, which will test the fiber positioning system for DESI. The ProtoDESI focal plate, consisting of 8 fiber positioners, illuminated fiducials, and a guide, focus and alignment (GFA) sensor module, will be installed behind the prime focus corrector. A Fiber View Camera (FVC) will be mounted to the lower surface of the primary mirror cell and a subset of the Instrument Control System (ICS) will control the ProtoDESI subsystems, communicate with the Telescope Control System (TCS), and collect instrument monitoring data. Short optical fibers from the positioners will be routed to the back of the focal plane where they will be imaged by the Fiber Photometry Camera (FPC) or back-illuminated by a LED system. Target objects will be identified relative to guide stars, and using the GFA in a control loop with the ICS/TCS system, the guide stars will remain stable on pre-identified GFA pixels. The fiber positioners will then be commanded to the target locations and placed on the targets iteratively, using the FVC to centroid on back-illuminated fibers and fiducials to make corrective delta motions. When the positioners are aligned with the targets on-sky, the FPC will measure the intensities from the positioners' fibers and can then be dithered to look for intensity changes indicating how well the fibers were initially positioned on target centers. The final goal is to operate ProtoDESI on the Mayall telescope for a 6-hour period during one night, successfully placing targets on > 75% of the intended fibers.

9908-297, Session PS5

Integration and characterization of the cryogenic system of MEGARA

Daniel Ferrusca Rodriguez, Miriam Estefania Cisneros G., José Arturo Zenteno H., Miguel Velázquez de la Rosa, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Armando Gil de Paz, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco-Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); María Luisa García-Vargas, FRACTAL S.L.N.E (Spain); Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain)

MEGARA (Multi-Espectrógrafo en GTC de Alta Resolución para Astronomía) is an optical Integral-Field Unit and Multi-Object Spectrograph designed for the GTC (Gran Telescopio de Canarias) 10.4 m telescope in La Palma, it is expected that the spectrograph will be delivered to GTC towards the end of 2016. The LN2 open-cycle cryostat of the instrument has been designed by the "Astronomical Instrumentation Lab for Millimeter Wavelengths" at the Instituto Nacional de Astrofísica, Óptica y Electrónica (INAOE) in Mexico. According to the design, the MEGARA cryostat should have a hold time of 40 hours or more to keep operating the scientific CCD at 150 K. The cryostat has finished its fabrication and now it is on AIV phases. In this paper we summarize the cryostat integration method, the adjustment procedure of the kinematic CCD support, the tests related with its general operation at cryogenic temperatures and the thermal link behavior from the LN2 tank to the CCD mounting, as well as pressure characterization performance.

9908-298, Session PS5

Towards the cryogenic sliding mechanism for MOONS-ESO

Andrea Tozzi, Ernesto Oliva, Luca Carbonaro, Marcella Iuzzolino, INAF - Osservatorio Astrofisico di Arcetri (Italy); Philip Rees II, Jonathan Strachan, Science and Technology Facilities Council (United Kingdom)

The Multi-Object Optical and Near-Infrared Spectrograph (MOONS) shall be installed at one of the Very Large Telescopes (VLT) at the European Southern Observatory (ESO) in Paranal Chile. The instrument is being designed and built by an international consortium on behalf of ESO. The design is based on a three arms configuration, RI, YJ and H band, where RI and H have two possible resolutions. To achieve this goal it will be necessary to implement a sliding mechanism changing the dispersers, the filters and the cross dispersion prisms. This article describes the cryogenic exchanger mechanism that is under realization and the preliminary mechanical and optical tests that we have done at the cryogenic facility of Arcetri observatory of Florence. Parts of these test are based on interferometric measurements of the optics to study the behaviour of the mechanical supporting structure, and part are based on the cryogenic sliding system that will be used to move approximately 200 Kg of mass for 350 mm of travel range. The cryogenic sliding system, rails, screws, motors, is based on commercial components as the position measurement device that is based on commercial potentiometers. The results of the tests and performances at cryogenic temperature are reported in this paper.

9908-299, Session PS5

VIRUS characterization development and results from first batches of delivered units

Briana L. Indahl, Jason Ramsey, Gary J. Hill, Sarah E. Tuttle, Niv Drory, Taylor S. Chonis, Hanshin Lee, Brian L. Vattiat, Eva Noyola, Linda Elliot, Karl Gebhardt, The Univ. of Texas at Austin (United States)

The Visible Integral Field Replicable Unit Spectrograph (VIRUS), the instrument for the Hobby Eberly Telescope Dark Energy Experiment (HETDEX), consists of 78 replicable units, each with two integral field spectrographs. Each spectrograph has its own 2kx2k CCD detector with 15 micron pixels. Following alignment, the final stage prior to deployment of each unit is characterization of the 156 spectrograph channels and their CCDs. We describe the laboratory calibration system and scripting that automates this process. Both fiber and continuous (non-spatially modulated) input slits are utilized. Photon transfer curves are made to measure the gain and read noise of each CCD. Pixel flats are also made to correct for pixel-to-pixel QE variations. Throughput measurements of each unit are made using the same lab fiber bundle for consistency, and fiber profiles are characterized for later use by the Cure data reduction package. Replicable unit instruments provide a cost effective solution for scaling up instruments for large and extremely large class telescopes. Because VIRUS is the first massively replicated instrument, we have the opportunity to examine the end result of variations in the manufacturing processes that go into production. This paper presents the characterization setup for VIRUS units and compares the performance and variability of processed units with specifications for HETDEX.

9908-300, Session PS5

The current status for metroloogy camera system of Subaru prime focus spectrograph

Shiang-Yu Wang, Chueh-Yi Chou, Pin-Jie Huang, Hung-Hsu Ling, Jennifer E. Karr, Yin-Chang Chang, Yen-Sang Hu, Shu-Fu Hsu, Hsin-Yo Chen, Academia Sinica (Taiwan); James E. Gunn Sr., Princeton Univ. (United States); Daniel J. Reiley, California Institute of Technology (United States); Naoyuki Tamura, The Univ. of Tokyo (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Atsushi Shimono, Ken Sakamoto, The Univ. of Tokyo (Japan)

The Prime Focus Spectrograph (PFS) is a new optical/near-infrared multi-fiber spectrograph designed for the prime focus of the 8.2m Subaru telescope. PFS will cover 1.3 degree diameter field with 2394 fibers to complement the imaging capability of Hyper SuprimeCam. To retain high throughput of PFS, the final positioning accuracy between the fibers and observing targets of PFS is required to be less than 10 microns. The metrology camera system (MCS) serves as the optical encoder of the fiber motors for the configuring of fibers. MCS provides the fiber positions within 3 microns error over the 45 cm focal plane. The information from MCS will be fed into the fiber positioner control system for the close loop control.

MCS locates at the Cassegrain focus of Subaru telescope to cover the whole focal plan with one 50M pixel Canon CMOS camera. It is a 380mm Schmidt type telescope which generats uniform spot size around 10 microns FWHM across the field for reasonable sampling of the point spreading function. Carbon fiber tubes are used to provide stable structure over the operation conditions without focus adjustments. The CMOS sensor can be read in 0.8s to reduce the overhead for the fiber configuration. The positions of all fibers can be obtained within 0.5s after the readout of the frame. This enables the overall fiber configuration to be less than 2 minutes. MCS will be installed inside a standard Subaru Cassgrain Box. All components generate heat are located inside a glycol cooled cabinet to reduce the possible image motion due to the heat. The optics and camera for MCS have been delivered and tested. The mechanical parts and support structure are ready in spring 2016. The integration of MCS will start in the summer of 2016.

In this report, the performance of MCS component, the alignment and testing procedure as well as the status of the PFS MCS will be presented.

9908-301, Session PS5

The current status of prime focus instrument of Subaru prime focus spectrograph

Shiang-Yu Wang, Academia Sinica (Taiwan); Mark A. Schwochert, Jet Propulsion Lab. (United States); Pin-Jie Huang, Hsin-Yo Chen, Masahiko Kimura, Yen-Sang Hu, Yin-Chang Chang, Hung-Hsu Ling, Cheuh-Yi Chou, Shu-Fu Hsu, Academia Sinica (Taiwan); Daniel J. Reiley, California Institute of Technology (United States); Chaz N. Morantz, Jet Propulsion Lab. (United States); Peter H. Mao, David F. Braun, California Institute of Technology (United States); Chih-Yi Wen, Chi-Hung Yan, Jennifer E. Karr, Academia Sinica (Taiwan); James E. Gunn Sr., Princeton Univ. (United States); Graham J. Murray, Durham Univ. (United Kingdom); Naoyuki Tamura, The Univ. of Tokyo (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Atsushi Shimono, The Univ. of Tokyo (Japan)

The Prime Focus Spectrograph (PFS) is a new optical/near-infrared multi-fiber spectrograph designed for the prime focus of the 8.2m Subaru telescope. PFS will cover 1.3 degree diameter field with 2394 fibers to complement the imaging capability of Hyper SuprimeCam (HSC). The prime focus unit of PFS called Prime Focus Instrument (PFI) provides the interface with the top structure of Subaru telescope and also accommodates the optical bench in which Cobra fiber positioners locate. In addition, acquisition and guiding cameras (AG cameras), center viewing camera, cable wrapper, field element, fiducial fiber illuminators and telemetry system are located inside the PFI. The flat fielding and spectrum calibration lamps are positioned on the top of PFI.

Being at the prime focus environment of Subaru telescope, tight space, weight and heat dissipation constraints are applied to PFI. Furthermore, the structure stiffness of PFI is also limited to avoid any possible damage of the fragile ceramic lens barrel of the wide field corrector. A combination of different materials at different locations in height is used in PFI to provide a stable focal plane position over the operation temperature range (5 to -5 degree C) of PFS. A glycol based cooling system removes the heat generated from the electronics of various components of PFI to avoid the possible seeing degradation. To share the same wide field corrector with HSC, a flat glass called field element is added in front of the fibers for compensating the optical path difference.

Six FLI ML4720 cameras are installed at the periphery of the effective field for field acquisition and guiding. With 1s exposures, each AG camera can provide at least 2 guide stars at any pointing of the sky. A 0.9mm BK7 glass is installed inside each camera to cover half of the CCD sensor to accelerate the focus sequence. Together with the tiny 0.7 mm center viewing camera, AG cameras provide essential information for the pointing and distortion map of the focal plane. The relative distance between the AG camera sensors to the reference fiducial fibers is calibrated and kept

stable within 5 microns with different operation conditions to meet the alignment requirement of the fibers. A high brightness red LED with a light diffusor is used as the light source to illuminate 20mm diameter area of 96 fiducial fibers. The integration and verification of PFI starts in early 2016. The integration and testing of the Cobra positioner modules will take about 13 months. The position and the angle of each fiber will be measured to the precision of 10 microns in x, y, z directions and 0.17 degrees in tilt at the operation temperature range and with different elevation angles. Such information will provide important calibration data for the fiber configuration during the operation.

In this report, the latest status of PFI development will be given including the performance of PFI components, the setup and performance of the integration and testing equipment, and the progress of PFI integration work.

9908-302, Session PS5

Developing multi-fibers connectors device for FOCCoS-PFS-Subaru

Antonio C. de Oliveira Sr., Lab. Nacional de Astrofísica (Brazil); Lígia Souza de Oliveira, Lucas Souza Marrara, OIO - Oliveira Instrumentação Óptica Ltda. (Brazil); Leandro Henrique dos Santos, Jesulino Bispo dos Santos Sr., Lab. Nacional de Astrofísica (Brazil); Josimar A. Rosa, Lab. Nacional de Astrofisica (Brazil); Laerte Sodré Jr., Claudia L. M. de Oliveira, Univ. de São Paulo (Brazil); James E. Gunn Sr., Princeton Univ. (United States); Naoyuki Tamura, Atsushi Shimono, Naruhisa Takato, Kavli Institute for the Physics and Mathematics of the Universe (Japan) and The Univ. of Tokyo (Japan); Décio Ferreira Sr., Lab. Nacional de Astrofísica (Brazil)

The Fiber Optical Cable and Connector System (FOCCoS), provides optical connection between 2400 positioners and a set of spectrographs through optical fibers cables as part of PFS instrument for Subaru telescope. The optical fiber cable will be segmented in 3 parts along the route, cable A, cable B and cable C, connected by a set of multi-fiber connectors. The company USCONEC produces the multi-fiber connector under study. The USCONEC 32F model can connect 32 optical fibers in a 4 x 8 matrix arrangement. The ferrules are made of a durable composite, Polyphenylene Sulfide (PPS) based thermoplastic. The connections are held in place by a push-on/pull-off latch, and the connector can also be distinguished by a pair of metal guide pins that protrude from the front of the connector. Two fibers per connector will be used for monitoring the connection procedure. It was found to be easy to polish and it is small enough to be mounted in groups.

Highly multiplexed instruments like PFS require a fiber connector system that can deliver excellent optical performance and reliability. PFS requires two different types of structures to organize the connectors. The Tower Connector system, with 80 multi-fiber connectors, will be a group of connectors for connecting cable B (Telescope Structure) with cable C (Positioners Plate). The Gang Connector system is a group of 8 gang connectors, each one with 12 multi-fibers connectors, for connecting cable B (Telescope Structure) with cable A (Spectrograph). The bench tests with these connector systems and the chosen fibers should measure the throughput of light and the stability after many connections and disconnections. In this paper we describe possible tests and procedures to evaluate the throughput and FRD increment. The lifetime of the ferrules is also in evaluation.

9908-303, Session PS5

iSHELL: a 1-5 micron R=70,000 immersion grating spectrograph for IRTF

John Rayner, Alan T. Tokunaga, NASA Infrared Telescope Facility (United States) and Univ. of Hawai'i (United States); Daniel T. Jaffe, The Univ. of Texas at Austin (United States); Morgan B. Bonnet, Gregory K. Ching, Michael S. Connelley, NASA Infrared Telescope Facility (United States) and Univ. of Hawai'i (United States); Daniel Kokubun, BAE Systems (United States); Charles Lockhart, Eric Warmbier, NASA Infrared Telescope Facility (United States) and Univ. of Hawai'i (United States)

iSHELL is a 1-5 micron cross-dispersed echelle spectrograph being built for the 3-m NASA Infrared Telescope Facility (IRTF) on Maunakea, Hawaii. The instrument is currently undergoing all-up testing and is scheduled for first light in 2016. It is a white pupil spectrograph that produces measured resolving powers of up to R=75,000 matched to a 0.375" slit. In order to keep iSHELL small enough to be mounted at the Cassegrain focus of the telescope, dispersion is accomplished with a silicon immersion grating, fabricated at the University of Texas, Austin. The blaze angle is 71.6 degrees (R3) with an entrance aperture of 30 mm x 35 mm to accommodate a collimated beam diameter of 22 mm diameter. Except for gaps in the deep telluric features centered at 2.6 and 4.4 microns the entire 1.15-5.3 micron wavelength range is covered in 17 settings with seven first-order tilt-able cross-dispersing gratings, in combination with a slit wheel and dekker mechanism. Slit widths of 0.375", 0.75", 1.5" and 4.0", and slit lengths of 5", 15" and 25", are available. One Teledyne 2048x2048 Hawaii 2RG array is used in the spectrograph, and one Raytheon 512x512 Aladdin 2 array is used in a slit viewer for object acquisition and guiding.

The cryostat contains three major optical assemblies: the foreoptics, the slit viewer and the spectrograph. A warm calibration system consisting of calibration lamps, integrating sphere and illumination optics is mounted on top of the cryostat vacuum jacket. The foreoptics and slit viewer are mounted on one side of a cold optical bench and the spectrograph to the opposite side. Liquid nitrogen cools the optics and optical bench to 75K to keep the instrument background below the detector dark current of 0.1 e/s. The first stage of a closed-cycle cooler cools a radiation shield surrounding the optical bench enclosure while the second stage cools the spectrograph and slit viewing detectors to 37K and 30K respectively. Eight mechanisms run by cold motors are mounted on the optical bench. The size of the vacuum jacket is 1.3 m x 0.6 m x 0.7 m and the instrument weighs about 600 kg (not including ancillary electronics).

Astronomical Research Camera (ARC) Generation 3 controllers are used to run both arrays. The H2RG spectrograph array is wired for 32 channels and the smaller InSb slit-viewer array is wired for 8 channels. Each of the array controllers is controlled with a dedicated PC. Observers interface with iSHELL via GUIs that run on the spectrograph and slit-viewer PCs.

iSHELL is designed to do a variety of science across 1-5 micron including planetary atmospheres, comets, exoplanets, protostellar objects and stars. It is optimized for observations at 3-4 microns. This paper discusses the design, and performance and characterization of iSHELL in the lab.

9908-304, Session PS5

Performance of MEGARA spectrograph optical elements

Esperanza E. Carrasco-Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Gonzalo Páez, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Rafael Izazaga-Pérez, José Luis Avilés Urbiola, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Alfonso

Salas-Sánchez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico) and Univ. de Sinaloa (Mexico); Armando Gil de Paz, Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain)

MEGARA is the new IFU and multi-object spectrograph for GTC. The spectograph will offer spectral resolution R=6,000-20,000 thanks to a spectrograph design based in the used of volume phase holographic gratings in combination with prisms to keep fixed the collimator and camera angle. Except for the optical fibers and micro lenses, the complete MEGARA optical system has been manufactured in Mexico, shared between the workshops of INAOE and CIO. This includes a field lens, a 5-lenses collimator, a 7-lenses camera, four of them of CaF2. It also includes a complete set of volume phase holographic gratings with 36 flat windows and 24 prisms. All these elements are very large and complex, with very efficient anti reflection coatings. The optomechanics of the collimator and camera was also manufactured in Mexico. The optical performance of MEGARA spectrograph elements and of the collimator and camera as subsystems will be described

9908-305, Session PS5

Design and testing of AR coatings for MEGARA optics

Rafael Ortiz, Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Gonzalo Páez, Octavio Pompa, Ctr. de Investigaciones en Óptica, A.C. (Mexico); Armando Gil de Paz, Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain)

Antireflection (AR) coatings are fundamental in the design of astronomical instruments. The purpose of such coatings is to reduce reflection and to increase the transmission properties of the optical surfaces to improve optical efficiency in a specific spectral band. In this work we present the AR coating design procedure for the optical elements of MEGARA, the integral field and multi-object spectrograph for the Gran Telescopio de Canarias (GTC). In this instrument, the AR coatings are particularly challenging, due to the fact that the main optics require a wide spectral band coverage at very low reflectivity.

The methodology for optimizing the solutions at particular angles of incidence and the testing of the final deposited coatings is presented. The main optics of the spectrograph require broadband coatings in the wavelength range from 370 to 980 nm for materials ranging from Nd=1.43 to Nd=1.83 with an average reflection less or equal to 1.3% at distinct angles of incidence (AOI) in each surface, this was achieved by design of eight layer AR coatings. The pupil elements of the instrument consist of prisms and windows for which four layer AR coatings were designed and produced aiming for an average reflection as low as 0.3% in distinct spectral bands, defined by the different spectral configurations: six for low resolution (LR), ten for medium resolution (MR) and two for high resolution (HR).

Regarding main optic elements, for each substrate, AR coatings consisting in a specific arrangement of thicknesses of eight layers of different materials were produced and tested in witness samples prior to the final evaporation. For the pupil elements, the LR windows are already evaporated with their final coatings, for the MR and HR prisms the designs are ready and are currently being tested towards final evaporation.

For the testing of the coatings a spectrophotometer was used to determine the total transmission of each element, then a method for the subtraction of the Fresnel losses is implemented, finally the total surface reflectance is reported. The measurements are obtained at AOI=0 and then extrapolated to the desired AOI, depending on each element.

We provide the results of the testing of the AR coatings of the main optics and the LR windows. The designs have been effectively tested using a method of analysis to implement the subtraction of the Fresnel effects. In most of the spectral band the AR coatings exceed the performance requirements and the average reflectance is equal or less than 1.3% for. The main optics elements are undergoing final coatings, and the pupil element coatings for MR and HR are currently under testing. A further analysis will be made with the final depositions to estimate the total average transmittance of the optics system.

9908-306, Session PS5

The Australian ESO positioner (AESOP) for 4MOST facility on the Vista Telescope

Andrew I. Sheinis, Gabriella Baker, Peter R. Gillingham, Scott Smedley, Jurek Brzeski, Lewis G. Waller, Australian Astronomical Observatory (Australia)

We present the Australian ESO Positioner (AESOP) for 4MOST facility on the Vista telescope. AAO is part of the multi-national 4Most consortium whose goal is to outfit the Vista telescope with a massively multiplexed wide-field spectroscopic capability to solve a wide range of scientific problems, including cosmology, galaxy evolution, high-energy and galactic science. For 4Most, AESOP will position 2400 fibers over a hexagonal field-of-view of 4 square degrees (2.5 degree diameter) feeding two sets of spectrographs at R=5000 and R=20,000. AESOP is based on the patented Echidna 'tilting spine' fiber positioner technology that has been in operation since 2007 on the SUBARU telescope in the FMOS system. An update to the AESOP project, which is in Critical Design Phase will be presented along with throughput comparisons to other positioner types, where we find that losses due to tilt are generally outweighed by the increased allocation yield, greater patrol area and reduced fiber stress FRD of the Echidna design.

9908-307, Session PS5

Optical design for the TAIPAN and HECTOR transmissive spectrographs

Robert Content, Australian Astronomical Observatory (Australia)

TAIPAN is a multi-fibre project for the UK-Schmidt telescope and Hector is a multi-IFU project for the Anglo-Australian Telescope (AAT) using fibres. Many different transparent designs were studied covering a large parameter space. An important trade-off study was for the use of microlenses on the slit or not. Microlenses have disadvantages but permit considerable simplification of the collimator by making the beam very slow. The disadvantages are more important with the UK-Schmidt due to the faster beam from the telescope. With microlenses, the collimator is a unique spherical plano-convex lens significantly smaller than the mirror that would be needed in a reflective design. For Hector, 24 different camera designs where done to cover the parameter space for 2k x 2k, 2k x 4k, or 4k x 4k detectors, and for 50, 75 or 100 micron fibre cores, with or without microlenses, with a triplet in the camera or a doublet plus singlet, and with a maximum wavelength of 1 or 1.05 microns. Not all combinations were designed but for each parameter there are at least two representative cameras with all other parameters identical. This permits, in principle, the identification of the minimal cost design. Also, a theoretical study was done of the PSF obtained with highly packed microlenses at the slit with no space between them and imaging to 2 pixels per microlenses. This maximizes the number of fibres per spectrograph, and thus the total field of view of all IFUs together, but it comes with some disadvantages.

9908-308, Session PS5

Wide-field corrector for 4MOST: design details and MAIV processes

Nicolas Azais, Gregory A. Smith, Samuel C. Barden, Leibniz-Institut für Astrophysik Potsdam (Germany); Bernard-Alexis Delabre, European Southern Observatory (Germany); Damien J. Jones, Prime Optics (Australia); Sylvain Egron, Aix-Marseille Univ. (France) and ONERA (France) and Space Telescope Science Institute (United States)

4MOST is a wide-field, high-multiplex spectroscopic survey facility under development for the VISTA telescope of the European Southern Observatory (ESO). Its main science drivers are in the fields of galactic archeology, high-energy physics, galaxy evolution and cosmology. In particular, 4MOST will provide the spectroscopic complements to the large area surveys coming from space missions like Gaia, eROSITA, Euclid, and PLATO and from ground-based facilities like VISTA, VST, DES, LSST and SKA. The 4MOST baseline concept features a 2.5 degree diameter field-of-view with ~2400 fibres in the focal surface, configured by a tilting spine fibre positioner.

The primary and secondary mirrors (M1&M2) together with the Wide Field Corrector (WFC) system provide a pupil-centric and aberration corrected focal surface. The WFC incorporates an atmospheric dispersion corrector utilizing two wedge lenses moving independently in rotation around the optical axis. The WFC is also an integral part of the metrology system, which permits determination of fiber positions in the focal plane.

At the focal plane, two wave front sensing (WFS) systems obtain aberration data used to maintain accurate figure on M1. At commissioning, a deployable camera will move along the focal surface to provide high order wavefront information verifying the performance of the WFC. A permanently mounted pair of low order wavefront sensor cameras provides information for M2 positioning. An acquisition and guiding (A&G) unit provides images for science field acquisition, for auto guiding and for monitoring plate scale changes and distortions (e.g. from atmospheric dispersion). Secondary guiding is provided using guide fibres interspersed within the science field.

This paper provides an overview of design details and Manufacture, Assembly, Integration and Verification (MAIV) processes for the 4MOST WFC system.

9908-309, Session PS5

DESI-GFA test bench for the CCDs characterization

Jorge Jiménez Rojas, José María Illa, Javier Gaweda, Institut de Física d'Altes Energies (Spain); Juan de Vicente, Ctr. de Investigaciones Energéticas, Medioambientales y Tecnológicas (Spain); Ricard Casas, Institut de Ciències de l'Espai (Spain)

The DESI instrument (Dark Energy Spectroscopic Instrument) will be devoted to measure the effect of the dark energy on the expansion of the universe and it will be installed on the Mayall 4-meter telescope at Kitt Peak National Observatory starting in 2018.

One of the key parts of this instrument is the subsystem named DESI-GFA (Guiding, Focusing and Alignment) which is composed of ten small cameras distributed along the DESI focal plane and using one e2v CCD230-42 type each one, which is back-illuminated and 2k by 2k pixels and readout with a custom readout electronics developed from scratch at IFAE up to the readout speed of 750 KHz. The image area of this CCD has four separately sections which allow to readout the CCD in full frame and frame transfer modes by the four output amplifiers located at the top and bottom edges of the CCD. For guiding issues, it is foreseen to readout the CCD with several regions of interest (ROI) by split frame transfer mode through four amplifiers.

In order to perform the acceptance tests and then characterize the CCDs for our purposes while debugging clocks and bias signals, there was build a small cryostat with capacity to allocate one CCD at a time and able to be readout with a standard MONSOON/panVIEW solution.

Despite that the CCDs for the DESI-GFA are expected to be use at room temperature, there is necessary to perform the acceptance tests at -25 ºC, on that way, the CCD located at the cryostat focal plane will be cooled down by means a couple of Peltier elements which heat is dissipated using a cold water closed cycle system. The final element to control and stabilize the temperature is a Lakeshore controller using a 50W heater and a silicone diode temperature sensor both located just behind the CCD.

On the focal plane, the CCD will be illuminated with a flat field tool and the characterization will include some standard tests as the Photon Transfer Curve (PTC), Charge Transfer Efficiency (CTE), Dark Current tests covering a wide range of temperatures (from -25 ºC up to 30 ºC), Conversion Factor (Gain) calculated by means of a Fe-55 radioactive source and a short Quantum Efficiency test with just few wavelength points using colored light emitting diodes (led) already included in the flat field tool.

Once developed the custom readout electronics, it would be attached to the cryostat and connected to the CCD by means a DSUB50 pins hermetic connector, which will allow us to re-characterize a tested CCD with our system and compare results.

This paper will present the full setup layout, its description and the CCD characterization main results.

9908-310, Session PS5

4MOST preliminary instrument design

Steffen Frey, Olga Bellido-Tirado, Samuel C. Barden, Joar G. Brynnel, Dionne M. Haynes, Roger Haynes, Andreas Kelz, Allar Saviauk, Olivier Schnurr, Jakob C. Walcher, Gregory A. Smith, Roland Winkler, Roelof S. de Jong, Leibniz-Institut für Astrophysik Potsdam (Germany)

The systems engineering team of the "4-meter Multi-Object Spectroscopic Telescope" (4MOST) presents the preliminary design of the instrument in development. Systems engineering is part of the 4MOST project office at the Leibniz-Institut für Astrophysik Potsdam (AIP). We intend to pass the preliminary design review in 2016.

4MOST will be manufactured, assembled and verified, starting in 2017 with the purchase of long lead items for the subsystems, and finishing with the initial system verification at AIP in 2020. The instrument will then be transported to and installed, commissioned and verified at the "Visible and Infrared Survey Telescope for Astronomy" (VISTA), part of ESO's Paranal Observatory in Chile, in 2021.

The 4MOST instrument will provide more than 2400 separately movable fiber apertures located in an optically and atmospheric dispersion corrected wide field at the Cassegrain focus of VISTA. One high resolution spectrograph with a spectral resolving power R > 18000 and two low resolution spectrographs with R ~ 5000 will each image more than 800 spectra. The spectrographs are three camera arm designs. Each of the two low resolution spectrographs will cover a spectral range from 400 to 885 nm each, without gaps. The high resolution spectrograph has 3 separated wavelength ranges covering 392.8 to 435.5 nm in the blue, 516 to 573 nm in the green and a 69 nm wide band in the red.

The installation and interface of 4MOST to VISTA is challenging because the telescope was originally optimized optimized for the VIRCAM infrared wide field camera system. Active Optics and guiding sensors have to be rebuilt and accommodated within 4MOST, because they are currently part of VIRCAM. A secondary guiding system will be added to ensure the accurate positioning of the fiber apertures on the targets during the

exposure times of about 20 minutes, that are much longer than the current VISTA observations.

This paper is focused on the system design and performance drivers of the 4MOST instrument in preliminary design. We present crucial system budgets, simulation results and trade-offs which are incorporated in the presented design. We o present key parameters such as: the anticipated optical throughput, pointing accuracy, homogeneity of aperture transmission, homogeneity of spectral response, wavelength calibration, overhead at night time, availability and reliability of 4MOST.

We acknowledge and explicitly appreciate the contributions from all parties of the 4MOST consortium to the system and subsystem design of the 4MOST instrument. The design is based on the work of many excellent minds, not all of whom are authors of this paper.

9908-311, Session PS5

The alignment and assembly of the DESI prime focus corrector

David Brooks, Univ. College London (United Kingdom); Robert W. Besuner, Lawrence Berkeley National Lab. (United States); Peter Doel, Univ. College London (United Kingdom); Brenna L. Flaugher, Giuseppe Gallo, Gaston Gutierrez, Stephen Kent, Fermi National Accelerator Lab. (United States); Michael Lampton, Michael E. Levi, Lawrence Berkeley National Lab. (United States); Ming Liang, National Optical Astronomy Observatory (United States); Timothy N. Miller, Lawrence Berkeley National Lab. (United States); David Sprayberry, National Optical Astronomy Observatory (United States); Andrew Stefanik, Fermi National Accelerator Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs.

The prime focus corrector consists of six lenses that range in diameter from 0.80 – 1.14 meters and from 83 – 237 kg in weight. The alignment of the lenses of the optical corrector poses a significant challenge as in order to meet the fiber throughput goals they have to be positioned to a tolerance of 75 micrometers. This paper details the design for lens cells and the alignment and assembly procedure for the mounting of the lenses into the cells and into to the complete barrel assembly. This is based on the experience obtained from the alignment of the DECam instrument which was successfully assembled and aligned by the same team and we include in the paper the lessons learnt and design modifications that will be implemented on the DESI system

9908-312, Session PS5

The prime focus corrector for dark energy spectroscopic instrument

Peter Doel, David Brooks, Univ. College London (United Kingdom); Robert W. Besuner, Lawrence Berkeley National Lab. (United States); Brenna L. Flaugher, Giuseppe Gallo, Gaston Gutierrez, Stephen Kent, Fermi National Accelerator Lab. (United States); Michael Lampton, Lawrence Berkeley National Lab. (United States); Ming Liang, National Optical Astronomy Observatory (United States); Michael E. Levi, Timothy N. Miller, Lawrence Berkeley National Lab. (United States); David Sprayberry, National Optical Astronomy Observatory (United States); Andrew Stefanik, Fermi National Accelerator Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs.

This paper describes the overall design and construction status of the prime focus corrector. The size and complexity of the system poses significant design and production challenges and the solutions adopted to these are presented. The optics of the corrector consists of six lenses, ranging from 0.8 - 1.14m in diameter, two of which can be rotated to act as an atmospheric dispersion corrector. These lenses are mounted in custom cells, designed to give low thermally induced stresses, that in turn are mounted in a barrel assembly. The barrel is mounted on a hexapod system which can actively position it to a few micrometers precision. The whole assembly will be mounted at the prime focus of the Mayall 3.8m telescope at Kitt Peak observatory and will be one of the largest lens systems ever built for an optical telescope. Construction of the corrector began in 2014 and is well advanced. The system is due to be delivered to the telescope for installation in early 2018.

9908-313, Session PS5

Implementation of the metrology system for MOONS

Holger Drass, Leonardo Vanzi, Miguel Torres-Torriti, Rolando Dünner Planella, Tzu-Chiang Shen, Francisco I. Belmar, Lousie C. Dauvin, Tomás Staig, Jonathan A. Antognini, Mauricio Flores, Yerko Luco, Pontificia Univ. Católica de Chile (Chile); Steven M. Beard, David M. Montgomery, UK Astronomy Technology Ctr. (United Kingdom); Alexandre Cabral, Mahmoud Hayati, Manuel Abreu, Univ. de Lisboa (Portugal); Philip Rees II, UK Astronomy Technology Ctr. (United Kingdom); Michele Cirasuolo, European Southern Observatory (Germany); William D. Taylor, Alasdair E. Fairley, UK Astronomy Technology Ctr. (United Kingdom)

The Multi-Object Optical and Near-infrared Spectrograph (MOONS) is a new fiber-fed spectrograph for the VLT. MOONS will exploit the full 500 square arcmin field of view offered by the Nasmyth focus of VLT and will be equipped with two dual-arm spectrographs covering the wavelength range 0.645 ?m-1.8 ?m. Each double-arm spectrograph will produce spectra for 500 targets simultaneously. To ensure the accurate positioning of the 1000 fibers over the focal plane that has 880 mm in diameter, a metrology system has been designed to provide position measurements within ~10 ?m. The paper presents the hardware and software design of the metrology system as accepted by the end of the preliminary design phase and subsequent improvements. The metrology system is based on the analysis of images taken by a circular array of 12 cameras located close to the VLT's derotator ring around the Nasmyth focus. The system includes 24 individually adjustable lamps . The fiber positions are measured through dedicated metrology targets mounted on top of the fiber positioning units (FPU) and fiducial markers connected to the FPU support plate which are imaged at the same time. A flexible pipeline based on VLT standards is used to process the images. The image processing includes target identification, filtering of stray light contamination and false positives. The resulting catalogs contain the position of the metrology targets hampered

by the distortion of the camera's CCD chip. Using information from off-line camera characterization the pipeline corrects the target positions. The final coordinates are used as input for a least square minimization algorithms to calculate the camera position making use of the known fiducial positions and then the position of the fibers on the plate. The method is validated by comparisons with an independent metrology system. The position accuracy was determined to ~5 um in the central region of the images. Including the outer regions the overall positioning accuracy is ~25 um. The MOONS metrology system is fully set up with a working prototype. The results in parts of the images are already excellent. By using upcoming hardware and improving the calibration it is expected to fullfill the accuracy requirement over the complete field of view for all metrology cameras.

9908-314, Session PS5

Impact of optical distortions on fiber positioning in the dark energy spectroscopic instrument

Stephen Kent, Fermi National Accelerator Lab. (United States); Michael Lampton, Timothy N. Miller, Space Sciences Lab. (United States); Peter Doel, David Brooks, Univ. College London (United Kingdom); Robert W. Besuner, Space Sciences Lab. (United States); Joseph H. Silber, Lawrence Berkeley National Lab. (United States); Charles Baltay, David Rabinowitz, Yale Univ. (United States); David Sprayberry, Ming Liang, National Optical Astronomy Observatory (United States)

The Dark Energy Spectroscopic Instrument (DESI), currently under construction, will measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs.

A six-element corrector gives a useful field-of-view of 3.2 degrees diameter. A fiber view camera located near the primary mirror is used to image and measure the positions of back-illuminated fibers relative to a set of known fiducials; the absolute positioning on the sky is achieved with six guider CCDs. A major challenge is dealing with the large amount of distortion introduced by the optics (of order 10% scale change), including non-axisymmetric distortions introduced by the atmospheric dispersion compensator (ADC). This work describes all the effects that need to be tracked in mapping the focal plane to the sky, including astronomical and atmospheric effects, time-varying distortion patterns, figure and polishing errors in the corrector lenses, corrector assembly misalignments, and offsets between the fiber view camera and main camera centroids. Solutions are presented to measure or mitigate these effects.

9908-315, Session PS5

The MEGARA fiber MOS positioning tool

Jorge Iglesias-Páramo, Isaac Morales Durán, Instituto de Astrofísica de Andalucía (Spain); África Castillo Morales, Armando Gil de Paz, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Francisco Manuel Sánchez-Moreno, Univ. Politécnica de Madrid (Spain); María Luisa García Vargas, FRACTAL S.L.N.E (Spain)

MEGARA (Multi Espectrógrafo en GTC de Alta Resolución para Astronomía) is the future optical Integral-Field Unit (IFU) and Multi-Object Spectrograph (MOS) for the 10.4-m Gran Telescopio CANARIAS (GTC).

MEGARA at the GTC will be the first instrument providing Multi Object Spectroscopy (MOS) based on robotic positioners (RPs) in a 10m-class telescope, a unique feature in terms of on-target observing time.

The MEGARA Fiber MOS Positioning Tool (FMPT) is a software suite designed to (i) confirm that the assignment of the MEGARA Robotic Positioners (RPs) for a given observing configuration issue from the Fiber MOS Assignment Tool (FMAT, also presented in this meeting) is free from dynamic collisions, and (ii) to compute the sequence of movements of the MEGARA RPs from the parking positions to the configuration defined by the FMAT, avoiding dynamic collisions between adjacent RPs. The inverse sequence of movements that will send the RPs to the parking positions is also computed. These two functionalities will be executed by the GTC staff from the FMPT Stand Alone Application, which is a command line application that makes use of the FMPT library.

In addition to this, two more functionalities have been designed for the FMPT to be performed if any of the RPs is stopped by any non expected reason: (iii) to generate a depositioning sequence that moves all the enabled RPs to security positions, and (iv) to regenerate a new positioning sequence (and the corresponding depositioning sequence) for the current observing block with all the available RPs when it is still possible. These two last functionalities will be automatically called by the MEGARA Control System in the case of necessity.

A complete description of the capabilities of the FMPT as well as the compatibility with the FMAT will be described in this talk. The performance of the FMPT will be illustrated with real time examples based on real scientific cases.

9908-316, Session PS5

The MIRADAS macro-slicer optical and opto-mechanical design

Richard Deno Stelter, Stephen S. Eikenberry, Univ. of Florida (United States); David J. Robertson, Cyril J. Bourgenot, Durham Univ. (United Kingdom); Salvador Cuevas Cardona, Univ. Nacional Autónoma de México (Mexico)

We present the innovative macro-slicer optical and opto-mechanical designs for the MIRADAS instrument, the second-generation Mid-resolution InfraReD Astronomical Spectrograph for the 10.4m Gran Telescopio Canarias in the 1-2.5 micron bandpass. MIRADAS uses up to 12 cryogenic, fully steerable probes to select simultaneous targets in a 5 arcminute field of view. The probe arms use a collimator-camera relay to slightly speed up the native F/17 beam from the telescope to an F/14.2 beam at the macro-slicer input. The macro-slicer is a 2:1 relay which rearranges the 12 disparate inputs from the probe arms into a tightly-packed pseudo-longslit for the spectrograph module input. The spectrograph module is a cross-dispersed echelle spectrograph. The macro-slicer is effectively an advanced image slicer IFU and, like other IFUs designed and built at the University of Florida, uses a 'bolt-and-go' approach to minimize alignment challenges and maximize robustness. The 'bolt-and-go' approach developed at UF puts the onus of alignment in the opto-mechanical design/fab phase, rather than the assembly and integration phase. Because our mirrors are monolithically constructed out of aluminum blocks, we are able to add in mounting pads, tapped bolt holes, and dowel pin holes whose location precision with respect to the optical system is limited only by the machining process. The MIRADAS macro-slicer uses three sets of mirrors that work together to geometrically rearrange the very loosely packed inputs from the probe arms into a tightly packed psuedo-slit: Slicer mirrors, which live at the focal plane; pupil mirrors, which are at the pupil plane of the slicer mirrors; field mirrors, which live at the focal plane produced by

the slicer and pupil mirrors. The macro-slicer also functions to maintain the spectral resolution of MIRADAS fixed at R>20,000 with simultaneously excellent throughput in seeing conditions from 0.4-1.2 arcsec (typical at GTC in the near-infrared). We accomplish this with three slices, each 0.4 arcseconds wide, and multiplex two probes per slicer module. There are 6 slicer modules in total. Each slice has its own pupil mirror with its own tip/tilt and radius of curvature (although all radii of curvature are within 5% of the average radius). The field mirrors are unpowered, but have individual tip/tilts to correct for minor telecentric errors introduced by the IFU optics. There are 6 field mirrors per slicer (and thus 6 per set of 2 probes, 36 in total). Each field mirror is one slice of one probe. The field mirrors are also staggered slightly from one set of 6 to another. This stagger partially compensates for the tilt introduced by the geometry of the cross-dispersed echelle at the detector plane and allows us to tightly pack the spectra onto the detector.

9908-317, Session PS5

4MOST fiber feed preliminary design: prototype testing and performance

Dionne M. Haynes, Andreas Kelz, Svend-Marian Bauer, Allar Saviauk, Katjana Ehrlich, Thomas Jahn, Roland Winkler, Samuel C. Barden, Roger Haynes, Leibniz-Institut für Astrophysik Potsdam (Germany)

The 4MOST instrument is a multi-object-spectrograph for the ESO-VISTA telescope. Its fibre subsystem is a central part of the facility, and is situated between the fibre positioner at the Cassegrain instrument rotator of the VISTA telescope and the spectrographs. It facilitates the transport of the light from the science targets (imaged) at the focal surface of the telescope to the slits of the 4MOST spectrographs.

The full fibre subsystem is composed of the fibre postitioner (AESOP), based on the Echidna (FMOS) tilting spine concept, and the fibre cable, which feeds two low-resolution spectrographs and one high-resolution spectrograph. The positioner holds 2436 science fibres and 12 guide spines containing 7 fibres each. They are arranged in a hexagonal pattern of which 1624 science fibres are feeding the two low-resolution spectrographs and 812 science fibres are feeding the high-resolution spectrograph. The fibre mapping scheme is complex and has been driven by the desire to have fibres for each spectrograph evenly distributed across the entire telescope field of view, as this mapping negates the risk of field loss if a spectrograph is offline for technical reasons. The focal plane (positioner) to spectrograph mapping has a significant impact on the fibre feed and dictates much of the fibre layout, modularity and routing. Fibre connectors are being used in order to facilitate 4MOST assembly, integration, maintenance as well as the VISTA primary mirror removal for re-coating.

In order to optimize the fibre feed subsystem design and provide essential information required for the spectrograph design, prototyping and testing has been undertaken. In this paper we give an overview of the current fibre feed subsystem design and present the preliminary FRD, scrambling, throughput and system performance impact depending on fibre-spine tilt, fibre connectors, de-rotator simulator and fibre cable lifetime tests.

9908-318, Session PS5

Progress on the fabrication of the DESI corrector optics

Timothy N. Miller, Lawrence Berkeley National Lab. (United States); Peter Doel, David Brooks, Univ. College London (United Kingdom); Michael J. Sholl, Lawrence Berkeley National Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the status of the DESI corrector optics, a series of 0.8 to 1.1-meter fused silica and borosilicate lenses currently being fabricated to demanding requirements. We will describe the specs for lenses that are finished or underway, including surface figure, homogeneity, and other parameters; the current schedule for lens production; verification testing; and a comparison against DESI corrector requirements.

9908-319, Session PS5

Commissioning of VIRUS integral-field units at the Hobby-Eberly Telescope

Andreas Kelz, Thomas Jahn, Leibniz-Institut für Astrophysik Potsdam (Germany); Gary J. Hill, Sarah E. Tuttle, Brian L. Vattiat, The Univ. of Texas at Austin (United States); Svend-Marian Bauer, Leibniz-Institut für Astrophysik Potsdam (Germany)

VIRUS is the visible, integral-field replicable unit spectrograph for the Hobby-Eberly-Telescope (HET). It consists of modular spectrographs, that are being fed by 78 optical fiber-bundle IFUs, to enable the Dark Energy survey HETDEX.

In 2016, the VIRUS instrument is being deployed in modular batches at the upgraded wide-field HET. The 20 meter long fiber-bundles connect the prime focus with the spectrographs, mounted at the telescope structure. We descibe the installment and commissioning procedure of the VIRUS-IFUs. The on-sky results are compared to data from the acceptance testing in the laboratory prior shipment to evaluate the performance of the IFUs.

9908-320, Session PS5

MEGARA fiber MOS assignment tool (FMAT)

Pedro Gómez-Álvarez, FRACTAL S.L.N.E (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain); África Castillo Morales, Armando Gil de Paz, Univ. Complutense de Madrid (Spain); Emma Mujica-Alvarez, María Luisa García Vargas, FRACTAL S.L.N.E (Spain); José M. Vílchez Medina, Instituto de Astrofísica de Andalucía (Spain); Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain); Isaac Morales Durán, Instituto de Astrofísica de Andalucía (Spain); Francisco Manuel Sánchez-Moreno, Univ. Politécnica de Madrid (Spain)

MEGARA (Multi Espectrógrafo en GTC de Alta Resolución para Astronomía) is the future optical Integral-Field Unit (IFU) and Multi-Object Spectrograph (MOS) for the 10.4-m Gran Telescopio CANARIAS (GTC).

FMAT is the tool developed by MEGARA Instrument Team to assist observers during the GTC-MEGARA proposal preparation in the MOS mode. This software allows instrument users to optimally assign targets to MEGARA fiber positioners.

FMAT starts from a list of targets with their corresponding scientific priority assigned by the user. FMAT allows to position and rotate the focal plane over the astronomical region of interest; it then allows to manually assign sources to positioners or to perform automatic assignations based

on the sources priority. Once the user is satisfied with the result of the assignment, the tool allows to produce the needed files to be sent to GTC telescope for Phase-2. The tool is also capable to assess whether a given configuration is reachable and produces and errors report. FMAT has a very intuitive GUI and an easy and flexible workflow, which allows users to iteratively assign and optimize their observations while maximizing the scientific return of the instrument.

9908-321, Session PS5

MEGARA exposure time calculator

África Castillo Morales, Alexandre Bouquin, Nicolás Cardiel, María del Carmen Eliche Moral, Armando Gil de Paz, Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain); María Luisa García Vargas, FRACTAL S.L.N.E (Spain); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Francisco Manuel Sánchez-Moreno, Univ. Politécnica de Madrid (Spain)

MEGARA (Multi-Espectrógrafo en GTC de Alta Resolución para Astronomía) is an optical Integral-Field Unit (IFU) and Multi-Object Spectrograph (MOS) designed for the GTC 10.4m telescope in La Palma. We present in this talk the capabilities of the MEGARA Exposure Time Calculation (ETC), which will provide the potential users with the necessary tool for preparing an observing program. MEGARA ETC is a web-based tool (written in Python) that computes realistic estimates of the SNRs and limiting magnitudes, for a given input source, instrumental setup, and observing conditions of the run. It also provides estimates on the required exposure times to achieve a given SNR in the continuum or in an emission line of an input source, as well as simulated spectra observed with MEGARA at a certain setup from an input library of possible astronomical objects.

The ETC has into account several instrumental effects: (i) the transmission of the telescope; (ii) the instrument transmission, accounting for that of the lenslets, the fibers, the internal optics, and the VPHs; (iii) the detector quantum efficiency as a function of wavelength; (iv) the spatial and spectral profiles in one voxel on the detector to estimate maximum and minimum SNRs.

Moreover, the tool includes the effects of the atmospheric and observing conditions of the run. In particular, they account for: (i) the atmospheric transmission as a function of the wavelength in the observatory; (ii) the effect of airmass on the light absorbed by the atmosphere in the observatory; (iii) the atmospheric extinction in the observatory; (iv) the sky emission background depending on the night of the run (if it is dark, grey, or bright); (v) the seeing of the night, considering the effect of airmass on it.

The performance of the MEGARA ETC will be illustrated with some examples based on real scientific cases.

9908-322, Session PS5

MEGARA control system

Bertrand B. L. Lefort, CERN (Switzerland) and FRACTAL S.L.N.E (Spain); África Castillo Morales, José Antonio López Orozco, Segundo Esteban, Juan Bonache, Javier Dormido, Jesús Manuel de la Cruz Garcia, Sergio Pascual Ramirez, Armando Gil de Paz, Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain); Francisco Manuel Sánchez-Moreno, Univ. Politécnica de Madrid (Spain); María Luisa García Vargas, Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain)

MEGARA (Multi-Espectrógrafo en GTC de Alta Resolución para Astronomía) is an optical Integral-Field Unit (IFU) and Multi-Object Spectrograph (MOS) designed for the GTC 10.4m telescope in La Palma that will be commissioned in the early 2017. MEGARA will allow observing up to 100 objects in a region of 3.5' x 3.5' . In its actual configuration,the MEGARA Control System has the capability to interchange between 11 Volume Phase Holographic (VPH) gratings placed on a large wheel, It integrates a state of the art Fiber-MOS system composed by 184 interconnected micro motors moving jointly mini-bundles of fibers to match the desired spatial configurations and a Data Acquisition System that images simultaneously the 600+ fibers spectra over the required spectral range.

9908-323, Session PS5

Stray light assessment and mitigation for the DESI front-end optical system

Timothy N. Miller, Michael Lampton, Robert W. Besuner, Lawrence Berkeley National Lab. (United States); Ming Liang, National Optical Astronomy Observatory (United States); Michael J. Sholl, Lawrence Berkeley National Lab. (United States); Scott Ellis, Photon Engineering LLC (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe modeling and mitigation of stray light within the front end of DESI, consisting of the Mayall telescope and the corrector assembly. This includes the creation of a stray light model, quantitative analysis of the unwanted light at the corrector focal surface, identification of the main scattering sources, and a description of mitigation strategies to remove the sources.

9908-324, Session PS5

PSF modeling by spikes simulations and wings measurements for the MOONS multi-fiber spectrograph

Gianluca Li Causi, Fabrizio Vitali, INAF - Osservatorio Astronomico di Roma (Italy); David Lee, UK Astronomy Technology Ctr. (United Kingdom); Frédéric Royer, Observatoire de Paris à Meudon (France); Ernesto Oliva, INAF - Osservatorio Astrofisico di Arcetri (Italy)

Optical design of MOONS, the next generation thousand-fiber NIR spectrograph for the VLT, involves on-axis reflective collimators and cameras, thus producing beam obstruction by fiber slit and detector support. The need to control i) the effect of the diffraction spikes produced by these obstructions, ii) the detector-induced shape variation of the PSF, and iii) the intensity profile of the PSF wings, leads us to perform both simulations and lab measurements in order to optimize the spider design and to produce a reliable PSF model useful for simulate realistic raw images for testing the data reduction. Starting from the unobstructed PSF variation, as computed with ZEMAX, we numerically computed the

diffraction spikes for different spider shapes, to which we added the PSF wing profile, as measured on a sample of the MOONS grating. Finally, we implemented the PSF defocusing due to the thick detector layer (for the visible channel), and we convolved the fiber core image and the optical ghosts, thus obtaining a detailed and realistic PSF model, that we use for spectral extraction testing, cross talk estimation and sensitivity prediction.

9908-325, Session PS5

DESI focal plate mechanical integration and cooling

Andrew Lambert, Robert W. Besuner, Todd M. Claybaugh, Joseph H. Silber, Lawrence Berkeley National Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the mechanical integration of the DESI focal plate and the thermal system design. The DESI focal plate is comprised of ten identical petal assemblies. Each petal contains 500 robotic fiber positioners. Each petal is a complete, self-contained unit, independent from the others, with integrated power supply, controllers, fiber routing, and cooling services. The major advantages of this scheme are: (1) we support installation and removal of complete petal assemblies in-situ, without disturbing the others, (2) component production, assembly stations, and test procedures are repeated and parallelizable, (3) a complete, full-scale prototype can be built and tested at an early date, (4) each production petal can be surveyed and tested as a complete unit, prior to integration, from the fiber tip at the focal surface to the fiber slit at the spectrograph. The ten petal assemblies will be installed in a single integration ring, which is mounted to the DESI corrector. The aluminum integration ring attaches to the steel corrector barrel via a flexured steel adapter, isolating the focal plate from differential thermal expansions. The plate scale will be kept stable by conductive cooling of the petal assembly. The guider and wavefront sensors (one per petal) will be convectively cooled by forced flow of air. Heat will be removed from the system at ten liquid-cooled cold plates, one per petal, operating at ambient temperature. The entire focal plate structure is enclosed in an insulating shroud, which serves as a thermal barrier between the heat-generating focal plate components and the ambient air of the Mayall dome, to protect the seeing.

9908-326, Session PS5

Design of the calibration unit for the WEAVE multi-object spectrograph at the WHT

Lilian Domínquez Palmero, Diego Cano Infantes, Neil O'Mahony, Carlos Martín, Sergio Picó Rueda, Isaac Newton Group of Telescopes (Spain); Scott C. Trager, Univ. of Groningen (Netherlands); Émilie Lhomé, Chris R. Benn, Cecilia Fariña, Isaac Newton Group of Telescopes (Spain); Michael J. Irwin, James R. Lewis, Univ. of Cambridge (United Kingdom); Marc Balcells, Don Carlos Abrams, Isaac Newton Group of Telescopes (Spain); Gavin B. Dalton, Univ. of Oxford (United Kingdom); Jose Alfonso López Aguerri, Instituto de Astrofísica de Canarias (Spain); Piercarlo Bonifacio, Observatoire de Paris à Meudon (France); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Kevin F. Middleton, STFC Rutherford Appleton Lab. (United Kingdom); Antonella Vallenari, INAF - Osservatorio Astronomico di Padova (Italy)

WEAVE is the next-generation spectroscopic facility for the William Herschel Telescope (WHT), offering multi-object (1000 fibres) and integral-field spectroscopy at two resolutions (R ~ 5000, 20000) over a 2-deg field of view at prime focus.

WEAVE will (mainly) provide optical follow up of ground-based (LOFAR) and space-based (Gaia) surveys. First light is expected towards the end of 2017.

Here we describe the calibration unit, which will be adapted from an existing unit for the AF2+WYFFOS spectrograph (WEAVE's precursor) at the WHT. We present the science and operational requirements for the unit, and summarise results from a thorough characterisation of current performance (e.g. intensity, stability and focal-plane coverage of illumination as a function of lamp type and wavelength). We then set out our plans for upgrading the unit and its control systems to meet the WEAVE science and operational requirements.

9908-327, Session PS5

MEGARA spectrograph mechanics and opto-mechanics in the AIV phase

Manuel Maldonado Medina, Ana Pérez-Calpena, María Luisa García Vargas, Ernesto Sánchez-Blanco Mancera, Ismael Martínez Delgado, FRACTAL S.L.N.E (Spain); Armando Gil de Paz, Univ. Complutense de Madrid (Spain); Xabier Arrillaga Echaniz, AVS Added Value Industrial Engineering Solution S.L.U. (Spain); Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain); Francisco Manuel Sánchez-Moreno, Univ. Politécnica de Madrid (Spain)

MEGARA (Multi-Espectrógrafo en GTC de Alta Resolución para Astronomía) is the future optical Integral-Field Unit (IFU) and Multi-Object Spectrograph (MOS) for the GTC 10.4m telescope. MEGARA is a fiber-fed spectrograph with two modes: a large Integral Field Units (IFU), called LCB (Large Compact Bundle), and the Multi-Object Spectroscopy (MOS) thanks to the use of a set of 92 robotic positioners that will place their corresponding 7-fiber mini-bundle within the 3.5arcmin x 3.5 arcmin FOV. The focal plane will be installed at Folded-Cassegrain F focus of the GTC. The fibers will feed the spectrograph that will be placed in the Nasmyth-A platform of the telescope. The spectrograph is placed on a 3m x 2m optical bench. MEGARA has four mechanisms: one at the pseudo-slit plane to do focus adjustment, the second one to allow exchaning between the fiber bundles of the two configurations (LCB and MOS), a third one that combines the functionality of a rotating shutter for exposure time control with the placement of an order-sorting filter for the red VPHs and, finally, a mechanism that allows the automat exchange among the 11 large pupil elements (containing Volume Phase Holograms, VPHs) that are simultaneously mounted. The Main optical elements (pseudo-slit assembly, collimator and camera) and the cryostat with the detector are located on another table (the auxiliary bench) that is 290mm above the main bench. There is an electro-mechanical actuator below the auxiliary bench that extracts the grating from the wheel and insert it in the optical path with high precision. The wheel is a stiffened and sandwiched-like Ø1530 mm 5083 aluminum alloy. The platforms that carry the VPH mounts will be made of AISI 316 L and a micro shot penning surface treatment will be applied to prevent scatter light. Their size is 449 mm long, 18 mm thick

and 249 mm wide at its maximum. Some mechanizing has been defined to reduce the weight. The mechanical mounts of the VPHS (up to 33kg weight each) are attached to the platforms with a kinematic 3 groove configuration.The actuators proposed for driving the wheel are a pair of servomotors with planetary reducers preloaded on a crossed rolled bearing gear by pinions in order to remove backlash. The actuators are made up of a servomotor with brake attached to a planetary reducer and a pinion. The control electronics shall control the preload in real time. Both servomotors include an encoder on axis.Together with a summary of the design and simulations, we present the real status of the spectrograph integration, the performance of the mechanisms and the alignment procedure.

9908-328, Session PS5

The DESI slit design: science and calibration solutions

Jürgen Schmoll, Durham Univ. (United Kingdom)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryonic Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn will feed 10 broad-band spectrographs. We will describe the science, calibration and tests slits that are interchangeable to allow spectrograph quality assurance, alignment and calibration during construction and maintenance periods. While the calibration slits share the mechanical interface with the science slits, the architecture differs depending on the test slit purpose.

The science slit consists of 500 fibers in 20 blocks of 25 fibers, where the blocks follow the slit curvature. Each block consists of a parallel v-groove array with a flat antireflective window on the top. It has been shown that the deviation from a spherical slit to a slit approximating the curvature by flat blocks is compliant to the specifications on defocus and pupil position, as the small variations introduced are within the error budget. The science slit of each spectrograph can be removed and reproducibly replaced to allow exchange to one of two calibration and test slits, namely the sparsely populated slit and the flat field slit.

The sparsely populated slit has only the outer single fiber groove of each block populated, with the exception of one central block that bears the full 25 fibers. The purpose of this slit is to measure the point spread function and stray light behaviour of the spectrograph. This will help to align and verify the quality of the spectrograph optics during manufacture and enables quality monitoring during the life time of the instrument. The slit will be illuminated by an Offner system that projects the uniform output of an integration sphere onto a connector that holds the 44 fiber inputs for the slit.

The flat field slit consists of a single leaky optical fiber. Leaky fibers can mimick a continuous slit by emitting light sideways in a uniform glow. At the same time the source extension along the dispersion direction is of the same magnitude as the science slit width. The leaky fiber runs in a groove that follows the slit curvature, and both sides are fed with light from a conventional optical fiber. Hence, illuminating the input with white continuum light will allow a flat field illumination of the spectrograph system.

Both calibration slits will be portable setups consisting of a 4m long optical fiber run that passes the light source, conduit, strain relief box and slit breakout. The portability of the system enables testing of the spectrograph optics at the manufacturer and system monitoring of all ten spectrographs during the operational lifetime.

9908-329, Session PS5

SUBARU prime focus spectrograph: integration, testing and performance for the first spectrograph

Fabrice Madec, David Le Mignant, Rudy Barrette, Mohamed Belhadi, Patrick Blanchard, Kjetil Dohlen, Didier Ferrand, Marc Jaquet, Arnaud Le Fur, Joel Le Merrer, Sandrine Pascal, Lab. d'Astrophysique de Marseille (France); James E. Gunn Sr., Princeton Univ. (United States); Stephen A. Smee, Johns Hopkins Univ. (United States); Naoyuki Tamura, Atsushi Shimono, Kavli Institute for the Physics and Mathematics of the Universe (Japan)

The Prime Focus Spectrograph (PFS) of the Subaru Measurement of Images and Redshifts (SuMIRe) project for Subaru telescope consists in four identical spectrographs fed by 600 fibers each. Each spectrograph is composed by an optical entrance unit that creates a collimated beam and distributes the light to three channels, two visible and one near infrared. We present here the integration process and test results of the first spectrograph channel.

The Assembly Integration and Test (AIT) plan is presented, as well as the methods, detailed processes and I&T tools we developed. We described the extensive tests and report on the performance results for the first visible red channel at LAM. We analyze the spectrograph performance by comparing the tests results with model data and specifications.

We also report on and discuss the technical difficulties that did appear during this integration phase. Finally, we detail the future integration plan for the next two years: the four spectrograph modules, each including the three spectral channels and their integration at the SUBARU telescope.

9908-330, Session PS5

SAMOS: a versatile multi-object-spectrograph for the GLAO system SAM at SOAR

Massimo Robberto, Space Telescope Science Institute (United States) and Johns Hopkins Univ. (United States); Megan Donahue, Michigan State Univ. (United States); Zoran Ninkov, Rochester Institute of Technology (United States); Stephen A. Smee, Robert H. Barkhouser, Johns Hopkins Univ. (United States); Mario Gennaro, Space Telescope Science Institute (United States); Andrei Tokovinin, Cerro Tololo Inter-American Observatory (Chile)

Following the advent of LSST there will be enormous pressure on 4m class telescopes for immediate followup and long-term monitoring of transients. The 4.1-m SOAR telescope can play a key role in this field, especially with its laser-guided Adaptive Optics Module (SAM) that routinely delivers images with FWHM <0.5" (frequently ~0.32") over a uniquely large 3'x3' field of view. To exploit this platform we have conceived SAMOS, a Micro-Electro-Mechanical-System based spectrograph capable of acquiring single or multiple targets in a few seconds with extreme precision. SAMOS can capture R~2,000-2,500 spectra with nominal 0.33" slit width in the 3,500-9,500 Angstrom spectral range reaching in 3600 s median SNR=5 at AB=22.9 with the red grating and 23.5 with the blue grating, comparable to 8-m class telescopes working in seeing limited conditions. In this contribution we present the SAMOS opto-mechanical design, concept of operation and provide a few examples of compelling science programs that can uniquely benefit from SAMOS sensitivity, angular resolution, versatility and simplicity of use.

9908-331, Session PS5

4MOST metrology system optical and mechanical design

Samuel C. Barden, Allar Saviauk, Roland Winkler, Leibniz-Institut für Astrophysik Potsdam (Germany)

The 4-metre Multi-Object Spectroscopic Telescope (4MOST) instrument uses ~2400 individually positioned optical fibres to couple the light of targets into its spectrographs. The fibre positioner is mounted at the Cassegrain focus of the VISTA telescope and is based on the Echidna tilting spines concept. The fibres are located in a hexagon-like structure with a diameter of 535 mm and cover a corresponding field of view on the sky with a linear diameter of 2.5 deg. Fibres are positioned relative to fixed fiducial fibres that are assumed to be very stable. Aligning the fibres with the sky is done by the pointing model for 4MOST.

The metrology system determines the position of the fibres on the focal surface of the telescope relative to the fiducial fibres. The location of the fibres needs to be measured to better than 5 micron (3 sigma). We assume that it is possible to determine the centroid of a fibre image to 1/15th of a pixel (3sigma). Four imaging cameras are mounted on the on the VISTA spider vanes. The cameras look through the entire optical train, including primary, secondary and the WFC/ADC unit. Narrow band light is illuminated through each fibre probe by a back illumination system located at the spectrograph slit. The light from the ~2400 science fibres and ~20 fiducial fibres is imaged by the metrology cameras. The software (see related paper) extracts the profiles and determines the centroids for each fibre image such that the position of the fibre can be measured to ~5 microns (~0.08 arc-sec) at the 4MOST focal surface.

We present the optical and mechanical designs of the metrology cameras and the design of the back illumination system.

9908-332, Session PS5

DESI fiber positioner performance verification

Michael S. Schubnell, Univ. of Michigan (United States); Robert W. Besuner, Parker Fagrelius, Joseph H. Silber, Lawrence Berkeley National Lab. (United States); Fransheska Berrios, Irena Gershkovich, Gregory Tarlé, Univ. of Michigan (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14,000 square degrees will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5,000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. The fiber positioner system, composed of 5,000 10mm diameter robotic arms, is designed to be able to position all fibers on target in less than 120 seconds with an accuracy of better than 5 microns. We will describe the qualification of the fiber positioners following assembly to verify the micron level position accuracy. Positioner production is planned at a rate of between 25 and 30 positioners per day and will be followed by immediate inspection and positioning accuracy verification. A quality control test set-up has been designed and built. This set-up will allow to control and measure 15 positioners concurrently. A Python based software package communicates with the positioners through a CAN bus, controls a fiber view camera and performs calibration and accuracy measurements. We will describe the set-up, performance characteristics and show results from pre-production tests.

9908-333, Session PS5

Visible camera cryostat design and performance for the SuMIRe Prime Focus Spectrograph (PFS)

Stephen A. Smee, Johns Hopkins Univ. (United States); James E. Gunn Sr., Princeton Univ. (United States); Mirek Golebiowski, Johns Hopkins University (United States); Stephen C. Hope, Johns Hopkins Univ. (United States); Craig P. Loomis, Princeton Univ. (United States); Robert H. Barkhouser, Johns Hopkins Univ. (United States); Michael A. Carr, Princeton Univ. (United States); Murdock Hart, Johns Hopkins Univ. (United States); Naoyuki Tamura, Atsushi Shimono, Kavli Institute for the Physics and Mathematics of the Universe (Japan); Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (Japan)

We describe the design and performance of the SuMIRe Prime Focus Spectrograph (PFS) visible camera cryostats. SuMIRe PFS is a massively multi-plexed ground-based spectrograph consisting of four identical spectrograph modules, each receiving roughly 600 fibers from a 2394 fiber robotic positioner at the prime focus. Each spectrograph module has three channels covering wavelength ranges 380 nm – 650 nm, 650 nm – 940 nm, and 940 nm – 1.26 um, with the dispersed light being imaged in each channel by a f/1.07 vacuum Schmidt camera. The cameras are very large, having a clear aperture of 300 mm at the entrance window, and a mass of ~ 250 kg. Visible channel cameras utilize a pair of Hamamatsu 2K x 4K edge-buttable CCDs with 15 um pixels to form a 4K x 4K array. In this design, the camera cryostat supports the camera optics in addition to providing the vacuum space and cooling for the detector array. A single Stirling-cycle cryo-cooler from Sunpower is used to provide the cooling, a choice that was driven by the desire for high lift performance, low ambient heat dissipation, and high reliability. To mitigate cooler vibration, an active-damping control system provided by Sunpower is used. In this paper we describe the design of the cryostat and discuss various aspects of cryostat performance, including thermal performance and dynamic response.

9908-334, Session PS5

EMIR electronics AIV and commisioning

Miguel Núñez Cagigal, Enrique Joven Álvarez, Carmen Marillai Barreto Cabrera, Jesús Patrón Recio, Francisco Garzón López, Instituto de Astrofísica de Canarias (Spain)

EMIR is the wide field NIR imager and multiobject spectrograph being built as a common user instrument for the 10-m class GTC. EMIR detector is a Hawaii 2 with a controller from Astronomical Resesarch Camera and home made firmware. EMIR has several cryogenics mechanism: Multi Object Slits for 55 slits, Detector translation unit in x, y and Z axis, filters wheel and grism wheels. It has 3 electrónics cabinets including a PLC controlling the vacuum pumps and the 4 helium closed cycle cold heads. In this paper it is described the adjustments, modifications and lessons learned related to electronics for all these subsystems during the AIV stages and the commissioning in the GTC.

9908-335, Session PS5

4MOST: the high-resolution spectrograph

Walter Seifert, Landessternwarte Heidelberg (Germany); Wenli Xu, Wenli Xu Optical System Engineering

(Germany); Peter Buschkamp, Max-Planck-Institut für extraterrestrische Physik (Germany); Carmen Feiz, Andreas Quirrenbach, Holger G. Mandel, Landessternwarte Heidelberg (Germany); Allar Saviauk, Leibniz-Institut für Astrophysik Potsdam (Germany)

4MOST (4-meter Multi-Object Spectroscopic Telescope) is a wide-field, fiber-feed, high-multiplex spectroscopic survey facility to be installed on the 4-meter ESO telescope VISTA in Chile. It consists of two identical low resolution spectrographs and one high resolution spectrograph. The instrument is presently in the preliminary design phase (review May 2016) and is expected to get operational end of 2020.

The high resolution spectrograph described in the paper will afford simultaneous observations of up to 820 targets - over a hexagonal field of view of ~ 4.1 degrees on sky - with a spectral resolution R>18,000 covering a wavelength range from 392 to 681nm in three channels. The athermal design of the three cameras as well as the fiber-feed exit with respect to the collimator allow a very stable spectral format on the detectors over the full operational temperature range rendering an active thermal control unnecessary.

The optical bench is mounted atop a central support structure inside a passive thermal insulation via attachment points that serve as thermal insulators and vibrational dampers.

The support structure mounts to the VISTA telescope front side below the telescope chamber's azimuth floor. Thus the fiber bundle coming from the telescope enters the spectrograph through the floor and the instrument's top cover via a service port. On the support frame's bottom side, the detector electronics and vacuum pump systems are attached, making it easy to service and install the HRS as an integrated component.

Both, the optical and mechanical design of the high resolution spectrograph are presented in detail in this paper. The expected optical performance including the highly multiplexed fiber slit concept will be given and compared to the specifications.

The thermal and finite element analyses and the resulting stability of the spectrograph under operational conditions will be shown.

The mechanical layout of the optics mounts as well as the passive thermal insulation system will be shown.

The further schedule of the 4MOST high resolution spectrograph will be outlined.

9908-336, Session PS5

4MOST metrology system image processing

Roland Winkler, Samuel C. Barden, Allar Saviauk, Leibniz-Institut für Astrophysik Potsdam (Germany)

The 4-metre Multi-Object Spectroscopic Telescope (4MOST) instrument uses ~2400 individually positioned optical fibres to couple the light of targets into its spectrographs. The fibre positioner is mounted at the Cassegrain focus of the VISTA telescope and is based on the Echidna tilting spines concept. The fibres are located in a hexagon-like structure with a diameter of 535 mm and cover a corresponding field of view on the sky with a linear diameter of 2.5 deg. Fibres are positioned relative to fixed fiducial fibres that are assumed to be very stable. Aligning the fibres with the sky is done by the pointing model for 4MOST.

The metrology system determines the position of the fibres on the focal surface of the telescope relative to the fiducial fibres. The location of the fibres needs to be measured to better than 5 micron (3-sigma) in the focal surface, approximately 0.08 arc seconds on sky. We assume that it is possible to determine the centroid of a fibre image to 1/15th of a pixel (3-sigma). Four imaging cameras are mounted on the on the VISTA spider vanes that look through the entire optical train, including primary, secondary and the WFC/ADC unit. Narrow band light is illuminated through each fibre probe by a back illumination system located at the spectrograph slit. The light from the ~2400 science fibres and ~20 fiducial fibres is imaged by the metrology cameras. The software extracts the profiles and determines the centroids for each fibre image.

This paper is focused on the image processing aspect of the metrology system, the opto-mechanical aspects are discussed in (4MOST Metrology System Optical and Mechanical Design, submitted this SPIE 2016 conference).

To assure a good sampling, we artificially broaden the fibre images to a FWHM size between 2.5 and 3 pixels. For centroiding, a gaussian profile is fitted to the fibre images, which very similar to the core profile of the fibres images. It is expected that the metrology system has to deal with a variety of different effects that can cause errors in the centroiding procedure, sorted into three categories:

Static effects that can be mitigated by calibration: CCD pixel responds, optical aberrations, CCD pixel layout (pixel locations on CCD), fiducial spine inaccuracies, calibration target errors.

Dynamic errors that change over time, but are quite predictable given the correct information: Cassegrain rotation, nonuniform refraction index of optical elements in the WFC/ADC, plate scale due to heat, WFS errors, ADC offsets and spectral spot broadening, fibre tilt, spot brightness variations, ghosts and background light.

Random effects are not precisely predictable but should be characterizable in terms of probability distribution and magnitude: pixel noise (dark current, photon noise, readout noise), pixel responds degradation, spectral freckles, dirt on lenses and detector, dome seeing, temperature gradients, back-illumination wavelength shifts, fibre mode pattern inaccuracies, coordinate transformations algorithm errors.

In this paper, we describe how we plan to counter the mentioned effects and how we want to achieve the goal of 5 microns, 3 sigma centroiding accuracy. We also present the results from our 1 in 10 scale prototype, build in our lab.

9908-337, Session PS5

The DESI fiber positioner system *(Invited Paper)*

Gregory Tarlé, Michael S. Schubnell, Jon Ameel, Curtis Weaverdyck, Irena Gershkovich, Univ. of Michigan (United States); Henry D. Heetderks, Joseph H. Silber, Robert W. Besuner, Lawrence Berkeley National Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14,000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5,000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the fiber positioner system, composed of 5,000 10mm diameter robotic arms, designed to be able to position all fibers on target in less than 120 seconds with an accuracy of better than 5 microns. The positioners have eccentric axis kinematics. Actuation is provided by two 4 mm diameter DC brushless gearmotors. An electronics board attached to the rear accepts a DC voltage for power and CAN messages for communications and then drives the two motors. The positioner accepts the ferrulized and polished science fiber and provides a mechanically safe path through its internal mechanism. Accuracy and lifetime tests were performed.

9908-338, Session PS5

Detector and control system design and performance for the SuMIRe prime focus spectrograph (PFS) cameras

James E. Gunn Sr., Princeton Univ. (United States); Stephen A. Smee, Johns Hopkins Univ. (United States); Roger E. Fitzgerald, Fitzgerald Engineering, Inc. (United States); Murdock Hart, Stephen C. Hope, Johns Hopkins Univ. (United States); Craig P. Loomis, Princeton Univ. (United States); Grant O. Peacock, Johns Hopkins Univ. (United States); Naoyuki Tamura, Atsushi Shimono, Kavli Institute for the Physics and Mathematics of the Universe (Japan); Naruhisa Takato, National Astronomical Observatory of Japan (Japan)

We discuss the design, construction, and performance of the detector system for the SuMIRe Prime Focus Spectrograph (PFS). SuMIRe PFS is a massively multi-plexed ground-based spectrograph consisting of four identical spectrograph modules, each receiving roughly 600 fibers from a 2394 fiber robotic positioner at the prime focus. Each spectrograph module has three channels covering wavelength ranges 380 nm – 650 nm, 650 nm – 940 nm, and 940 nm – 1.26 um, with the dispersed light being imaged in each channel by a f/1.07 vacuum Schmidt camera. In this paper we describe the CCD system for the two visible channels and the overall control and data acquisition systems for the cameras, and discuss the test system for detector characterization. This system will also serve for testing the H4RG infrared detectors for the near IR channel. The first red system, utilizing a 200-micron thick fully depleted p-channel Hamamatsu CCD, is finished and has been tested. The performance is excellent, with low noise, high CTE, and very good low-level and overall linearity.

The test system uses essentially all the `flight' electronics and power supplies, in an effort to assess performance in an environment as nearly like the one to be seen in operation as possible.

9908-339, Session PS5

MEGARA: collimator and camera opto-mechanics; integration and verification strategy

José Luis Avilés Urbiola, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Armando Gil de Paz, Jorge Iglesias-Páramo, Univ. Complutense de Madrid (Spain); Esperanza E. Carrasco-Licea, Edgar Castillo-Domínguez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

MEGARA is the new generation integral and multi-object optical spectrograph for Gran Telescopio Canarias. The whole camera and collimator opto-mechanics of the MEGARA spectrograph stands out, among other things, for the extent of its dimensions. In order to maintain the optical components constrained, so that they remain within tilt and decentration budgets, the diameters of both the mechanical housings and the optics itself have been specified in such a way that every pair of concentric mating-surfaces be manufactured by converging to the same nominal diameter, and therefore, by allowing the assembly-process be achieved at the expense of tight radial-clearances, standardized along with a narrow margin of manufacturing error. Such margin will be constrained by the ISO system of limits and fits-tolerances under the category of a "sliding fit" assembly (the H7/g6 designation according to the standard nomenclature). So, while the dimension of the involved diameters spans from 110 to 307 mm, the range of allowed radial-clearances spans from 10 to 100 microns, which makes the assembly process complicated if, additionally, the mass and structural brittleness of the lenses are considered. Here we present a detailed description of the strategy we will follow for integrating, and verifying, the MEGARA's collimator and camera opto-mechanics. The AIV process will be carried out at the INAOEs facilities, in México, with a custom designed mechanical set-up. The mechanical device manufactured to assist the integration is presented, along with a description of the difficulties overcome, and the dimensional verification procedure we will follow along with the assembly of the opto-mechanics.

9908-340, Session PS5

Development of the fibre positioning unit of MOONS

David M. Montgomery, UK Astronomy Technology Ctr. (United Kingdom)

The Multi-Object Optical and near-Infrared Spectrograph (MOONS) will exploit the full 500 square arcmin field of view offered by the Nasmyth focus of the Very Large Telescope and will be equipped with two identical triple arm cryogenic spectrographs covering the wavelength range 0.64μm-1.8μm, with a multiplex capability of over 1000 fibres. Each spectrograph will produce spectra for 500 targets simultaneously, each with its own dedicated sky fibre for optimal sky subtraction. The system will have both a medium resolution (R~4000-6000) mode and a high resolution (R~20000) mode.

The fibres positioning units are used to position each fibre independently in order to pick off each sub field of 1.0" within a circular patrol area of ~85" on sky (50mm physical diameter). The nominal physical separation between FPUs is 25mm allowing a 100% overlap in coverage between adjacent units. The design of the fibre positioning units allows parallel and rapid reconfiguration between observations. The geometry is such that pupil alignment is maintained over the patrol area.

This paper presents the design of the Fibre Positioning Units at the preliminary design review and the results of verification testing of the advanced prototypes.

Submit: MOONS will be a fibre-fed, optical to near-infrared multi-object spectrograph designed to utilise the full 25 arc minute field of view and with a multiplex capability of over 1000 fibres. The fibres will make the link between the focal plane and the two spectrographs.

9908-341, Session PS5

Very fast transmissive spectrograph designs for highly multiplexed fiber spectroscopy

Will Saunders, Australian Astronomical Observatory (Australia)

The increasing multiplex factor and resolution requirements of wide-field spectroscopic telescopes means that instrument costs are usually dominated by the spectrographs. For most projects, cost, resolution and read-noise considerations all drive camera speeds to be as fast as practicable. A simple highly efficient, fully transmissive spectrograph design is presented, which depends heavily on Calcium Fluoride aspheres, which are now routinely available via diamond turning with MRF post-polishing. For the proposed Hector instrument on the AAT, a 3-armed design with F/1.4 cameras and 4Kx4K detectors is presented. The largest optical apertures are 225mm, and the rms radii < 9microns for all wavelengths and slit positions. For larger telescopes such as the proposed Mauna Kea Spectroscopic Explorer, even faster cameras are desirable. By using existing curved detectors, the design can be pushed to F/1, while retaining excellent throughput and image quality.

9908-342, Session PS5

The Dark Energy Spectroscopic Instrument (DESI) spectrographs

Patrick N. Jelinsky, Jerry Edelstein, Univ. of California, Berkeley (United States); DESI Collaboration, Lawrence Berkeley National Laboratory (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe by observing the spectra of 40 million galaxies over the five-year life of the project. DESI, to be installed on the Mayall 4-m telescope at KPNO in 2018, includes a new, 8 square degree field-of-view corrector at prime focus that simultaneously delivers target flux to 5,000 optical fibers, each driven by a robotic positioners. Groups of 500 fibers are fed to one of 10 high-throughput spectrographs that each covers a 360–980 nm pass band. Dichoric filters divide the pass band into three simultaneous spectral channels that each contains a transmission diffraction grating and a camera system. The spectrograph delivers a spectral resolutions reaching R = 4000. The DESI spectrograph and cameras represent a substantial advance in highly efficient, wide-field optical design. We review the performance, design and plan for the DESI spectrograph system, highlighting essential subsystems and elements of these instruments. Plans for and progress of the fabrication and testing of the spectrographs are described.

9908-343, Session PS5

The Dark Energy Spectroscopic Instrument (DESI) guide, focus and alignment system

Kevin A. Reil, SLAC National Accelerator Lab. (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We describe the Guide, Focus and Alignment (GFA) cameras designed for DESI. These cameras, as titled, will keep DESI in focus, optically aligned and guided to stay on target. We discuss design considerations, current status and construction of the first GFA camera in support of the proto-DESI effort in late 2016.

9908-344, Session PS5

Building BATMAN: a new generation spectro-imager on TNG telescope

Frédéric Zamkotsian, Harald Ramarijaona, Lab. d'Astrophysique de Marseille (France); Manuele Moschetti, INAF - Osservatorio Astronomico di Brera (Italy); Patrick Lanzoni, Lab. d'Astrophysique de Marseille (France); Marco Riva, Paolo Spano, INAF - Osservatorio Astronomico di Brera (Italy); William Bon, Romain Alata, Lab. d'Astrophysique de Marseille (France); Luciano Nicastro, INAF - IASF Bologna (Italy); Emilio Molinari, Rosario Cosentino, Adriano Ghedina, Manuel Gonzalez, Walter Boschin, Telescopio Nazionale Galileo (Spain); Paolo Di Marcantonio, Igor Coretti, Roberto Cirami, INAF - Osservatorio Astronomico di Trieste (Italy); Filippo Maria Zerbi, INAF - Osservatorio Astronomico di Brera (Italy); Luca Valenziano, INAF - IASF Bologna (Italy)

Next-generation infrared astronomical instrumentation for ground-based and space telescopes could be based on MOEMS programmable slit masks for multi-object spectroscopy (MOS). This astronomical technique is used extensively to investigate the formation and evolution of galaxies.

We are developing a 2048x1080 Digital-Micromirror-Device-based (DMD) MOS instrument to be mounted on the Galileo telescope (TNG) and called BATMAN. A two-arm instrument has been designed for providing in parallel imaging and spectroscopic capabilities. The field of view (FOV) is 6.8 arcmin x 3.6 arcmin with a plate scale of 0.2 arcsec per micromirror and per detector pixel. The wavelength range is in the visible and the spectral resolution is R=560 for 1 arcsec object (typical slit size). The instrument will have two 2k x 4k CCD detectors. The two arms with F/4 on the DMD are mounted on a common bench, and an upper bench supports the detectors thanks to two independent hexapods. The stiffness of the instrument is guaranteed thanks to a box architecture linking both benches. The volume of BATMAN is 1.4x1.2x0.75 m3, with a total mass of 400kg.

BATMAN will be mounted on the folded Nasmyth platform of TNG and then rotate during observation. A Finite Element Modeling (FEM) has been done under different gravity vector orientation for simulating extreme instrument locations, and the deformations of the main bench as well as translation/rotation of each detector are calculated. We reach an ultimate displacement of the center of the detectors below 20µm (i.e. <1.5 detector pixel) with respect to DMD center, for any position of the instrument on the rotator.

Hexapod have been designed, realized and delivered to LAM. They are under test for validating their ability to reach a positioning precision on the 6 degrees of freedom below 5µm. All optics have been delivered as well as fore-optics mounts, and the calibration unit including one flat field and two line lamps are under final integration. Preliminary instrument software as well as data handling philosophy have been developed. The two detectors with tilted focal planes inside the dewars have been designed, parts have been built, and they are under integration at TNG. All remaining parts including the main bench are at detailed design phase, and they will be realized during first 2016 semester.

Integration of the instrument is then scheduled during summer 2016. At this stage, we will use the experience learnt during the integration of ROBIN, a BATMAN demonstrator. ROBIN permitted to determine the instrument integration and alignment procedure, to confirm the resulting very good optical quality, both on imagery and spectroscopic arms (typically with spot diagrams within one detector pixel), and to develop the scientific optimization strategy over the whole FOV.

BATMAN on the sky is of prime importance for characterizing the actual performance of this new family of MOS instruments, as well as investigating the new operational procedures on astronomical objects. This instrument will be placed on the Telescopio Nazionale Galileo at the end-2016.

9908-345, Session PS5

Fiber system design for the Dark Energy Spectroscopic Instrument (DESI)

Claire L. Poppett, Jerry Edelstein, Space Sciences Lab. (United States); Jürgen Schmoll, David G. Bramall, Ray M. Sharples, Durham Univ. (United Kingdom)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the fiber systems design with specific emphasis on novel approaches and essential elements that lead to exceptional performance.

The function of the fiber system is to transmit the light from 5,000 science-targets imaged at the telescope prime focus to the spectrograph optical input. Each optical fiber, with a 107m diameter core, is terminated in a ferrule that is then mounted in a positioner arm. The fibers are collected behind the focal plane into ten groups of 500. Each group spans 38 m from the focal plane to the spectrograph room via guides, supports, strain-relieving spool boxes, and ruggedized cables. Each group of 500 fibers is then precisely arranged and terminated into a linear arc that provides the optical entrance-slit illumination to an associated spectrograph.

The fiber run includes a fusion-splice connection near the focal plane to allow for positioner installation and to facilitate fabrication, integration and testing flow. In order to retain maximum throughput and minimize the focal ratio degradation (FRD) when connecting the fiber system, we are employing fusion splicing as opposed to mechanical connectorization. We report results from the splicing process, measuring a collimated focal ratio degradation (FRD) increase of less than 0.5 degrees for a f/3.9 input beam compared to >1 degree increase for mechanical connectors. We also show that the near field performance is not degraded after splicing. These results represent the first of their kind for a fiber-fed astronomical instrument.

The other novel aspect of the fiber system is that the input of the fibers are optically terminated via cleaving rather than polishing. The major advantage to cleaving is that the fibers can be held in ferrules with a much softer glue than is required for polishing. This results in lower stress being imparted onto the fiber which is especially important for the near field performance. In addition to the exceptional performance, this method has also proven to produce a higher yield than polishing since there are fewer variables.

9908-346, Session PS5

Optical fiber termination method for the Dark Energy Spectroscopic Instrument (DESI)

Claire L. Poppett, Jerry Edelstein, Yuzo Ishikawa, Space Sciences Lab. (United States); Parker Fagrelius, Lawrence Berkeley National Lab. (United States); Zak Meghrouni-Brown, Dartmouth College (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of 40 million galaxies over 14000 sq deg will be measured during the life of the experiment. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs. We will describe the method we use to optically terminate the fibers which offers many advantages over methods that have been used in the past.

In most astronomical fiber-fed instruments the fibers are terminated via bonding in a ferrule and then polishing with progressively finer grades of polishing paper and polishing solutions until the required performance is achieved. Since the fibers have to be held within the ferrules securely to withstand the relatively violent polishing process, a hard glue must be used. This introduces stress onto the end of the fiber and dominates the focal ratio degradation performance.

We have demonstrated that simply bonding cleaved fibers to glass ferrules is a more efficient alternative without sacrificing fiber performance, which was determined by measuring the focal ratio degradation (FRD). In this study we found that by minimizing the FRD contributions from the fiber-ferrule bonding and fiber cleaving, we can quickly produce high-performance fibers satisfying the DESI science requirements.

9908-347, Session PS5

The Maunakea Spectroscopic Explorer: throughput optimization

Nicolas Flagey, Canada-France-Hawaii Telescope (United States); Shan B. Mignot, Observatoire de Paris à Meudon (France); Kei Szeto, Alan McConnachie, Rick Murowinski, Canada-France-Hawaii Telescope (United States)

The Maunakea Spectroscopic Explorer (MSE) will each year obtain millions of spectra in the optical to near-infrared, at low (R~2,500) to very high (R~40,000) spectral resolution by obtaining ~3000 spectra per pointing via a highly multiplexed fiber-fed system. Key science programs for MSE include black hole reverberation mapping, stellar population analysis of faint galaxies at high redshift, and sub-km/s velocity accuracy for stellar astrophysics. Most science objectives require observations of faint Galactic (visual magnitudes up to 20) and very faint extra-galactic targets (visual magnitudes up to 24). As a consequence, MSE will need to achieve the highest throughput possible over a spectral range that extends from 360 to 1800 nm. In this paper, we present the different components that affect the throughput, from the atmosphere to the detectors, and the technical solutions we are considering to optimize the overall throughput of the project and meet the science requirements.

9908-66, Session 14

Cosmological surveys with multi-object spectrographs *(Invited Paper)*

Matthew M. Colless, The Australian National Univ. (Australia)

Multi-object spectroscopy has been a key technique contributing to the current era of 'precision cosmology'. From the first exploratory surveys of the large-scale structure and evolution of the universe to the current generation of superbly detailed maps spanning a wide range of redshifts, multi-object spectroscopy has been a fundamentally important tool for mapping the rich structure of the cosmic web and extracting cosmological information of increasing variety and precision. This will continue to be true for the foreseeable future, as we seek to map the evolving geometry and structure of the universe over the full extent of cosmic history in order to obtain the most precise and comprehensive measurements of cosmological parameters. In this talk I will briefly summarize the contributions that multi-object spectroscopy has made to cosmology so far, then review the major surveys and instruments currently in play and their prospects for pushing back the cosmological frontier. Finally, I will examine some of the next generation of instruments and surveys to explore how the field will develop in coming years, with a particular focus on specialised multi-object spectrographs for cosmology and the capabilities of multi-object spectrographs on the new generation of extremely large telescopes.

9908-67, Session 14

Progress along the E-ELT instrumentation roadmap *(Invited Paper)*

Mark M. Casali, Suzanne K. Ramsay, European Southern Observatory (Germany)

A suite of seven instruments and associated AO systems have been planned as the "E-ELT Instrumentation Roadmap". Following the E-ELT project approval in December 2014, rapid progress has been made in organising and signing the agreements for construction with European universities and institutes. Three instruments (HARMONI, MICADO and

METIS) and one MCAO module (MAORY) have now been approved for construction. In addition, Phase-A studies have begun for the next two instruments - a multi-object spectrograph and high-resolution spectrograph. Technology development is also ongoing in preparation for the final instrument in the roadmap, the planetary camera and spectrograph.

In this talk I will give a summary of the strategies, problems and capabilities of this first set of instruments for the E-ELT, and outline the organisation of the instrumentation programme.

9908-68, Session 14

Instrumentation progress at the Giant Magellan Telescope project *(Invited Paper)*

George H. Jacoby, Rebecca A. Bernstein, GMTO Corp. (United States) and Carnegie Observatories (United States); Antonin H. Bouchez, GMTO Corp. (United States); Matthew M. Colless, The Australian National Univ. (Australia); Darren L. DePoy, Texas A&M Univ. (United States); Brady Espeland, The Australian National Univ. (Australia); Daniel T. Jaffe, The Univ. of Texas at Austin (United States); Jonathan S. Lawrence, Australian Astronomical Observatory (Australia); Jennifer L. Marshall, Texas A&M Univ. (United States); Peter McGregor, Robert Sharp, The Australian National Univ. (Australia); Andrew Szentgyorgyi, Harvard Univ. (United States); Brian Walls, GMTO Corp. (United States)

Instrument development for the 24 m Giant Magellan Telescope (GMT) will be described: current activities, progress, status, and schedule. One instrument team has completed its preliminary design and is currently performing its final design (G-CLEF, an optical 350-950 nm high-resolution and precision radial velocity echelle spectrograph). A second instrument team is in its conceptual design phase (GMACS, an optical 350-950 nm low-to-medium resolution 6-10 arcmin field multi-object spectrograph). A third instrument team is midway through its preliminary design phase (GMTIFS, a near-IR YJHK diffraction-limited imager/integral-field-spectrograph), focused on risk reduction prototyping and design optimization. A fourth instrument team is currently fabricating the 5 silicon immersion gratings it needs as a critical element of its preliminary design phase (GMTNIRS, a JHKLM high-resolution AO-fed echelle spectrograph). And, another instrument team is focusing on technical development and prototyping (MANIFEST, a facility robotic multi-fiber-feed with a 20 arcmin field of view). In addition, a medium-field (6 arcmin, 0.07 arcsec/pix) optical imager has been added to support telescope and AO commissioning activities, and to provide narrow-band science imaging. In the spirit of advancing synergies with other groups, I will discuss the challenges of running an ELT instrument program, lessons learned, and opportunities for cross-ELT collaboration.

9908-69, Session 14

Thirty Meter Telescope science instruments: a status report *(Invited Paper)*

Luc Simard, Thirty Meter Telescope (United States) and National Research Council Canada (Canada); Brent L. Ellerbroek, Ravinder S. Bhatia, Thirty Meter Telescope (United States); Matthew V. Radovan, Univ. of California Observatories (United States) and Thirty Meter Telescope (United States); Eric M. Chisholm, Thirty Meter Telescope (United States)

An overview of the current status of the Thirty Meter Telescope (TMT) science instruments is presented. Work on the three first-light instruments (WFOS, IRIS and IRMS) has made significant progress in many key areas. IRIS has been re-designed end-to-end to provide an expanded imaging field of view of 34'' x 34'' that is now very well-matched to the corrected field delivered by the NFIRAOS AO system. WFOS has been the focus of a extensive set of mini-studies conducted by 15 institutes across the TMT partnership, and these mini-studies have provided many new ideas that will be included in future design phases. A very low-vibration facility cryogenic cooling system for the instruments based on gaseous helium turbine expanders has also been designed and may provide a new way to cool instruments on extremely large telescopes. Finally, many groups in TMT partner communities are developing future instruments concepts in preparation for a future call for second-generation instrument proposals.

9908-70, Session 15

The Infrared Imaging Spectrograph (IRIS) for TMT: instrument overview

James E. Larkin, Univ. of California, Los Angeles (United States); Anna M. Moore, California Institute of Technology (United States); Shelley A. Wright, Univ. of California, San Diego (United States); James E. Wincentsen, California Institute of Technology (United States); Eric M. Chisholm, Thirty Meter Telescope (United States); Richard G. Dekany, California Institute of Technology (United States); Jennifer S. Dunn, NRC - Herzberg Astronomy & Astrophysics (Canada); Brent L. Ellerbroek, Thirty Meter Telescope (United States); Yutaka Hayano, National Astronomical Observatory of Japan (Japan); Andrew C. Phillips, Univ. of California Observatories (United States); Luc Simard, NRC - Herzberg Astronomy & Astrophysics (Canada); Roger M. Smith, California Institute of Technology (United States); Ryuji Suzuki, National Astronomical Observatory of Japan (Japan); Jason L. Weiss, Univ. of California, Los Angeles (United States); Kai Zhang, National Astronomical Observatories (China)

IRIS is a near-infrared (0.84 to 2.4 micron) integral field spectrograph and wide-field imager being developed for first light with the Thirty Meter Telescope (TMT). It mounts to the advanced adaptive optics (AO) system NFIRAOS and has integrated on-instrument wavefront sensors (OIWFS) to achieve diffraction-limited spatial resolution at wavelengths longer than 1 μm. With moderate spectral resolution (R ~ 4000 – 8,000) and large bandpass over a continuous field of view, IRIS will open new opportunities in virtually every area of astrophysical science. It will be able to resolve surface features tens of kilometers across Titan, while also mapping the most distant galaxies at the scale of an individual star forming region. This paper summarizes the entire design and capabilities, and includes the results from the completed preliminary design phase.

9908-71, Session 15

The E-ELT first light spectrograph HARMONI: capabilities and modes

Niranjan A. Thatte, Univ. of Oxford (United Kingdom); HARMONI Consortium, Univ of Oxford (United Kingdom)

HARMONI is the first light, visible and near-infrared integral field

spectrograph for the European Extremely Large Telescope (E-ELT). A work-horse instrument, it provides a range of spatial scales, ranging from diffraction limited to a factor of 15 coarser, coupled with a range of spectral resolving powers, ranging from R~3500 to R~20000. A “point-and-shoot” instrument, HARMONI is ideally suited for spatially resolved spectroscopy of astrophysical sources, whilst also providing ultra-sensitive point-source spectroscopy over the 0.5 to 2.45 micrometres wavelength range.

The technical specifications are now well established, and we will present a summary of HARMONI’s capabilities. Following contract signature, we have expanded the consortium’s efforts to include the HARMONI Laser Tomographic Adaptive Optics (H-LTAO) capability. During the preliminary design phase, we are exploring telescope-instrument interface architectures that will allow seeing limited observing at visible and near-IR wavelengths, as well as bright natural guide star (SCAO) and H-LTAO adaptive optics assisted observing at near-infrared wavelengths. We will also discuss baseline solutions that support all these observing modes and optimal performance.

9908-72, Session 15

GMTIFS: The Giant Magellan Telescope integral fields spectrograph and imager

Rob Sharp, Gabriel J. Bloxham, Robert Boz, David Bundy, John Davies, Brady Espeland, John Hart, Jon Nielsen, Colin Vest, Annino Vaccarella, Peter J. Young, Peter McGregor, The Australian National Univ. (Australia)

GMTIFS is to be the first-light adaptive optics spectrograph for the GMT, having been selected as a first generation instrument through a competitive review process in 2010. The GMTIFS concept is for a workhorse single-object integral field spectrograph, operating at intermediate resolution (R~5,000 & 10,000) with a parallel imaging channel. The IFS offers variable spaxel scales to Nyquist sample the diffraction limited GMT PSF from ? ~ 1-2.5 ?m as well as a 50 mas scale to provide high sensitivity for low surface brightness objects. GMTIFS will operate with all AO modes of the GMT (Natural guide star - NGSAO, Laser Tomography – LTAO, and, Ground Layer - GLAO) with a strong emphasis on achieving high sky coverage for LTAO observations. We summarize the principle science drivers for GMTIFS, the major design concepts that allow these goals to be achieved, and the principle challenges being addressed in the preliminary design study (via prototyping) to ensure GMTIFS meets its ambitious specification.

9908-73, Session 15

MICADO: first light imager for the E-ELT

Richard Davies, Max-Planck-Institut für extraterrestrische Physik (Germany); João Alves, Univ. Wien (Austria); Yann Clénet, Observatoire de Paris à Meudon (France); Florian Lang-Bardl, Ludwig-Maximilians-Univ. München (Germany); Harald Nicklas, Georg-August-Univ. Göttingen (Germany); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Josef Schubert, Eckhard Sturm, Max-Planck-Institut für extraterrestrische Physik (Germany); Eline Tolstoy, Univ. of Groningen (Netherlands)

MICADO, the Multi-AO Imaging Camera for Deep Observations, will equip the E-ELT with a first light capability for diffraction limited imaging at near-infrared wavelengths. The instrument is optimised to work with a 1arcmin field corrected by the laser guide star multi-conjugate adaptive optics module MAORY, but it also includes a simple and robust natural guide star wavefront sensor for single-conjugate adaptive optics. And it will be able to function in a “stand-alone” mode that involves operating with the SCAO wavefront sensor but without MAORY. The instrument’s observing modes focus on various flavours of imaging, including astrometric, high contrast, and time resolved. There is also a single object spectroscopic mode optimised for wavelength coverage at moderately high resolution. In this contribution, we begin by outlining the scientific rationale for the observing modes. We then describe the design of MICADO, and explain how it has been developed to fulfil the science requirements, as well as meet the observatory operational and maintenance requirements.

9908-74, Session 15

Status of the mid-infrared E-ELT imager and spectrograph METIS

Bernhard R. Brandl, Leiden Univ. (Netherlands) and Technische Univ. Delft (Netherlands); Roy van Boekel, Max-Planck-Institut für Astronomie (Germany); Sascha P. Quanz, ETH Zürich (Switzerland); Rieks Jager, Nederlands Centrum voor Laser Research B.V (Netherlands); Markus Feldt, Max-Planck-Institut für Astronomie (Germany); Alistair C. H. Glasse, UK Astronomy Technology Ctr. (United Kingdom); Manuel Güdel, Univ. Wien (Austria); Michael R. Meyer, ETH Zürich (Switzerland); Eric J. Pantin, CEA-Ctr. de SACLAY (France); Christoffel Waelkens, KU Leuven (Belgium)

METIS is one the first three instruments on the E-ELT, expected to see first light in 2025. Apart from diffraction limited imaging, METIS will provide coronagraphy and medium resolution slit spectroscopy over the 3 - 19um range, as well as high resolution (R ~ 100,000) integral field spectroscopy from 2.9-5.3μm, including a mode with extended instantaneous wavelength coverage. The unique combination of these observing capabilities, makes METIS the ideal instrument for the study of circumstellar disks and exoplanets. Additional science topics include our Solar system, the Galactic center, brown dwarfs, evolved stars, massive stellar clusters, active galactic nuclei (AGN), local starbursts, transient events, and luminous infrared galaxies at intermediate redshift. In this paper we provide an update of the relevant science drivers, together with simulated science observations. We discuss the programmatic status and present a preliminary design of the instrument. The latter will focus on the areas of the revised optical design, the adaptive optics concept, data reduction pipeline, and the challenges with regard to calibration of observations at thermal infrared wavelengths on a six-mirror ELT.

9908-75, Session 15

GMTNIRS: progress toward the Giant Magellan Telescope near-infrared spectrograph

Daniel T. Jaffe, The Univ. of Texas at Austin (United States); Stuart I. Barnes, Leibniz-Institut für Astrophysik Potsdam (Germany); Cynthia B. Brooks, Hanshin Lee, Gregory Mace, The Univ. of Texas at Austin (United States); Soojong Pak, Kyung Hee Univ. (Korea, Republic of); Byeong-Gon Park, Chan Park, Korea Astronomy and Space Science Institute (Korea, Republic of)

GMTNIRS is a first-generation instrument for the Giant Magellan Telescope. It is a high-resolution spectrograph that will cover the 1.15-5.5 ?m range in a single exposure with R=?/??= 60,000 in the J, H, and K bands and R=85,000 in the L and M bands. It resides on the rotating instrument platform and employs the facility adaptive optics system. GMTNIRS design

is evolving in response to lessons from its highly successful forerunner instrument, IGRINS. These lessons include the utility of an infrared slit viewing camera, the need to consider extended targets in the science plan, the importance of precise and straightforward wavelength calibration in all observing windows, and the value of a simple-to-use pipeline that produces science-ready data products. Technical changes are also driving evolution of the design. It has proven impractical to manufacture quality 200mm long immersion gratings at the necessary precision. The success of primary mirror phasing efforts has removed the need for a very wide entrance slit that would have been needed to accommodate the Airy pattern of individual segments. The high efficiency of our double-side coated JWST grisms introduces the possibility of transmissive cross-dispersers at L and M. These changes move us toward a design with almost the same R (see above) as presented in our previous work but with a much more compact physical envelope. We will report on the optimization of the instrument design with these technical changes in mind. We are also producing the critical Si immersion gratings. The grating production is well under way and includes manufacture of H and K gratings and process development for the precision needed in the J band and for the manufacture of larger gratings for the L and M band. The development of GMTNIRS is on track with the results from IGRINS and the progress in the lab giving us substantial assurance that the new instrument can meet its performance goals.

9908-76, Session 16

The GMT-Consortium Large Earth Finder (G-CLEF): an optical Echelle spectrograph for the Giant Magellan Telescope (GMT)

Andrew Szentgyorgyi, Daniel Baldwin, Harvard-Smithsonian Ctr. for Astrophysics (United States); Jacob L. Bean, The Univ. of Chicago (United States); Sagi Ben-Ami, Patricia Brennan, Jamie A. Budynkiewicz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Moo-Young Chun, Korea Astronomy and Space Science Institute (Korea, Republic of); Charlie Conroy, Harvard Univ. (United States); Jeffrey D. Crane, Carnegie Observatories (United States); Harland Epps, Lick Observatory (United States); Ian N. Evans, Janet Evans, Jeff Foster, Harvard-Smithsonian Ctr. for Astrophysics (United States); Anna Frebel, Massachusetts Institute of Technology (United States); Thomas Gauron, Harvard-Smithsonian Ctr. for Astrophysics (United States); Christian Dani Guzmán, Pontificia Univ. Católica de Chile (Chile); Tyson Hare, Carnegie Observatories (United States); Bin-Ho Jang, Jeong-Gyun Jang, Korea Astronomy and Space Science Institute (Korea, Republic of); Andres Jordan, Pontificia Univ. Católica de Chile (Chile); Jihun Kim, Kang-Miin Kim, Korea Astronomy and Space Science Institute (Korea, Republic of); Claudia L. M. de Oliveira, Univ. de São Paulo (Brazil); Mercedes Lopez-Morales, Kenneth McCracken, Stuart McMuldroch, Joseph B. Miller, Mark A. Mueller, Harvard-Smithsonian Ctr. for Astrophysics (United States); Jae Sok Oh, Korea Astronomy and Space Science Institute (Korea, Republic of); Mark P. Ordway, Harvard-Smithsonian Ctr. for Astrophysics (United States); Byeong-Gon Park, Chan Park, Sung-Joon Park, Korea Astronomy and Space Science Institute (Korea, Republic of); Charles Paxson, David F. Phillips, David A. Plummer, William A. Podgorski, Harvard-Smithsonian Ctr. for Astrophysics (United States); Andreas Seifahrt, The Univ. of Chicago (United States); Daniel Stark, The Univ. of Arizona (United States); Joao Steiner, Univ. de São Paulo (Brazil); Alan Uomoto, Carnegie Observatories (United States); Ronald L. Walsworth, Harvard-Smithsonian Ctr. for Astrophysics (United States); Young-Sam Yu, Korea Astronomy and Space Science Institute (Korea, Republic of)

The GMT-Consortium Large Earth Finder (G-CLEF) will be a cross-dispersed, optical band echelle spectrograph to be delivered as the first light scientific instrument for the Giant Magellan Telescope (GMT) in 2021. G-CLEF is vacuum-enclosed and fiber-fed to enable precision radial velocity (PRV) measurements, especially for the detection and characterization of low-mass exoplanets orbiting solar-type stars. The passband of G-CLEF is very broad, extending from 3500Å to 9500Å. This passband provides good sensitivity at blue wavelengths for stellar abundance studies and deep red response so as to permit observations of high-redshift phenomena.

The design of G-CLEF incorporates several novel technical innovations and methodologies when compared with previous PRV instruments and instrumentation for ground based telescopes in general. G-CLEF has recently passed preliminary design review (PDR) and a subsequent gate review of the spectrograph optical design. In this paper we give an overview of the innovative features of the post-PDR design; detailed discussion of these are provided in other submissions to these proceedings (Baldwin et al., Ben-Ami et al., Evans et al., Mueller et al., Oh, et al.).

In particular, G-CLEF will be the first PRV spectrograph to have a composite optical bench to exploit that material's extremely low coefficient of thermal expansion and high stiffness-to-mass ratio. The design also incorporates a unique thermal control system design that maximizes instrumental immunity to ambient temperature fluctuations. This system has been prototyped and has demonstrated sub-millikelvin thermal stability on diurnal time scales.

The spectrograph camera subsystem is divided into a red and a blue channel, split by a dichroic beamsplitter, so there are two independent refractive spectrograph camera designs. These designs minimize lens fabrication risk while maximizing performance as measured by point spread function size, throughput and immunity from ghosting and scattered light. The exposure meter has been implemented as a subsystem of the camera and harvests out-of-order light at the volume phase holographic gratings, which cross-disperse the two spectrograph beams after the dichroic.

The control system software is being developed in model-driven software context that has been adopted globally at the GMT for all telescope systems. We discuss control software as well as other G-CLEF software, prominently the reduction pipeline.

G-CLEF has been conceived and designed within a strict systems engineering framework. As a part of this process, we have developed a powerful tool set to assess the predicted performance of G-CLEF as it has evolved through subsequent design phases.

In addition to discussing these innovations, we review the design status of major subsystems, especially the telescope interface and flexure control system, the optical fiber feed for the spectrograph, the calibration system and the interface to the multi-object spectroscopy feed (MANIFEST) being developed by the Australian Astronomical Observatory.

9908-77, Session 16

HIRES the high-resolution spectrograph for the E-ELT

Alessandro Marconi, Univ. degli Studi di Firenze (Italy) and INAF - Osservatorio Astronomico di Arcetri (Italy); François Bouchy, Lab. d'Astrophysique de Marseille

(France); Stefano Cristiani, INAF - Osservatorio Astronomico di Trieste (Italy); José Renan de Medeiros, Univ. Federal do Rio Grande do Norte (Brazil); Paolo Di Marcantonio, INAF - Osservatorio Astronomico di Trieste (Italy); Johan Fynbo, Niels Bohr Institute (Denmark); Martin Haehnelt, Roberto Maiolino, Univ. of Cambridge (United Kingdom); Andrzej Niedzielski, Nicolaus Copernicus Univ. (Poland); Ernesto Oliva, INAF - Osservatorio Astrofisico di Arcetri (Italy); Livia Origlia, INAF - Osservatorio Astronomico di Bologna (Italy); Phil M. Parr-Burman, UK Astronomy Technology Ctr. Lagrange (France); Igor DiVarano, Leibniz-Institut für Astrophysik Potsdam (Germany); Valentina D'Odorico, INAF - Osservatorio Astronomico di Trieste (Italy); Artie P. Hatzes, Thüringer Landessternwarte Tautenburg (Germany); Jochen Liske, Univ. Hamburg (Germany); Christophe Lovis, Observatoire de Genève (Switzerland); Carlos J. A. P. Martins, Univ. do Porto (Portugal); Harald Nicklas, Georg-August-Univ. Göttingen (Germany); Didier Queloz, Univ. of Cambridge (United Kingdom); Andreas Quirrenbach, Landessternwarte Heidelberg (Germany); Ansgar Reiners, Georg-August-Univ. Göttingen (Germany)

The current E-ELT instrumentation plan foresees a High Resolution Spectrograph conventionally indicated as HIRES whose Phase A study will start in 2016. Such an instrument is capable of providing unique breakthroughs in the fields of exoplanets, star and planet formation, physics and evolution of stars and galaxies, cosmology and fundamental physics.

A consortium composed of institutes and organizations from many ESO member states has conducted a preliminary scientific and technical study of a modular instrument able to provide high-resolution spectroscopy (R~100,000) in a wide wavelength range (0.37-2.5 μm).

We will present the technical solutions envisaged by the HIRES consortium and an outline of the many exciting science cases that the use of HIRES at the E-ELT will allow to address.

MOSAIC: the E-ELT multi-object spectrograph

François Hammer, Observatoire de Paris à Meudon (France); Beatriz Barbuy, Univ. de São Paulo (Brazil); Jean-Gabriel Cuby, Lab. d'Astrophysique de Marseille (France); Lex Kaper, Univ. van Amsterdam (Netherlands); Simon L. Morris, Durham Univ. (United Kingdom); Christopher J. Evans, UK Astronomy Technology Ctr. (United Kingdom); Pascal Jagourel, Observatoire de Paris à Meudon (France); Ewan Fitzsimons, UK Astronomy Technology Ctr. (United Kingdom); Gavin B. Dalton, Univ. of Oxford (United Kingdom); Mathieu Puech, Myriam Rodrigues, Observatoire de Paris à Meudon (France)

The MOSAIC case draws on all fields of contemporary astronomy. When combined with the unprecedented sensitivity of the E-ELT, MOSAIC will be the world unique MOS facility having both multiplex and multi-IFU capability.

We argue that the most compelling and competitive cases for ELT science demand such a capability as soon as possible. MOS observations in the early stages of E-ELT operations will be essential for follow-up of sources identified by the JWST. In particular, multi-object adaptive optics and accurate sky subtraction with fibers have both recently been demonstrated on sky, making fast-track development of MOSAIC feasible.

In this paper I'll review the preliminary results of the Phase A, including the scientific, technical and managerial aspects of MOSAIC.

9908-79, Session 16

The Giant Magellan Telescope multi-object astronomical and cosmological spectrograph (GMACS)

Darren L. DePoy, Jennifer L. Marshall, Erika Cook, Texas A&M Univ. (United States); Cynthia S. Froning, Univ. of Texas at Austin (United States); Tae-Geun Ji, Kyung Hee Univ. (Korea, Republic of); Damien J. Jones, Prime Optics (Australia); Hye-In Lee, Kyung Hee Univ. (Korea, Republic of); Claudia Mendes de Oliveira, Univ. de São Paulo (Brazil) and Cidade Univ. (Brazil); Soojong Pak, Kyung Hee Univ. (Korea, Republic of); Casey Papovich, Travis Prochaska, Texas A&M Univ. (United States); Rafael Ribeiro, Univ. de São Paulo (Brazil) and Cidade Univ. (Bouvet Island); Luke M. Schmidt, Texas A&M Univ. (United States); Keith Taylor, Instruments4 (United States)

We review the latest conceptual design for a moderate resolution optical spectrograph for the Giant Magellan Telescope (GMT). The spectrograph is designed to make use of the large field-of-view of the GMT and be suitable for observations of very faint objects across a wide range of wavelengths. We summarize important science drivers and present the technical specifications for the instrument. Other papers at this conference will present more details of the mechanical and optical design.

9908-80, Session 16

The wide-field optical spectrometer for TMT

Matthew V. Radovan, Univ. of California Observatories (United States)

The Wide Field Optical Spectrometer (WFOS) is the seeing-limited, visible-wavelength imaging multiobject spectrograph (MOS) planned for first-light use on the Thirty Meter Telescope (TMT). The WFOS project is an international collaboration between the TMT partners in the USA, Japan, China and India and is being led by the University of California Observatories at UC Santa Cruz.

WFOS will provide 0.2 arc sec image quality and high throughput (>30%) over a 40.5 square arc minute field of view with a spectral resolution of 500 to 5000 for a 0.75 arc second slit. Wide wavelength coverage (310-1000 nm) is accomplished with two color channel sharing a common collimator.

We report here on developments since 2014 related to the optical and mechanical design to improve the flexure performance of this extremely large Nasmyth instrument on the 30 meter TMT.

9908-348, Session PS6

Study of the impact of E-ELT wavefront errors residuals on the MICADO astrometric observations

Gabriele Rodeghiero, Jörg-Uwe Pott, Peter Bizenberger, Max-Planck-Institut für Astronomie (Germany)

The paper describes an end-to-end optical simulation developed using commercial ray tracing software that allows studying the effect of the E-ELT telescope instabilities on the Multi-AO Imaging Camera for Deep Observations (MICADO). The primary goal and observing mode of MICADO is imaging, with a focus on astrometry with an accuracy of about 50 ?as. To achieve this ambitious goal a careful examination of the possible statistical and systematic effects that can influence the astrometric accuracy is required. Here we concentrate on the perturbations coming from different telescope instabilities, related to high spatial frequency errors (M1 segments scale) and dynamical effects (wind and vibrations) of the E-ELT primary and secondary mirror. ESO has been developing an extended dataset of these perturbations that are integrated inside the optical model of the telescope and the instrument relay optics for gathering the aberrated wavefronts to be compensated by the adaptive optics (AO) system. The wavefront error residuals reflected off the E-ELT adaptive mirrors are then propagated inside the MICADO camera to check the distortions and the possible effects on the astrometric measurement at the instrument focal plane. This tool is conceived to get both a reliable estimate of the effect of wavefront residuals errors on the astrometric observations and to drive the calibration scheme of the instrument.

9908-349, Session PS6

GMTIFS: challenging optical design problems and their solutions for the GMT integral-field spectrograph

John Hart, Gabriel J. Bloxham, Robert Boz, Brady Espeland, Robert Sharp, The Australian National Univ. (Australia)

GMTIFS is a first light instrument for the Giant Magellan Telescope (GMT). It is a combined Imager and Integral Field Spectrograph (IFS) designed to work with Adaptive Optics (AO) System of the GMT. Working at the diffraction limit of the GMT and satisfying the challenging AO interface requirements and constraints results in unique optical challenges. We describe several of these unique challenges and how we have solved them. The GMT has a direct feed architecture which increases transmission and reduces emissivity, however one of the major challenges is the cryostat window which must be tilted to reflect visual wavelengths to the AO system. The window must be large enough to transmit the both the central science field to the Imager and IFS, and the full 180 arcsecond diameter guide field to the on-instrument wavefront sensor. For a plane-parallel window, this tilt causes astigmatism in the transmitted beam that must be corrected. A corrective system using two plates, tilted and slightly wedged in opposite directions, is proposed. Geometry and performance of the system is described. Another challenging optical design is the anamorphic field projector. The Integral Field Unit of GMTIFS requires that a small field delivered by the telescope be projected onto an Image Slicer at much larger scale, with the magnification in the spectral direction being twice that in the spatial direction to make the spaxels square when projected onto the sky. Output images must be coincident in the spectral and spatial projections for both the field and pupil. Additionally, field and pupil image locations must be independently controllable so that they can be made coincident for interchangeable units that provide a range of output field scales. A two-mirror system that satisfies these requirements is described.

9908-350, Session PS6

MICADO: the camera support structure at the E-ELT Nasmyth focus

Harald Nicklas, Heiko M. Anwand-Heerwart, Petra Rhode, Georg-August-Univ. Göttingen (Germany); Josef Schubert, Max-Planck-Institut für extraterrestrische Physik (Germany)

MICADO is one of the first light instruments at the E-ELT and is designed to work with the MCAO system MAORY. The ability to operate in a stand-alone mode without MAORY includes an additional SCAO system. Therefore, the instrument support structure has to fulfil two purposes, the positioning of the camera in a) its stand-alone mode and b) when it will mounted underneath the MCAO facility MAORY. The structure is addressed regarding its functionality such as passive and possible active positioning of the instrument. Very first FEA results will be given as well as other performance assessments.

9908-351, Session PS6

Design of a large image derotator for the E-ELT instrument MICADO

Santiago Barboza, Jörg-Uwe Pott, Ralf-Rainer Rohloff, Friedrich Müller, Max-Planck-Institut für Astronomie (Germany); Jörg Wagner, Deutsches SOFIA Institut (Germany); Hans J. Kärcher, MT Mechatronics GmbH (Germany)

The Multi-AO Imaging Camera for Deep Observations (MICADO), a first light instrument for the 39 m European Extremely Large Telescope (E-ELT), is being designed and optimized to work with the Multi-Conjugate Adaptive Optics (MCAO) module MAORY (0.8-2.5 ?m) using laser guide stars. The MICADO-MAORY configuration will provide diffraction limited imaging over a large 53-arcsec field of view. During the early operational phase, MICADO will operate with its own Single-Conjugate Adaptive Optics (SCAO) system using natural guide stars, for on-axis diffraction limited performance. The MICADO consortium has started the preliminary design phase with the kick-off meeting held in Vienna, on October 7, 2015.

The current concept of the MICADO instrument consists of a structural

cryostat (2.1 m diameter and 2 m height) with the SCAO wavefront sensor (WFS) on top (cryostat + WFS ≈ 3.000 Kg). The cryostat is mounted via its central flange with a direct interface to a large 2.5-m-diameter high-precision image derotator. The whole assembly is suspended at 3.6 m above the E-ELT Nasmyth platform by a Hexapod-type support structure. The MICADO calibration unit, the relay optic components and the M7 mirror are located on a dedicated optical bench above the cryostat/SCAO-WFS assembly, mounted on an auxiliary hexapod also attached to the static mechanical interface of the derotator. The instrument electronics cabinets, the cable-wrap and the cooling system are placed on a separated coarse-precision co-rotating platform below the cryostat.

We describe the design and development of the MICADO derotator, a key mechanism that must precisely rotate the cryostat/SCAO-WFS assembly around its optical axis with an angular positioning accuracy lower than 10 arcsec, in order to compensate the field rotation due to the alt-azimuth mount of the E-ELT. This device consists of a high precision bearing, drivers, motors, encoders and very stiff mechanical interfaces. A trade-off analysis considering different bearing technologies was performed to select the most suitable one for this application. As a result, the MICADO derotator is being developed using a custom-made four-point contact ball bearing. Special attention is being given to estimate and simulate the performance of the derotator during the design phase, while both static and dynamics behaviors are being considered in parallel. The statics flexure analysis is done using a detailed Finite Element Model (FEM). The dynamics simulation is being developed with the mathematical model of the derotator implemented in Matlab/Simulink. Finally, both aspects must be combined through a realistic end-to-end model of the derotator, verifying that the concept matches the requirements. The main challenges to be handled in this project are: (i) the design of the mechanical interfaces to minimize mass, as well as the deformation and the effect of the warping moment on the bearing and, (ii) the analysis of the friction in the bearing at low tracking velocities to compensate the Stick-slip effect with a position-velocity closed-loop control system.

9908-352, Session PS6

A new test facility for the E-ELT infrared detector program

Jean-Louis Lizon, Paola Amico, Matteo Accardo, Martin Brinkmann, Bernard-Alexis Delabre, Gert Finger, Ivan M. Guidolin, Renate Hinterschuster, Ronald Guzman, Barbara Klein, Marco Quattri, Derek Yves, European Southern Observatory (Germany)

During the development of the VLT instrumentation program, ESO acquired considerable expertise in the area of infrared detectors, their testing and optimizing their performance. This can be mainly be attributed to a very competent team and most importantly to the availability of a very well suited test facility, namely, IRATEC.

This test facility, was designed more than 15 years ago, specifically for 1K x 1K detectors such as the Aladdin device, with a maximum field of only 30 mm square. Unfortunately, this facility is no longer suited for the testing of the new larger format detectors that are going to be used to equip the future E-ELT instruments. It is projected that over the next 20 years, there will be of the order of 50-100 very large format detectors to be procured and tested for use with E-ELT first and second generation instruments and VLT third generation instruments.

For this reason ESO has initiated the in-house design and construction of a dedicated new IR detector arrays test facility: the Facility for Infrared Array Testing (FIAT). It will be possible to mount two 60 mm square detectors in the facility, as well as mosaics of smaller detectors. It is being designed to have a very low thermal background such that detectors with 5.3 um cut-off material can routinely be tested.

The paper introduces the most important use cases for which FIAT is designed: they range from performing routine performance measurements on acquired devices, optimization setups for custom applications (like spot scan intra-pixel response, persistence and surface reflectivity measurements), test of new complex operation modes (e,g, high speed sub-windowing mode for low order sensing, flexure control, etc) and the development of new tests and calibration procedures to support the scientific requirements of the the E-ELT and to allow troubleshooting the unexpected challenges that arise when a new detector system in brought online. The facility is also being designed to minimize the downtime required to change to a new detector then cool it down, ready for testing.

The status of the opto-mechanical and cryogenic design is also described in detail, with particular emphasis on the technical solutions identified to fulfill the FIAT top level requirements.

We will also describe how the FIAT project has been set-up as a training facility for the younger generation of engineers who are expected to take over the job from the experienced engineers and ensure that the lessons learnt in so many years of successful IR instrumentation projects at ESO are captured for this next generation.

9908-353, Session PS6

Science requirements and trade-offs for the MOSAIC spectrograph for the European ELT

Christopher J. Evans, UK Astronomy Technology Ctr. (United Kingdom); Mathieu Puech, Observatoire de Paris à Meudon (France); Ewan Fitzsimons, UK Astronomy Technology Ctr. (United Kingdom); Beatriz Barbuy, Univ. de São Paulo (Brazil); Jean-Gabriel Cuby, Lab. d'Astrophysique de Marseille (France); François Hammer, Pascal Jagourel, Observatoire de Paris à Meudon (France); Simon L. Morris, Durham Univ. (United Kingdom); Lex Kaper, Univ. van Amsterdam (Netherlands)

Building on the comprehensive White Paper on the scientific case for multi-object spectroscopy on the European ELT, we present the top-level instrument requirements that are being used in the Phase A design study of the MOSAIC concept. The assembled cases span the full range of E-ELT science and generally require observations with two modes ('high multiplex' and 'high definition') to best exploit the exciting sensitivity and spatial performance of the telescope. We will present the latest science simulations that are being used in trade-off studies to inform the capabilities of MOSAIC and the technical implementations required.

9908-354, Session PS6

The Infrared Imaging Spectrograph (IRIS) for TMT: preliminary design of image slicer

Kai Zhang, Nanjing Institute of Astronomical Optics & Technology (China); Anna M. Moore, California Institute of Technology (United States); Yongtian Zhu, Nanjing Institute of Astronomical Optics & Technology (China); James E. Wincentsen, California Institute of Technology (United States); James E. Larkin, Univ. of California, Los Angeles (United States); Shelley A. Wright, Univ. of California, San Diego (United States)

The InfraRed Imaging Spectrograph (IRIS) is one of three first light science instruments for the Thirty Meter Telescope (TMT). It will provide dedicated imaging and integral field spectroscopic observations in parallel fed by a Narrow Field InfraRed Adaptive Optics System (NFIRAOS). The IRIS imager delivers light to a dual-channel Integral Field Spectrograph (IFS) through a

pair of pick-off mirrors in the central field. The IFS creates multi-functional ability to explore the universe in IR (0.84 – 2.4um) with moderate spectral resolution of R=4,000/8,000 and four spaxel scales of 4, 9, 25, 50 milli-arc-seconds (mas). An image slicer serves one of the two spectral channels as its Integral Field Unit (IFU) in two spaxel scales of 25 and 50mas over the continuous science field of 2.2x1.125 mas and 4.4x2.25 mas respectively. It splits the field into 88 integral field units (IFU), the images of which are linearly arranged into two parallel slits due to the detector format (4Kx4K @ 15um). A novel all-reflective design of image slicer uses a new 'brick stage' layout to make the adjacent mirrors staggered in order, and deliver close to diffraction limited image quality. The detail of the image slicer design will be presented in this paper.

9908-355, Session PS6

HIRES the high-resolution spectrograph for the E-ELT: dynamics and control of the repositioning mechanism for the E-ELT HIRES polarimeter

Igor DiVarano, Klaus G. Strassmeier, Manfred Woche, Leibniz-Institut für Astrophysik Potsdam (Germany)

A full Stokes dual channel polarimeter for the E-ELT HIRES spectrograph has been envisioned for the intermediate focus f/4.4, operating within a spectral range of 0.4-1.6 μ. It will feed the HIRES instrument located on the Nasmyth platform via two pairs of dedicated fibers: one fibre pair optimized for the BVRI, the other one optimized for the JH band or any other feasible combination. The instrument must be retractable within a workspace in fulfillment with the ESO requirements on the allocated volume and the dynamic response of the AO tower. For such purpose a swinging arm has been designed with a rotation provided by 5 revolute joints plus a jackscrew. Moreover repeatability in repositioning has to be guaranteed by a parallel manipulator, performing an alignment procedure mainly along 5 axes. Dynamics and control criteria with a feedforward chain to compensate for vibration forces and feedback chain for tracking procedure are hereafter presented.

9908-356, Session PS6

Opto-mechanical design of the G-CLEF flexure control camera system

Jae Sok Oh, Chan Park, Sung-Joon Park, Jihun Kim, Kang-Min Kim, Moo-Young Chun, Young Sam Yu, Sungho Lee, Korea Astronomy and Space Science Institute (Korea, Republic of); Andrew Szentgyorgyi, Stuart McMuldroch, Timothy J. Norton, William A. Podgorski, Ian Evans, Mark A. Mueller, Harvard-Smithsonian Ctr. for Astrophysics (United States); Alan Uomoto, Jeffrey D. Crane, Tyson Hare, Carnegie Observatories (United States)

The GMT-Consortium Large Earth Finder (G-CLEF) is a fiber-fed, optical band echelle spectrograph that will be the first light instrument for the Giant Magellan Telescope (GMT). The G-CLEF Front End Assembly (GCFEA) including a tertiary mirror and a set of reimaging camera relays the telescope beam onto the surface of the fiber mirror installed on the GMT Instrument Platform. The light from the target object will be incident into the fiber and the outer field of 1.5 x 1.5 arcmin will be reflected to the Flexure Control Camera (FCC). The FCC is to monitor and control the local flexure of the GCFEA in order to guide the target within 7 milli-arcsec. The FCC includes a collimator made of a triplet lens, a folding mirror, a filter-wheel system housing four neutral density filters and a tent prism as focus analyzer, a reimaging camera with a pair of doublet lenses, and a CCD detector. The detector module has the features of the linear translation and field de-rotational function. We present in this study the current status of the optical and mechanical design of the FCC developed after the instrument Preliminary Design Review held in April 2015.

9908-357, Session PS6

Polishing test of a poly-crystal calcium fluoride lens: toward the development of TMT WFOS

Shinobu Ozaki, Satoshi Miyazaki, National Astronomical Observatory of Japan (Japan); Yoko Tanaka, National Astronomical Observatory of Japan (United States)

Wide-Field Optical Spectrograph (WFOS) is one of the first-light instruments of Thirty Meter Telescope (TMT). It offers the optical multi-slit spectroscopy and imaging functions. The project is an international collaboration led by University of California Santa Cruz. We have joined the WFOS project since 2010 and contributed on its science camera systems. WFOS divides light around 550 nm by a dichroic mirror located between the collimator and the dispersers. Each red and blue channel has the science camera system which is optimized for each wavelength range.

WFOS is the biggest instrument among the first-light ones, and the pupil image created in it is 300 mm in diameter. Therefore the science cameras need to be sufficiently large (> 400 mm) to capture light from this large pupil image. For such large camera systems, available optical glasses with high quality are very limited. One critical item is Calcium Fluoride (CaF2). CaF2 is very useful to reduce aberration, and hence many astronomical instruments use it as lens material. However large CaF2 with high quality is difficult to be manufactured. The current largest CaF2 is 440 mm in diameter. Although a mono-crystal blank with a diameter of 440 mm can be obtained at some yield, we might have to use poly-crystal depending on the funding and schedule situations. The poly-crystal blank has some internal regions with different crystal directions. Basically, CaF2 does not have an optical index dependency on the crystal direction. At the boundary between those regions, however, the optical index and the stress birefringence are different from the sounding regions. In addition, removal rate in polishing depends on the crystal direction, and hence a poly-crystal CaF2 lens is expected to have figure error after polishing. Those internal and surface possibly affect the image quality. This is one of the major risk items in the WFOS development.

To address this issue, we conducted a polishing test of a poly-crystal CaF2 lens with a diameter of 70 mm as a first step. One surface is convex with a radius of 164.74 mm and the other is flat. As expected, we found figure error around the boundary. The figure error is ~139 nm PV and ~26 nm rms. Those values themselves are not significant, but the figure error is much localized and the slop is steeper than that of the global pattern. The steeper slope makes a light ray more largely deviate from the ideal path. On the other hand, the figure error occupies a small fraction of the entire area of the lens. This invokes us a small effect on the image quality. We will carry out the Zemax simulation to study the effect.

9908-358, Session PS6

The MANIFEST prototyping design study

Jonathan S. Lawrence, David M. Brown, Rebecca A. Brown, Scott Case, Steve Chapman, Vladimir Churilov, Australian Astronomical Observatory (Australia); Matthew M. Colless, The Australian National Univ. (Australia); Robert Content, Michael Goodwin, Urs Klauser, Kyler Kuehn, Nuria P. F. Lorente, Slavko Mali, Rolf Muller, Vijay Nichani, Naveen Pai, Will Saunders, Keith Shortridge, Nicholas F. Staszak, Julia Tims, Minh V. Vuong, Lewis

G. Waller, Ross Zhelem, Australian Astronomical Observatory (Australia)

MANIFEST is a facility multi-object fibre system for the Giant Magellan Telescope, which uses 'Starbug' fibre positioning robots. MANIFEST, when coupled to the telescope's planned seeing-limited instruments, offers access to larger fields of view; higher multiplex gains; versatile reformatting of the focal plane via IFUs; image-slicers; and in some cases higher spatial and spectral resolution. The Prototyping Design Study phase for MANIFEST, nearing completion, has focussed on developing a working prototype of a Starbugs system called TAIPAN, for the UK Schmidt Telescope (UKST), which will conduct a stellar and galaxy survey of the Southern sky.

TAIPAN is a spectroscopic instrument designed for the UK Schmidt Telescope at the Australian Astronomical Observatory. The design for TAIPAN incorporates 150 optical fibres (with an upgrade path to 300) situated within independently-controlled robotic positioners known as Starbugs, allowing precise parallel positioning of every fibre, thus significantly reducing instrument configuration time and increasing the amount of observing time.

In addition to the positioning system prototype for MANIFEST, the TAIPAN project includes a new spectrograph and an upgrade to the UKST systems. The spectrograph is an all-refractive 2-arm design that delivers a spectral resolution of R>2000 over the wavelength range 370-870 nm. The UKST upgrade has included replacement of all telescope drive motors and encoders, new telescope hardware and software control systems, and an upgrade to the dome drive and shutter control systems.

In addition to the development of TAIPAN, the MANIFEST Prototyping Design Study has included continued development of the instrument concept to ensure that MANIFEST is optimal and consistent with GMT instrument and telescope designs and interfaces. We have also continued research and development work on key instrument subsystems (Starbugs and the glass field plate) to increase instrument throughput and operating efficiency, reduce costs, and reduce technical risks.

9908-359, Session PS6

WEBSIM-COMPASS: a new generation scientific instrument simulator for the E-ELT

Mathieu Puech, Yanbin Yang, Myriam Rodrigues, Karen Disseau, Isabelle Jégouzo, Michele Paillous, Sylvestre Taburet, Yann Clénet, Damien Gratadour, Observatoire de Paris à Meudon (France)

We present a new generation scientific instrument simulator dedicated to the E-ELT named WEBSIM-COMPASS, and developed in the frame of the COMPASS project. This simulator builds on the WEBSIM simulators developed during the ESO E-ELT Design Reference Mission and Instrument Phase A studies. The WEBSIM-COMPASS observations simulator consists in a web interface coupled to an IDL code, which allows the user to perform end-to-end simulations of all E-ELT optical/NIR imagers and spectrographs foreseen for the future 39m European Extremely Large Telescope, i.e., MICADO, HARMONI, and MOSAIC. The final products of the simulation pipeline correspond to the result of a data reduction softwares with perfectly extracted/reduced data without any systematic error. We give a functional description of this new simulator, emphasizing the new functionalities and current developments, and present science cases simulated.

9908-360, Session PS6

Preliminary optical design for the Common Fore Optics of METIS

Tibor Agócs, ASTRON (Netherlands)

METIS is the Mid-infrared E-ELT Imager and Spectrograph, which will provide outstanding observing capabilities, focusing on high angular and spectral resolution on the largest telescope on Earth. It consists of two diffraction-limited imagers, providing also low and medium resolution long slit spectroscopy, operating in the LM and NQ bands respectively and an IFU fed diffraction-limited high-resolution (R=100,000) LM band spectrograph. These science subsystems are preceded by the Common Fore Optics (CFO), which re-images the focal plane of the EELT inside METIS and provides the following essential functionalities: calibration, chopping, image de-rotation, thermal background and stray light reduction. The CFO will be the core optical system of the instrument and it will provide the interface towards the imagers, the spectrograph, the single conjugate adaptive optics system and the warm calibration unit. METIS will also provide coronagraphy for all operating modes to achieve high contrast imaging and the intermediate focal plane and pupil plane of the CFO will be populated by the components of apodizing phase plate and vortex coronagraphs.

In the current paper we discuss the optical requirements, external and internal interfaces of the CFO as a starting point and then present the design steps that were taken to fulfil those requirements. Different all-spherical optical architectures, based on Offner relays and modified Schwarzschild systems are presented and compared. A new type of all-spherical three mirror optical relay is presented based on the Offner system that has an accessible pupil and exceptional optical performance that fit the purpose of the CFO perfectly. After identifying the key components, we present the numerical scoring method that we use to determine the order of components that best fulfils the relevant scientific and technical requirements. We detail the manufacturing strategy of the optical components, discuss the alignment plan and elaborate on CFO folding and packaging that are always essential parts of the opto-mechanical design process, especially for cryogenic instruments. We show the evolution of the CFO optical design from the conceptual design, which was based on a single relay to the preliminary optical design containing two subsequent relays. We describe the optical performance of the baseline design and outline the necessary trade-offs regarding field of view, chop-throw, sampling, spectral coverage and optical system complexity. We present the wavefront error budget for the CFO, the corresponding tolerance analyses on manufacturing and alignment and we also show the results of the finite element analyses that address the heat- and gravity-induced surface form deformation of optical components.

9908-362, Session PS6

Can the European ELT detect super-Earths? Measuring the contrast limit of an image slicer spectrograph in a laboratory experiment

Matthias Tecza, Niranjan A. Thatte, Univ. of Oxford (United Kingdom)

The European Extremely Large Telescope (E-ELT) is a 39-m telescope currently being constructed in Northern Chile. It will revolutionary step in capabilities for ground-based astronomy when it goes on sky in around 2024. One of the highest scientific priorities for the E-ELT is to characterise exo-planets and to take images of Earth-like planets. A dedicated planetary camera and spectrograph (ELT-PCS, also called EPICS) is part of the planned suite of ELT instruments and will provide a complete toolkit to characterise planetary systems. Detailed design and construction (Phase B) of ELT-PCS will start as soon as the R&D for specific components reaches

the required technology readiness level.

In this paper we discuss part of the ELT-PCS R&D work comparing different integral-filed-spectrograph (IFS) concepts, in particular our work on image-slicer based spectrographs. This builds on the IFS work package of the EPICS Phase A study investigating both lenslet-array and image-slicer based IFSs, where we demonstrated that an image-slicer based IFS can provide the required contrast. In the current ELT-PCS R&D phase we will confirm these very promising results with a laboratory experiment to quantify the limitations on the contrast ratio that can be achieved with an image-slicer based IFS. The Oxford test-bed will use components from the Phase A experimental setup with the exception of the image slicer (that was borrowed from another instrument that is now on-sky) and a new, low resolution prism disperser. The image slicer and new prism disperser will be designed and manufactured for high-contrast and a large number of spaxels to match the specifications of the lenslet-array. Over a two year period we setup, aligne and test the bench spectrographs including the new disperser and image slicer. Finally we integrate our image-slicer based IFS with the ESO test bench, conduct contrast measurements, and analyse our results.

9908-363, Session PS6

Developing an integrated concept for the E-ELT Multi-Object Spectrograph (MOSAIC): design issues and trade-offs

Gavin B. Dalton, Univ. of Oxford (United Kingdom) and STFC Rutherford Appleton Lab. (United Kingdom); Myriam Rodrigues, Observatoire de Paris à Meudon (France); Ewan Fitzsimons, Philip Rees II, Christopher J. Evans, UK Astronomy Technology Ctr. (United Kingdom); Fanny Chemla, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Ian J. Lewis, Univ. of Oxford (United Kingdom); Cornelis M. Dubbeldam, Timothy J. Morris, Durham Univ. (United Kingdom); Andreas Kelz, Leibniz-Institut für Astrophysik Potsdam (Germany); Ramón Navarro, NOVA Optical Infrared Instrumentation Group (Netherlands); Pascal Jagourel, Mathieu Puech, Observatoire de Paris à Meudon (France)

We present a discussion of the design issues and trade-offs that have been considered in putting together a new concept for MOSAIC, the multi-object spectrograph for the E-ELT. MOSAIC aims to address the combined science cases for E-ELT MOS that arose from the earlier studies of the multi-object and multi-adaptive optics instruments, OPTIMOS-EVE and EAGLE. The resulting concept provides an integrated focal plane that can deliver either GLAO-fed multi-object spectroscopy of single targets with high multiplex, or a more modest multiplex for MOAO-fed integral field spectroscopy of extended targets at medium-high spatial resolution in the red/NIR.

9908-364, Session PS6

Preliminary design study of the integral field unit for the E-ELT Harmoni instrument

Johan Kosmalski, Ctr. de Recherche Astrophysique de Lyon (France) and European Southern Observatory (Germany); Matthias Tecza, Univ. of Oxford (United Kingdom); Ian Bryson, UK Astronomy Technology Ctr. (United Kingdom); Fraser Clarke, Univ. of Oxford (United Kingdom); David Freeman, Kidger Optics Associates (United Kingdom); Magali Loupias, Jean-Emmanuel Migniau, Alban Remillieux, Ctr. de Recherche Astrophysique de Lyon (France); Niranjan A. Thatte, Univ. of Oxford (United Kingdom)

HARMONI is a visible and near-infrared (0.47 to 2.45 μm) integral field spectrograph, providing the E-ELT's core spectroscopic capability, over a range of resolving powers from R~500 to R~20000.

We present in this paper, the different concepts for the design of the HARMONI Integral Field Unit for the visible and IR science. This subsystem makes the link between HARMONI Preoptic and the 4 Spectrographs. It is composed of a field splitter/ relay system and an image slicer that creates from a rectangular Field of View a very long (532mm) pseudo-slit at the entrance of each spectrograph. We present 2 solutions based on a parabolic image slicer and one based on a cylindrical image slicer. From one concept to the other, we seek to reduce cost and improve ease of manufacture and alignment.

HARMONI is also considering a single visible spectrograph for the full field of view and we present a possible image slicer for this option.

9908-365, Session PS6

Development of cryogenic components based on COTS parts for the HARMONI instrument

José Vicente Gigante, Elvio Hernández Suárez, Luis Fernando Rodríguez-Ramos, Instituto de Astrofísica de Canarias (Spain)

HARMONI is an integral field spectrograph working at visible and near-infrared wavelengths over a range of spatial scales from ground layer corrected to fully diffraction-limited. The instrument has been chosen to be part of the first-light complement at the European Extremely Large Telescope (E-ELT). The large size of the HARMONI instrument and its cryogenic operation is a challenge from the point of view of the mechanics and electronics design. The IAC is in charge of the development of the 'Instrument Pre-Optics' and the 'Instrument Control Electronics'. As a part of these work packages, the design and prototyping of two important components is ongoing. One of the main goals of these developments is the use of COTS (Commercial-Off-The-Shelf) parts as much as possible, since their use will benefit the project reducing costs and shortening the schedule. Nevertheless, the applications of these standard commercial parts in cryo-vacuum environments is often very difficult and represents a technological challenge.

The first development is a 'Cryogenic Pupil Mask Rotator' in charge of shielding the image of the secondary mirror spider in the pupil of the instrument. Since the position of the spider image in the instrument's pupil depends on the telescope position, the mask rotator must track very accurately the telescope motion. Its design is based on a hollow shaft brushless motor and a high resolution capacitive encoder, both being standard industrial grade parts. One first prototype of a direct drive motor has been built and tested. The necessary extremely slow rotary motion (typ. 15 arcsec /s) is a challenge for controlling the direct drive motor since doesn't exists any mechanical reduction. The design of the direct drive motor and the obtained results so far are presented.

The second development is a 'Cryogenic Fast Shutter' in charge of set the instrument detectors exposure time. The position and speed shape of the shutter motion must be accurate and synchronized with the detector controller electronics. Our design is based on a voice coil and a commercial encoder as motion feedback. Several feedback sensor technologies have been considered. The main difficulty is to find a feedback sensor able to work in cryo-vacuum environment and fast enough to close the position control loop of the shutter. A promising technology based on conductive plastic is currently being tested and the present paper describes the results obtained up to now.

9908-366, Session PS6

Novel instrument concepts for characterizing directly-imaged exoplanets

Christoph U. Keller, Leiden Observatory (Netherlands)

Current high-contrast imagers are optimized to find new exoplanets; they minimize diffracted starlight in a large area around a star. I will present novel instrumental approaches that are optimized to characterize these discoveries by minimizing starlight in a small area around the known location of an exoplanet. By trading higher performance for a smaller dark area, it is possible to obtain spectra of known exoplanets with up to 100 times better contrast and 1000 times higher spectral resolution than planet-finding imagers.

I will discuss 5 innovative technologies that minimize the starlight at the location of an exoplanet to achieve breakthrough performance improvements: 1) coronagraphs that remove virtually all starlight over an octave in wavelength while transmitting more than 90% of the exoplanet signal; 2) holographic wavefront sensors that measure aberrations in the science focal plane; 3) ultra-fast adaptive optics systems that minimizes these aberrations; 4) direct minimization of the remaining starlight; and 5) observing and data reduction strategies that use stored focal-plane-sensor and adaptive-optics information to optimally extract the exoplanet spectrum.

By integrating these technologies with a high-resolution, integral-field spectrograph that can resolve the Doppler shift and the polarization difference between the starlight and the reflected light from the exoplanet, it will be possible to determine the atmospheric composition, temperature and velocity structures of cool and warm giant gas exoplanet and their spin rotation rate and orbital velocity. This will ultimately allow the upcoming 25-40-m telescopes to characterize rocky exoplanets in the habitable zone to look for signatures of life.

9908-367, Session PS6

Challenges and proposal of a MUSE-like instrument for the E-ELT

Patrick Caillier, Johan Richard, Roland M. Bacon, Aurélien Jarno, Emmanuel Pécontal, Michel Tallon, Ctr. de Recherche Astrophysique de Lyon (France)

The extraordinary technical and scientific success of MUSE since its installation on the VLT raises inevitably the question of the next step in terms of Wide Field Integral Field Spectrograph Instrumentation.

The natural trend is to follow the telescope evolution with the start of the different ELT projects and their dramatic increase of primary mirror diameter. However this evolution opens new questions and new challenges.

The first one is of course related to the larger primary mirror and as consequence, the increased plate scale of instrument focal plane. If ultimately this increase is greatly beneficial in terms of sensitivity and diffraction limit, it also strongly limits at the end the size of one instrument Field of View.

The second natural tendency, as one can observe on the different ELTs instruments is to go to the infrared wavelength region and reach for the higher redshifts. But in the context of a Wide Field Integral Field Spectrograph this becomes, because of the IR detector cost, economically and industrially particularly challenging, if not impossible at all.

Then on the other side, the visible and moreover, the bluer part of the spectra coupled with a Wide Field of View presents a real challenge for the Adaptive Optics system.

After discussing the possible science case of such an instrument, this paper will present the different technical options to face these challenges, discuss their performances and feasibility. The choice to move towards the infrared and/or the blue end of the spectra will then be discussed and evaluated in terms of science, feasibility and general interest in the ELT instrumental scene.

Finally an instrument concept will be proposed for the E-ELT. This concept will hold the feasibility and possible performances of such instrument and show a path towards a new generation of Wide Field Integral Field Spectrograph for the ELTs.

9908-368, Session PS6

Serendipitous surveys on extremely large telescopes: their scientific goals and constraints on instrument design

Matthew Horrobin, Univ. zu Köln (Germany)

The upcoming generation of Extremely Large Telescopes represent an unprecedented leap in the collecting power of optical telescopes. As the majority of proposed science instruments only use a small part of the focal plane, there is an opportunity to design an off-axis instrument for serendipitous surveys. Such a survey will be capable of sampling millions of faint galaxies and will also be a powerful tool for sampling transient objects, both near and far. This talk discusses the scientific goals of such a survey, and the instrumentation need to make it successful.

By analysing a typical years set of VLT observations we have defined a baseline serendipitous survey, which we use to predict the depth and coverage of ELT observations. We predict the number of faint targets and transient events that will be observed. These results are compared with those expected for the LSST and we highlight the advantages of parallel serendipitous surveys.

9908-369, Session PS6

Simulated observations of high-redshift galaxies with the HARMONI spectrograph for the European Extremely Large Telescope

Sarah Kendrew, Univ. of Oxford (United Kingdom) and European Space Agency (United Kingdom); Simon D. Zieleniewski, Niranjan A. Thatte, Ryan C. W. Houghton, Julien Devriendt, Boris Haeussler, Matthias Tecza, Fraser Clarke, Kieran O'Brien, Univ. of Oxford (United Kingdom)

We show the results of a study into the performance of the E-ELT integral field spectrograph HARMONI for observations of galaxies at redshift 2-4. Using the instrument simulation pipeline HSIM, we performed mock observations of galaxies extracted from high-resolution cosmological simulations, which provide far richer input data than simple model galaxies and for which we have complete knowledge of their "true" properties. We describe the software tools developed to convert the simulation data into a spectral cube containing the spatial and spectral properties of the galaxy's light. From the mock observations we estimate how well the intrinsic properties of the galaxy, not just its kinematics but also its stellar population characteristics and star formation history, can be recovered using commonly used analysis tools. The HSIM pipeline also allows us to study observational biases and their likely impact on the data. We discuss the implications of the project for the future science with HARMONI in the critical redshift regime for mass assembly in galaxies.

9908-370, Session PS6

Development of the LOTUCE2 prototype for E-ELT's dome-seeing measurements

Amokrane Berdja, Christian Dani Guzmán, Eduardo Garcés Santibañez, Pontificia Univ. Católica de Chile (Chile); Marc S. Sarazin, European Southern Observatory (Germany); Aziz Ziad, Lab. J.L. Lagrange (France)

LOTUCE2 (LOcal TUrbulenCe Experiment 2) is based upon the simultaneous measurement of the angle-of-arrival fluctuations affecting four or more laser beams in order to characterise the optical turbulence occurring within a telescope enclosure. The first prototype comprised a series of mirrors and beam-splitters that redirected the incoming laser beams into a single CCD detector through a telescope. Tests carried out with a predecessor prototype at La Silla observatory have shown that vibration-induced signal corruptions are not only of the same amplitude as the turbulence-induced signals, but are furthermore cross-correlated throughout the different baselines. LOTUCE2 upgrade's main objectives are the isolation of the instrument from environment-induced vibrations, and even more importantly the minimisation of any residual vibration cross-contamination, which significantly corrupts the angle-of-arrival fluctuation covariances. In Proc. SPIE 91479R, 2014 we presented the main design of LOTUCE2 and the rational behind it, including the choice of detectors and the corresponding off-the-shelf spherical lenses-based optical design according to the desired sensitivity to optical turbulence-induced angle-of-arrival fluctuations. We have also discussed a generic optical turbulence model and how it may manifest in LOTUCE2's data, including the effects of a non-Kolmogorov turbulence and inner scale parameterisation.
The assembly of LOTUCE2 however posed a few technical challenges, especially related to the key aspect of the simultaneousness of measurements. We have to ensure that all measurements taken at each detector correspond to simultaneous (within an acceptable range of error) snapshots of the optical turbulence. The reason for this is that the main analysis of the optical turbulence statistical properties is based upon spatial covariances, and only partially on temporal spectra. Other important aspects to be sure of are that the system is stable, that there are no losses in data, that time sampling (primarily for spectral analysis) is uniform, and that the performance of the system does not degrade over time. A laboratory experiment to ensure these conditions has been conducted, which has led to some modifications of the computational hardware setup and the corresponding software implementation relatively to what were anticipated initially. We submit a presentation where we detail the results from the above-mentioned experiments, the new hardware setup and software implementation of the instrument, as well as the actual opto-mechanical assembly we realised so that the turbulence in an enclosure is probed with non-horizontally propagating beams. Other aspects we present include a different strategy for the plate-scale calibration. In addition to presenting LOTUCE2's assembly layout, we present the results of the preliminary results from optical-turbulence measurements, highlighting the methods we implemented for data reduction and real-time optical turbulence parameters inversion using artificial neural networks. We also discuss the reliability of the measurements, the precision of the results, as well as the robustness of the instrument overall.

9908-371, Session PS6

Preliminary design study of the high-contrast mode of E-ELT/HARMONI

Alexis Carlotti, Christophe Vérinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France); Jean-François Sauvage, Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Kacem El Hadi, Lab. d'Astrophysique de Marseille (France); Mickaël Bonnefoy, Gaël Chauvin, Institut de Planétologie et d'Astrophysique de Grenoble (France); Niranjan A. Thatte, Univ. of Oxford (United Kingdom); Ian Bryson, UK Astronomy Technology Ctr. (United Kingdom); Matthias Tecza, Fraser Clarke, Univ. of Oxford (United Kingdom); Hermine Schnetler, UK Astronomy Technology Ctr. (United Kingdom)

HARMONI is a near-IR, IFU-based, first-light instrument of the E-ELT. The spectral characterization of young Jupiter like planets is one of its science cases. High-contrast observations of exoplanets and disks with a medium spectral resolution (R=3500) in a 1.4-2.45 microns band would greatly improve our understanding of the formation process of planets, as well as making it possible to measure chemical abundances in the atmosphere of young Jupiter-like planets. In particular, the planets that will have been observed with SPHERE and the other current direct imaging instrument will be natural targets for HARMONI. This is reflected in the choice of the goal of the high-contrast (HC) mode of HARMONI: to obtain a 1e-6 contrast at 200 mas from the star.

Because HARMONI does not use an atmospheric dispersion corrector (ADC), the HC mode cannot increase contrast by using a focal plane mask such as a Lyot mask or a vortex mask. We have thus proposed to use shaped pupil apodizers to create contrast at about 40-60 mas from the star, and up to 300-500 mas from it (the latter distance corresponds to the AO control radius at 1.4-2.4 microns).

Nevertheless, the star must be blocked to prevent the detector from saturating. This could be done in either two ways: (a) by using a vertical bar in an image plane to block the vertically dispersed image of the star, or (b) by forming the image of the star next to the edges of the splitter pyramid prism, instead of at the center of one of its four surfaces. The first option requires the modification of the current optical design to accommodate for an extra image plane, while the second option raises some concern about light diffusion in the instrument.

We present the methodology and the results of the preliminary study of the HC mode of HARMONI. Our main objective is to estimate the contrast limitation of the instrument. Many factors impact this limitation, and a system analysis of the telescope and the instrument must be performed to take them all into account. We start by considering the residual phase and amplitude errors due to the telescope and its highly segmented primary mirror. The absence of an ADC induces a stronger chromatic beam shift than in a dedicated HC imaging instrument such as SPHERE. This limits the correction of the common path aberrations by the SCAO system. Its impact depends on the conjugated heights of the different optical elements in the instrument prior to the coronagraph. Non-common path aberrations have also been modeled, as well as aberrations due to the rotation of a few optical elements as the telescope tracks a given star. Finally the aberrations associated with the IFS (spatial and spectral cross-talks & diffusion) are also simulated. Raw images obtained with the IFS are fed to post-processing routines that take advantage of field rotation and spectral information to perform differential imaging.

9908-372, Session PS6

The optical design of the G-CLEF Spectrograph: the first light instrument for the GMT

Sagi Ben-Ami, Smithsonian Astrophysical Observatory (United States); Harland Epps, Lick Observatory (United States) and Univ. of California, Santa Cruz (United States); William A. Podgorski, Andrew Szentgyorgyi, Smithsonian Astrophysical Observatory (United States)

The GMT-Consortium Large Earth Finder (G-CLEF) is a fiber-fed, high-resolution echelle spectrograph for the Giant Magellan Telescope (GMT).

G-CLEF, to be commissioned in 2021, will be the first scientific instrument operated on the GMT. The G-CLEF passband covers a wide wavelength range, from 350-950nm, and implements an asymmetric white pupil design. Large format CCDs and a dichroic, which separates the dispersed beam into two channels, blue (350-540nm) and red (540-950nm), allow G-CLEF to cover its entire wavelength range in a single exposure on a single CCD in each arm.

In the following paper we present the optical design of G-CLEF. We emphasize some of the unique solutions that allow G-CLEF to deliver excellent performance for several operational modes that address different scientific cases.

The G-CLEF spectrograph is located inside a vacuum chamber within a thermal control system and is mounted on a gravity invariant platform. It is fed by a novel fiber-feed that allows observations at several resolutions and modes: two high-resolution pupil-sliced modes (R=108,000), each using seven 100um core fibers, a medium resolution mode (R=40,000) using a 320um core fiber, and a high throughput mode (R=20,000) using a 450um core fiber. G-CLEF operates in a Multi-Object Spectrograph (MOS) mode using the GMT Many Instrument Fiber System (MANIFEST) interface. In order to minimize focal ratio degradation the fibers are fed at f/3 by focal ratio reducers located at the telescope telescope-fiber interface. Custom optics located inside the spectrograph vacuum enclosure convert the fiber output beams to f/8 – the working focal ratio of the spectrograph.

G-CLEF uses volume phase holographic (VPH) grism cross dispersers that offer higher throughput than surface relief gratings. Pick-off mirrors inside the G-CLEF cameras deflect light that is dispersed by the cross dispersers into the zeroth order to feed exposure meters (one per camera) located outside of the instrument vacuum enclosure. Finally, we describe the spectrograph blue and red cameras, comprised of 8 and 7 elements respectively, with one aspheric surface in each camera. Both cameras have a focal length of 450mm and a working f/# of 2.25, resulting in an image scale of 93.75 microns/arcsec. Both cameras utilize a common Mangin mirror, located at an intermediate focus between the spectrograph's two off-axis collimating mirrors, to correct for the cylindrical field curvature inherent in white pupil echelle spectrographs and deliver excellent image quality. Both cameras are independently testable outside of the spectrograph optical train using collimated white light.

9908-373, Session PS6

The Infrared Imaging Spectrograph (IRIS) for TMT: the ADC optical design

Andrew C. Phillips, Univ. of California Observatories (United States); Ryuji Suzuki, National Astronomical Observatory of Japan (United States); James E. Larkin, Univ. of California, Los Angeles (United States); Anna M. Moore, California Institute of Technology (United States); Toshihiro Tsuzuki, National Astronomical Observatory of Japan (Japan); Shelley A. Wright, Univ. of California, San Diego (United States)

We present the current optical design for the IRIS Atmospheric Dispersion Corrector (ADC). The ADC is designed for residual dispersions less than ~1mas across a given passband at elevations of 25 degrees. Since the last report, the area of the IRIS Imager has increased by a factor of four, and the pupil size has increased from 75 to 90mm, both of which contribute to challenges with the design. Several considerations have led to the current design: residual dispersion, amount of introduced distortion, glass transmission, glass availability, and pupil displacement. In particular, it was found that there are significant distortions that appear (two different components) that can lead to image blur over long exposures. Also, pupil displacement increases the wave front error at the imager focus. We discuss these considerations, discuss the compromises, and present the final design choice and expected performance.

9908-374, Session PS6

The opto-mechanical design of the GMT-Consortium Large Earth Finder (G-CLEF)

Mark A. Mueller, Andrew Szentgyorgyi, Daniel Baldwin, Sagi Ben-Ami, Ian N. Evans, Jeff Foster, Thomas M. Gauron, Stuart McMuldroch, David A. Plummer, William A. Podgorski, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The GMT-Consortium Large Earth Finder (G-CLEF) is a fiber-fed, optical echelle spectrograph that has been selected as the first light instrument for the Giant Magellan Telescope (GMT) which has begun construction at the Las Campanas Observatory in Chile. G-CLEF has been designed to be a general-purpose echelle spectrograph with precision radial velocity (PRV) capability for exoplanet detection. The radial velocity (RV) precision goal of G-CLEF is 10 cm/sec, necessary for detection of Earth-sized exoplanets. This goal imposes challenging stability requirements on the optical mounts and the overall spectrograph support structures especially when considering the instrument's operational environment. The accuracy of G-CLEF's PRV measurements will be influenced by minute changes in temperature and ambient air pressure as well as vibrations and micro gravity-vector variations caused by normal telescope tracking. For these reasons we have chosen to enclose G-CLEF's spectrograph optics in a thermally controlled, vibration isolated vacuum chamber at a gravity invariant location on GMT's azimuth platform. Additional design constraints posed by the GMT telescope include: a limited space envelope, a thermal emission ceiling, and a maximum weight allowance. Other factors, such as manufacturability, serviceability, available technology and cost are also significant design drivers. These considerations must all be managed while ensuring that performance requirements are achieved.

In this paper, we discuss the design of G-CLEF's optical mounts and support structures including the choice of a low-CTE carbon-fiber optical bench to minimize the system's sensitivity to thermal gradients. We discuss design choices made within the vacuum chamber geared towards minimizing the influence of daily ambient pressure variations on image motion during observation. We discuss the design of G-CLEF's insulated enclosure and thermal control systems which maintain the spectrograph at milli-Kelvin level temperature stability while simultaneously limiting the maximum thermal emission into the telescope dome. Also discussed are micro gravity-vector variations caused by normal telescope slewing, their uncorrected influence on image motion, and how they are dealt with in the design. We discuss G-CLEF's front-end assembly and fiber-feed system as well as other interface challenges presented by the telescope, enclosure and neighboring instrumentation.

9908-375, Session PS6

Optomechanical design concept for the Giant Magellan Telescope Multi-object Astronomical and Cosmological Spectrograph (GMACS)

Travis Prochaska, Luke M. Schmidt, Texas A&M Univ. (United States); Rafael Ribeiro, Univ. de São Paulo (Brazil) and Cidade Univ. (Burkina Faso); Darren L. DePoy, Jennifer L. Marshall, Erika Cook, Texas A&M Univ. (United States); Cynthia S. Froning, Univ. of Texas at Austin (United States); Keith Taylor, Instruments4 (United States); Damien J. Jones, Prime Optics (Australia); Soojong Pak, Kyung Hee Univ. (Korea, Republic of); Tae-Geun Ji, Kyung Hee Univ. (Korea, Republic of); Hye-In Lee, Kyung Hee Univ. (Korea, Republic of); Claudia

Mendes de Oliveira, Univ. de São Paulo (Brazil) and Cidade Univ. (Brazil); Casey Papovich, Texas A&M Univ. (United States)

We describe the conceptual optomechanical design for the Giant Magellan Telescope Multi-object Astronomical and Cosmological Spectrograph (GMACS), a wide-field, multi-object, moderate-resolution optical spectrograph for the Giant Magellan Telescope (GMT). In this paper we describe the details of the GMACS optomechanical design, including the requirements and considerations leading to the design, mechanisms, optical mounts, and predicted flexure performance.

9908-376, Session PS6

Optical design concept for the Giant Magellan Telescope Multi-object Astronomical and Cosmological Spectrograph (GMACS)

Luke M. Schmidt, Texas A&M Univ. (United States); Rafael Ribeiro, São Paulo (Brazil) and Cidade Univ (Brazil); Keith Taylor, Instruments4 (United States); Damien J. Jones, Prime Optics (Australia); Travis Prochaska, Darren L. DePoy, Jennifer L. Marshall, Erika Cook, Texas A&M Univ. (United States); Cynthia S. Froning, Univ. of Texas at Austin (United States); Tae-Geun Ji, Kyung Hee Univ. (Korea, Republic of); Hye-In Lee, Kyung Hee Univ. (Korea, Republic of); Claudia Mendes de Oliveira, Univ. de São Paulo (Brazil) and Cidade Univ. (Brazil); Soojong Pak, Kyung Hee Univ. (Korea, Republic of); Casey Papovich, Texas A&M Univ. (United States)

We present a conceptual optical design for GMACS, a wide field, multi-object, optical spectrograph currently being developed for the Giant Magellan Telescope (GMT). We include details of the optical design requirements derived from the instrument scientific and technical objectives and demonstrate how these requirements are met by the current design. Detector specifications, field acquisition/alignment optics, and optical considerations for the active flexure control system are also discussed.

9908-377, Session PS6

Design and analysis of the NFIRAOS thermal optics enclosure

Joeleff Fitzsimmons, David R. Andersen, Jenny Atwood, Peter W. G. Byrnes, Glen Herriot, Alexis Hill, Kei Szeto, NRC - Herzberg Astronomy & Astrophysics (Canada)

The Narrow Field InfraRed Adaptive Optics System (NFIRAOS) will be the first-light facility Adaptive Optics system for the Thirty Meter Telescope (TMT). In order to meet the optical performance and stability specifications essential to leveraging the extraordinary capabilities of the TMT, all of the optical components within NFIRAOS will be protected within a large thermally-controlled optics enclosure (ENCL). Among the many functions performed by the ENCL, the most critical functions include providing a highly stable, light-tight, cold, dry environment maintained at 243±0.5 K for the NFIRAOS opto-mechanical sub-systems and supporting TABL structure. Although the performance of the ENCL during the science operation of NFIRAOS is critical, the maximum thermal loading will be defined by the cool-down/warm-up cycle which must be accomplished within a time-frame that will minimize the on-sky operational impact due to daytime maintenance work. This study describes the thermal/mechanical design development and supporting analyses (analytical and finite element analyses (FEA)) completed during the preliminary design phase and through the current progression of the ENCL final design phase.

The walls of the ENCL consist of interlocking, multilayered, thermally insulated panels, which are supported by an externally located structural framework which attaches to the NFIRAOS Instrument Support Structure. The regulation of the interior ENCL wall surface temperature to within ±0.5 K requires that the heat flux into the interior of NFIRAOS be eliminated by cooling a thermal conduction plate embedded between multiple layers of insulation. The thermal design of the enclosure was evaluated for both steady-state (SS) performance and transient performance (cool-down and warm-up cycles). The transient analysis utilizes a hybrid of a one-dimensional thermal network approach combined with three-dimensional conjugate heat transfer analyses of explicit opto-mechanical components within the ENCL. Many design-parameter combinations were evaluated to determine the performance impact of cooling power and transient temperature profiles. The results derived from the analyses of these design iterations indicate the multi-layer enclosure wall design will meet all thermal requirements. During SS operation, the interior temperature variation is within ±0.5 K of the target operational temperature, while the heat influx from the exterior TMT environment is 1528 W (extracted by the embedded cold plate). The transient cool-down cycle will take approximately 15 hours to complete and requires the in-situ air handling units (AHU) to deliver 14KW of cooling power (derated for the TMT site conditions) throughout the interior space of the NFIRAOS ENCL.

9908-378, Session PS6

High-contrast imaging with METIS

Matthew A. Kenworthy, Leiden Observatory (Netherlands); Olivier Absil, Univ. de Liège (Belgium); Eric J. Pantin, CEA-Ctr. de SACLAY (France); Tibor Agócs, ASTRON (Netherlands); Sascha P. Quanz, ETH Zürich (Switzerland); Remko Stuik, Bernhard R. Brandl, Leiden Observatory (Netherlands)

The Mid-infrared E-ELT Imager and Spectrograph (METIS) for the European Extremely Large Telescope (E-ELT) consists of a diffraction-limited imager at L/M and N/Q band with medium resolution spectroscopic capabilities, and an integral field unit for high spectral resolution spectroscopy over the L and M bands. One of the science cases that METIS addresses is the characterization of faint circumstellar material and exoplanet companions through imaging and spectroscopy.

We present our approach for high contrast imaging with METIS, covering diffraction suppression with coronagraphs, the removal of slowly changing optical aberrations with focal plane wavefront sensing, interferometric imaging with non-redundant masks, and observing strategies for both the imagers and IFU image slicers.

9908-379, Session PS6

Generalized atmospheric dispersion correctors for TMT

Brian M. Sutin, Thirty Meter Telescope (United States)

The Thirty Meter Telescope (TMT) is unbaffled and has stability requirements tighter than the previous generation of 10-m class telescopes, leading to tougher requirements on atmospheric dispersion correctors (ADC's). Since instruments are internally baffled, ADC's may no longer shift the position of the telescope exit pupil. Designs that control pupil position are explored.

9908-380, Session PS6

The Infrared Imaging Spectrograph (IRIS) for TMT: Prototyping of cryogenic compatible stage for the Imager

Fumihiro Uraguchi, Yoshiyuki Obuchi, Bungo Ikenoue, Sakae Saito, Ryuji Suzuki, Yutaka Hayano, National Astronomical Observatory of Japan (Japan)

The IRIS Imager requires multi-axis motion control of optical components in order to change observation modes and minimize the wave front error due to motion of the field. The motion control can be provided by an opt-mechanical stage which is operable under vacuum and cryogenic environment. Also the stage for the IRIS Imager is required to survive for 10 years without maintenance. One of the stages is for the cold stop that is located at pupil. First of all, we assumed that a stage for the cold stop carries an 80 mm diameter pupil mask and requires one rotational axis and two translational axes to align and retract the pupil mask. We noticed that it was hard to obtain a 3-dof stage with 80 mm clear aperture from commercial market and then decided to start prototyping.

Mechanical design of the prototype was started based on the requirement for the cold stop stage. However, degree of freedom of the stage was reduced to one rotation and one translation due to constraint of test environment. The prototype was designed as a double-deck stage, upper rotational stage and lower translational stage. The rotary stage is made of stainless steel with consideration of CTE of rotary bearing material, however the other parts are made of Aluminum because of its high thermal conductivity and specific rigidity. The rotary stage base equips stress relief mechanisms to absorb CTE difference between Stainless steel and Aluminum. One of concerns was that heat from the motor will generate temperature gradient and would cause unexpected stress to linear motion guide and failure. To control that, the rotary stage base was designed as not ordinary shape but horseshoe shape. Most of components are selected to take advantage of heritage from existing astronomical instruments. Stepper motors from Phytron, Inc. were chosen because of their proven performance under cryogenics. In contrast, mechanical components with lubricants such as bearings, linear motion guides and ball screws were modified to survive cryogenic environment. Standard balls were replaced with ones made of ceramics or processed with MoST(TM) coating. A drive mechanism including 160 teeth driven gear for rotary stage was fabricated at Mechanical Engineering Shop of Advanced Technology Center, National Astronomical Observatory of Japan. A motion controller and motor drivers from Newport Corporation is employed for the prototype. The performance proving test was carried out to evaluate errors such as wobbling, rotational and translational positioning error. We achieved 0.002 deg rms wobbling, 0.03 deg rms rotational positioning error and 0.017 mm rms translational positioning error. Also durability under anticipated load condition has been conducted.

In this article, we report the detail of mechanical design, fabrication, performance and durability of the prototype.

9908-381, Session PS6

The Infrared Imaging Spectrograph (IRIS) for TMT: multi-tiered wavefront measurements and novel mechanical design

Jennifer S. Dunn, David R. Andersen, Edward L. Chapin, Vladimir A. Reshetov, Ramunas Wierzbicki, Glen Herriot, NRC - Herzberg Astronomy & Astrophysics (Canada); Victor Isbrucker, Isbrucker Consulting Inc. (Canada); James E. Larkin, Univ. of California, Los Angeles (United States); Anna M. Moore, California Institute of Technology (United States)

The InfraRed Imaging Spectrograph (IRIS) will be the first light adaptive optics instrument on the Thirty Meter Telescope (TMT). IRIS is a collaboration between Caltech, the University of California, NAOJ and NRC Herzberg. In this paper, we present novel aspects of the Support Structure, Rotator and On-Instrument Wavefront systems being developed at NRC Herzberg. IRIS is suspended off the bottom port of the Narrow Field Infrared Adaptive Optics System (NFIRAOS) and provides its own image derotation to compensate for sidereal rotation of the focal plane. This arrangement is a challenge because NFIRAOS is designed to host two other science instruments, which imposes strict mass requirements on IRIS. As the mechanical design of all elements has progressed, we have been tasked with keeping the instrument under seven tonnes. This requirement has resulted in a mass reduction of 30 percent for the support structure and rotator compared to the most recent IRIS designs. To accomplish this goal while still being able to withstand earthquakes, we developed a new design with composite materials. As IRIS is a client instrument of NFIRAOS, it benefits from NFIRAOS' superior AO correction. IRIS plays an important role in providing this correction by sensing low-order aberrations with three On-Instrument Wavefront Sensors (OIWFS). The OIWFS consist of three independently positioned natural guide star wavefront sensor probe arms that patrol a 2-arcminute field of view. We expect tip-tilt measurements from faint stars within the IRIS imager focal plane will further stabilize the delivered image quality. We describe how the use of On-Detector Guide Windows (ODGWs) in the IRIS imaging detector can be incorporated into the AO correction. In this paper, we present our strategies for acquiring and tracking sources with this complex AO system, and for mitigating and measuring the various potential sources of image blur and misalignment due to properties of the mechanical structure and interfaces.

9908-382, Session PS6

A concept for seeing-limited IR spectroscopy at GMT

Robert A. Simcoe, Gábor F?rész, MIT Kavli Institute for Astrophysics and Space Research (United States)

The initial instrument suite for the Giant Magellan Telescope includes seeing-limited multi-object and precision radial velocity spectrometers, but no capability for infrared spectroscopy. Several high level science objectives of the observatory (e.g. Epoch of Reionization studies) can only be realized in the IR, and this need will eventually be addressed by instruments optimized for use with GMT's adaptive optics system. In this contribution we explore designs for an affordable seeing-limited near-IR spectrometer that could be developed on a short time scale, enabling early science for a range of topics highlighted in the GMT Science Book.

We have considered multiple design options; the principal model presented here draws heritage from the Magellan FIRE instrument, with a number of important differences. It is a cross-dispersed R2 echelle, based around a white pupil layout with a small degree of asymmetry. This design delivers continuous wavelength coverage from 0.88-2.50 microns at R=6000 for a single 0.7" x 8.0" entrance slit.

It uses a monolithic echelle grating over 42 orders, with dichroics splitting the dispersed beam into J, H, and K arms prior to cross dispersion. By isolating these arms, we may use VPH gratings for cross dispersion to maximize efficiency, and the spectral format maps well onto H2RG focal plane arrays. The echelle grating may be swapped with a flat mirror to access an alternate operating mode, with simultaneous JHK longslit coverage at R~1000.

Fast camera optics are required to best leverage the GMT's collecting area, since detector read noise limits the performance of FIRE and similar instruments on 6-10 meter telescopes. Accordingly, near-IR spectroscopy is a regime where giant telescopes offer favorable performance scaling, even in the seeing limit. Near 1 micron such instruments also complement JWST because their inter-line background remains low and JWST/NIRSPEC

is read-noise limited. Our optical design uses cameras with F/1.0 - F/1.25, with polychromatic entrance pupil diameter of 120mm.

Every effort has been made to reduce cost and mechanical complexity, with budget constraints in mind. All detectors and gratings are available as catalog items, and the optical layout fits within a vessel 1 meter in diameter and 2 meters long, simplifying design of the vacuum cryogenic system. There are only two user-controlled cryogenic mechanisms, one to select slits, and another to switch to low dispersion mode. We discuss concepts for additional servo mechanisms to condition instrument pointing/flexure and control the pupil stop.

This relatively small instrument can easily be accommodated in the volume envelope of GMT's Gregorian instrument platform. By using a dichroic to fold the telescope beam, it may be used in conjunction with the direct Gregorian optical spectrometer to achieve complete and simultaneous coverage of the full optical and near-IR bands. This conceptual design study demonstrates the potential for development of relatively affordable instruments at the ELT scale, in response to the pressures of joint funding for these telescopes and their associated instrument suites.

9908-383, Session PS6

Optical design of the post-focal relay of MAORY

Matteo Lombini, INAF - Osservatorio Astronomico di Bologna (Italy); Adriano De Rosa, INAF - IASF Bologna (Italy); Paolo Ciliegi, Fausto Cortecchia, INAF - Osservatorio Astronomico di Bologna (Italy); Vincenzo De Caprio, INAF - Osservatorio Astronomico di Capodimonte (Italy); Emiliano Diolaiti, Italo Foppiani, INAF - Osservatorio Astronomico di Bologna (Italy); Gianluca Morgante, INAF - IASF Bologna (Italy); Marco Riva, INAF - Osservatorio Astronomico di Brera (Italy); Philippe Feautrier, Institut de Planétologie et d'Astrophysique de Grenoble (France)

The Multi Conjugate Adaptive Optics Relay (MAORY) for the European Extremely Large Telescope is planned to be located on the straight-through port of the telescope Nasmyth platform and shall re-image the telescope focal plane to a wide field camera (MICADO) and a possible future second instrument. By means of natural and artificial (laser) reference sources for wavefront sensing, and of deformable mirrors for wavefront correction, MAORY shall be able to compensate the wavefront disturbances affecting the scientific observations, achieving high Strehl ratio and high sky coverage.

A trade-off study among different design options has been carried out addressing optical performance at the exit ports (wave front error, field distortion, throughput), structure stability, interface constraints (mass, size, location and accessibility of the two client instruments), adaptive optics performance and budget.

We show the consolidated baseline configuration of the opto-mechanical design as a result of Phase B1.

9908-384, Session PS6

Wavelength dependence of star images formed by large ground-based telescopes including ELTs

T. Stewart McKechnie, McKechnie Optics Research (United Kingdom)

The angular size and shape of star images delivered by large ground-based telescopes – with or without Adaptive Optics (AO) – can vary greatly over the optical wavelength region, 0.3 ?m – 1000 ?m. A particularly diverse range of appearances is anticipated for future images delivered by the eagerly-anticipated 40-meter diameter European-Extremely Large Telescope (E-ELT). In this talk, we examine star image properties as a function of wavelength and use a simple, expedient formulation to generate representative images. Because of its origins in a rigorous formulation that relies only on Maxwell's equations, the formulation does not require 'a priori' assumptions about atmospheric turbulence properties, Kolmogorov or other. These turbulence properties, together with relevant properties of the telescope and AO system, combine to determine the average star image intensity envelopes. As indicated in the talk, all of these properties can be established (on-site and as-needed) from readily-measurable properties of the most general kind of star image – the core and halo image. As wavelengths range from near-UV towards long-wavelength IR, sooner or later all star images ultimately morph through the same three basic forms: halo-only, core-and-halo, and core-only. Given any large reflector telescope, by simply imaging a star at a wavelength consistent with a core-and-halo image and then measuring certain basic properties of that image, we can immediately predict from these properties how the star will look at any other wavelength.

A core-and-halo star image obtained at 1.65 ?m by the AO-equipped Keck II instrument is used to illustrate both the image-characterization and image-generation procedures. Images created in this way show how stars might have looked with the Keck II instrument in the same seeing conditions at various other visible and IR wavelengths. Other images show how stars will likely appear in the 40-meter E-ELT instrument, with present-day AO performance levels assumed, and also marginally improved levels in anticipation of future AO advances.

The effects on star images of scintillation and residual uncorrected phase are examined in detail. Both mechanisms cause light energy to be scattered from the centers of star images, degrading Strehl intensity and creating background haze that can conceal faint nearby objects. While an efficiently-functioning AO-equipped telescope should, in theory, be able to deliver substantially diffraction-limited images at all optical wavelengths, because of the practical limitations of present-day AO technology, usually only partial correction is possible at shorter wavelengths, visible wavelengths in particular. In the case of the E-ELT telescope, unless significant advances have been made in AO technology by the time of first light, the irradiance in the center of star images delivered by this instrument at the shortest visible wavelength, 0.4 ?m, is reasoned to be about 10-magnitudes less than the theoretical maximum value. Consequently, star images delivered by the E-ELT instrument at visible wavelengths may be no better than those delivered by a diffraction-limited, space-based 1-meter instrument. However, for wavelengths longer than about 1.5 ?m, scattering issues rapidly subside and it then becomes increasingly likely that the formidable diffraction-limited resolution potential of this magnificent instrument will be fully realized.

9908-385, Session PS6

Flowdown of the TMT astrometry error budget(s) to the design of the first-light instrument IRIS

Matthias Schöck, Thirty Meter Telescope (United States); David R. Andersen, NRC - Herzberg Astronomy & Astrophysics (Canada); John Rogers, Thirty Meter Telescope (United States)

TMT has defined the accuracy to be achieved for both absolute and differential astrometry in its top-level requirements documents. Because of the complexities of different types of astrometric observations, these requirements cannot be used to specify system design parameters directly. The TMT astrometry working group therefore developed detailed astrometry error budgets for a variety of science cases. These error budgets detail how astrometric errors propagate through the calibration,

observing and data reduction processes, and need to be condensed into sets of specific requirements that can be used by each subsystem team for design purposes. We show how this flowdown from error budgets to design requirements is achieved for the case of TMT's first-light Infrared Imaging Spectrometer (IRIS) instrument. We describe the process in general, provide examples of how it is executed and list the most significant consequences for the IRIS design.

9908-386, Session PS6

The Infrared Imaging Spectrograph (IRIS) for TMT: optical design of IRIS imager with "co-axis double TMA"

Toshihiro Tsuzuki, Ryuji Suzuki, Hiroki Harakawa, Bungo Ikenoue, National Astronomical Observatory of Japan (Japan); James E. Larkin, Univ. of California, Los Angeles (United States); Anna M. Moore, California Institute of Technology (United States); Yoshiyuki Obuchi, National Astronomical Observatory of Japan (Japan); Andrew C. Phillips, Univ. of California Observatories (United States); Sakae Saito, Fumihiro Uraguchi, National Astronomical Observatory of Japan (Japan); James E. Wincentsen, California Institute of Technology (United States); Shelley A. Wright, Univ. of California, San Diego (United States); Yutaka Hayano, National Astronomical Observatory of Japan (Japan)

IRIS (InfraRed Imaging Spectrograph) is one of the first generation instruments for Thirty Meter Telescope (TMT). IRIS is composed of a combination of near-infrared (0.84-2.4um) diffraction limited imager and integral field spectrograph. To achieve diffraction limited resolutions at wavelengths longer than 1 um, IRIS can utilizes the advanced adaptive optics system NFIRAOS (Narrow Field Infrared Adaptive Optics System) and has integrated on-instrument wavefront sensors (OIWFS). However, IRIS itself has challenging specifications. Firstly, wavefront error of overall system should be less than 40 nm in Y, z, J, and H-band and 42 nm in K-band over a 34.0x34.0 arcsecond field of view. Secondly, throughput of the imager components should be more than 42%. To achieve the extremely low wavefront error and high throughput, all reflective design has been newly proposed. We have adopted a new design policy called "Co-Axis double-TMA", which cancels the asymmetric aberrations generated by "Collimator TMA" and "Camera TMA" efficiently. The latest imager design meets all specifications, especially, wavefront error is less than 17.3 nm and throughput is more than 50.8 %. However, to meet the specification of wavefront error and high throughput as built performance, IRIS imager requires the mirrors with low surface irregularity and high throughput coating in cryogenic and high-level AIV. To deal with these problems, we have done the tolerance analysis and found that total pass rate is almost 99% in the case of gauss distribution and more than 90% in the case of parabolic distribution using four compensators. We also have done AIV plan and feasibility check of the optical elements. In this paper, we will present the detail of this optical system.

9909-1, Session 1

MagAO: status and science

Katie M. Morzinski, Laird M. Close, Jared R. Males, Philip M. Hinz, The Univ. of Arizona (United States)

The AO system at the Magellan Clay telescope at Las Campanas Observatory, Chile, "MagAO," has a 585-actuator adaptive secondary mirror and 1000-Hz pyramid wavefront sensor, operating on natural guide stars from R-magnitudes of -1 to 16. MagAO has been in operation for ~150 regular science nights in the 3 years post-commissioning. MagAO's unique capabilities are simultaneous imaging in the visible and infrared with VisAO and Clio, high performance at an excellent site, and a lean operations model. A wide range of science is pursued with the instrument, from Solar System studies to extrasolar planets, circumstellar disks, and galactic science, with (thus far) ~60 users producing ~20 refereed publications. Some of MagAO's science results include the first ground-based CCD image of an exoplanet, discovery of the first accreting protoplanets, discovery of a new wide-orbit exoplanet, and the first empirical bolometric luminosity of an exoplanet. We will describe the system, operations, calibrations, and science results of this unique facility-class AO instrument.

9909-2, Session 1

imaka: ground-layer AO at Maunakea

Mark R. Chun, Jessica R. Lu, Institute for Astronomy (United States); Douglas Toomey, Mauna Kea Infrared LLC (United States); Olivier Lai, Subaru Telescope, National Astronomical Observatory of Japan (United States); Maxwell Service, Institute for Astronomy (United States); Yutaka Hayano, National Astronomical Observatory of Japan (Japan); Shin Oya, Subaru Telescope, National Astronomical Observatory of Japan (Japan); Michael S. Connelley, Institute for Astronomy (United States); Denis Brousseau, Simon Thibault, Univ. Laval (Canada)

We present the integration and commissioning status for the ground-layer adaptive optics (GLAO) system `imaka on the University of Hawaii 2.2-meter telescope on Maunakea, Hawaii. This GLAO system exploits Maunakea's highly confined ground layer and weak free-atmosphere to push the corrected field of view to ~1/3 of a degree. By using natural guide stars spread over this wide field, we will demonstrate the efficacy of AO with an areal field approaching an order of magnitude larger than any existing or planned GLAO system.

In this presentation we present the unique aspects of the system implementations, how the science cases impact the system, as well as the lessons learned to date designing/fabricating the instrument. The large field of view and the astrometric science case drive the instrument to large optics with strict stability requirements. These bring strong design constraints. In particular, the size, mass, and stability requirements led us to a stiff, lightweight, athermal structure made from carbon-fiber panels. The choice of carbon fiber, however, has other design/use impacts on its use in astronomical instruments. For example, (1) the carbon-fiber panels are hygroscopic so long term changes in their moisture content affect the optical alignment of the system. Since these changes occur over long periods (weeks to months) we believe their effects can be mitigated with care in storage, use, and regular long-term monitoring/calibrations. (2) Given the size of the instrument and the assembly techniques, the carbon-fiber structure on its own has positional accuracies nearly an order of magnitude worse than commonly obtain with aluminum structures (e.g. machine tolerances). We are able to compensate for this initial reduced precision with some forethought on the design of the instrument. In particular, to position elements in the structure we designed in the means to establish, after the structure fabrication, a positional accuracy for each of the critical elements. This combined with an optical design tolerant to misalignment allows us to meet our image quality error budget.

The path-finder nature of `imaka combined with access to a telescope on Maunakea provides a powerful platform for testing a variety of approaches for wide-field AO at a premier astronomical site. `imaka is flexible - at the instrument's front focus different calibration units can slot into a "calibration drawer" to test basic functionality of the GLAO system, provide "pre AO" wavefront sensor telemetry, or calibrate optical distortions. At the rear focus we effectively have an optical table capable of holding a variety of science or "scoring" cameras/wavefront sensors. In addition, `imaka's operational model provides flexibility - we can access useful periods of time on the telescope for each experiment with the instrument configured for a specific set of observations. We summarize the experiments we will be conducting with the system over next year. These include tackling the astrometric precision and accuracy of GLAO with the system in embedded star formation regions with the distortion calibration unit and a wide-field near infrared science camera based on a Teledyne H4RG-15 detector.

9909-3, Session 1

Engineering aspects of the Large Binocular Telescope Observatory adaptive optics systems

Guido Brusa Zappellini, Michael J. Lefebvre, Gregory Taylor, Xianyu Zhang, Douglas L. Miller, Gustavo Rahmer, Julian C. Christou, Conrad Vogel, Jonathan Kern, Large Binocular Telescope Observatory (United States); Richard Gonzalez Sosa, The Univ. of Arizona (United States); David S. Ashby, Large Binocular Telescope Observatory (United States)

The Large Binocular Telescope (LBT) is equipped with two advanced adaptive optics systems named first light adaptive optics (FLAO), these systems comprise two new and challenging technologies, namely: adaptive secondary mirrors (ASM) and pyramid wavefront sensors (PWS) both requiring significant engineering support.

To maintain two functional and operational AO systems several engineering aspects of both ASMs and PWSs need to be considered, in particular in this paper we address: system safety and reliability, maintenance and repairs, AO calibrations and improvements to the initial design.

The ASMs are subject to several significant risks, the highest being related to human intervention during handling of the units themselves or direct handling of the fragile thin shells. In order to limit these risks we have developed very strict procedures and an inspection regimen to be used during: removal, installation and coating. Other risks are related to wind effect on the thin shells and cooling system. To protect against the first of these risks a safety scheme was implemented in the design phase and has been improved during the operation phase. To protect against the second risk we have had to redesign the cooling system, introducing a more effective coolant leak detection system and temperature control.

In terms of reliability one of the main areas of activity is related to actuator malfunction or loss of calibration. This occurs intermittently causing loss of observing time. We present a plan to implement an automatic scheme for actuator monitoring with a disabling/enabling mechanism in order to prevent time loss due to manual intervention.

We will also discuss optical calibration of the ASMs at the telescope using a dynamic interferometer operating at the long conjugate focus of the ASMs.

For the PWSs the main effort is directed towards keeping the various electro-mechanical components in good conditions as well as developing

reliable and effective procedures for the units' alignment.

While the work towards improving the original design of the ASMs and PWSs is demanding and challenging we demonstrate that the rewards, in terms of reduced downtime and increased performance are significant. This leads us towards our goal of having manageable systems that can operate routinely and with limited oversight.

9909-4, Session 1

ALES: a 1.5-5 micron adaptive optics integral field spectrograph for the LBT

Andrew J. Skemer, Univ. of California, Santa Cruz (United States); Philip M. Hinz, The Univ. of Arizona (United States); Michael F. Skrutskie, Univ. of Virginia (United States); Charles E. Woodward, Univ. of Minnesota, Twin Cities (United States); Jordan Stone, Oscar Montoya, Olivier Durney, Jarron M. Leisenring, The Univ. of Arizona (United States); John C. Wilson, Matthew J. Nelson, Univ. of Virginia (United States); Vanessa P. Bailey, Stanford Univ. (United States); Denis Defrere, The Univ. of Arizona (United States)

Integral field spectrographs are an important technology for exoplanet imaging, due to their ability to take spectra in a high-contrast environment, and improve planet detection sensitivity through spectral differential imaging. ALES is the first integral field spectrograph capable of imaging exoplanets from 3-5 μm, and will extend our ability to characterize self-luminous exoplanets into a wavelength range where they peak in brightness. ALES is installed inside LBTI/LMIRcam on the Large Binocular Telescope, and saw first light in June 2015. In 2016A, we are beginning science observations with ALES, which will include spectroscopy of directly-imaged exoplanets, debris and transition disks, comets, and Jovian moons. Additionally, we are planning upgrades that will (1) increase ALES's field-of-view, spectral resolution and wavelength range, (2) decrease inter-spaxel crosstalk at the edges of the ALES field, and (3) implement an interferometric plate-scale that will take IFS images at the diffraction limit of the full 23-meter baseline LBT.

9909-5, Session 2

The infrared imaging spectrograph (IRIS) for TMT: latest science cases and simulations *(Invited Paper)*

Shelley A. Wright, Gregory Walth, Daniel Marshall, Univ. of California, San Diego (United States); Tuan Do, James E. Larkin, Univ. of California, Los Angeles (United States); Anna M. Moore, California Institute of Technology (United States); Máté Ádámkovics, Univ. of California, Berkeley (United States); David R. Andersen, NRC - Herzberg Astronomy & Astrophysics (Canada); Lee Armus, California Institute of Technology (United States); Aaron J. Barth, Univ. of California, Irvine (United States); Patrick Côté, NRC - Herzberg Astronomy & Astrophysics (Canada); Jeffrey Cooke, Swinburne Univ. of Technology (Australia); Timothy J. Davidge, Jennifer S. Dunn, NRC - Herzberg Astronomy & Astrophysics (Canada); Christophe Dumas, Thirty Meter Telescope (United States); Brent L. Ellerbroek, California Institute of Technology (United States); Andrea M. Ghez, Univ. of California, Los Angeles (United States); Lei Hao, Shanghai Astronomical Observatory (China); Yutaka Hayano, Advanced Technology Ctr., NAOJ (Japan); Michael C. Liu, Univ. of Hawai'i (United States); Jessica R. Lu, Institute for Astronomy (United States); Shude Mao, National Astronomical Observatories (China); Christian Marois, NRC-Dominion Astrophysical Observatory (Canada); Shashi B. Pandey, Aryabhatta Research Institute of Observational Sciences (India); Andrew C. Phillips, Univ. of California, Santa Cruz (United States); Matthias Schöck, Thirty Meter Telescope (United States); Annapurni Subramanian, Indian Institute of Astrophysics (India); Smitha S. H. Sharma, Kavli Institute for Astronomy and Astrophysics (China); Jonathan C. Tan, Univ. of Florida (United States); Tsuyoshi Terai, National Astronomical Observatory of Japan (Japan); Tommaso Treu, Univ. of California, Los Angeles (United States); Ryuji Suzuki, Advanced Technology Ctr., NAOJ (Japan); Luc Simard, NRC - Herzberg Astronomy & Astrophysics (Canada) and Thirty Meter Telescope (United States); Jason L. Weiss, Univ. of California, Los Angeles (United States); James E. Wincentsen, California Institute of Technology (United States); Michael H. Wong, Univ. of California, Berkeley (United States)

The Thirty Meter Telescope (TMT) first light instrument, IRIS (Infrared Imaging Spectrograph), will complete the preliminary design phase in 2016. The IRIS instrument design includes a near-infrared (0.85 - 2.4 micron) integral field spectrograph (IFS) and wide field imager (32.8"x32.8") that is able to conduct simultaneous diffraction-limited observations behind the advanced adaptive optics system NFIRAOS. The IRIS science case has continued to be developed and new science studies have been investigated to aid in technical performance and design. The IRIS science team has paid particular attention in the selection of filters, gratings, and sensitivities of the entire system. We will present science cases that directly benefit from the parallel mode between IFS and imager, as well as uniqueness of the combination of IFS high spatial resolution observations with moderate (R= 4000 - 8000) resolving power. We discuss the overarching science case for IRIS, and we will present latest results from the end-to-end data simulator for IFS and imager on a variety of science cases, ranging from solar system objects, extrasolar planets, active galactic nuclei, to nearby and distant galaxies. Each of these science cases will be put in context with other upcoming facilities and the importance of complementary high spatial resolution observations. Lastly, we will briefly discuss the necessity of an advanced data management system and data reduction pipeline as further outlined in Walth et al., this conference.

9909-6, Session 2

Photometry in MCAO *(Invited Paper)*

Giuliana Fiorentino, INAF - Osservatorio Astronomico di Bologna (Italy); Alan W. McConnachie, Peter B. Stetson, NRC - Herzberg Astronomy & Astrophysics (Canada); Davide Massari, Laura Schreiber, INAF - Osservatorio Astronomico di Bologna (Italy); Paolo Turri, Univ. of Victoria (Canada); Giuseppe Bono, Univ. degli Studi di Roma "Tor Vergata" (Italy)

We will make an overview of the current status of photometric analyses performed with Multi Conjugate Adaptive Optics (MCAO) mounted on 10-m class of telescopes that operated, or are operating, on sky.

Particular attention will be payed to resolved stellar population studies. In fact stars in crowded stellar systems, such as globular clusters or distant galaxies, are ideal test--particles in order to test AO performance. We will present recent results obtained in our observational campaign (PI A. Mc Connachie) using the MCAO system mounted at the Gemini-South telescope, i.e. GeMS. Six globular clusters have been observed in J and K bands. As expected, thanks to the AO system, the K-band limiting magnitude approaches Ks~ 22 mag. The accuracy reached for most of the globular clusters allowed us to reconstruct their Colour Magnitude diagram down to their main sequence knees. The detection and characterization of this feature has permitted to constrain with unprecedented accuracy the absolute ages of some of these clusters (e.g. NGC1851, NGC2808 and NGC5904). For the remaining clusters (e.g. NGC6681, NGC6723 and NGC6652) near Infrared calibration data are needed and have been required. This is a crucial point when exploiting very deep near IR AO imaging.

We will focus on the sensitivity and on the photometric precision reached nowadays. In order to quantify our ability in performing PSF photometry on MCAO images with existing photometric packages, we will use different software (DAOPHOT, Starfinder, Romaphot) on images taken with laser (and eventually natural) guide stars systems, e.g. GeMS@Gemini-South.

Finally, we discuss the kind of science we plan to do and the errors expected when coming (e.g. Linc Nirvana) or future (e.g. MAORY) facilities will be operational on 10-m class or giant ground based telescopes.

9909-7, Session 2

Photometric techniques, performance, and PSF characterization of GeMS, the MCAO system on Gemini South

Paolo Turri, Univ. of Victoria (Canada) and NRC - Herzberg Astronomy & Astrophysics (Canada); Alan W. McConnachie, Peter B. Stetson, NRC - Herzberg Astronomy & Astrophysics (Canada); Giuliana Fiorentino, INAF - Osservatorio Astronomico di Bologna (Italy); David R. Andersen, NRC - Herzberg Astronomy & Astrophysics (Canada)

GeMS is the first facility class multi-conjugate adaptive optics (MCAO) instrument on the 8-m Gemini South telescope in Chile, and the first to use laser guide stars. We have observed six Galactic globular clusters in J (1.25 ?m) and Ks (2.15 ?m) band for which we have also HST/ACS observations in the visible. We use NGC 1851 as a benchmark with which to judge the science performance of GeMS for photometry, and to develop procedures to best extract the best science performance of the system. We develop techniques to best characterize the empirical PSF, and determine with high accuracy the PSF model for the PSF fitting photometry. We show that the PSF model has to have a large degree of spatial and temporal variability. We use the bright stars in our target also to measure the performance of the MCAO correction in terms of Strehl ratio, FWHM and ellipticity of the PSF. The performance maps provide an additional proof for the need of a varying PSF, and demonstrate that scientific images produced by MCAO require a more careful photometric reduction than seeing-limited observations. Understanding the correct PSF fitting techniques will prove useful for observing with the next generation of Extremely Large Telescopes like TMT and E-ELT, where MCAO will be a central technology.

9909-8, Session 3

Adaptive optics program update at TMT

Corinne Boyer, Brent L. Ellerbroek, Thirty Meter Telescope (United States); Sean M. Adkins, W. M. Keck Observatory (United States); David R. Andersen, Glen Herriot, Jean-Pierre Véran, National Research Council Canada (Canada); Luc Gilles, Lianqi Wang, Angel C. Otárola, Tony Travouillon, Thirty Meter Telescope (United States); Kai Wei, Jinlong Tang, Institute of Optics and Electronics (China); Theresa L. Bruno, Jeffrey Cavaco, AOA Xinetics (United States); Hubert Pages, Jean-Christophe Sinquin, CILAS (France); Jennifer S. Dunn, National Research Council Canada (Canada); Robert W. Leach, Astronomical Research Cameras, Inc. (United States); Matthias Schöck, Thirty Meter Telescope (United States)

The TMT first light AO facility consists of the Narrow Field Infra-Red AO System (NFIRAOS), the associated Laser Guide Star Facility (LGSF) and the AO Executive Software (AOESW). Design, fabrication and prototyping activities of the TMT first light AO systems and their components are now ramping up in Canada, China and in the US. NFIRAOS is an order 60 x 60 laser guide star (LGS) multi-conjugate AO (MCAO) system, which provides uniform, diffraction-limited performance in the J, H, and K bands over 15-30 arc sec diameter fields with 50 per cent sky coverage at the galactic pole, as required to support the TMT science cases. NFIRAOS includes two deformable mirrors, six laser guide star wavefront sensors, one high order Pyramid WFS for natural guide star AO, up to three low-order, IR, natural guide star on-instrument wavefront sensors (OIWFS) within each client instrument, and up to four guide windows on the science detectors (ODGW). The first light LGSF system includes six sodium lasers to generate the NFIRAOS laser guide stars.

In this paper, we will provide an update on the progress in designing, prototyping, fabricating and modeling the TMT first light AO systems and their AO components over the last two years. This will include final design and prototyping/benchmarking activities for NFIRAOS and the NFIRAOS Real Time Controller (RTC), preliminary design and prototyping activities for the LGSF and AOESW, design and prototyping for the deformable mirrors and the visible WFS camera, fabrication and tests for the visible WFS detectors, and further development and tests of candidate lasers. TMT is continuing with detailed AO modeling to support the design and development of the first light AO systems and components. Major modeling topics studied during the last two years include further studies in the area of pyramid wavefront sensing, high precision astrometry, PSF reconstruction for LGS MCAO, LGSF wavefront error budget and sophisticated low order mode temporal filtering.

9909-9, Session 3

The HARMONI laser tomography module

Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, ONERA (France); Carlos M. Correia, Kjetil Dohlen, Kacem El Hadi, Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, ONERA (France); Noah Schwartz, UK Astronomy Technology Ctr. (United Kingdom); Fraser Clarke, Univ. of Oxford (United Kingdom); Morgan Gray, Emmanuel Hugot, Lab. d'Astrophysique de Marseille (France); Miska Le Louarn, European Southern Observatory (Germany); Niranjan A. Thatte, Matthias Tecza, Univ. of Oxford (United Kingdom); Leonardo Blanco, ONERA (France); Hermine Schnetler, Ian Bryson, Angus M. Gallie, David M. Henry, UK Astronomy Technology Ctr. (United Kingdom); Timothy J. Morris, Richard M. Myers, Durham Univ. (United Kingdom); Joël D. R. Vernet, Jérôme Paufique, Peter Hammersley, European Southern Observatory (Germany); Jean-Luc Gach, Laboratoire d'Astrophysique de Marseille (France)

HARMONI is a visible and near-infrared integral field spectrograph, providing the E-ELT's core spectroscopic capability. It will exploit the E-ELT's scientific niche in its early years, starting at first light. To get the full sensitivity and spatial resolution gain, HARMONI will work at diffraction limited scales. This will be possible thanks to two adaptive optics systems, complementary to each other. Both systems will make use of the telescope's adaptive M4 and M5 mirrors. The first one is a simple but efficient Single Conjugate AO system (good performance, low sky coverage), fully integrated in HARMONI itself. The second one is a Laser Tomographic AO system (medium performance, very good sky coverage). In this paper, we focus on the Laser Tomography AO module.

We present the system choices that has been made, in particular regarding the LGS constellation and the complementary measurement done with the NGS.

In particular, we detail the WFS concept choice that are envisioned for the LGS, and present a first trade-off in terms of performance, of different potential designs. This is particularly relevant for HARMONI, as the baseline will be to work with sub-optimal detectors in terms of total number of pixels. Hence, trade-offs are made between LGS spot sampling, truncation and optical spot shrinking. Still regarding the LGSWFS path, we explore the impact of static aberrations, and differential quasi-static aberrations between the different LGS paths. Finally, we present a first trade-off study between different tomographic approaches.

Regarding the NGS path, we describe the NGSWFS design choice, and the expected performance for a focal plane solution in order to measure Tip-Tilt and Focus. We discuss the definition and required performance for a truth WFS. Finally, we present the estimated performance and resulting sky-coverage based on a full E2E simulation model. Telescope effects such as spyders, phasing, scalloping and wind-shake are introduced in the model.

Finally, we present a list of the required calibrations, and the need for telescope calibration sources vs. on-sky calibration.

9909-10, Session 3

MICADO SCAO specifications, prototyping, concepts and current preliminary design

Yann Clénet, Jean-Tristan M. Buey, Gérard Rousset, Éric Gendron, Zoltan Hubert, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Mathieu Cohen, Observatoire de Paris à Meudon (France); Frédéric Chapron, Arnaud Sevin, Pierre Baudoz, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Philippe Feautrier, Gérard Zins, Institut de Planétologie et d'Astrophysique de Grenoble (France); Damien Gratadour, Fabrice Vidal, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Fanny Chemla, Observatoire de Paris à Meudon (France); Florian Ferreira, Observatoire de Paris (France); Nicolas Doucet, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Alexis Carlotti, Institut de Planétologie et d'Astrophysique de Grenoble (France); Josef Schubert, Richard Davies, Max-Planck-Institut für extraterrestrische Physik (Germany)

MICADO is the E-ELT first light imager, working at the diffraction limit in the near infrared. Optimized to work with the MAORY multi-conjugate adaptive optics module, MICADO will also come with a single conjugate adaptive optics (SCAO) capability motivated by scientific programs for which SCAO will deliver the best AO performance (e.g. exoplanets, solar system science, bright AGNs, etc).

This SCAO capability will be developed within MICADO through a dedicated SCAO module with its natural guide star (NGS) wavefront sensor (WFS), allowing MICADO to work in SCAO stand alone mode without MAORY, and inside MAORY with the same dedicated NGS WFS.

The project has just entered in phase B in October 2015. We are then currently in a phase of prototyping, simulations and preliminary design.

The MICADO SCAO prototyping activities are concerning first the WFS, aiming at guiding the choice of the wavefront sensor, either Shack-Hartmann or pyramid. Real-time computer (RTC) prototyping activities are also ongoing, as part of the H2020 Green Flash project, which, more broadly, aims at prototyping RTC for complex AO systems such as MCAO. These two activities are planned to be coupled to build a SCAO prototype for MICADO. The last prototyping is concerning the MICADO coronagraphic mode and is planned to begin in 2016.

On the AO side, simulations activities are being performed to guide the choice of the SCAO sensor, in addition to the prototyping activity, to start the dimensioning of the WFS and to draw an AO error budget. These simulations are performed with COMPASS, our GPU-based end-to-end simulation software. We made a major upgrade of this software, developing a user interface layer in Python in replacement of the Yorick one. New functionalities have also been implemented to better match the E-ELT configuration (M1 pupil, co-phasing errors, etc). Simulations are also starting for the MICADO coronagraphic mode to derive a first assessment of the performance of this mode.

Finally, opto-mechanical preliminary design is in progress. The SCAO WFS has been allocated a volume, the so-called "Green Doughnut", that fits the two configurations, MICADO in standalone mode and when coupled to MAORY. In this volume will be implemented the SCAO WFS, its dedicated calibration unit and the three MAORY NGSs.

We will present here first the MICADO SCAO top-level specifications, the current SCAO prototyping activities, the concepts contemplated for SCAO subsystems (WFS, RTC) as well as the current preliminary design of the MICADO SCAO system.

9909-11, Session 3

Designing the METIS SCAO and LTAO systems

Remko Stuik, Leiden Observatory (Netherlands); Markus Feldt, Stefan Hippler, Thomas Bertram, Silvia Scheithauer, Max-Planck-Institut für Astronomie (Germany); Andreas Obereder, MathConsult GmbH (Austria); Daniela Saxenhuber, Johannes Kepler Univ. Linz (Austria); Bernhard R. Brandl, Leiden Univ. (Netherlands); Matthew A. Kenworthy, Leiden Observatory (Netherlands); Rieks Jager, Leiden Univ. (Netherlands); Lars Venema, ASTRON (Netherlands)

METIS, the Mid-infrared E-ELT Imager and Spectrometer, will be providing high-sensitivity imaging and high-resolution spectroscopy in the mid-infrared (3-19 micrometer) to the E-ELT. In order to achieve the exceptional performance required by its driving science cases, exoplanets and proto-planetary disks, METIS will be featuring two Adaptive Optics (AO) systems—a first-light Single Conjugate Adaptive Optics (SCAO) system, complemented by a Laser Tomographic Adaptive Optics (LTAO) system, most likely, a few years after first light. METIS, being one of the three first light science instruments on the European Extremely Large Telescope (E-ELT), will be one of the first instruments using the integrated deformable mirror of the E-ELT for its Adaptive Optics (AO) correction.

The internal SCAO system designed to maximize the performance for bright targets and has its wavefront sensors (WFSs) build inside the METIS cryostat to minimize the number of warm surfaces towards the science detectors. Although the internal dichroic will reflect all light short wards of 3 micrometers towards the WFS, only the IR light will most likely be used,

mainly due to the expected improved performance at longer wavelengths for the WFS. A trade-off has been made between both visible versus infrared wave front sensing as well as Pyramid versus Shack-Hartmann, under various observing conditions and target geometries, taking into account performance, target availability, reliability and technology readiness level. The base line for the SCAO system is to minimize system complexity, thereby ensuring system availability and reliability even under first-light conditions.

Since the SCAO system will require a bright guide star near the science target, it can only be used for a limited number of targets. The LTAO system, consisting of up to 6 LGS and up to 3 low-order NGS WFS and located outside the cryostat, is designed to increase the sky coverage on arbitrary targets to >80%. Investigations are ongoing if the internal SCAO system can be used as either a Low-Order WFS or metrology system.

This paper describes the most recent developments of the SCAO and LTAO designs.

9909-12, Session 4

Final two stage MOAO on-sky demonstration with CANARY

Éric Gendron, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Timothy J. Morris, Alastair G. Basden, Durham Univ. (United Kingdom); Fabrice Vidal, Jean-Tristan M. Buey, Damien Gratadour, Carine Morel, Fanny Chemla, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Mathieu Cohen, Observatoire de Paris à Meudon (France); Arnaud Sevin, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Eddy J. Younger, James Osborn, Durham Univ. (United Kingdom); David M. Henry, UK Astronomy Technology Ctr. (United Kingdom); Nigel A. Dipper, Richard W. Wilson, Timothy Butterley, Urban Bitenc, Andrew P. Reeves, Durham Univ. (United Kingdom); Jean-Michel Huet, Observatoire de Paris à Meudon (France); Denis Perret, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Colin Dickson, David C. Atkinson, Andy Longmore, Stephen Todd, UK Astronomy Technology Ctr. (United Kingdom); Robert G. Talbot, Simon L. Morris, Durham Univ. (United Kingdom); Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Richard M. Myers, Durham Univ. (United Kingdom)

In 2007, the project developing an on-sky demonstrator for multi-object adaptive optics (MOAO) was initiated. This was in the framework of the pre-phase A study of the EAGLE instrument, a MOAO-assisted IR spectrograph for the observation of distant galaxies. At that time, MOAO was regarded as an uncertain, challenging technique by the European community. This led the University of Durham and Paris Observatory to propose to install an MOAO pathfinder called CANARY on the William Hershel Telescope in La Palma. The programme for setting up the full complete experiment was established through 3 main phases of increasing complexity, starting from the demonstration of open-loop tomography on natural guide stars (NGS) in 2010, to the open-loop tomography behind a wide-field closed-loop first stage using mixed laser guide star (LGS) and NGS control.

First images were successfully obtained in July 2010. Then, MOAO coupling 3 NGS and 4 Rayleigh LGS in open loop in 2013 and laser tomography AO (LTAO) in 2014 were demonstrated. In 2015 CANARY obtained the final results as a two-stage system that mimics the future E-ELT: a LTAO-driven woofer based on 4 LGS delivers a ground-layer compensated field to a figure-sensor locked tweeter DM, that achieves the final on-axis tomographic compensation.

CANARY has four Rayleigh LGS wave-front sensors (WFS), three off-axis NGS WFS, two figure sensors, and a so-called truth sensor that do not take part to the correction, but allows us to assess the error breakdown, perform calibrations, and close a classical SCAO loop for reference images. The total number of slopes and actuators crunched by the real-time computer (RTC) went from 288x54 in 2010 to 2042x297 in 2015, a factor of 40 ahead, while the control law went from the simplest of all correctors in 2010 to a rather complex mixed LGS-NGS LTAO pseudo open-loop woofer control completed by a differential tomographic open-loop figure-locked tweeter control in 2015. All this was accompanied by an increase of efficiency of the instrument, from 50 to 200 files archived per night, now processed during the night as they are produced by an automated dedicated pipeline.

We will present the overall system, the control strategy and an overview of its on-sky performance, as well as the ensemble of tools and techniques that were used to assess, at each phase of the project, the wave-front error breakdown.

The perspective for the new E-ELT project of multi object spectrograph, so-called MOSAIC, will be given.

9909-13, Session 4

Keck planet imager and characterizer (KPIC): concept and phased implementation

Dimitri Mawet, California Institute of Technology (United States)

The Keck Planet Imager and Characterizer (KPIC) concept is a cost-effective proposed upgrade to the Keck II adaptive optics system, building on the lessons learned from the extreme-AO systems (ExAO: P3K, SPHERE, GPI, SCExAO, MagAO) that will mature system-level and critical components for future segmented ground and space-based instrumentation (e.g. TMT, HDST). The advent of fast low-noise infrared cameras (e.g. IR-APD/MKIDS), the rapid maturing of efficient wavefront sensing techniques (e.g. Pyramid/Zernike), small inner working angle coronagraphs (e.g. vortex, HLC, APP, PIAA) and associated low-order wavefront sensors, as well as recent breakthroughs in high contrast Doppler imaging techniques, open new avenues complementary to first and second-generation ExAO systems. For instance, ExAO in the infrared enables the search and characterization of planetary systems around cool and red M-dwarfs.

The KPIC concept consists of a set of upgrade modules to the Keck II AO system: 1- a Pyramid infrared wavefront sensor (IR WFS) using the latest low-noise IR-APD detector technologies from SELEX ES (see P. Wizinowich et al. for more details, this conference) with an optional high-order deformable mirror, 2- a state-of-the-art starlight suppression device (e.g. the vortex coronagraph, see O. Absil et al., and G. Ruane et al. for more details, this conference), and 3- a fiber-injection unit (FIU) to link the diffraction limited output of the AO system and coronagraph to the Keck II high-resolution infrared spectrograph NIRSPEC (R~37,000 post upgrade). The fiber injection unit contains its own infrared tracking camera and calibration source to allow precise guiding, positioning and injection in the J, H, K or L-band single mode fibers. The choice of monomode fibers ensures modal noise suppression and minimal contamination from the sky background, which is critical for precise spectroscopy and radial velocity measurements. The new AO-fed FIU will enable Doppler imaging of exoplanets and precise radial velocity measurements in the infrared.

KPIC showcases a unique combination of infrared sensing extreme adaptive optics high contrast imaging and high-resolution spectroscopy, integrated at the system level for optimal exoplanet signal extraction around cool stars. The KPIC concept was submitted to the Keck Science Steering Committee as a white paper in June 2015. The KSSC recommended the demonstration of IR WFS technologies, and the implementation of the fiber injection unit. Here, I will report on each element not covered elsewhere in this conference.

9909-14, Session 4

Coronagraphy with two PSFs

Frans Snik, Gilles P. P. L. Otten, Matthew A. Kenworthy, Leiden Observatory (Netherlands); Jared R. Males, Katie Morzinski, Laird M. Close, Philip M. Hinz, The Univ. of Arizona (United States)

We present on-sky results from our vector Apodizing Phase Plate coronagraph deployed inside MagAO/Clio at the 6.5-m Magellan Clay telescope. The vAPP consists of a single optic with patterned liquid crystals that is located in the filter wheel in the reimaged pupil plane. By superimposing a grating pattern on the coronagraphic phase pattern, the vAPP produces two complementary coronagraphic PSFs with dark holes. The multi-layer liquid crystal pattern furnishes efficient coronagraphic observations for an extremely wide wavelength range of 2-5 microns (KLM bands). Leakage terms due to retardance offsets of the liquid crystals form a third, unsaturated non-coronagraphic PSF in between the coronagraphic PSFs, suitable for photometry and astrometric calibration of substellar companions. On-sky observations show a small amount of non-common path error in the form of primarily trefoil. Such an odd-mode phase aberration induces an imbalance in the intensity of the speckle structure inside the dark holes of the two PSFs, but it leaves intact the symmetry of this structure if the amount of aberration is small. Hence, we can use one PSF to clean up the other, and we employ a simple rotation-subtraction algorithm with an optimized scaling factor to subtract quasi-static speckles inside the dark holes. We demonstrate that with such a data-reduction approach, the vAPP coronagraph at MagAO delivers a 5-sigma contrast of ~1E-5 for 2.5-7 lambda/D. We introduce more advanced methods to extract wavefront information from the two (or three) PSFs to provide focal-plane wavefront sensing.

9909-15, Session 4

The rapid transient surveyor

Christoph Baranec, Jessica R. Lu, Marianne Takamiya, John L. Tonry, R. Brent Tully, Univ. of Hawai'i (United States); Shelley A. Wright, Univ. of California, San Diego (United States); Lisa Hunter, Univ. of California, Santa Cruz (United States); Reed L. Riddle, California Institute of Technology (United States)

The next decade of astronomy will be dominated by large area surveys: ground-based optical transient surveys, e.g., LSST, ZTF and ATLAS and space-based exoplanet, supernova, and lensing surveys such as TESS and WFIRST will join the Gaia all-sky astrometric survey in producing a flood of data that will enable leaps in our understanding of the universe. There is a critical need for further characterization of these discoveries through high angular resolution images, deeper images, spectra, or observations at different cadences or periods than the main surveys.

The Rapid Transient Surveyor (RTS) is a proposed rapid-response, high-cadence facility on the U. of Hawaii 2.2-m telescope on Maunakea, and will uniquely address the need for follow-up characterization of an extensive number of transient objects by combining an excellent observing site with access to the Southern Hemisphere, the unmatched efficiency of the Robo-AO system, and copious available time on the host telescope. This will enable the high-acuity and sensitive spectral follow-up observations of tens of thousands of objects in mere months.

RTS will comprise an upgraded version of the Robo-AO robotic laser adaptive optics (AO) system: using a 492-actuator MEMS deformable a mirror and a UV-optimized EMCCD wavefront sensor camera that has a 2kHz framerate with <0.3e- of readnoise. The system will respond quickly to target-of-opportunity events, minimizing the time between discovery and characterization, and will interleave different science programs with its intelligent queue. RTS will exploit Maunakea's superior observing conditions to routinely acquire simultaneous-multicolor images with an acuity of 0.07-0.10" across the entire visible spectrum (20% i-band Strehl in median conditions and 7% g-band Strel in 25th percentile conditions) and <0.16" in the near infrared, and to detect companions at a contrast ratio of ~500 at 0.5". In addition to the two visible-light EMCCD cameras (for broad and narrowband imaging) and photon-counting infrared camera (based on a SAPHIRA array), the system will include a high-effiency prism integral field unit spectrograph: a spectral resolution of 70-140 over a total bandpass of 850-1830nm with an 8.7" by 6.0" field of view (0.15" spaxels). For the spectrograph, the AO correction boosts the infrared point-source sensitivity against the sky background by a factor of nine, giving the UH 2.2-m the infrared sensitivity of a 6.3-m telescope without adaptive optics.

Our primary RTS science program is to map the dark matter distribution in the z < 0.1 local universe with ten times better accuracy and precision than previous experiments. We will use the Asteroid Terrestrial-Impact Last Alert System (ATLAS) to discover several thousand SNIa per year using automatic detection routines, and follow discoveries with triggered observations with the RTS spectrograph. ATLAS will measure SNIa peak brightness, and decline rates, and the RTS observations will measure reddening by dust, confirm SN type and confirm approximate redshifts of the host galaxies. This unique combination of automated detection and characterization of astrophysical transients during a sustained observing campaign will yield the necessary statistics to precisely map dark matter in the local universe.

9909-76, Session PSun1

Commissioning and first light results of an L'-band vortex coronagraph with the Keck II adaptive optics NIRC2 science instrument

Bruno Femenia-Castella, W. M. Keck Observatory (United States); Eugene Serabyn, Jet Propulsion Lab. (United States); Dimitri Mawet, California Institute of Technology (United States); Olivier Absil, Univ. de Liège (Belgium); Peter L. Wizinowich, W. M. Keck Observatory (United States); Keith Y. Matthews, California Institute of Technology (United States); Elsa Huby, Univ. de Liège (Belgium); Michael Bottom, California Institute of Technology (United States); Randall D. Campbell, W. M. Keck Observatory (United States); Brunella Carlomagno, Univ. de Liège (Belgium); Dwight D. Chan, Sylvain Cetre, W. M. Keck Observatory (United States); Denis Defrère, The Univ. of Arizona (United States); Christian Delacroix, Cornell Univ. (United States); Carlos A. Gomez Gonzalez, Aïssa Jolivet, Univ. de Liège (Belgium); Mikael Karlsson, Uppsala Univ. (Sweden); Kyle Lanclos, Scott J. Lilley, Steven Milner, W. M. Keck Observatory (United States); Henry Ngo, California Institute of Technology (United States); Maddalena Reggiani, Univ. de Liège (Belgium); Julia Simmons, Hien D. Tran, W. M. Keck Observatory (United States); Ernesto Vargas Catalan, Uppsala Univ. (Sweden); Olivier Wertz, Univ. de Liège (Belgium)

More than 2000 exoplanets have been discovered to date and yet only for a small fraction of exoplanets has it been possible to acquire direct images. The reason for this lies in the extraordinary technological challenge associated with the large flux ratio between the host star and its planets as

well as the small angular separation between star and planets. To achieve exoplanet direct imaging we inevitably require high contrast imaging systems capable of suppressing the stellar light fed by high angular resolution systems. Nearly all high contrast imaging systems rely on the use of a coronagraphic system and among all the families of coronagraphs the vortex coronagraphs have been gaining extensive credit as one of the most promising solutions due to their excellent properties in terms of very small inner working angle, high transmission, clear 360° discovery space and ease of implementation in existing coronagraphic systems. This latter feature has allowed the deployment of vortex coronagraphs in systems originally designed and built as classical Lyot coronagraphs. Over the last couple of years this has been the case for vortex coronagraphs with different infrared instruments on 8-m diameter monolithic primary mirror class telescopes: VLT, LBT and Subaru.

We present the details of the commissioning of an Annular Groove Phase Mask (AGPM) vector vortex coronagraph with the Adaptive Optics (AO) fed NIRC2 instrument at the segmented 10-m diameter Keck II telescope. This vortex operates in the L' band not only in order to take advantage from the favorable star/planet contrast ratio when observing beyond the K band, but also to exploit the fact that the Keck II AO system delivers nearly extreme adaptive optics image quality (Strehl ratios values near 90%) in L' band.

In this paper we will present the requirements to implement the vortex and the optimization of the Keck II AO system to satisfy these requirements. We will describe the hardware installation of the vortex phase mask during a routine-basis NIRC2 service mission remarking on the ease of installation and the fact that the new vortex phase mask can cohabit with the previously installed classic Lyot coronagraph. We will stress how the success of the project depends on an extensive software development which has allowed the achievement of exquisite real-time pointing control as well as further contrast improvements by implementing speckle nulling to mitigate the effect of static speckles.

During the commissioning of the vortex at NIRC2 part of the team conducted their research programs achieving notable results, some of them briefly presented here to provide evidence of its scientific potential. These science projects are being conducted in parallel to the ongoing commissioning tasks during which we have continued to implement new features.

9909-77, Session PSun1

A versatile natural guide star adaptive optics system for the Eastern Anatolian Observatory (DAG) 4m Telescope

Laurent Jolissaint, HEIG-VD (Switzerland); Onur Keskin, Isik Üniv. (Turkey); Sinan K. Yerli, Middle East Technical Univ. (Turkey); Cahit Yesilyaprak, Atatürk Üniv. (Turkey)

DAG adaptive optics

Turkey is taking a lift in astronomical science by preparing a new 4-m telescope for infrared observation at high angular resolution. First light is scheduled for 2019. One of the Nasmyth platform will be equipped with a versatile adaptive optics (AO) system, able to offer all options between GLAO and SCAO, to serve the various observation programs of the Turkish astronomical community. Our objective is to make use of the most successful techniques of AO today, i.e. pyramid wavefront sensors (PS) on natural guide stars, tomographic reconstruction, Kalman filtering to compensate for unexpected vibrations, phasor diversity to track and compensate non common path aberrations, and if possible use medium or microsize deformable mirrors. The wavefront sensing and reconstruction scheme is simple: make use of the stars can be found around the target to reconstruct the phase in the volume, then decide how to use this knowledge - either locally, or over some field-of-view. This paper presents these ideas and a study of how these techniques can work together, and most importantly, verify if a PS can be used in open or pseudo-open loop.

9909-78, Session PSun1

The AO system of the 1.5m GREGOR solar telescope: four years of operation

Thomas Berkefeld, Kiepenheuer-Institut für Sonnenphysik (Germany); Dirk Schmidt, National Solar Observatory (United States); Dirk Soltau, Frank Heidecke, Andreas Fischer, Kiepenheuer-Institut für Sonnenphysik (Germany)

We present the properties of the AO system of the 1.5m solar telescope GREGOR.

The conventional AO system uses a correlating Shack-Hartmann-Sensor with 10cm subaperture size and a 256-actuator stacked-piezo DM.

The modal controller is based on an optimized Karhunen-Loeve function basis and allows the correction of up to 180 modes.

The control loop frequency of 2100 Hz and an optional modal gain optimizer keep bandwidth errors low.

AO performance results such as modal attenuation factors and power spectra as well as practical experience based on the last years of operation are presented.

A rececently installed alternate wavefront sensor with 24cm subaperture size and an EM-CCD camera is used for low light observations such as polarimetric measurements of the solar system gas giants and Venus.

From 2016, an additional narrow-band H-alpha filter will allow this sensor to lock on (off-limb) solar prominences.

Finally a short overview of the MCAO activities and plans concludes the paper.

9909-79, Session PSun1

Status and new developments with the Keck I near-infrared tip-tilt sensor

Bruno Femenia-Castella, Peter L. Wizinowich, Rachel Rampy, Sylvain Cetre, Andrew Cooper, Scott J. Lilley, James E. Lyke, Sam Ragland, Paul J. Stomski Jr., W. M. Keck Observatory (United States)

The sky coverage and performance of laser guide star (LGS) adaptive optics (AO) systems are limited by the natural guide star (NGS) used for low order correction. This limitation can be reduced by measuring image motion of the NGS in the near-infrared where it is partially corrected by the LGS AO system and where stars are generally several magnitudes brighter than at visible wavelengths. Based on these principles we initiated the Near-Infrared Tip-Tilt Sensor project (NIRTTS, a.k.a. TRICK for Tilt Removal with IR compensation at Keck) to design and implement a near-infrared tip-tilt sensor based on achieving low readout noise via multiple reads of a 2kx2k pixel H2RG-based detector. A plate scale of 0.05 arcseconds/pixel was chosen to provide a 100 arcsecond diameter field.

On November 2013 we started commissioning of TRICK at the Keck I AO system. We have presented updated reports of the integration and performance of TRICK basic operation mode as a barycenter-based centroid TT sensor on Wizinowich et al. (2014) and Rampy et al. (2015). During 2015 TRICK has been transitioning into shared-risk science operation as TRICK main operating mode has nearly completed full comissioning. The first part of this paper details on the on-sky performance and how it compares against the performance achieved with the visible APD-based tip-tilt sensor at Keck 1 AO system. We also present how TRICK is used operationally and some preliminary scientifc results already achieved.

In the second part of this paper we will discuss the enhanced-TRICK project which builds on the TRICK system to provide additional capabilities and performance gains. The TRICK system supports imaging and integral

field spectroscopic science short of K-band and we will be implementing a new dichroic to allow K-band integral field science. The enhanced-TRICK system has the capability to read out multiple regions of interest (ROIs) on the detector and to use the existing visible tip-tilt sensor simultaneously. We are therefore testing the use of multiple NGS to improve performance and sky coverage via reduced angular anisoplanatism and/or better tip-tilt signal-to-noise ratio (SNR). This involves determining how best to optimize the read rates for each NGS and the relative weighting for each NGS tip-tilt measurement in the commands to the tip-tilt mirror. We will also be testing improved tip-tilt algorithms, specifically a correlation algorithm expected to improve performance on dim NGS due to its low sensitivity to background effects. Overall we are also studying how to optimize the system's performance and how to make use of this knowledge 0operationally.

9909-80, Session PSun1

Infrared differential imager and spectrograph for SPHERE: very high-contrast performances analysis based on SPHERE/GTO observations

Maud P. Langlois, Ctr. de Recherche Astronomique de Lyon (France); Anne-Marie Lagrange, Institut de Planétologie et d'Astrophysique de Grenoble (France); Anthony Boccaletti, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Gaël Chauvin, Institut de Planétologie et d'Astrophysique de Grenoble (France); Silvano Desidera, INAF - Osservatorio Astronomico di Padova (Italy); Raphaël Galicher, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Raffaele G. Gratton, INAF - Osservatorio Astronomico di Padova (Italy); Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Claire Moutou, Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, ONERA (France)

SPHERE (Spectro-Polarimetric High-contrast Exoplanet Research) is a second-generation instrument for the VLT, optimized for very high-contrast imaging around bright stars. Its primary goal is the detection and characterization of new giant planets around nearby stars, together with the observation of early planetary systems and disks. The Infrared Dual Imager and Spectrograph (IRDIS), one of the three SPHERE subsystems, providing dual-band imaging in the near-infrared, among with other observing modes such as long slit spectroscopy, classical imaging and infrared polarimetry, is able to achieve extremely high contrast with the help of extreme-AO turbulence compensation, coronography, exceptional image quality, very accurate calibration strategies and advanced data processing. The SPHERE garanteed time Survey observations has started early 2015, and so far approximately 150 stars have already been observed. IRDIS achieves the sensitivity and resolution compatible with detection planetary companions with separations of 0.2" to 1" around a very large set of selected stars. We will review the high contrast performances achieved at this stage of the GTO observations with IRDIS. In particular we will present an analysis of the level of contrast achieved and relate these performances to the star magnitude, the atmospheric conditions, and the strehl ratio. We will also show typical detection limits for extra-solar planets and for circumstellar disks. We will conclude with highlighting few excquisite astrophysical results obtained with SPHERE/IRDIS.

9909-81, Session PSun1

The ZIMPOL high-contrast imaging polarimeter for SPHERE: polarimetric high-contrast commissioning results

Ronald Roelfsema, NOVA Optical Infrared Instrumentation Group (Netherlands); Andreas Bazzon, Hans Martin Schmid, ETH Zürich (Switzerland); Johan H. Pragt, Alain Govaert, NOVA Optical Infrared Instrumentation Group (Netherlands); Daniel Gisler, ETH Zurich (Switzerland); Carsten Dominik, Univ. van Amsterdam (Netherlands); Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Anne Costille, Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Mark Downing, European Southern Observatory (Germany); Eddy Elswijk, Menno de Haan, NOVA Optical Infrared Instrumentation Group (Netherlands); Norbert Hubin, Markus E. Kasper, European Southern Observatory (Germany); Christoph U. Keller, Leiden Univ. (Netherlands); Jean Louis Lion, European Southern Observatory (Germany); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Alexey Pavlov, Max-Planck-Institut für Astronomie (Germany); Pascal Puget, Institut de Planétologie et d'Astrophysique de Grenoble (France); Bernardo Salasnich, INAF - Osservatorio Astronomico di Padova (Italy); Jean-François Sauvage, ONERA (France); François Wildi, Observatoire de Genève (Switzerland)

SPHERE (Spectro-Polarimetric High-contrast Exoplanet Research) is a second generation VLT instrument aimed at the direct detection of exo-planets. ZIMPOL (Zurich Imaging Polarimeter) is the imaging polarimeter subsystem of the SPHERE instrument. During the SPHERE fourth commissioning period (October 2014) we have made deep coronagraphic observations of the bright star alpha Gru (mR = 1.75) to assess the high contrast polarimetric performance of SPHERE-ZIMPOL. We reach contrasts of 10-6 and 10-7 at a radial distances of respectively 7 and 14 lambda/D from the PSF core.

9909-82, Session PSun1

Status of the HARMONI single conjugate adaptive optics module

Jean-François Sauvage, ONERA (France); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Cyril Petit, ONERA (France); Carlos M. Correia, Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Noah Schwartz, UK Astronomy Technology Ctr. (United Kingdom); Christophe Vérinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France); Kacem El Hadi, Lab. d'Astrophysique de Marseille (France); Jean-Luc Gach, First Light Imaging S.A.S. (France); Alexis Carlotti, Institut de Planétologie et d'Astrophysique de Grenoble (France); Vincent Michau, ONERA (France); Joël D. R. Vernet, Peter Hammersley, Jérome Paufique, European Southern Observatory

(Germany); Ian Bryson, UK Astronomy Technology Ctr. (United Kingdom); Matthias Tecza, Fraser Clarke, Univ. of Oxford (United Kingdom); Hermine Schnetler, UK Astronomy Technology Ctr. (United Kingdom); Niranjan A. Thatte, Univ. of Oxford (United Kingdom)

HARMONI is a visible and near-infrared (0.47 to 2.45 μm) integral field spectrograph, providing the E-ELT's core spectroscopic capability, over a range of resolving powers from R~500 to R~20000. HARMONI is conceived as a workhorse instrument, addressing many of the key E-ELT science cases. It will exploit the E-ELT's scientific niche in its early years, starting at first light. To get the full sensitivity and spatial resolution gain, HARMONI will work at diffraction limited scales. This will be possible thanks to two adaptive optics systems, complementary to each other. Both systems will make use of the telescope's adaptive M4 and M5 mirrors. The first one is a simple but efficient Single Conjugate AO system (good performance, low sky coverage), fully integrated in HARMONI itself. The second one is a Laser Tomographic AO system (medium performance, very good sky coverage).

The SCAO module consists in a high precision Wave-front sensor [WFS] dedicated to the measurement of turbulence and telescope perturbations, a WFS-path dedicated to the beam shaping (pupil rotation and shifts, modulation, potential atmospheric compensation) and finally a Real-Time computer for Instrument providing a wave-front interface to the telescope for further compensation.

We present in this paper the chosen concept for SCAO module, based on trade-off on available technology, performance, operation and calibration considerations. Some main performance results based on both E2E simulation models as well as fast Fourier simulations are synthesized, including some detailed aspects on WFS capability but also on Telescope perturbations. These last ones are one large contribution to the final performance, and include wind shake effects, spider shape, primary mirror phasing and scalloping effect.

9909-83, Session PSun1

Progress with multi-conjugate adaptive optics at the Big Bear Solar Observatory

Dirk Schmidt, José Marino, National Solar Observatory (United States); Nicolas Gorceix, Big Bear Solar Observatory (United States); Xianyu Zhang, Large Binocular Telescope Observatory (United States); Thomas Berkefeld, Kiepenheuer-Institut für Sonnenphysik (Germany); Philip R. Goode, Big Bear Solar Observatory (United States); Thomas R. Rimmele, National Solar Observatory (United States)

The MCAO system at the BBSO off-axis telescope is the pathfinder system for a future system at the 4-meter off-axis DKIST. Therefore, the MCAO system purposefully has maximal design flexibility. It deploys three DMs, one in the pupil and two conjugated to higher altitudes. The design allows rapid, simple, independent adjustments of conjugate altitudes of the latter two to adapt to changing the turbulence profile ranging from 2-9 km. Either of two DMs are available to accommodate a pupil DM - before or after the high-altitude DMs - to address the relevance of the correction sequence. Wavefront sensing is based on correlating Shack-Hartmann sensors, which can used in various configurations. The optical path has been improved during 2015 to yield satisfying solar images. The MCAO controlled field of view is about 1 arcmin, and the closed loop was able to slightly reduce the wavefront error across the field as compared to the classical AO. We are looking into strategies and modifications, such as decreasing the controlled field of view, to further improve the benefits of MCAO over classical AO. We will report the latest on-Sun results and motivate the design of the system.

9909-84, Session PSun1

In-lab characterization of the DARK-speckle near-infrared energy-resolving superconducting spectrophotometer (DARKNESS)

Seth R. Meeker, Benjamin A. Mazin, Matthew J. Strader, Alex B. Walter, Clint Bockstiegel, Paul Szypryt, Giulia Collura, Gerhard Ulbricht, Univ. of California, Santa Barbara (United States)

The DARK-speckle Near-infrared Energy-resolving Superconducting Spectrophotometer (DARKNESS) is a 10-kilopixel Microwave Kinetic Inductance Detector (MKID) integral field spectrograph developed for high-contrast astronomy applications with Project 1640 and the Stellar Double Coronagraph (SDC) at Palomar Observatory. Leveraging the energy resolution and read-noise-free photon-counting capabilities of optical/near-IR MKIDs, DARKNESS generates data cubes with >1kHz frame rates, which allows for simultaneous spectral and statistical discrimination of faint companions from residual stellar speckles. When interfaced directly with the PALM-3000 adaptive optics system, these frame rates will allow closed-loop focal plane wavefront control for active speckle nulling at >100 Hz. Here we present the in-lab characterization of the completed DARKNESS instrument in preparation for its July 2016 commissioning.

9909-85, Session PSun1

VODCA (the vortex optical demonstrator for coronagraphic applications) and first results with L-band AGPMs

Aïssa Jolivet, Olivier Absil, Serge Habraken, Elsa Huby, Jean Surdej, Univ. de Liège (Belgium); Dimitri Mawet, California Institute of Technology (United States); Mikael Karlsson, Pontus Forsberg, Ernesto Vargas Catalan, Uppsala Univ. (Sweden)

We are developing at the University of Liège (Belgium) a vortex coronagraph based on sub-wavelength gratings (SGVC). The first generation of these SGVCs is known as the Annular Groove Phase Mask (AGPM), a charge-2 vector vortex phase mask. Etched onto diamond substrates, the AGPMs are produced at Uppsala University. Four of them have now been installed on world-leading diffraction-limited infrared cameras, namely VLT/NACO, VLT/VISIR, LBT/LMIRCam, and Keck/NIRC2. As a part of the VORTEX project, it has become crucial to have at the University of Liège our own dedicated optical bench, VODCA (the Vortex Optical Demonstrator for Coronagraphic Applications), to perform the tests and to assess the quality of the produced components. This high contrast test bench has been developed over the last two years. It operates in the same wavelengths as our AGPMs, i.e., the near- to mid-infrared (between 1 and 5 μm). We use different broad-band and narrow-band filters to cover this wavelength range. Analyzing the results of the AGPM at different wavelengths give us strong indications about the physical characteristics of a single component. This infomation is used to improve the performance of the component by ecthing it again.

In the first part of this talk, I will describe VODCA's layout and some of its key features, such as the possibility to image the pupil, and the recent addition of two polarizers to measure the phase ramp induced by the vortex phase mask. I will also present our automatic procedure to center the AGPM onto the infrared beam. The aberrations are a decisive factor in the best starlight cancellation a coronagraph could achieve. A deformable mirror will soon be integrated in VODCA to first provide a wavefront with the lowest possible amount of aberrations. The deformable mirror will also be used to study how robust the vortex phase mask performance is

against some of the main aberrations (tip/tilt/focus). Others pre-/post coronagraphic concepts, which will be implemented on VODCA, will also be described.

In the second part of this talk, I will report on the performance of the bench in terms of achievable contrast, and show the first results obtained with L-band AGPMs on VODCA.

9909-86, Session PSun1

Preliminary result of the solar multi-conjugate adaptive optics for 1m new vacuum solar telescope

Lanqiang Zhang, Lin Kong, Hua Bao, Lei Zhu, Xuejun Rao, Changhui Rao, Institute of Optics and Electronics (China)

Solar observation with high resolution in large field of view (FoV) is required for some solar active regions with the typical sizes of 1' to 3'. Conventional adaptive optics could not satisfy this demand because of the atmospheric anisoplanatism. Through compensating the turbulence in different heights, multi-conjugate adaptive optics (MCAO) has been proved to obtain a larger corrected FoV. We had built a multi-direction Shack-Hartmann wavefront sensor (MD-SHWFS) with 7?7 subaperture array and 60 arcsec field of view. The three-dimensional wavefront sensing utilizing atmospheric tomography had been validated by on sky solar observation. Based on this result, a MCAO system including a conventional 151-element AO system and a 37-element AO system with the MD-SHWFS a 37-element deformable mirror conjugated into the 2km to 5km height has been developed. The frame rate of the MD-SHWFS is about 840Hz. In this paper, this MCAO system will be introduced. The preliminary experimental results on the 1m New Vacuum Solar Telescope (NVST) of Full-shine Lake Solar Observatory are presented.

9909-87, Session PSun1

MAORY adaptive optics module for E-ELT: instrument design overview

Emiliano Diolaiti, Paolo Ciliegi, Renata Abicca, INAF - Osservatorio Astronomico di Bologna (Italy); Guido Agapito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Carmelo Arcidiacono, INAF - Osservatorio Astronomico di Bologna (Italy); Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Michele Bellazzini, Giovanni Bregoli, INAF - Osservatorio Astronomico di Bologna (Italy); Enrico Cascone, INAF - Osservatorio Astronomico di Capodimonte (Italy); Fausto Cortecchia, INAF - Osservatorio Astronomico di Bologna (Italy); Giuseppe Cosentino, Univ. degli Studi di Bologna (Italy); Vincenzo De Caprio, INAF - Osservatorio Astronomico di Capodimonte (Italy); Adriano De Rosa, INAF - IASF Bologna (Italy); Gianluca Di Rico, Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Daniela Fantinel, INAF - Osservatorio Astronomico di Padova (Italy); Philippe Feautrier, Institut de Planétologie et d'Astrophysique de Grenoble (France); Giuliana Fiorentino, Italo Foppiani, INAF - Osservatorio Astronomico di Bologna (Italy); Mauro Ghigo, INAF - Osservatorio Astronomico di Brera (Italy); Christophe Giordano, INAF - Osservatorio Astrofisico di Arcetri (Italy); Enrico Giro, INAF - Osservatorio Astronomico di Padova (Italy); Matteo Lombini, INAF - Osservatorio Astronomico di Bologna (Italy); Gianluca Morgante, INAF - IASF Bologna (Italy); Mauro Patti, INAF - Osservatorio Astronomico di Bologna (Italy); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Armando Riccardi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Sara Ricciardi, INAF - IASF Bologna (Italy); Marco Riva, INAF - Osservatorio Astronomico di Brera (Italy); Bernardo Salasnich, INAF - Osservatorio Astronomico di Padova (Italy); Laura Schreiber, INAF - Osservatorio Astronomico di Bologna (Italy); Paolo Spanò, INAF - Osservatorio Astrofisico di Arcetri (Italy); Eric Stadler, Institut de Planétologie et d'Astrophysique de Grenoble (France); Filippo M. Zerbi, Istituto Nazionale di Astrofisica (Italy); Mark M. Casali, Florian Kerber, Enrico Marchetti, Sylvain Oberti, Suzanne K. Ramsay, European Southern Observatory (Germany)

MAORY is a post-focal adaptive optics module for the European Extremely Large Telescope (E-ELT) that forms part of the first light instrument suite for the telescope. It enables wide-field diffraction-limited observations with the E-ELT by real-time compensation of the wavefront distortions due to the atmospheric turbulence and to the wind action on the telescope.

MAORY supports the MICADO near-infrared camera by offering two adaptive optics modes: Multi-Conjugate Adaptive Optics (MCAO) and Single-Conjugate Adaptive Optics (SCAO). Development of the SCAO mode is a joint endeavour between the MAORY and MICADO instrument teams.

The MCAO mode is required to achieve high quality and spatially uniform adaptive optics compensation over the full MICADO field of view; sky coverage, i.e. the capability to achieve such a level of performance over a large fraction of the sky, is also an essential feature. The SCAO mode is required for peak adaptive optics performance, rather than uniformity over the field or sky coverage.

In the MCAO mode, wavefront sensing is performed by real-time analysis of the light from six artificial Laser Guide Stars and of three Natural Guide Stars, respectively for the measurement of high and low-order wavefront perturbations; wavefront compensation is achieved by one or two adaptive mirrors in MAORY, which work together with the telescope adaptive and tip-tilt mirrors M4 and M5 respectively.

In the SCAO mode, wavefront distortions are measured by a single Natural Guide Star wavefront sensor and compensated using the telescope M4 and M5 mirrors, while the adaptive mirrors inside MAORY are kept fixed at their reference shape.

MAORY also offers provision for a second port for a future instrument, as yet undefined.

From the opto-mechanical point of view, MAORY is a large instrument, with typical size of 8-10 meter, including an optical relay which creates an image of the telescope focal plane at the entrance of the client instruments. The relay also hosts the two adaptive mirrors for the MCAO mode. The instrument is supported by an hexapod structure which is fixed onto the E-ELT Nasmyth platform.

The phase B of the MAORY instrument project is in progress. Consolidation of the baseline instrument design is underway, taking into account scientific performance requirements, interface constraints and technology readiness of crucial hardware components.

A system level overview of the instrument preliminary design and of its expected performance is presented in this contribution.

9909-88, Session PSun1

Adaptive optics capabilities at the Large Binocular Telescope

Julian C. Christou, Guido Brusa Zappelini, Douglas L. Miller, Gregory Taylor, Xianyu Zhang, Gustavo Rahmer, Michael J. Lefebvre, John M. Hill, Albert R. Conrad, Large Binocular Telescope Observatory (United States); Philip M. Hinz, The Univ. of Arizona (United States); Sebastian Rabien, Max-Planck-Institut für extraterrestrische Physik (Germany); Thomas M. Herbst, Max-Planck-Institut für Astronomie (Germany); Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The Large Binocular Telescope (LBT) is unique in that it has two permanently mounted adaptive secondary mirrors (ASM) to control the wavefront correction as measured by different wavefront sensors located at different Gregorian focal stations of the telescope. The First Light Adaptive Optics (FLAO) systems are located at the Front Bent Gregorian (FBG) foci and provide correction for the two LUCI NIR imagers/spectrographs; the ARGOS wavefront sensors are also accessed via the FBG and provide ground-layer correction for the two LUCIs; the two Large Binocular Telescope Interferometer (LBTI) systems are located at the Center Bent Gregorian stations and provide correction for the LBTI Optical Bench including the beam combiner; and the Rear Bent Gregorian stations are being prepared for the installation of LINC-NIRVANA. In addition to the overview of the current status and future plans for the AO systems and the ASMs, we will also discuss the current and planned AO fed instrumentation outlining the scientific capabilities of the LBT AO systems ranging from narrow-field visible light imaging and coronagraphy to wide-field enhanced seeing imaging and spectroscopy in the NIR to 23m baseline diffraction-limited imaging in the NIR and MIR.

9909-89, Session PSun1

Reshaping and polishing the GeMS MCAO system

Vincent Garrel, Gaetano Sivo, Eduardo Marin, Gemini Observatory (Chile); Chadwick A. Trujillo, Gemini Observatory (United States); Eleazar R. Carrasco Damele, Gemini Observatory (Chile); Marcos A. Van Dam, Flat Wavefronts (New Zealand); Francois Rigaut, Céline d'Orgeville, The Australian National Univ. (Australia); Caroline Kulcsár, Rémy Juvénal, Institut d'Optique Graduate School (France); Vanessa Montes, Manuel Lazo, Pedro Gigoux, Cristian Moreno, Gemini Observatory (Chile); Jeff Donahue, Gemini Observatory (United States); Constanza Araujo Hauck, LSST (United States); S. Mark Ammons, Lawrence Livermore National Lab. (United States); Benoît Neichel, Lab. d'Astrophysique de Marseille (France)

GeMS, the Gemini South MCAO System, has now been in operation for 3 years with the near infrared imager GSAOI. We first review the performance obtained by the system, the science cases and the current operational model. In the very near future, GeMS will undergo a profound metamorphosis, as we will integrate a new NGS wavefront sensor called NGS2, replace the current 50W laser with a more robust one and prepare for a new operational model where the system will be operated from the base facility. Along this major evolution, we are also presenting several improvements on the loop control, calibrations and automatisation of this complex system. We discuss here the progress of the different upgrades and the consequence we are expecting in terms of performance and operational efficiency.

9909-90, Session PSun1

Adaptive optics operations at the Large Binocular Telescope Observatory

Douglas L. Miller, Julian C. Christou, Guido Brusa Zappellini, Gregory Taylor, Xianyu Zhang, Gustavo Rahmer, Michael J. Lefebvre, Large Binocular Telescope Observatory (United States); Enrico Pinna, Simone Esposito, Alfio T. Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The goal for the adaptive optics systems at the Large Binocular Telescope Observatory (LBTO) is for them to operate fully automatically, without the need for an AO Scientist except on-call, and to be able to be run by the observers and/or the telescope operator. In its initial operational configuration, the AO systems would optimally close the loop using parameters acquired from a look-up table. These parameters determined the maximum number of modes and frame rate when using guide stars of differing magnitude. After the AO systems were closed, a procedure to optimize the loop gains for the observing conditions was applied. If the observing conditions changed significantly the gains would have to be changed manually or else the loop would open. If the loop opened, the observing sequence would have to be restarted from the beginning.

To improve the observing efficiency, the following have been implemented. Firstly, a modified state machine which permits the loop to be reclosed without returning to the beginning of the sequence. And secondly, the application of an algorithm which dynamically computes the optimal gain for changing observing conditions. Additionally, we have implemented a non-common path aberration procedure to remove quasi-static aberrations not sensed by the pyramid wavefront sensor. The software permitting these updates is now uniformly implemented on the two FLAO systems as well as the two LBTI/AO systems.

We have also implemented an enhanced seeing mode operation which closes the loop with ~ 10 modes which improves the natural seeing by ~ 2x-3x across fields up to 4 arcminutes diameter.

9909-91, Session PSun1

GRAAL on the mountaintop

Jérôme Paufique, Pierre-Yves Madec, Johann Kolb, Harald Kuntschner, Javier Argomedo, Mario J. Kiekebusch, Robert H. Donaldson, Robin Arsenault, Ralf Siebenmorgen, Christian Soenke, Sebastien Tordo, Ralf D. Conzelmann, Andreas Jost, Javier Reyes-Moreno, Mark Downing, Jose Javier Valenzuela, Pierre Haguenauer, European Southern Observatory (Germany)

GRAAL is the adaptive optics module feeding the wide-field IR imager HAWK-I at the VLT observatory. As part of the adaptive optics facility, GRAAL is equipped with 4 Laser-guide star wave-front sensors and provides a large field-of-view, ground layer correction system to HAWK-I.

After a successful testing in Europe, the module has been re-assembled in Chile and installed at the Nasmyth-A platform of Yepun, the fourth Unit telescope of the observatory. We report on the installation of GRAAL on the mountain and on its first testing in stand-alone and on-sky.

The system is now operational and waiting for the installation of the deformable secondary mirror to perform fully fledged tests.

We address the performance of the system, including

- verification of a large co-rotator tracking the pupil for the four LGS-WFS,

- positioning of the tip-tilt sensor on-sky,
- interaction of the system with the preparation tools necessary for observation: the selection of a TT star on a large 13 arcmin diameter annulus must be combined with the avoidance of telescope probes shading
- L3-CCD, CCD-220 based WFS camera operation and performance characterization

9909-92, Session PSun1

Solar adaptive optics for 1m new vacuum solar telescope

Changhui Rao, Lei Zhu, Xuejun Rao, Lanqiang Zhang, Hua Bao, Institute of Optics and Electronics (China)

Adaptive Optics (AO) has become the requisite equipment of the ground-based large solar telescope to correct the wavefront aberration induced by the atmospheric turbulence. Two generation solar AO systems, one is the 37-element low-order AO system with 2100Hz frame rate and the other is 151-element high-order AO system with 3500Hz frame rate, were successfully developed in 2013 and 2015 respectively. In this presentation, the development of the two AO systems for 1-m New Vacuum Solar Telescope (NVST) at Fuxian Solar Observatory (FSO) will be introduced and the solar high resolution observational results are presented.

9909-94, Session PSun1

LGSAO 10th anniversary: recent and future upgrades for Subaru adaptive optics

Christophe S. Clergeon, Yosuke Minowa, Takashi Hattori, Subaru Telescope, National Astronomical Observatory of Japan (United States); Yutaka Hayano, Shin Oya, Subaru Telescope, National Astronomical Observatory of Japan (Japan)

The Subaru laser guide star adaptive optics (LGSAO) will celebrate this summer the 10th anniversary of its first light. Since the last decade, LGSAO has been an integral part of Subaru telescope instruments but also one of the most efficient adaptive optics on MaunaKea.

During this meeting, we will present the recent optimizations and upgrades of the instrument including the new bimorph deformable mirror integration, the AO telemetry analyzer and the transponder-based aircraft detector (TBAD), which will permit to increase the number of science night allocated for Laser guide star observations.

During this meeting, we will also take the opportunity to present the future Subaru GLAO project, Ultimate Subaru, with its adaptive secondary mirror and the new 20W laser which will replace our actual system in the next few years.

9909-95, Session PSun1

High resolution sodium layer plume profiles and parameters for the CANARY experiment

James Osborn, Timothy J. Morris, Alastair G. Basden, Durham Univ. (United Kingdom); Éric Gendron, Fabrice Vidal, Damien Gratadour, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Richard M. Myers, Andrew P. Reeves, Durham Univ. (United Kingdom); Fanny Chemla, Jean-Tristan M. Buey, Lisa Bardou, Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Robert G. Talbot, Durham Univ. (United Kingdom); Domenico Bonnaccini Calia, Thomas Pfrommer, European Southern Observatory (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy)

The column density of the sodium layer is of vital importance for LGS assisted AO instrument simulation, development and operation. This becomes even more important for Extremely Large Telescopes where the laser launch can be far from the AO wavefront sensor subapertures, resulting in a substantial perspective elongation of the sodium spot. Variations in the sodium layer can cause significant variation in the wavefront measured from an LGS, meaning the properties of the sodium layer must be well understood and characterised. This is not only critical during operation, but must be investigated during instrument design phases also.

CANARY is the tomographic AO testbed on the 4.2m William Herschel Telescope, La Palma. The latest upgrade to the CANARY system allows observations of a sodium LGS, launched from a point 40 m off-axis. In addition to observing the sodium LGS with the CANARY WFSs, the sodium profile is also monitored from the 2.5m Isaac Newton Telescope. The INT is approximately 420m further off-axis resulting in a sodium LGS elongation of over 5 arc minutes. This allows a high-vertical resolution profile of the sodium LGS to be measured synchronised with the wavefront sensors of CANARY.

Here we show the results from the first commissioning study in La Palma, examine the appearance of the sodium elongation on realistic wavefront sensors and compare the sodium statistics to published data. Finally we describe how the measured sodium profile could be used with the CANARY system to improve LGS AO performance.

9909-96, Session PSun1

Performance monitoring of an AO instrument: the case of SINFONI

Angela Cortes, José Luis Alvarez, George Hau, European Southern Observatory (Chile)

We present how we perform the characterisation of the performances of an instrument at the Paranal Observatory, how we follow the history line of its key parameters and detect possible problems, taking the example of the AO-assisted SINFONI instrument. We will make a review of the health check performed on the instrument, with analysis of the long term trends. We will analyse the reliability of the data recorded during daily calibrations and night operations, and evaluate their sensitivity and relation to external parameters. This study of the trends of the key parameters of the instrument provides useful analysis and monitoring to determine when an instrument eventually starts to degrade or to trace in time the different events in its maintenance.

One can also determine when a major intervention or upgrade of the system might be necessary. In this eventuality, the long term monitoring can be used to determine the elements to be upgraded, where to focus the efforts to maximise the gain versus the work performed, and provides useful information on the status of the instrument prior to the intervention giving a zero point. The continuous monitoring of all the key parameters and the obtained history line is a valuable information to determine across time the changes obtained through an upgrade.

9909-97, Session PSun1

CIAO: wavefront sensors for GRAVITY

Silvia Scheithauer, Wolfgang Brandner, Max-Planck-Institut für Astronomie (Germany); Henri M. Bonnet, European Southern Observatory (Germany); Pierre Bourget, European Southern Observatory (Chile); Yann Clénet, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Casey P. Deen, Max-Planck-Institut für Astronomie (Germany); Françoise Delplancke-Stroebele, European Southern Observatory (Germany); Monica Ebert, Max-Planck-Institut für Astronomie (Germany); Frank Eisenhauer, Max-Planck-Institut für extraterrestrische Physik (Germany); Michael Esselborn, European Southern Observatory (Germany); Éric Gendron, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Frédéric Yves Joseph J. Gonté, European Southern Observatory (Germany); Thomas Henning, Stefan Hippler, Armin Huber, Max-Planck-Institut für Astronomie (Germany); Zoltan Hubert, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France) and Max-Planck-Institut für Astronomie (Germany); Liselotte Jochum, European Southern Observatory (Germany); Ralf Klein, Max-Planck-Institut für Astronomie (Germany); Johann Kolb, European Southern Observatory (Germany); Martin Kulas, Rainer Lenzen, Eric Müller, Javier Moreno-Ventas Mateos, Udo Neumann, Max-Planck-Institut für Astronomie (Germany); Sylvain Oberti, European Southern Observatory (Germany); Jürgen Ott, redlogix Software & System Engineering GmbH (Germany); Laurent Pallanca, European Southern Observatory (Chile); Johana Panduro, José R. Ramos, Max-Planck-Institut für Astronomie (Germany); Miguel Riquelme, European Southern Observatory (Chile); Ralf-Rainer Rohloff, Max-Planck-Institut für Astronomie (Germany); Nicolas Schuhler, European Southern Observatory (Chile); Marcos Suárez Valles, European Southern Observatory (Germany); Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Gérard Zins, European Southern Observatory (Chile)

GRAVITY is a near-infrared instrument that will combine the light of the four unit or four auxiliary telescopes of the ESO Paranal observatory in Chile. The major science goals of GRAVITY are the observation of objects in close orbit around, or spiraling into the black hole in the Galactic center with unrivaled sensitivity as well as studies of young stellar objects and evolved stars.

In order to cancel out the effect of atmospheric turbulence for each of the unit telescope and to be able to see beyond dusty layers, GRAVITY needs infrared wavefront sensors when operating with the unit telescopes. Therefore GRAVITY consists of the Beam Combiner Instrument (BCI) located in the VLTI laboratory and a wavefront sensor in each unit telescope Coude room, thus aptly named Coude Infrared Adaptive Optics (CIAO). The BCI has been recently installed at Paranal and testing with the auxiliary telescopes is ongoing. The first results are very promising.

The CIAO wavefront sensors are built under the responsibility of the Max Planck Institute for Astronomy (MPIA) and shall be installed at Paranal between February and September 2016. Lessons learned during the prototyping phase were applied to the production systems of CIAO to facilitate a more streamlined and stable alignment and operation at Paranal. In close cooperation with ESO and the GRAVITY consortium under the lead of the PI institute MPE (Max Planck Institute for Extraterrestrial Physics), the MPIA team plans to finish the first CIAO system by end 2015 to be ready for shipment to Paranal observatory in early 2016.

This presentation will give an overview of the design of the CIAO production systems, the Assembly, Installation and Test process at MPIA and the Assembly, Installation and Verification activities at Paranal.

By the time this conference will take place, two of four wavefront sensors should have been installed at Paranal allowing already a first test together with the Beam Combiner Instrument.

9909-98, Session PSun1

System tests and on-sky commissioning of the GRAVITY-CIAO wavefront sensors

Casey P. Deen, Wolfgang Brandner, Max-Planck-Institut für Astronomie (Germany); Henri M. Bonnet, Pierre Bourget, European Southern Observatory (Germany); Yann Clénet, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Françoise Delplancke-Stroebele, European Southern Observatory (Germany); Frank Eisenhauer, Max-Planck-Institut für extraterrestrische Physik (Germany); Michael Essenborn, European Southern Observatory (Germany); Éric Gendron, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Frédéric Yves J. Gonté, European Southern Observatory (Germany); Thomas Henning, Max-Planck-Institut für Astronomie (Germany)

GRAVITY is a near-infrared intererometric instrument that allows astronomers to combine the light of the four unit or four auxiliary telescopes of the ESO Very Large Telescope in Paranal, Chile. GRAVITY will deliver extremely precise relative astrometry and spatially resolved spectra. In order to study objects in regions of high extinction (e.g. the Galactic Center, or star forming regions), GRAVITY will use infrared wavefront sensors. The suite of four wavefront sensors located in the Coudé room of each of the unit telescopes are known as the Coudé Integrated Adaptive Optics (CIAO). The CIAO wavefront sensors are being constructed by the Max Planck Institute for Astronomy (MPIA) and will be installed and commissioned at Paranal between February and September of 2016. This presentation will focus on system tests performed in the MPIA adaptive optics laboratory in Heidelberg, Germany in preparation for shipment to Paranal, as well as on-sky data from the commissioning of the first instrument. We will discuss the CIAO instruments, control strategy, optimizations, and performance at the telescope.

9909-99, Session PSun1

Status of Hida solar adaptive optics system and experiment of tomographic wavefront sensing

Noriaki Miura, Akira Oh-ishi, Susumu Kuwamura, Kitami Institute of Technology (Japan); Naoshi Baba, Hokkaido Univ. (Japan); Yoichiro Hanaoka, National Astronomical Observatory of Japan (Japan); Satoru Ueno, Yoshikazu Nakatani, Kiyoshi Ichimoto, Kyoto Univ. Hida Observatory (Japan)

We are developing a solar adaptive optics (AO) system for the 60-cm domeless solar telescope of the Hida Observatory, Japan. The optical path of the AO system is alternative to a horizontal or vertical spectrograph by

changing mirror combinations. Such an optics design will allow various solar observations, such as high-dispersion spectroscopy, narrow-band imaging and high-precision polarimetry. The AO system has a deformable mirror with 97 piezo-actuators, a Shack-Hartmann (SH) wavefront sensor with a 10x10-array microlens and a CMOS camera with 4000 fps. We reported the preliminary status of the AO system in the 2014-SPIE conference.

We conducted computer simulations to analyze performances of our AO system, and then found two major points to be improved. One of them was the use of Karhunen-Loève (KL) functions instead of the Zernike polynomials in the expansion of wavefront phases. That greatly reduced fitting errors near the aperture edge, in particular, when using a large number of orthogonal functions. The other point was the reduction of the total time of computation and exposure. We simulated AO behaviors with various parameters, such as image size, the number of subapertures and the field of view (FOV) per subaperture, and evaluated the residual wavefront errors. We then determined the best parameters for our AO system, but not yet apply them to the true system at time when we are writing this abstract. In the coming SPIE conference, we will show effects of the above improvements.

In parallel to improving the AO system, we are introducing a ground-layer (GL) AO system and/or a multi-conjugate (MC) AO system in order to widen the FOV to be corrected. Although the GLAO is incapable of realizing the diffraction limit, we decided to develop a GLAO system first because it does not require the addition of a deformable mirror and the modification of optical system. It is necessary to develop a technique of tomographic wavefront sensing for implementing a GLAO system. The sensor must be a SH type, but its subaperutres have a wider FOV than that in conventional sensors. Wavefront sensing using several targets studding over the field implements sampling of wavefront errors on upper layers with several different directions. We are developing software of deriving wavefront errors on the ground-layer and on an upper layer from a tomographic SH image.

We set an experimental tomographic SH sensor on the telescope focus to collect the test data. The sensor was with a 12x12-array microlens and a 512x512-pixel image. The FOV was 54 arcsec per subaperture. We applied our software to the observed data and derived wavefront-phase maps both on the ground-layer and on an upper layer. We are now improving the software code to raise the accuracy of derived phase errors. We will report the detail of the solar tomographic wavefront sensing.

9909-100, Session PSun1

Getting ready for procurement on the NFIRAOS sub-systems, relay optics, and 1st test instrument

Frédéric J. Grandmont, ABB Inc. (Canada); David R. Andersen, Jenny Atwood, National Research Council Canada (Canada); Louis-Philippe A. Bibeau, Eric Carbonneau, ABB Inc. (Canada); Joeleff Fitzsimmons, National Research Council Canada (Canada); Martin Gagne, ABB Inc. (Canada); Glen Herriot, National Research Council Canada (Canada); Martin Larouche, Jean-Francois Lavigne, Julie Mandar, Guillaume Thériault, ABB Inc. (Canada); Jean-Pierre Véran, National Research Council Canada (Canada)

With the official financial commitment of Canada in the TMT project, the work on NFIRAOS is now entering into production phase. The first part of this effort was to grow the production team beyond that invested in the design up to now. Industry was invited to review the existing preliminary design of the various NFIRAOS sub-systems and propose a final detailed version that meets the latest TMT requirements and allows to scope out the integration and test phases. We present here the detailed design of the NFIRAOS main relay optics consisting in a series of 6 large off-axis parabolas (OAPs) mounted on tip-tilt platforms and set to operate at -30 degrees Celsius. Wavefront error simulation for gravity, temperature and pointing adjustment are presented as well as methods for verifying results experimentally. Also presented is the plan for characterizing their optical axis and focal distance in order to guide their integration into the NFIRAOS optical train. We also report on similar work done for the NFIRAOS near-IR high resolution wavefront sensor and acquisition camera subsystem, a standalone instrument that will allow to verify the NFIRAOS performance in each of the three instrument port. NSEN will also serves at the absolute optical and mechanical reference to adjust the beam position and orientation with respect to the large 6 meter mounting interface. Getting the instruments optical axis right on that of NFIRAOS is critical as the field rotates in the instrument ports. NSEN will patrol the FOV at high and low spatial sampling and carry a wavefront sensor to verify performance at high temporal resolution. The NSEN will be the first instrument mounted on NFIRAOS and will thus allow experimenting and refining the approaches and tools that support this critical task. We will report on the NSEN final design and technical challenges of experimentally characterizing the position of a virtual focal plane at tens of microns precision with respect to distant mechanical references with an instrument structure spanning over different thermal zones and set to operate in three orthogonal orientations.

9909-102, Session PSun1

NFIRAOS AO for the Thirty Meter Telescope

Glen Herriot, David R. Andersen, Jenny Atwood, Peter W. G. Byrnes, Krzysztof Caputa, Joeleff Fitzsimmons, Alexis Hill, Olivier Lardière, Malcolm Smith, Jonathan Stocks, NRC - Herzberg Astronomy & Astrophysics (Canada)

NFIRAOS is the facility Adaptive Optics system for the Thirty Meter Telescope, being designed and integrated at NRC Herzberg in Victoria Canada. In April 2015 the Canadian federal government announced funding for full membership in TMT, and consequently final design and construction activity has ramped up. Approximately a dozen major subsystems in NFIRAOS are under contract with Canadian industry. NFIRAOS is cooled to -30°C and has two deformable mirrors, six laser wavefront sensors, and uses up to three low-order (tip/tilt and/or focus) IR wavefront sensors (OIWFS) on each instrument and up to four guide windows on the science detectors (ODGW) to correct atmospheric turbulence, telescope windshake and quasi-static optical errors. We present recent intensified engineering work and design revisions to NFIRAOS such as a pyramid WFS for a truth wavefront sensor and for NGS-mode observing without lasers, and NFIRAOS' CPU-based real time computer.

9909-103, Session PSun1

Design and development of adaptive optics system in visible and near-IR band for IUCAA 2m Telescope

Jyotirmay Paul, Anamparambu N. Ramaprakash, Mahesh P. Burse, Hillol Kanti Das, Pravinkumar A. Chordia, Sujit P. Punnadi, Abhay Kohok, Pravin Khodade, Deepa Modi, Chaitanya V. Rajarshi, Chikku Shekhar, Inter-Univ. Ctr. for Astronomy and Astrophysics (India)

Reason of blurring of celestial objects when observing through telescopes are well understood and is correctable by using Adaptive Optics (AO).

AO techniques have been successfully employed in astronomy for more than three decades with large overheads and low efficiency at large telescopes. A reasonably powerful AO system, which works with minimal

overheads and provides good sky coverage, will greatly enhance the scientific capabilities of small and medium sized telescopes.

The Palomar 60-inch telescope currently incorporates Robo-AO, which is the product of a collaborative effort between Caltech, USA and IUCAA, India which started in mid-2009. A second version of Robo-AO called iRobo-AO is currently under development at IUCAA for deployment on the 2m telescope at IUCAA Girawali Observatory.

There are three arms in the AO system. One of them is called wavefront sensing or uv arm. Others are Visible and IR, used for science observation and atmospheric tip-tilt correction. The entire instrument will be mounted at the Cassegrain focus-direct port (behind the primary mirror).

AO system can not correct atmospheric dispersion, which deteriorates resolution normal to horizontal direction. We have designed a rotating type ADC and incorporated in AO system. Generic atmospheric parameter sensitive code is developed to rotate the ADC prisms at any location on the globe, over the wide range of atmospheric condition. Only maximum correctable (atmospheric dispersion) zenith angle gets changed.

To overcome the scarcity of natural guide star, Rayleigh scatter Laser guide star will be created by an independent laser projector system. This system will be attached on side of telescope tube and through periscope system laser will be launched from the back of secondary mirror to create LGS at 10km above the ground. There is a range gate system allows back scattered photons from the LGS to enter in wavefront sensing arm. Range gate system completely works on polarization property. Polarization of LGS light continuously change due to rotation of cassegrain de-rotator to counteract field rotation (Alt- Azimuth types telescope). There is a rotating retarder in range gate system to freeze the polarization of incoming LGS light. The algorithm to freeze the LGS polarization is developed and implemented.

This paper presents the salient features of the Robo-AO concept, optical design, software architecture of ADC & retarder.

9909-104, Session PSun1

NGS WFSs module for MAORY at E-ELT

Paolo Spanò, Guido Agapito, Luca Carbonaro, Gianluca Di Rico, INAF - Osservatorio Astrofisico di Arcetri (Italy); Christophe Giordano, INAF-Osservatorio Astrofisico di Arcetri (Italy); Alfio T. Puglisi, Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Emiliano Diolaiti, INAF - Osservatorio Astronomico di Bologna (Italy); Yann Clénet, Jean-Tristan M. Buey, Gérard Rousset, Éric Gendron, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Richard Davies, Max-Planck-Institut für extraterrestrische Physik (Germany)

We report on the natural guide star (NGS) wavefront sensors (WFS) module for MAORY, the multi-cojugate adaptive optics (MCAO) system for the ESO E-ELT. Three low–order, near–infrared (H-band), Shack–Hartmann sensors provide fast acquisition of the first 5 modes (tip, tilt, focus, astigmatism) on 3 natural guide stars over a 160 arcsec field of view. Three moderate-order (20x20), visible (600-800 nm), pyramid WFSs provide the slow Truth sensing to correct LGS wavefront estimates of low–order modes. These sensors are mounted onto three R–theta stages to patrol the field of view. The module is also equipped with a retractable, on-axis, high–order (80x80), visible, pyramid WFS for the single–conjugate AO (SCAO) mode of MAORY and MICADO. The visible WFSs share the same 80x80 pyramid WFS design. This choice enables also a MCAO NGS capability. Simulations show that Strehl ratios (SR) over 40% are reached with MCAO and three, 2x2 sub-apertures, NIR low-order WFSs working with H-mag=20 reference stars. In SCAO mode, 90% SR for a 8mag stars with a contrast down to 10??5, and 45% SR for a 16mag star, are achieved.

9909-105, Session PSun1

Laboratory results of the AO facility system testing

Johann Kolb, Pierre-Yves Madec, Robin Arsenault, Sylvain Oberti, Jérôme Paufique, Paolo La Penna, Stefan Stroebele, Robert H. Donaldson, Christian Soenke, Marcos Suárez Valles, Mario J. Kiekebusch, Javier Argomedo, Miska Le Louarn, Elise Vernet, European Southern Observatory (Germany); Pierre Haguenauer, Philippe R. Duhoux, Jose Javier Valenzuela, Juan Carlos Guerra, European Southern Observatory (Chile)

For two years starting in February 2014, the AO modules GRAAL for HAWK-I and GALACSI for MUSE of the Adaptive Optics Facility project have undergone System Testing at ESO's Headquarters. They offer four different modes: NGS SCAO, LGS GLAO in the IR, LGS GLAO and LTAO in the visible.

A detailed characterization of those modes was made possible by the existence of ASSIST, a Test bench emulating an adaptive VLT including the Deformable Secondary Mirror (DSM), a star simulator and turbulence generator and a VLT focal plane re-imager.

This phase aimed at validating all the possible components and loops of the AO modules before installation at the actual VLT that comprises the added complexity of real LGSs, a harsher non-reproducible environment and the adaptive telescope control.

In this paper we will present some of the major results obtained and challenges encountered during the phase of System Tests, like the preparation of the acquisition sequence, the testing of the Jitter loop, the performance optimization in GLAO and the offload of low-order modes from the DSM to the telescope (restricted to the M2 hexapod).

The System Tests concluded with the successful acceptance, shipping, installation and first commissioning of GRAAL in 2015 as well as the acceptance and shipping of GALACSI, ready for installation and commissioning early 2017.

9909-106, Session PSun1

Ten years maintaining MACAO-VLTI units in operation in the Very Large Telescope at Paranal Observatory

Fernando Salgado, Gerhard Hüdepohl, European Southern Observatory (Chile)

The first Multi Array Curvature Adaptive Optics (MACAO) facilities got its first light in UT2 the 18th of April, 2003, at the Very Large Telescope (VLT), Paranal Observatory.

The achievable image sharpness of a ground-based telescope is normally limited by the effect of atmospheric turbulence. However, with Adaptive Optics (AO) techniques, this major drawback can be overcome so that the telescope produces images that are almost as sharp as theoretically possible, i.e., as if they were taken from space.

We summarize some highlights related to the activities needed to keep the MACAO units in operation. Some statistics of problems based on our Action Remedy tool are included, showing how the number of problems has been reduced through the years, although there are still some unsolved ones. Some lessons learned are presented. Corrective and predictive maintenance performed are also shown like the current measurements, transfer functions measurements, thermography pictures, health checks measuring interaction matrix and flat vectors to detect dead APDs or short circuits in the DM, etc. Some forced interventions are presented , for example: the removal of the cabinets from the Coude rooms to avoid

disturbance of acoustic noise and vibrations, the contamination by cooling leaks of the deformable mirrors, and other mirror degradations.

Proper knowledge of the system, good interaction between different discipline groups to perform corrective and preventive maintenance have been key aspects for keeping the MACAOs under control and operative during all these years.

9909-107, Session PSun1

ShaneAO at work: on-sky performance characterization of the adaptive optics system on the Shane 3-meter telescope at Lick Observatory

Srikar Srinath, Constance Rockosi, Donald T. Gavel, Renate Kupke, Univ. of California, Santa Cruz (United States)

The ShaneAO adaptive optics (AO) system and ShARCS near-infrared detector on the Shane 3-meter telescope at Lick Observatory have been in operation since mid-2014. It features a dual-deformable mirror design, 8-, 16- and 30-across wavefront sensing modes, and a dye laser (soon to be replaced by a fiber laser) fed laser guide star system. We report the results of on-sky performance characterization and compare them to prior estimates from optical pipeline modeling. A measured throughout drop in the J-band is investigated and mitigated. The AO system's performance is characterized and presented in detail. Figures of merit from the AO system such as Strehl ratio as a function of guide star brightness and separation are reported.

Why bother with a small telescope at a non-optimal observing site in this era of extremely large telescopes? The Shane telescope and Lick Observatory have been at the cutting edge of AO system research for many years and our current push to demonstrate wind predictive control on-sky to eliminate temporal errors has resulted in significant modifications to the system and many valuable lessons learned that are directly to applicable to all telescopes with AO systems, regardless of size and location. In addition, the utility of a state-of-the-art AO system on a small telescope at a non-optimal observing site is demonstrated.

9909-108, Session PSun1

LINC-NIRVANA MCAO at the LBT: final preparations for first light

Thomas M. Herbst, Max-Planck-Institut für Astronomie (Germany); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Thomas Bertram, Peter Bizenberger, Florian Briegel, Ralph Hofferbert, Martin Kürster, Max-Planck-Institut für Astronomie (Germany)

We present an update on LINC-NIRVANA (LN), an innovative, high-resolution infrared imager for the Large Binocular Telescope (LBT). LN employs layer-oriented, natural guide-star, Multi-Conjugate Adaptvie Optics (MCAO) using the Multiple Field of View approach. It delivers a diffraction-limited field of view two arcminutes across, although the current science camera field is considerably smaller. LINC-NIRVANA actually has two identical MCAO systems, one for each of the 8.4 m mirrors of the LBT. The instrument accepts light from both telescopes and is designed for interferometric combination with off-axis fringe tracking. When implemented, this will provide panoramic Fizeau-mode imagery over much of the sky with the 10 mas spatial resolution corresponding to a 23-meter diameter telescope.

Since the last SPIE, the LINC-NIRVANA team has completed lab integration, system level tests, and preparation of the early science plan. This effort culminated in Preliminary Acceptance Europe in May 2015, followed by several months of final testing, disassembly and shipping. We report on these efforts with a focus on laboratory and on-telescope demonstration of the various AO loops and their performance.

LINC-NIRVANA is now in the mountain laboratory at the Large Binocular Telescope undergoing final alignment and testing prior to first on-sky measurements in Fall 2016. An initial craning and fit-test in November 2015 placed the instrument on the telescope itself within the capture range of the LBT bulk optics. Transportation and installation of such a large, complex instrument presented a number of challenges. We report on several technical and logistical issues that are very relevant to the next generation of extremely large telescopes.

Bringing LINC-NIRVANA into operation will involve a hierarchical sequence of internal instrument alignment, followed by alignment of the telescope, and finally on-sky verification and commissioning. We report on this strategy and its interaction with the Early Science plan, which has been designed to maximize the astronomical return of the instrument during this complicated phase between installation and routine operations.

9909-110, Session PSun1

On-sky AO test bench: testing future AO technologies

Denis Brousseau, William S. Deschenes, Simon Thibault, Univ. Laval (Canada); Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada); Jean-Francois Lavigne, ABB Inc. (Canada)

We present an AO system specially designed for the 1.6-m diameter telescope of the Observatoire du Mont-Mégantic (OMM). The system has been mounted and tested at the OMM. It can be used to evaluate, directly on the sky, the performance of a number of next generation adaptive optics related technologies. The AO system is based on a 97-actuator ALPAO DM and a high-speed Optocraft Shack-Hartmann wavefront sensor (SHWFS). A beam splitter is located in front of the SHWFS to relay the wavefront to a second optical port which can accommodate a second wavefront sensor. During the initial observing run, the second wavefront sensor was a pyramidal wavefront sensor developed by INO. The AO control is achieve using the ALPAO Core Engine (ACE) software which can be used for closing the loop using one of the wavefront sensor while monitoring the wavefront with the other one. An Andor EMCCD camera is used to record the AO optimized PSF for performance analysis. We present the AO system design and results from tests made in the lab during the opto-mechanical integration. The results from the observing run at the OMM are also presented. The results have demonstrated that this setup can be a highly flexible tool that can allow the direct side-by-side evaluation of new types of wavefront sensors.

9909-111, Session PSun1

Lick Observatory's Shane telescope adaptive optics system (ShaneAO): research directions and progress

Donald T. Gavel, Renate Kupke, Alexander R. Rudy, Srikar Srinath, Daren Dillon, Univ. of California, Santa Cruz (United States); Lisa A. Poyneer, Lawrence Livermore National Lab. (United States)

We present a review of the ongoing research activity surrounding the adaptive optics system at the Shane telescope (ShaneAO) particularly the R&D efforts on the technology and algorithms for that will advance AO into wider application for astronomy. We are pursuing the AO challenges for whole sky coverage diffraction-limited correction down to visible

science wavelengths. This demands high-order wavefront correction and bright artificial laser beacons. We present recent advancements in the development of MEMS based AO correction, woofer-tweeter architecture, wind-predictive wavefront control algorithms, atmospheric characterization, and a pulsed fiber amplifier guide star laser tuned for optical pumping of the sodium layer. We present the latest on-sky results from the new AO system and present status and experimental plans for the optical pumping guide star laser.

The new ShaneAO system (the second generation system at Lick Observatory) was commissioned last year with great success. The system uses MEMS high-order AO correction to achieve fine wavefront correction, combined with a woofer DM to provide high dynamic range. The woofer-tweeter control architecture, described theoretically at the previous SPIE Telescopes meeting (9148), has proven on sky to operate extremely well, with the imaging system achieving Strehl ratios near 0.8 in H band with bright natural stars. In order to handle the increased demand for sampling the wavefront on a finer scale, it is necessary to upgrade the laser to one that provides a much brighter guide star. To this end we are planning to commission the fiber amplified sum-freqency laser developed by Jay Dawson at LLNL (SPIE 6102) at the observatory next year (2016). This laser is specifically tuned to enhance the optical pumping of the mesospheric sodium so that the return signal per watt of laser power is optimized. Furthermore it is a flexible pulsed design that enables us to experiment with spectral and pulse formats that simulations have shown potential improvement in return efficiency. With the laser returns we expect (conservatively from nominal format parameters) we expect to achieve near 90% sky coverage for AO in the near IR (J, H, and K) bands. Furthermore, in ongoing experiments we are developing an improved understanding of atmospheric conditions and developing predictive control algorithms that will take advantage of learning the Taylor frozen-flow and quasi-static (dome seeing and telescope aberrations) components. With a combination of predictive control and improved laser return we expect to correct down to visible science wavelengths using the laser guide star. The results of our site testing and progress to the date of the meeting will be presented.

9909-112, Session PSun1

Single-mode fiber coupling measurements using extreme adaptive optics at the Large Binocular Telescope

Andrew Bechter, Jonathan Crass, Justin R. Crepp, Ryan Ketterer, Eric Bechter, Michael Foley, Univ. of Notre Dame (United States); Robert O. Reynolds, Large Binocular Telescope Observatory (United States)

A key requirement to enable an astronomical diffraction-limited Doppler spectrograph is efficiently injecting starlight into single-mode fibers (SMFs). Efficient coupling requires a stable, high Strehl ratio incident beam that matches the mode field diameter of the fiber. In preparation for the installation of 'iLocater', a high-resolution SMF-fed spectrograph for the Large Binocular Telescope (LBT), we have commissioned a fiber coupling system that operates behind the LBT "extreme" adaptive optics (AO) system. Using 6 ?m diameter SMF's, we have measured on-sky coupling efficiencies at near-infrared wavelengths (Y-band: 970-1070nm). In addition to exploring coupling efficiencies as a function of natural guide star magnitude and airmass, our system simultaneously records diagnostic data used to identify effects that limit fiber-coupling efficiency. We discuss how on-sky results compare to theory and previous lab experiments, as well as implications for the design of the final iLocater fiber coupling system.

9909-113, Session PSun1

Rejuvenation of a 10 year old AO curvature wavefront sensor: combining obsolescence correction and performance upgrade of MACAO

Pierre Haguenauer, European Southern Observatory (Chile); Enrico Fedrigo, Lorenzo Pettazzi, European Southern Observatory (Germany); Claudio Reinero, European Southern Observatory (Chile); Frédéric Yves J. Gonté, European Southern Observatory (Germany); Laurent Pallanca, European Southern Observatory (Chile); Robert Frahm, Julien Woillez, European Southern Observatory (Germany)

The MACAOs curvature wavefront sensors have been designed as a generic adaptive optics sensor for the Very Large Telescope, and six systems have been manufactured and implemented on sky: four installed in the UTs Coude train as an AO facility for the VLTI, and two in UT's instruments, SINFONI and CRIRES. The MACAO-VLTI have now been in use for scientific operation for more than a decade and are planned to be operated for at least ten more years. As second generation instruments for the VLTI were planned to start implementation in end of 2015, accompanied with a major upgrade of the VLTI infrastructure, we saw it as a good time for a rejuvenation project of these systems, correcting there the obsolete components. This obsolescence correction also gave us the opportunity to implement improved capabilities: the correction frequency was pushed from 420 Hz to 1050 Hz, and an automatic vibrations compensation algorithm was added. The implementation on the first MACAO was done in October 2014 and the first phase of obsolescence correction was completed in all four MACAO-VLTI systems in October 2015, and the systems were delivered back to operation. The resuming of the scientific operation of the VLTI on the UTs in November 2015 will allow to gather statistics in order to evaluate the improvement of the performances through this upgrade. A second phase of obsolescence correction has now been started, together with a global reflection on possible further improvements to secure observations with the VLTI.

9909-114, Session PSun1

AOF: standalone test results of GALACSI

Paolo La Penna, Stefan Stroebele, Emmanuel Aller-Carpentier, Javier Argomedo, Robin Arsenault, Ralf D. Conzelmann, Robert H. Donaldson, Fernando Gago Rodriguez, Pablo Gutierrez, Norbert Hubin, Paul D. Jolley, Mario J. Kiekebusch, Jean-Paul Kirchbauer, Barbara Klein, Johann Kolb, Harald Kuntschner, Miska Le Louarn, Jean-Louis Lizon, Pierre-Yves Madec, Leander H. Located at the VLT UT4 Nasmyth B, GALACSI is the Adaptive Optics (AO) module of the ESO Adaptive Optics Facility (AOF) that will correct the optical beam wavefront delivered to the MUSE Integral Field Spectrograph (operating between 465 and 930 nm). It will sense with four 40?40 subapertures Shack-Hartmann wavefront sensors the AOF 4 Laser Guide Stars (LGS), acting on the 1170 voice-coils actuators of the Deformable Secondary Mirror (DSM).

In Wide Field Mode (WFM), the first of its two AO operating modes, GALACSI will enhance the collected energy in a 0.2"?0.2" pixel by a factor 2 at 750 nm over a Field of View (FoV) of 1'?1' using the Ground Layer

AO (GLAO) technique. The Narrow Field Mode (NFM, second mode of GALACSI), provides an enhanced wavefront correction (Strehl Ratio of 5% (goal 10%) at 650 nm) but in a smaller FoV (7.5”?7.5” FoV), using Laser Tomography AO (LTAO. In NFM the near infrared light of on axis science object is detected by a specific infrared truth sensor (IRLOS, InfraRed Low Order Sensor) and used for tip tilt and focus sensing.

GALACSI is an over 1 ton heavy complex AO module, including internal calibration and commissioning units, truth sensors, tracking and closed loop functionalities. Before being ready for shipping to Paranal, the system has gone through an extensive testing phase in Europe, first in standalone mode and then in closed loop with the DSM in Europe. After outlining the technical features of the system, we describe here the first part of that testing phase and the integration with the AOF ASSIST (Adaptive Secondary Setup and Instrument Stimulator) testbench, including a specific adapter for the IRLOS truth sensor. The procedures for the standalone verification of the main system performances are outlined, and the results of the internal functional tests of GALACSI after full integration and alignment on ASSIST are presented.

9909-115, Session PSun1

CHOUGH: spatially filtered Shack-Hartmann wave-front sensor for HOAO

Daniel Hölck-Santibanez, Nazim A. Bharmal, Richard M. Myers, Durham Univ. (United Kingdom)

The CANARY-Hosted Upgrade for High-Order Adaptive Optics (CHOUGH), is a narrow-field of view High-Order Single Conjugate on-sky AO demonstrator, to be placed on the 4.2m WHT telescope. It aims to produce a Strehl ratio greater than 0.5 in the visible region of the spectrum (>640nm). A High-Order wave-front sensor (HOWFS) is a central piece of the experiment; it is a Shack-Harmann with a sampling of 31x31 subapertures across the pupil. A variable aperture spatial filter designed to reduce aliasing for high-spatial frequencies, located at a focal plane preceding the lenslet array. The HOWFS has a quad-cell configuration on the detector with a one-pixel guard ring and 72?m subperture. The detector is a NüVü EMCCD camera, 24?m pixel size, operating at >500Hz. The lenslet array, collimator and relay are commercial off-the-shelf. This was technically challenging due to the small size of the pupil, 2.3mm, and the small optics involved in the design. We present the lab testing results and performance characterisation for the HOWFS obtained in the laboratory.

9909-116, Session PSun1

SHARK-NIR: from K-band to a key instrument, a status update

SHARK-NIR channel is one of the two coronagraphic instruments proposed for the Large Binocular Telescope, in the framework of the call for second generation instruments, issued in 2014. Together with the SHARK-VIS channel, it will offer a few observing modes (direct imaging, coronagraphic imaging and coronagraphic low resolution spectroscopy) covering a wide wavelength domain, going from 0.6μm to 1.65μm.

Initially proposed as an instrument covering also the K-band, the current design foresees a camera working from Y to H bands, exploiting in this way the synergy with other LBT instruments such as LBTI, which is actually covering wavelengths greater than L’ band, and it will be soon upgraded to work also in K band.

SHARK-NIR has been undergoing the conceptual design review at the end of 2015 and it has been approved to proceed to the final design phase, receiving the green light for successive construction and installation at LBT.

The current design is significantly more flexible than the previous one, having an additional intermediate pupil plane that will allow the usage of coronagraphic techniques very efficient in term of contrast and vicinity to the star, increasing the instrument coronagraphic performance.

The latter is necessary to properly exploit the search of giant exo-planets, which is the main science case and the driver for the technical choices of SHARK-NIR. We also emphasize that the LBT AO SOUL upgrade will further improve the AO performance, making possible to extend the exo-planet search to target fainter than normally achieved by other 8-m class telescopes, and opening in this way to other very interesting scientific scenarios, such as the characterization of AGN and Quasars (normally too faint to be observed) and increasing considerably the sample of disks and jets to be studied.

Finally, we emphasize that SHARK-NIR will offer XAO direct imaging capability on a FoV of about 15”x15”, and a simple coronagraphic spectroscopic mode offering spectral resolution ranging from few hundreds to few thousands.

This article presents the current instrument design, together with the milestones for its installation at LBT.

9909-117, Session PSun1

Adaptive system for solar telescope for working in the conditions of strong atmospheric turbulence

Vladimir P. Lukin, Leonid V. Antoshkin, Nina N. Botygina, Lidia A. Bolbasova, Oleg N. Emaleev, Petr A. Konyaev, Evgeny A. Kopylov, Vitaly V. Lavrinov, Lidia N. Lavrinova, V.E. Zuev Institute of Atmospheric Optics (Russian Federation); Viktor M. Grigoryev, Pavel G. Kovadlo, Artem Y. Shihovtsev, Institute of Solar-Terrestrial Physics (Russian Federation); Alexis V. Kudryashov, V.E. Zuev Institute of Atmospheric Optics (Russian Federation); Viktor D. Trifonov, Mikhail L. Demidov, Institute of Solar-Terrestrial Physics (Russian Federation)

Command of project on creation of the adaptive optical (AO) system for a solar vacuum telescope (BSVT), working in the Baikal Astrophysical Observatory, are having about 10 years an experience. During this time a few stages of system development are passed, from cross-correlation tracker to the low-order adaptive correction.

Our data of astronomic supervisions in BSVT site talk about that is present strong turbulence in an atmosphere here. To one of feature, created system, there is a necessity of work in the conditions of strong turbulence. Leaning against world experience consider correct above all things to create the two-mirrors AO-system, using tip-tilt of wave- front corrector and flexible (bimorph) mirror with the suitable number of actuators. The algorithms of simultaneous controlling by two active mirrors will be exhaust – by the tip-tilt corrector and flexible bimorph mirror. The leadthrough of statistical analysis of fluctuations of wave-front is assumed, including decomposition in the base of polynomials of Zernike, from data of measurings of wave-front sensor (WFS) for forming of requirements to the parameters of the corrected mirrors.

We are considering the creation of perspective high-speed of wave-front sensor as the following important step. Development of cross-correlation high-res WFS will be carried out for measuring of wave-front in the conditions of strong atmospheric turbulence. Conducted also work on creation of computer model of the AO-system for solar telescope with the use of technologies of the parallel programming. Realization of design of signal will be well-to-do for WFS with the use of multi-layered model of vertical evolution of turbulence intensity. We consider that to the construction of the multi-mirror AO- system it is necessary to befit only after the careful analysis of level of turbulence vertical evolution, as proof-readers of wave-front must be set in planes attended with the most strong layers of atmospheric turbulence.

It information can be got only by a supervision in the telescope site. Therefore constantly conducted work on the set of information of measuring of turbulence in the different seasons of year. Along 2015 a several out-door expeditions were conducted in all seasons for the construction of local seasonal model of turbulence in the point of standing of BSVT. For the receipt of information on the parameters of turbulence the followings measurings devices and equipment are used: differential image motion meter (DIMM) on the base of telescope of MEADE, acoustic weather-station, cross-correlation S-H WFS set on a telescope, a Brandt's sensor. Doppler lidar was episodically used for measuring of wind speed profiles up to the 2 km height. Used, created before, local model of vertical change speed of wind. A task is put – to build the local model of types of turbulence and speed of wind for the BSVT point of standing.

And also to expose the possible going near creation of WFS for the multi-mirror AO-systems controlling. Experience, got at creation of the AO-system for BVST will be further used for the construction the system for new 3-m solar telescope (KST).

A project is financially supported by the grant of the Russian Scienc? Foundation ?15-19-20013.

9909-118, Session PSun1

Adaptive optics on-sky demonstrator for the Anglo-Australian Telescope

Michael Goodwin, Jessica R. Zheng, Australian Astronomical Observatory (Australia); Samuel N. Richards, Australian Astronomical Observatory (Australia) and The Univ. of Sydney (Australia); Jonathan S. Lawrence, Australian Astronomical Observatory (Australia); Nick Cvetojevic, The Univ. of Sydney (Australia) and Australian Astronomical Observatory (Australia); Barnaby R. Norris, The Univ. of Sydney (Australia); Simon Gross, Alexander Arriola Martiarena, Macquarie Univ. (Australia) and The Univ. of Sydney (Australia)

The Australian Astronomical Observatory is currently investigating the use of adaptive optics technologies for the 3.9m Anglo-Australian Telescope at Siding Spring Observatory. It might be that ground-layer or multi-object adaptive optics is beneficial for the Anglo-Australian Telescope (seeing ~1.6"). Key to achieving this goal is an adaptive optics test-bench developed for laboratory experiments and on-sky demonstration. The test-bench provides a facility to demonstrate on-sky natural guide star adaptive optics as well as second stage correction with active injection into single mode waveguides. The test-bench provides wide field access of up to 20 arcminutes for testing our plug-plate distributed wavefront sensors. Data has been collected in a range of seeing conditions where closed-loop corrections were performed. We present the design, results and plans for the adaptive optics on-sky demonstrator.

9909-119, Session PSun1

NFIRAOS in 2015: engineering for future integration of complex subsystems

Jenny Atwood, David R. Andersen, Peter W. G. Byrnes, Joeleff Fitzsimmons, Glen Herriot, Alexis Hill, Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada)

The Narrow Field InfraRed Adaptive Optics System (NFIRAOS) will be the first-light facility Adaptive Optics (AO) system for the Thirty Meter Telescope (TMT). NFIRAOS will be able to host three science instruments that can take advantage of this high performance system. NRC Herzberg is leading the design effort for this critical TMT subsystem. As part of the final design phase of NFIRAOS, we have identified multiple subsystems to be sub-contracted to Canadian industry. The scope of work for each subcontract is guided by the NFIRAOS Work Breakdown Structure (WBS) and is divided into two phases: the completion of the final design and the fabrication, assembly and delivery of the final product. Integration of the subsystems at NRC will require a detailed understanding of the interfaces between the subsystems, and this work has begun by defining the interface physical characteristics, stability, local coordinate systems, and alignment features. In order to maintain our stringent performance requirements, the interface parameters for each subsystem are captured in multiple performance budgets, which allow a bottom-up estimate on image plane tolerances for our client instruments. In this paper we discuss our approach for defining the interfaces in a consistent manner and present an example error budget that is influenced by multiple subsystems.

9909-120, Session PSun1

GTC adaptive optics hardware electronics

Miguel Núñez Cagigal, Instituto de Astrofísica de Canarias (Spain); Rafael Vilela, Gran Telescopio de Canarias, S.A. (Spain); Noelia Martínez Rey, Carlos Martin-Diaz, Óscar Tubío Araújo, Luis Fernando Rodríguez-Ramos, Instituto de Astrofísica de Canarias (Spain)

The Adaptive optics for GTC is a single conjugated post focal AO system placed in the Nasmyth platform over a static optical table. It has been designed initially for natural guide star and in the later project phase adapted to one Laser guide star. After the AO system, FRIDA instrument will be installed which is a near infrared spectrograph. The AO system is composed of the following subsystems: wavefront corrector, wavefront sensor, structure, calibration system and test camera. This paper presents the hardware electronics to support all this subsystems fulfilling the GTCAO requirements.

9909-320, Session PSun1

First on-sky results with ARGOS

Gilles Orban de Xivry, Sebastian Rabien, Max-Planck-Institut für extraterrestrische Physik (Germany); Lorenzo Busoni, INAF - Osservatorio Astrofisico di Arcetri (Italy); Wolfgang Gaessler, Max-Planck-Institut für Astronomie (Germany); Marco Bonaglia, INAF - Osservatorio Astrofisico di Arcetri (Italy); José Luis Borelli, Max-Planck-Institut für Astronomie (Germany); Matthias Deysenroth, Max-Planck-Institut für extraterrestrische Physik (Germany); Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Hans Gemperlein, Max-Planck-Institut für extraterrestrische Physik (Germany); Martin Kulas, Max-Planck-Institut für Astronomie (Germany); Michael J. Lefebvre, Large Binocular Telescope Observatory (United States); Tommaso Mazzoni, INAF - Osservatorio Astrofisico di Arcetri (Italy); Diethard Peter, Max-Planck-Institut für Astronomie (Germany); Alfio T. Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Walfried Raab, European Space Research and Technology Ctr. (Netherlands); Gustavo Rahmer, Large Binocular Telescope Observatory (United States); A. Sivitelli, Max-Planck-Institut für Astronomie (Germany); Jesper Storm, Leibniz-Institut für Astrophysik Potsdam (Germany); Julian Ziegleder, Max-Planck-Institut für extraterrestrische Physik (Germany)

One year and an half after ARGOS first light, the LBT laser guided ground-layer adaptive optics system has been operated on both side of the Large Binocular Telescope. The system fulfills the GLAO promise and typically delivers an improvement by a factor of 2 in FWHM over the 4'x4' FoV of both LUCI instruments, the two near-infrared imagers and multi-object spectrographs. In this paper, we report on the first on-sky results and analyze the performances based on the statistics collected so far.

We also discuss adaptive optics procedures and the joint operations with LUCI for science observations.

9909-16, Session 5

Review on AO real-time turbulence estimation *(Invited Paper)*

Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile); Éric Gendron, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Elena Masciadri, INAF - Osservatorio Astrofisico di Arcetri (Italy); Timothy J. Morris, Durham Univ. (United Kingdom); Thierry Fusco, ONERA (France); Fabrice Vidal, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Gaetano Sivo, Gemini Observatory (Chile); James Osborn, Durham Univ. (United Kingdom); Vincent Garrel, Gemini Observatory (Chile); Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Francois Rigaut, The Australian National Univ. (Australia); Carlos M. Correia, Lab. d'Astrophysique de Marseille (France); Timothy Butterley, Durham Univ. (United Kingdom); Sylvain Oberti, Johann Kolb, Pierre-Yves Madec, European Southern Observatory (Germany); Olivier Lardière, Univ. of Victoria (Canada); Jean-Marc Conan, Clélia Robert, ONERA (France); Aziz Ziad, Lab. J.L. Lagrange (France); Olivier Martin, Lab. d'Astrophysique de Marseille (France); Yoshito H. Ono, Tohoku Univ. (Japan)

In this talk, we will review the different methods and results developed for estimating turbulence parameters from Adaptive Optics (AO) real-time data. Contrary to dedicated instrument aimed at measuring turbulence atmospheric parameters, like the MASS/DIMM for instance, the idea is to extract relevant atmospheric parameters directly from the AO telemetry. This has the main advantage that the parameters are extracted in the same line of sight as the science observations, and in the same environmental conditions (e.g. effect of dome, wind etc...)

There are many reasons why getting an information on the turbulence parameters is important for an AO system. First, it might be helpful to understand the delivered performance, and characterize an instrument. It might also be helpful to optimize in real time the numerous AO parameters, in order to get the best performance even when facing changing conditions, and atmospheric parameters can also serve for predictive control. It is also interesting to gather telescope site statistics, and potentially optimize the telescope queue scheduling. Finally, it is always relevant to get such informations when doing post-processing on the science images, and even more when considering PSF estimation across the field and over time. For wide-field AO systems, i.e. those using several Wave-Front Sensors (WFSs), the performance critically depends on a tomographic reconstruction of the turbulence volume. For those systems, having access to the vertical distribution of the atmospheric parameters above the telescope is particularly crucial.

In this paper, we will try to review the different methods and results that have been developed in the past years in order to estimate the required atmospherical and astroclimatical parameters. We will cover different systems, and compare the needs, and approaches developed in order to get the relevant information. Among others, we will review the strategies and techniques tested on a single conjugated AO system, SPHERE from ESO-VLT. We will then look at the methods developed for a Multi-conjugated AO system, installed at the Gemini South telescope, called GeMS. Finally, we will review the strategies developed for two Multi-Object AO systems, namely CANARY, installed at the WHT telescope in Canaries Islands, and RAVEN, an MOAO science demonstrator developed for the Subaru Telescope. For all these systems, we will review the parameters that are estimated, the methods developed, and the results in terms of atmospheric statistical parameters. Over the different atmospheric

parameters, we will especially focus on r0, tau0, Cn2(h), L0(h) and vertical wind amplitude (V(h)) and direction (Vd(h)). We will also explore how those methods can be adapted for future systems like the ESO AOF, or solar MCAO systems.

Finally, we will tentatively extrapolate those results for the future Extremely Large Telescopes, and show how important it is to get an accurate profile estimation for the future Wide-Field AO systems planned for these giants.

9909-17, Session 5

FASS: The full aperture seeing sensor

Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile); James Osborn, Durham Univ. (United Kingdom); Marc S. Sarazin, European Southern Observatory (Germany); Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Saavidra Perera, Richard W. Wilson, Durham Univ. (United Kingdom)

We describe a novel technique for the estimation of atmospheric turbulence profiler called FASS (full aperture seeing sensor) based on a low noise CCD detector. The method uses the full aperture of the telescope, with a single CCD detector and a Fourier processing approach that estimates the spatial frequency distribution of the scintillation speckles at the pupil. This frequency approach samples the pupil in rings, making the transformation from space to frequency circular and thus avoiding aliasing or disturbances due to otherwise finite nature of the data. The method provides excellent performance as demonstrated via simulation and on-sky data obtained from small and 1 m class telescopes. The profiles resulting from the technique are compared to those simultaneously obtained with the Durham Stereo-SCIDAR instrument.

It is shown that aspects such as detector exposure time, opto-mechanical stability, detailed spectrum modelling of noise and chromaticity of the stars, must be carefully addressed during the design and calibration stages.

Although the technique is expected to operate in the generalized mode ensuring a minimum speckle size, it is shown that the size of the detector pixel is also a crucial parameter that can severely limit the accuracy at low altitudes. This is especially valid if small or no negative conjugation altitudes are used as the size of the speckles becomes comparable to the pixel size and hence, difficult to disentangle from the detector's noise.

Differences in pixel gains and offsets are effectively corrected, so they don't significantly influence the accuracy of the profile estimation.

Temporal correlations are also shown to provide complementary information no only on the wind speed and direction of layers, but a coarse estimation of their altitude, as the width of correlation peaks moved by the wind depend on the propagation path followed by each one of them. Factors limiting the accuracy of this optional tool are discussed.

Finally, the resilience of the method to strong turbulence regimes (s2 > 0.4) is also addressed and its effect compensated.

9909-18, Session 5

Operational optical turbulence forecast for the service mode of top-class ground based telescopes

Elena Masciadri, Franck Lascaux, Alessio Turchi, Luca Fini, INAF - Osservatorio Astrofisico di Arcetri (Italy)

In this contribution we present the most relevant results obtained in the context of a feasibility study (MOSE) undertaken for ESO. The principal aim of the project was to quantify the performances of an atmospherical non-hydrostatical mesoscale model (Astro-Meso-NH code) in forecasting all the main atmospherical parameters relevant for the ground-based astronomical observations and the optical turbulence (CN2 and associated integrated astroclimatic parameters) above Cerro Paranal (site of the VLT) and Cerro Armazones (site of the E-ELT). A detailed analysis on the score of success of the predictive capacities of the system have been carried out for all the astroclimatic as well as for the atmospherical parameters. Considering the excellent results that we obtained, this study proved the opportunity to implement on these two sites an automatic system to be run nightly in an operational configuration to support the scheduling of scientific programs as well as of astronomical facilities (particularly those supported by AO systems) of the VLT and the E-ELT. A complete design for such a system has already been prepared. We are at present in negotiation with ESO for the set-up of a 'demonstrator' to be run on the two sites. The fact that the system can be run simultaneously on the two sites is an ancillary appealing feature of the system. We are, at the same time, responsible for the implementation of a similar automatic system at Mt.Graham, site of the LBT (ALTA Project). Our system/method will permit therefore to make a step ahead in the framework of the Service Mode for new generation telescopes. Among the most exciting achieved results we cite the fact that we proved to be able to forecast CN2 profiles with a vertical resolution as high as 150 m. Such a feature is particularly crucial for all WFAO systems that require such detailed information on the OT vertical stratification on the whole 20 km above the ground. This important achievement tells us that all the WFAO systems can rely on automatic systems that are able to support their optimized use.

9909-19, Session 5

Characterizing and mitigating vibrations for SCExAO

Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States) and The Univ. of Arizona (United States); Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Garima Singh, Jet Propulsion Lab. (United States); Sean B. Goebel, Institute for Astronomy (United States); Hirofumi Okita, Subaru Telescope, National Astronomical Observatory of Japan (United States)

The Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) instrument, under development for the Subaru Telescope, has currently the fastest on-sky wavefront control loop, with a pyramid wavefront sensor running at 3.5 kHz. But even at that speed, we are still limited by low-frequency vibrations. The current main limitation was found to be vibrations attributed mainly to the rotation of the telescope. Using the fast wavefront sensors, cameras and accelerometers, we managed to identify the origin of most of the vibrations degrading our performance. Low-frequency vibrations are coming from the telescope drive in azimuth and elevation, as well as the elevation encoders when the target is at transit. Other vibrations were found at higher frequency coming from AO188's image rotator.

Different approaches are being implemented to take care of these issues. The PID control of the image rotator has been tuned to reduce their high-frequency contribution. We are working with the telescope team to tune the motor drives and reduce the impact of the elevation encoder. A Linear Quadratic Gaussian controller (LQG, or Kalman filter) is also being implemented inside SCExAO to control these vibrations. These solutions will not only improve significantly SCExAO's performance, but will also help all the other instruments on the Subaru Telescope, especially the ones behind AO188. Ultimately, this study will also help the development of the TMT, which will face similar problems.

9909-20, Session 6

Review of AO calibrations, or how to best educate your AO system *(Invited Paper)*

Johann Kolb, European Southern Observatory (Germany)

If the Real-Time Computer is the heart of an AO system, the Wavefront Sensor (WFS) its eyes, the Deformable Mirror (DM) its hands and the control strategy its nervous system, the sum of all those parts is made into a harmonious entity thanks to calibrations.

This paper does not have the ambition to provide an overview of all the currently existing calibration strategies, but rather to focus on a few challenging problems and their recent evolution in the era of adaptive telescopes, mostly based on the experience of ESO's Adaptive Optics Instruments in general and the AO Facility in particular.

Single most important calibration in post-focal AO system, the recording of the Interaction Matrix (IM) between WFS and DM has since long evolved to use fast modulation techniques, has shown to be feasible on-sky and is now almost free from measurements thanks to its pseudo-synthetic generation, mandatory solution in an adaptive telescope. Pseudo- because it requires an unprecedented knowledge of the components' characteristics especially the WFS, DM and the optical registration between the two.

Bigger telescopes and the use of Laser Guide Stars (LGS) also mean that the properties of the system will change in time and thus need to be constantly updated thanks to online diagnosis tools for spot size measurement, atmosphere monitoring, Wavefront Sensing and control optimization.

New loops come into play like the one to minimize LGS Jitter and the one taking over the telescope active optics by means of offloading the DM low orders, and they all require calibration.

More calibration means more time and one has to carefully balance the calibrations that require precious telescope night time, day time or for the best, no telescope time at all.

Their importance sometimes underestimated, calibrations have repeatedly shown to be a vital part in the optimum functioning of present and future AO systems.

9909-21, Session 6

Solving the NFIRAOS calibration puzzle

Jean-Pierre Véran, Glen Herriot, David R. Andersen, NRC - Herzberg Astronomy & Astrophysics (Canada)

NFIRAOS, the first light MCAO system for the Thirty Meter Telescope is currently in its final design phase. In order to meet a very tight end-to-end error budget, many instrumental effects have to be calibrated and compensated for very accurately. These include alignment errors, wave-front errors, actual motion profiles, and sensitivities, for all the operating conditions of the instrument. We have therefore invested a lot of effort in developing a comprehensive calibration plan. In this paper we present the highlights of this plans, including the flow down from the top-level NFIRAOS requirements to the calibration hardware that we have specified for NFIRAOS and the calibration procedures that we have developed. When possible, these procedures are inspired from that developed for the current 8-meter class AO systems and are validated on Henos, the Herzberg NFIRAOS Optical Simulator, which is our scaled down NFIRAOS table-top demonstrator.

One of the calibration tasks that we develop in more details in this paper is the measurement and the correction of the non-common path aberrations, between the NFIRAOS WFSs and the science focal plane. This calibration is particularly challenging (i) because several contributors are outside NFIRAOS, i.e. in the client science instrument and in the telescope, (ii) because the errors to be corrected change continuously, since pupil planes and image planes rotate at different rates as the telescope tracks, and (iii) because measurement sensitivities change as observing conditions, such as seeing, change. As well, field dependent aberrations are particularly important in the context of tomographic AO, and must be addressed carefully. Full calibration performance budgets have been derived in order to make sure the NFIRAOS can be met. These budgets are critical to understand how many measurements need to be obtained to fully cover the full range of parameters while minimizing the time required to perform calibration, especially for telescope effects, since these measurements must be performed during precious sky-time.

9909-23, Session 6

Demonstration of predictive Fourier control for frozen flow wind turbulence on the ShaneAO 3-meter AO system

Alexander R. Rudy, Srikar Srinath, Univ. of California, Santa Cruz (United States); Lisa A. Poyneer, Lawrence Livermore National Lab. (United States); Donald T. Gavel, Univ. of California, Santa Cruz (United States); S. Mark Ammons, Lawrence Livermore National Lab. (United States)

We demonstre the application of a Kalman Filter to correct for atmospheric turbulence which can be characterized by Taylor's Frozen Flow Hypothesis. Approximately 30% of the total atmospheric wavefront error is correlated as it translates across a telescope aperture. We demonstrate the application of a Kalman Filter to remove this correllated atmospheric tubulent error, attributed to frozen flow wind. Using the ShaneAO system on the 3-meter telescope at Lick Observatory, we present the first on-sky demonstration of Predictive Fourier Control to reduce the temporal delay error in adaptive optics systems.

We present the results from a demonstration of Predictive Fourier Control on-sky, both in the identification of frozen flow wind velocity vectors, and the correction of those wind vectors using Kalman filters generated based on the latest wind measurements. Our wind identification system uses a Fourier decomposition technique to identify the correlated movement of the atmosphere from WFS telemetry data; the estimated wind vectors are then fed back to the predictive controller. The predictive controller works using a Kalman Filter in the Fourier Domain to filter out the temporal behavior of Fourier modes which show correllated frozen-flow motion. This is the first on-sky application of Predictve Fourier Control to a high-order ($d < 10$ cm) astronomical AO system. We present the impact that our predictive control algorithm has on the residual wavefront error measured in the ShaneAO system, and the effects that this reduction in wavefront error has on the output Strehl of the adaptive optics system.

9909-175, Session 6

Wide field LQG tomographic adaptive optics control with wind-dependent turbulence models

Rémy Juvénal, Institut d'Optique Graduate School (France) and ONERA (France); Caroline Kulcsár, Henri-François G. Raynaud, Institut d'Optique Graduate School (France); Jean-Marc Conan, ONERA (France)

Tomographic AO optimal control relies centrally on a stochastic model of the turbulence. For wide-field AO static reconstruction (as, e.g., on the CANARY Multi-Object AO instrument [1] or on NFIRAOS [2]), the models used so far incorporate physical priors on turbulence spatial distribution through Cn2 profiles. For Linear Quadratic Gaussian (LQG) control, models based on both spatial priors and temporal dynamics through wind velocity norm in each layer have been proposed [3,4,5]. As for performance, it depends both on the structure of the model on which is based the LQG

controller and on a good tuning of its parameters.

In this work, we propose turbulence models that account for both wind norm and direction in each layer. These new models combine a wind direction-dependent displacement operator with the "boiling turbulence" assumption (i.e. each turbulent mode can be viewed as a stationary stochastic process with known power spectral density). An explicit dynamical Markovian turbulence model of order 2 is obtained, that allows the design of an optimal LQG controller. Several methods that aim at accounting for wind direction in wide-field AO systems have been proposed in recent years. In, e.g., [6], a simple stabilized shift operator is used as turbulence model, while the approach in [7] does not explicitly reconstruct the phase in order to derive a sparse sub-optimal solution. Performance analysis and comparison with the standard MMSE reconstructor and with LQG control based solely on wind norm priors are performed using end-to-end simulations representative of a wide-field AO system.

Deformable mirrors development program at ESO

Stefan Stroebele, Elise Vernet, Martin Brinkmann, Gerd H. Jakob, Paul Lilley, Mark M. Casali, Pierre-Yves Madec, Markus E. Kasper, European Southern Observatory (Germany)

Over the last decade, adaptive optics has become essential in different fields of research including medicine and industrial applications. With this new need, the market of deformable mirrors has expanded a lot allowing new technologies and actuation principles to be developed.

Several E-ELT instruments have identified the need for post focal deformable mirrors but with the increasing size of the telescopes the requirements for the deformable mirrors become more demanding. A simple scaling up of existing technologies from few hundred actuators to thousands of actuators will not be feasible or sufficient to satisfy the future needs of ESO. To bridge the gap between available deformable mirrors and the future needs for the E-ELT, ESO started a development programme for deformable mirror technologies. The requirements and the path to get the deformable mirrors for post focal adaptive optics systems for the E-ELT is presented.

9909-25, Session 7

A new driving method for piezo deformable mirrors: open loop control and MOAO made easy

Jean-Luc Gach, Lab. d'Astrophysique de Marseille (France) and First Light Imaging S.A.S. (France); Issa Ouattara, Philippe Amram, Lab. d'Astrophysique de Marseille (France)

Usually piezo actuator elements suffer from strong non linearities such as hysteresis. While in closed loop one can easily accomodate for these non linearities ,this becomes a very challenging issue in open loop control which is the case for MOAO applications like the MOSAIC instrument. Previous works were caried out to cancel this hysteresis with charge command instead of voltage command, but this command suffers from low bandwidth and creep (which is a long term deviation in the steady state). Others methods were tried with complex models or mathematical models. All these methods suffer from high complexity, low fidelity and are CPU-time consuming. Moreover they often need an accurate modelization of the piezo element and don't take into account piezo model dispersion, leading to innacurate open loop control.

We have developped a new type of amplifier name the hybrid amplifier which takes the advantages of the voltage command (high speed, no creep, steady state stability) and the advantages of the charge command (hysteresis cancellation). We've demonstrated the aibility to drive hygly non linear piezo elements with a quasi linear behaviour. Moreover this amplifier does not need any knowledge or model of the piezo non linearities, simply we need to know the piezo capacitance which is a very easy measurement.

Using this hybrid amplifier to drive open loop DMs in MOAO systems or other open loop AO systems will give a better accuracy in the wavefront reconstruction and a simpler drive strategy.

9909-122, Session PMon1

Analysis and comparison of the atmospheric parameters retrieved from a XAO instrument with the astro-climatic monitoring system

Juan Carlos Guerra Ramon, Julio Navarrete, European Southern Observatory (Chile); Jean-François Sauvage, Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, ONERA (France); Jose Javier Valenzuela, Angela Cortes, European Southern Observatory (Chile)

Paranal Observatory has a set of astro-climate monitoring instruments such as DIMM, MASS and SLODAR, which are delivering information about the sky quality in terms of seeing, coherence time, high altitude wind speed (200mb) and the vertical profiles of the refractive index structure constant (Cn2) to support the observations. SPHERE is an Extreme Adaptive Optics instrument that uses a Shack-Hartmann wavefront sensor with 40x40 sub-apertures running with a close loop frequency of 1.2KHz. The instrument saves close loop snapshots every minute, and from the data saved the system retrieves the r0 and the cross wind speed. The wind speed is calculated using a cross-correlation based on the peak identification. The knowledge of this parameter is essential to understand the performances of the Adaptive Optics (AO) system, and to optimize its

control laws every minutes. The data from the astroclimatic system monitor will help to correlate the turbulence events with the transverse wind speed retrieved from SPHERE close loop data. The goal of this work is also to compare the different atmospheric monitors with the effective turbulence estimation from the focal plane itself (Differential Tip-Tilt Sensor).

9909-123, Session PMon1

Forecasts of the atmospherical parameters close to the ground at the LBT site in the context of the ALTA project

Alessio Turchi, Elena Masciadri, Luca Fini, INAF - Osservatorio Astrofisico di Arcetri (Italy)

In this paper we study the abilities of an atmospherical mesoscale model in forecasting the classical atmospherical parameters relevant for astronomical applications at the surface layer (wind speed, wind direction, temperature, relative humidity) on the Large Binocular Telescope (LBT) site - Mount Graham, Arizona. The study is carried out in the framework of the ALTA project aiming at implementing an automated system for the forecasts of atmospherical parameters (Meso-Nh code) and the optical turbulence (Astro-Meso-NH code) for the service-mode operation of the LBT. The final goal of such an operational tool is to provide predictions with high time frequency of atmospheric and optical parameters for an optimized planning of the telescope operation (dome thermalization, wind-dependent dome orientation, observation planning based on predicted seeing, adaptive optics optimization, etc...). Numerical simulations are carried out with the MESO-NH and Astro-Meso-Nh codes, which were proven to give excellent results in previous studies focused on the two ESO sites of Cerro Paranal and Cerro Armazones (MOSE Project). In this paper we will focus our attention on the comparison of atmospherical parameters forescasted by the model close to the ground with measurements taken by the observatory instrumentations and stored in the LBT telemetry in order to validate the numerical predictions. As previously done for Cerro Paranal (Lascaux et al., 2015), we will also present an analysis of the model performances based on the method of the contingency tables, that allows us to provide complementary key information with the respect to the bias and RMSE (systematic and statistical errors), such as the percentage of correct detection and the probability to obtain a correct detection inside a defined interval of values.

9909-125, Session PMon1

Stereo-SCIDAR atmospheric turbulence profiling: turbulence variability

James Osborn, Timothy Butterley, Timothy J. Morris, Douglas Laidlaw, Saavidra Perera, Richard W. Wilson, Durham Univ. (United Kingdom)

Stereo-SCIDAR is a generalised SCIDAR instrument which is used to characterise the atmospheric optical turbulence in terms of Cn2 and wind velocity profile using triangulation between two stars. Stereo-SCIDAR has demonstrated the capability to resolve turbulent layers with the required vertical resolution to support wide-field ELT instrument designs. These high resolution atmospheric parameters are critical for design studies and statistical evaluation of on-sky performance under real conditions.

Stereo-SCIDAR differs from most other SCIDAR instruments in that, instead of overlapping pupil images on a single detector, the image of each star is recorded on a separate EMCCD. Separating the pupil images in this way leads to several advantages, including better signal to noise ratios, larger useable magnitude difference of the target stars and reliable automated wind velocity measurements. The data is analysed and made available to observatory systems in real-time.

Here we review the Stereo-SCIDAR technique and present recent results from the instrument on the Isaac Newton Telescope, La Palma. We report on automated layer by layer variability measurements. The high temporal and spatial resolution of the Stereo-SCIDAR makes it ideal for studying the variability of both the wind velocity and Cn2, key parameters for wide field Adaptive Optics instrument design and operation.

In addition, we are investigating how we can use atmospheric models generated from Global Forecast System data to cross-validate these profiles. These models can then be used to forecast the distribution of optical turbulence above the observatory.

9909-128, Session PMon1

A turbulence profile for the NST MCAO system

Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile); Dirk Schmidt, José Marino, National Solar Observatory (United States); Benoît Neichel, Lab. d'Astrophysique de Marseille (France)

Optical observations of the Sun with higher and higher angular resolution are required for in-depth understanding of the Sun's physics. While today's facility class adaptive optics systems can achieve diffraction limited imaging for 0.7 - 1.6 m telescopes for typical seeing conditions, the field of view that is improved by such systems is often too small to study spatially extended features and events in detail. Multi-conjugate adaptive optics (MCAO) promises to enlarge the corrected field of view and by using the AO data from their multiple wavefront sensors (WFS), the performance of such systems can be significantly improved.

We describe a new turbulence profiler for the MCAO system of the New Solar Telescope (NST) at Big Bear Solar Observatory. The NST MCAO system features three deformable mirrors (DM); two of them are dedicated to compensation of high-altitude turbulence, whereas the third corrects aberrations at the pupil. The opto-mechanical design allows for changing the conjugate plane of the two high-altitude DMs independently between two and nine kilometers. The system also has two correlating Shack-Hartmann WFS. A high-order, narrow-field sensor dedicated to the optical axis, and a low-order wide-field sensor. The wide-field sensor can be subdivided into several guide regions (multi-direction WFSs), allowing a turbulence profile reconstruction, that can be directly estimated from the slopes of the associated WFS (open loop mode) or via pseudo-open-loop slopes when working in closed loop. The profiler can then offer valuable information to adjust the position of the DMs and optimize the tomographic algorithms on-line. Using simulated data we evaluate the profiler for different configurations, i.e. number of guide regions, field of view and number and size of subapertures. Finally, we test the profiler using onsky data from open and closed loop operation that provide estimations for the complete set of turbulence parameters, i.e. Cn2, r0, ?0, wind profile and outer scale profile (L0(h)).

9909-129, Session PMon1

Towards an automatic system for monitoring of Cn2 and wind speed profiles with GeMS

Elena Masciadri, INAF - Osservatorio Astrofisico di Arcetri (Italy); Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile); Alessio Turchi, INAF - Osservatorio Astrofisico di Arcetri (Italy)

Wide Field Adaptive Optics (WFAO) systems represent the more sophisticated AO systems available today at large telescopes. One critical aspect for these WFAO systems in order to deliver an optimized performance is the knowledge of the vertical spatio-temporal distribution of the Cn2 and the wind speed.

Previous studies (Cortes et al., 2012) already proved the ability of GeMS (the Gemini Multi-Conjugated AO system) in retrieving CN2 and wind vertical stratification using the telemetry data. To assess the reliability of the GeMS wind speed estimates a preliminary study (Neichel et al., 2014) compared wind speed retrieved from GeMS with that obtained with the atmospherical model Meso-Nh on a small sample of nights. The latter technique is very reliable for the wind speed vertical stratification. The model outputs gave, indeed, an excellent agreement with a large sample of radiosoundings (~50) both in statistical terms and on individual flights (Masciadri et al., 2013).

Such a tool could therefore be used as a valuable reference in this exercise of cross calibrating GeMS on-sky wind estimates with model predictions.

The main results of Neichel et al. (2014) analysis showed that, on a great number of cases, GeMS could reconstruct very good wind speed estimates. At the same time it has been put in evidence, on a number cases, not negligible discrepancies from the atmospherical model. However we observed that these discrepancies strongly decreased or even disappear if the GeMS data reduction could be done with the ‘a priori’ knowledge of the wind speed stratification provided by the model Meso-Nh. The goal of this contribution is two-fold: (1) from one side to confirm conclusions achieved in Neichel et al. (2014) on a more solid statistical sample (data related to ~ 46 nights), (2) from the other side to evaluate the possibility to use, as an input for GeMS, the Meso-Nh estimates of the wind speed stratification in an operational configuration. These estimates can be provided many hours in advanced with respect to the observations and with a very high temporal frequency (order of 2 minutes or less). Such a system would have a set of advantages: (a) to implement inside GeMS a total temporal and spatial coverage of the wind speed over ~ 20 km and all along the night not only in real-time but in advance of a few hours, (b) to improve the detection of the Cn2 vertical stratification from GeMS because a good wind speed estimation would improve the quality of the cross-correlation peaks detection, (c) the possibility to bypass the complex (and not necessarily reliable) procedures necessary to automatize the wind speed estimate of GeMS due to the relatively low vertical resolution of the system.

Such a study can obviously be considered as a demonstrator for multiple operational AO and WFAO systems (AOF, LINC-NIRVANA, RAVEN, ...) of present top-class telescopes and for the forthcoming generation. It might have, therefore, an interest for the AO community well beyond the improvement of GeMS performance.

9909-134, Session PMon1

On-line estimation of atmospheric turbulence parameters and outer-scale profiling

Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile); Benoît Neichel, Carlos M. Correia, Lab. d’Astrophysique de Marseille (France); Timothy Butterley, James Osborn, Durham Univ. (United Kingdom); Elena Masciadri, INAF - Osservatorio Astrofisico di Arcetri (Italy); Thierry Fusco, Jean-François Sauvage, ONERA (France) and Lab. d’Astrophysique de Marseille (France)

Estimating the outer scale profile, L0(h), is a highly complex problem. However, its estimation in the context of current very large and future extremely large telescopes is crucial, as it impacts the on-line estimation of turbulence parameters (Cn2(h), r0, ?0 and ?0) and potentially the performance of Wide Field Adaptive Optics (WFAO) systems. In this paper we describe an on-line technique that estimates the outer scale profile using AO loop data available at the facility instruments. It constructs the cross-correlation functions of the slopes of two or more wavefront sensors, which are fitted to linear combinations of theoretical responses for individual layers having different altitudes and outer scale values.

We analyze some restrictions found in the estimation process, which are general to any measurement technique. The insensitivity of the instrument to large values of outer scale is one of them, as the telescope is blind to outer scales much larger than its diameter. Another problem are the contradictory requirements imposed on the length of data for a single estimation: on the one hand, long sequences of minutes or more are necessary to provide sufficient independent data for the method to converge. However, long sequences imply that the stationarity assumption of the turbulence can be broken (turbulence parameters may change during the time span). We propose a method to determine if a satisfactory balance has been achieved to this conflict.

Our method deals effectively with problems such as noise estimation, asymmetric correlation functions and wavefront propagation effects. It is shown that the latter cannot be considered negligible in some cases (e.g. high resolution AO systems, strong turbulence in the free atmosphere especially at high altitudes). The method is applied to the Gemini South MCAO system (GeMS) that comprises five wavefront sensors and two DMs conjugated at the ground and 9Km. Statistical values of turbulence parameters at Cerro Pachón from reduced data acquired with GeMS along three years are shown. Especially interesting are the results for outer scale profiles, L0(h) where some interesting resemblance to other independent results in the literature are shown.

9909-135, Session PMon1

A single detector stereo-SCIDAR for Mount Stromlo

Doris Grosse, Francis Bennet, Francois Rigaut, The Australian National Univ. (Australia)

Laser ranging measurements and satellite imaging are conducted by the ANU Research School of Astronomy and Astrophysics and EOS (Electro-Optic System) at Mount Stromlo as part of the Space Environment Management Cooperative Research Centre (SEMCRC) to support debris tracking and orbit prediction. Atmospheric turbulence lead to distortions in the measured data. Adaptive optics (AO) systems counteract those distortions and improve the resolution of the laser ranging measurements and satellite imaging systems.

To assist in the design of the Adaptive Optics Systems, we need to gather information on the atmosphere at Mount Stromlo: r0, tau0, and the turbulence Cn^2 profile, so that the turbulence at the mirror and dome, ground layer and the free atmosphere can be distinguished. The SCIntillation Detection And Ranging (SCIDAR) Technique is used to measure Cn^2. With this technique the scintillation of two stars is measured and their autocorrelation function is computed, providing a measurement of the turbulence profile. This technique usually uses one detector on which the two images of the stars are simultaneously recorded. However, the images overlap which leads to a loss of information and hence a reduction of resolution for the different height layers.

The introduction of Stereo-SCIDAR (Shepherd et al 2014) overcomes this issue by separating the two images and applying two separate image sensors. However, this increases the opto-mechanical, the opto-electronic components and the cost. We introduce a new Stereo-SCIDAR system separating the scintillations from the double star, but using only one single detector. This has been shown for a Low Layer SCIDAR (LOLAS) system with extremely wide double stars (200 arcsec). We investigate this technique by detecting the scintillation patterns of double stars with separation from 4 to 30 arcsec, allowing some flexibility in the altitude span and resolution achievable with the system, while retaining a simple optical set-up. We selected a state of the art 2048 x 2048 pixels, high dynamic range sCMOS camera as the beam imager. We show first, preliminary results of this system and investigate its feasibility for further development.

9909-138, Session PMon1

The statistics of atmospheric turbulence at Maunkea measured by RAVEN

Yoshito H. Ono, Tohoku Univ. (Japan); Oliver Lardière, David R. Andersen, NRC - Herzberg Astronomy & Astrophysics (Canada); Carlos M. Correia, Lab. d'Astrophysique de Marseille (Japan); Darryl Gamroth, Univ. of Victoria (Canada); Kathryn Jackson, California Institute of Technology (United States); Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile); Olivier Martin, Lab. d'Astrophysique de Marseille (France); Shin Oya, Subaru Telescope, National Astronomical Observatory of Japan (Japan); Masayuki Akiyama, Tohoku Univ. (Japan); Colin Bradley, Univ. of Victoria (Canada)

Atmospheric tomography in adaptive-optics (AO) is a technique to reconstruct the 3-dimensional structure of the atmospheric turbulence with measurements from multiple wave-front sensors (WFS) in wide-field AO.

The performance of such systems depends strongly on the accuracy of the tomographic reconstruction. The latter relies on prior statistical knowledge of the turbulence such as layer altitude and strength of turbulence layers. Moreover, the wind speed and direction at each altitude is also required for some advanced algorithms such as predictive control.

These atmospheric parameters can be estimated from measurements of multiple Shack-Hartmann wave-front sensors (SH-WFSs). In addition, the (often short) time-scales on which the frozen-flow assumption is valid can be quantified.

In this paper, we show the statistics of turbulence strength, layer altitudes, outer scale, and wind speeds and directions at Mauna Kea estimated from telemetry of multiple SH-WFSs of RAVEN, an on-sky multi-object AO demonstrator tested at the Subaru telescope. We detail how to use spatial- and temporal-correlations of slopes for parameter estimation. We provide statistics of the temporal evolution and distribution of atmospheric parameters as well as the temporal de-coherence of turbulence based on telemetry acquired in 2014 and 2015.

9909-139, Session PMon1

Segment phasing: comparing diverse wavefront sensors for the characterisation of a high contrast turbulent module

Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, Lab. d'Astrophysique de Marseille (France) and ONERA (France); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, Lab. d'Astrophysique de Marseille (France) and ONERA (France); Mamadou N'Diaye, Space Telescope Science Institute (United States); Kacem El Hadi, Lab. d'Astrophysique de Marseille (France)

Future high-contrast imagers on ground-based extremely large telescopes will have to deal with the segmentation of the primary mirrors. Residual phase errors coming from the phase steps at the edges of the segments will have to be minimized in order to each the highest possible wavefront correction and thus the best contrast performance. To study these effects, we have developed the MITHIC high-contrast test bed, which is designed to test various strategies for wavefront sensing, including the Zernike sensor for Extremely accurate measurements of Low-level Differential Aberrations (ZELDA) and COronagraphic Focal-plane wave-Front Estimation for Exoplanet detection (COFFEE). We recently equipped the bench with a new atmospheric turbulence simulation module that offers both static phase patterns representing segmented primary mirrors and continuous phase strips representing atmospheric turbulence filtered by an AO or an XAO system. We characterize the turbulence introduced by the model using different wavefront sensors, and we compare the results. We also show the first results obtained on the bench with the simulator, and we present future prospects that will be explored with MITHIC for segment phasing.

9909-141, Session PMon1

Vibrations in MagAO: resonance sources identification and first approaches for modeling and control

Javier Garcés, Sebastián Zúñiga Fernández, Univ. Técnica Federico Santa María (Chile); Laird M. Close, Jared R. Males, Katie M. Morzinski, The Univ. of Arizona (United States); Pedro Escárate, Mario A. Castro R., José Luis Marchioni Clavería, Diego A. Rojas Zagals, Univ. Técnica Federico Santa María (Chile)

The 6.5m Magellan Telescope Adaptive Optics System (MagAO), designed by the MagAO Team from the University of Arizona, is noticeable for being the first AO system in the southern hemisphere based on an adaptive secondary mirror, and the first AO system able to provide high quality diffraction-limited images (0.6 to 1.0 microns), reaching resolutions up to 20 [mas].

The system, however, is not exempt from additional factors which are able to reduce the acquired data's reliability. These factors include resonance effect from the telescope itself, as well as the effect of certain instrumentation elements: the primary mirror cell fans, the primary mirror cell glycol cooling pump, and the louvers, among others. It is of great interest to identify these perturbation sources, to be able to recognize precisely how the instrumentation elements are influencing the data captured by the sensors.

This research work has been conducted using closed-loop on-sky data taken during observing runs of the MagAO Team at the Clay Telescope in Las Campanas Observatory, in order to study (under different operation conditions) the frequency-based information taken by sensors of the MagAO system. Data is obtained from both the VisAO science camera and the waveform sensor's modal amplitudes.

For each data acquisition test, the status of the instrumentation elements is registered and normalized Power Spectral Densities (PSDs) from the sensors data are computed. From this data, we are able to observe the main peaks induced by vibration disturbances, and by comparing WFS PSDs (for tests held under different operation conditions), resonance frequencies caused by the system's elements are identified. Additionally, since the PSDs are normalized, the resonance influences can be measured through the calculation of root-integrated-power.

The spectral analysis of the sampled data allows an extension of the research work into obtaining mathematical models to describe the system. For this process, a standard AO loop scheme is used, modelling the system and its inherent resonances, and on the other hand, the effects induced by the instrumentation elements are included as perturbations to the system. Previous work has been made using autoregressive models to obtain a space-state model for the AO loop, evaluating separately the effects of vibrations on each mode (since tip/tilt modes are usually more affected by these effects).

The next step is to improve the system's performance by designing a control scheme for the proposed model. Previous work has been made studying the design of LQG control or frequency-based control for specific AO systems. A predictive control approach (MPC) is proposed, focusing on studying the limitations the AO system may induce for this control alternative, and obtaining comparable results in relation to a LQG approach.

9909-144, Session PMon1

AIR-FLOW: airborne interferometric recombiner, fluctuations of light at optical wavelengths

Olivier Lai, Gemini Observatory (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States) and Observatoire de la Côte d'Azur (France); Mark R. Chun, Institute for Astronomy (United States) and Univ. of Hawai'i (United States); Kanoa K. Withington, Canada-France-Hawaii Telescope (United States) and Pikotek LLC (United States)

The local turbulence is the only part of the seeing degradation that we can actively improve and reduce at the source. It is often a major contribution to the overall seeing and introduces effects that are highly localized and may be difficult to correct. For example, dome seeing is expected to be non-Kolmogorov, with a very small outer scale leading to a preponderance of high spatial frequencies. The first step in controlling the local seeing is to locate and quantify the turbulence present. This requires the development of a new type of sensor, specifically designed to sensitively measure local optical turbulence.

We propose to develop such a sensor, based on a simple Mach-Zender interferometer layout. Two parallel beams traveling through turbulence will incur optical path differences. By measuring the intensity variations in the linear part of the sine wave function of the interferogram, we can extract the variance of the phase and therefore an estimate of the local Fried parameter r0. The instrument is simple in design and can easily be swept though a volume or incorporated into operations, for example to control dome vents. This optical turbulence sensor will be useful to detect local sources of turbulence, which is the first step to improve the image quality due to localized seeing within the dome and the telescope. Eventually it could even be used to optimize the air flow inside the dome by actively controlling dome venting, the implementation of the deflectors or the temperature of telescope components, such as the telescope tube or the secondary mirror spiders.

9909-146, Session PMon1

Turbulence profiling for adaptive optics tomographic reconstructors

Douglas Laidlaw, James Osborn, Timothy J. Morris, Richard W. Wilson, Timothy Butterley, Andrew P. Reeves, Matthew J. Townson, Durham Univ. (United Kingdom); Éric Gendron, Fabrice Vidal, Carine Morel, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France) and Observatoire de Paris (France)

To compensate for random phase fluctuations in the Earth's atmosphere ground-based telescopes employ Adaptive Optics (AO) systems. For high resolution, wide-field astronomy, it is essential that AO systems are capable of tomographically reconstructing the wavefront across a wide scientific field of view. Accounting for the atmospheric turbulence profile is vital for achieving optimal system performance. The accuracy of the turbulence profile can directly impact the AO system performance and these errors are dependent on how the profile is calculated.

Used in conjunction, two wavefront sensors can utilise sufficiently luminous stars to geometrically triangulate the 'seeing' strength as a function of altitude, outlining the heights at which there are layers of considerable turbulence. This can be achieved by external profilers however as there are multiple wavefront sensors within an AO system it is possible to make this measurement internally. Here we show the capabilities of several methods by which the turbulence profile may be calculated from AO telemetry data taken from CANARY, an AO testbed on the 4.2m William Herschel Telescope, La Palma. Simulations, theoretical expectations and on-sky measurements are considered, with the accuracy of the detailed profile outlined at each of these steps.

We then compare profiles determined from this CANARY AO telemetry data to those obtained using two external turbulence profilers, using the SLOpe Detection And Ranging (SLODAR) and SCIntillation Detection And Ranging (SCIDAR) methods. The implications of each approach on the measured profile and tomographic error are presented.

9909-148, Session PMon1

Seeing and turbulence monitor for astronomy

Saavidra Perera, Richard W. Wilson, James Osborn, Timothy Butterley, Durham Univ. (United Kingdom)

Optical turbulence characterisation is crucial to understanding site and observational limitations. One widely used instrument for measuring the total integrated seeing is the Differential Image Motion Monitor (DIMM).

We have designed, and successfully tested, a low cost, portable variation on the DIMM design that utilises a low order Shack-Hartmann lenslet array instead of the standard two hole aperture mask, with readily available components. This alternative method gives a better noise estimation, maximises use of the telescope aperture and increases the signal to noise. In addition, the instrument aims to determine limited turbulence altitude information based on scintillation measurements. We will describe the instrument and present measurements from two identical DIMM instruments as well as simultaneous optical turbulence profile data recorded with Stereo-SCIDAR and SLODAR techniques at the Isaac Newton Telescope, La Palma.

9909-149, Session PMon1

Closed-Loop control for tip-tilt compensation on systems under vibrations

Mario A. Castro R., Pedro Escárate, Javier Garces, Sebastián Zúñiga Fernández, Diego A. Rojas Zagals, José Luis Marchioni Clavería, Univ. Técnica Federico Santa María (Chile); Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile)

Adaptive optics (AO) is a technology that allows the operation of modern astronomical instruments with high accuracy, mitigating wavefront distortions by reducing the deleterious effects produced by the Earth's atmosphere. This technology has been successfully implemented in almost all modern telescopes. AO has demonstrated to be good mitigating atmospheric distortion, therefore, other sources of aberration have become important, such as mechanical vibrations. This structural vibration can be caused by motors, fans, tracking errors or wind shaking the structure. There have been measurements of vibration in several telescopes, in order to identify and reduce these aberrations. For example, the MACAO system at GEMINI SOUTH presents tip-tilt vibration produced by cryo-coolers.

Various researchers have concentrated on the design of sophisticated control methods for mitigate the vibration using spectral analysis over wavefront sensor measurements of the lower aberration modes, determining frequencies and amplitude of these vibrations. These advanced control methods consists basically in the minimization of a criterion function like LQG control or Predictive Control and Kalman, H-2 and H-infinity optimal control. They demonstrate an improvement in vibration rejection compared with classical control methods.

In this research we show a laboratory demonstration of vibration rejection

of tip-tilt modes using closed-loop control, inducing vibration on the test bench via an eccentric motor with controllable frequency, in order to simulate the structural vibrations mentioned above. We measure the laser vibration and its tip-tilt aberration by checking the spot position when the laser impinges on a camera, and also with a Shack Hartmann Wave Front Sensor. The control action is carried out by a Fast Steering Mirror (FSM) controlled by a Data Acquisition System (DAQ).

Finally, we conclude discussing the technological limitations and possible improvements of the demonstration and its implementation on a telescope.

9909-153, Session PMon1

Vibrations in MagAO: frequency-based analysis of on-sky data, resonance sources identification, and future challenges in vibrations mitigation

Sebastián Zúñiga Fernández, Javier Garcés, Univ. Técnica Federico Santa María (Chile); Laird M. Close, Jared R. Males, Katie M. Morzinski, The Univ. of Arizona (United States); Pedro Escárate, Diego A. Rojas Zagals, Mario A. Castro R., José Luis Marchioni Clavería, Univ. Técnica Federico Santa María (Chile)

Adaptive optics (AO) is a technology that compensates in real-time optical aberrations caused by atmospheric turbulence. Nowadays most of the large telescopes use this technology, one of these system is MagAO the 6.5m Magellan adaptive optics system. MagAO is the first adaptive secondary mirror based (ASM-based) AO system in the southern hemisphere, providing great diffraction-limited visible (0.6 - 1.0 micron) images down to 20 [mas]. These are the highest resolution filled aperture images ever made by a telescope from the ground or space. Despite these significant advances, other sources of perturbations still degrade the image quality, one of the most relevant are mechanical vibrations. Analysis of tip-tilt on-sky data is necessary in order to recognize the strongest vibrations components. Vibration peaks can be detected, power spectral densities (PSDs) are presented to reveal their presence. The main idea is to obtain information about the source of the vibrations and how this element(s) affect the tip and tilt modal amplitudes.

Instrumentation resonance and windshake noise is prejudicial for the performance of telescopes' adaptive optics systems. Thus, it is useful to analyze how the system's instrumentation is affecting the measured data. For this research, on-sky data taken with the MagAO system on October 31st, 2014 (FWHM of ~0.8 [arcsec], mean wind speed of 22 m.p.h.) at the Clay Telescope in LCO is analyzed and compared with data registered on April 17th, 2014. During this observing run, the system's elements, such as fans and pumps, are activated or deactivated in different configurations, collecting data from both the VisAO science camera and the waveform sensor (WFS). Power spectral densities (PSDs) of recorded data are obtained and influences of the system's elements on sensors' frequency response are identified.

The vibrations should be mitigated thanks to mechanical actions, but is highly desirable to develop new methods for measuring vibration in real time and also incorporate appropriate controllers in the adaptive optics systems in order to compensate this disturbance. Instrumentation-induced resonances, close-loop gain and future challenges in vibrations mitigation techniques are discussed.

9909-156, Session PMon1

The bistatic geometry for Na LGS profiling: results at Teide Observatory

Julio A. Castro-Almazán, Jesús J. Fuensalida, Angel Alonso-Sánchez, Instituto de Astrofísica de Canarias (Spain); Domenico Bonaccini Calia, European Southern Observatory (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Iciar Montilla Garcia, Marcos Reyes Garcia-Talavera, Instituto de Astrofísica de Canarias (Spain)

Here we are presenting the first results of Na Laser Guide Star (LGS) profiling in real time for the ESO-IAC LGS experiment at Teide Observatory (OT). In previous works, we have pointed out the importance of the bistatic configuration for mesosphere Na LGS profiling, while routinely operating in AO systems. The bistatic configuration is one possible solution. The configuration used in the experiment involved the ESO compact and transportable Wendelstein LGS Unit (WLGSU) and a secondary observing telescope (IAC80) with a baseline of 126 m, allowing real time monitoring of the LGS elongation and the relative Na distribution in the profile. Large telescopes might require real-time data of the Na layer as an input for the Wave Front (WF) reconstruction for AO. Therefore, these results are useful for a realistic modeling of the WF sensor (WFS) response working with LGS, especially in ELTs, in which the spot elongation is large. In this work, we also describe the geometry and observing strategies for the bistatic, non sidereal profiling of LGSs.

9909-157, Session PMon1

Simulations on accelerometer-based feedforward vibration suppression in an adaptive optics system for MICADO

Martin Glück, Univ. Stuttgart (Germany); Jörg-Uwe Pott, Max-Planck-Institut für Astronomie (Germany); Oliver Sawodny, Univ. Stuttgart (Germany)

In order to achieve diffraction-limited resolution of the near infrared camera MICADO disturbance effects such as atmospheric turbulences and wind induced vibrations at the telescope mirrors have to be compensated. These effects are compensated by the adaptive optics system using the adaptive mirrors M4 (deformable Mirror) and M5 (Tip-Tilt mirror) of the E-ELT. In MICADO a single conjugated adaptive optics (SCAO) system is used for the first light. Later it will combined with MAORY to an multi conjugated adaptive optics (MCAO) system.

The SCAO system uses the adaptive mirrors of the E-ELT and an additional wavefront sensor.

In the recent years, it was asserted that on large telescopes high frequent vibrations (5 Hz - 50 Hz) disturb the optical path. The common AO proportional integral (PI) controller was not able to completely compensate these vibrations. Hence a model based feedback controller (for example the linear quadratic gaussian controller (LQG)) was developed, which allowed a compensation for high frequency vibrations. However, for faint guide stars there is still a problem. The exposure time of the wavefront sensor is increased in order to achieve a larger signal to noise ratio. The consequence of a larger exposure time is a reduced bandwidth of the AO loop (Nyquist-Shannon sampling theorem). In that special case the feedback controller reaches its limits.

Therefore we developed a vibration suppression concept which is independent of the exposure time and is combined with the AO loop. The vibrations are measured by additional accelerometers at the telescope mirrors.

The vibrations are in particular visible in the tip-tilt Zernike modes. Therefore, the tip-tilt displacement of the telescope mirrors are reconstructed from the accelerometer data. The reconstruction is a challenge because of the small acceleration amplitudes and the sensor noise. The amplitudes are added to the control signal of the AO loop which is sent to the adaptive mirrors.

In order to evaluate the concept an AO end-to-end simulation was created including vibrational effects.

The simulation was verified based on measurements data of the first light camera of the large binocular telescope (LBT). We investigated the influence of vibrations on the strehl ratio of AO systems by using different vibration amplitudes, exposure time and magnitudes. Within these investigations, we discussed the use of an accelerometer-based feedforward vibration suppression system on the strehl ratio for faint guide stars. Subsequently an adaptive optics laboratory system was built to show the influence of a feedforward controller in a real environment. First results indicate that for typical high frequent telescope vibration amplitudes and frequencies, our accelerometer-based feedforward controller can fully compensate for the slow feedback control locking on a faint guide star smaller than 13 mag (R-Band). This operation mode will be of particular importance for extragalactic observations, where bright guide stars are rare.

9909-159, Session PMon1

Measuring vertical profiles of turbulence strength, outer scale, and frozen flow using simultaneous SCIDAR and SLODAR

Timothy Butterley, James Osborn, Richard W. Wilson, Durham Univ. (United Kingdom)

Scintillation detection and ranging (SCIDAR) and slope detection and ranging (SLODAR) are triangulation techniques for optical turbulence profiling. Both techniques involve fitting turbulence profiles to spatial covariances - pupil intensity covariances in the case of SCIDAR and wavefront slope covariances for SLODAR. The two techniques have different strengths and weakness. In general SCIDAR offers higher vertical resolution and is better suited than SLODAR to measuring the translational velocity of turbulent layers as a function of altitude. The SLODAR technique can often be applied using wavefront sensor data from an existing adaptive optics (AO) system and is more sensitive to outer scale effects than SCIDAR.

We describe a dual SCIDAR-SLODAR instrument that implements both techniques simultaneously on the 2.5-metre Isaac Newton Telescope on La Palma. We explore how a combined analysis of the data from the two methods can be used to compensate for the techniques' invidivual weaknesses. In particular we consider how non-Taylor flow and the outer scale affect the two techniques and how a combined analysis can help to make better-constrained measurements of these parameters.

9909-163, Session PMon1

Turbulence profiling using the MOAO pathfinder CANARY on-sky data

Olivier Martin, Éric Gendron, Observatoire de Paris à Meudon (France); Timothy J. Morris, Durham Univ. (United Kingdom); Fabrice Vidal, Observatoire de Paris à Meudon (France); Alastair G. Basden, Durham Univ. (United Kingdom); Yoshito H. Ono, Tohoku Univ. (Japan); Carlos M. Correia, Benoît Neichel, Thierry Fusco, Lab. d'Astrophysique de Marseille (France); Gérard Rousset, Observatoire de Paris à Meudon (France); Richard M. Myers, Durham Univ. (United Kingdom)

CANARY is the Multi-Object Adaptive Optics (MOAO) pathfinder for the future MOAO-assisted integral-field spectrograph proposed for the E-ELT. From 2010, the LESIA and Durham teams have acquired a very large amount of on-sky data, from both Natural and Laser Guide Stars (NGS,LGS) WaveFront Sensor (WFS) measurements.

The DMs are driven using a tomographic reconstruction of the on-axis turbulence based on off-axis measurements, which requires the computation of covariance matrices Cn2(h) and L0(h)- dependant. The turbulence spatial properties must thus be retrieved to perform the turbulence compensation. Moreover, the knowledge of the wind speed profile is also required for LQG command ([Sivo., 2014]) and data analysis.

We propose an overview of these home-made techniques developed to achieve this turbulence characterization based on the Learn & Apply algorithm. Thanks to a model of the WFS measurements spatial covariance, we are able to fit the turbulence and outer scale profiles, as parameters, to get the best matching between this model and the empirical covariance matrix.

About the wind speed, we work on the spatio-temporal cross-correlation of each WFS data and consider, using the Taylor hypothesis, that this cross-covariance map for a given delay can be fitted by a modeled spatial covariance map corresponding to some particular pupil shift. Using this retrieved shift and set temporal delay, we deduce the wind speed and direction.

We finally propose a statistical overview of these relevant parameters of the turbulence based on thousands data sets acquired on-sky using CANARY.

9909-165, Session PMon1

A new method for high fidelity sodium profiling

Damien Gratadour, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); James Osborn, Durham Univ. (United Kingdom)

The elongation and variability of Laser Guide Stars (LGS) created in the mesosphere are marginally known and not a limiting phenomena for the largest telescopes currently in operation. Nevertheless, across the E-ELT pupil, this elongation takes such proportions that it can significantly impact the quality of the turbulence measurements. Wavefront sensing on Laser guide stars with extreme elongation is a major area of research to overcome a critical technological issue for the commissioning of the E-ELT and the optimization of the scientific return from its instrumentation. A previous analytical and numerical study demonstrated that the impact of these effects could be minimized using dedicated numerical strategies both when processing the WFS data and for wavefront reconstruction. From this study it appears that an accurate knowledge of the Sodium layer profile is required to avoid biased estimates of the WF slopes, whatever the centroiding method.

We propose a new method to estimate the Sodium layer profile from images obtained with a dedicated profiler. This method is similar to image deconvolution and is based on the minimization of a maximum likelihood criterion with respect to the profile function and the position and brightness of possible background stars. In this paper, we first derive an image model as a function of the laser beam function, the turbulent PSF at the focus of the profiler, the Sodium profile and additional background stars modeled as point sources at given positions and with given brightness and express the maximum likelihood criterion from this model based on the noise model in the image. We introduce an appropriate regularization term on the profile to ease minimization and lower the impact of noise and some a priori on stars positions and brightness (from catalogs and / or previous images from the profiler and based on the tracking model). We also discuss implementation related issues and a possible optimization based on the use of GPUs to reach almost real-time performance. We finally discuss the performance of the method, in particular in the context of the elongated LGS experiment that will conducted during phase D of the CANARY project.

9909-168, Session PMon1

Atmospheric turbulence profiling using the SLODAR technique with ARGOS at LBT

Tommaso Mazzoni, Lorenzo Busoni, Marco Bonaglia, Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy)

ARGOS is the Ground Layer Adaptive Optics system of the Large Binocular Telescope, it uses three Laser Guide Stars, generated by Rayleigh backscattered light of pulsed lasers. Three Shack-Hartmann WFS measure the wavefront distortion in the Ground Layer.

The SLOpe Detection And Ranging (SLODAR) is a method used to measure the turbulence profiles. Cross correlation of wavefronts gradient from multiple stars is used to estimate the relative strengths of turbulent layers at different altitudes. We present here the results on sky of the SLODAR profile on ARGOS and the results of the wind profile.

9909-169, Session PMon1

The study of variability of the atmospheric turbulence in the region Lake Baykal

Vladimir P. Lukin, Evgeny A. Kopylov, V.E. Zuev Institute of Atmospheric Optics (Russian Federation); Pavel G. Kovadlo, Artem Y. Shihovtsev, Institute of Solar-Terrestrial Physics (Russian Federation)

It is known that the angular resolution of ground-based telescopes is limited by the influence of atmospheric turbulence. Increasing its parameter for solar and stellar telescopes is important problem of modern observational astronomy. Presented results allow to choose the levels for multi-mirrors adaptive optical (AO) systems, and to estimate the parameters of the classic AO-system.

The results of astroclimatic conditions research at the Sayan Solar Observatory (SSO) site and at the Baikal Astrophysical Observatory (BAO) site are shown in this article. Vertical distributions of temperature fluctuations are obtained using NCEP/NCAR Reanalysis data as well as atmospheric layers with high turbulisation are identified. To determine the heights of atmospheric layers with high air turbulence for BAO on the archive data of NCEP/NCAR Reanalysis data were estimated vertical profiles of values of dispersion fluctuations in air temperature. Dispersion pulsations of air temperature was estimated for frequencies corresponding to the natural synoptic period (5 – 7 days). We are presented over the period from 1984 to 2014 vertical averaged profiles of the variance of temperature pulsations of air for night and daytime, respectively.

In the daytime the intensity of the pulsations of temperature becomes higher than at night. For comparison we also analyzed vertical profiles of the variance of temperature, are presented too. The variance of temperature pulsations were evaluated according to the archive of NCEP/NCAR Reanalysis data available on each isobaric level at the location of the BAO during the same observation period. At the location of the BAO is the most turbulized layers are also located on the heights of 3 and 12 km altitude location BAO these layers correspond to the altitude of about 2.5 km and 11.5 km.

Evaluation of the Fried parameter from simultaneous optical and meteorological observations pent the period on March 2015 at average air temperature of -9*C. and average wind speed 2.2 m/s. Our data shows the probabilistic likelihood of the frequency of occurrence of values of the structural characteristics of the pulsations of the refractive index held between on March month 2015 at medium temperature. The values of the structural characteristics of the refractive index of air correspond to previously measured winter. The difference of values of meteorological observations over optical due to the location of the weather station in close proximity to the telescope.

The average values of the radius of the atmospheric coherence estimated from methods based on the spectral characteristics of atmospheric turbulence in a wide range of scales – 4.6 cm. Obtained atmospheric coherence is close to the observed or estimated values from other techniques.

A project is financially supported by the Russian Science Foundation grant ?15-19-20013.

9909-171, Session PMon1

A sensitive new instrument for atmospheric turbulence studies

Mohammed Sabil, Abdelfettah Habib, Zouhair Benkhaldoun, Youssef El Azhari, Univ. Cadi Ayyad (Morocco)

Using a numerical simulation, a new approach to determine the wave structure function and therefore the astronomical seeing, is presented and discussed. This method is based on the study of the diffraction pattern produced by a double-slit at the focus plane of a telescope. The phase screens are simulated by using the FFT based method and Kolmogorov's law about atmospheric turbulence. From the scattered wave intensity, the wave structure function is calculated by taking into account both phase and amplitude fluctuations.

This means that we can obtain a seeing value which is independent of the propagation distance between the turbulent layers and the ground level (Fresnel diffraction effect).

A mask with a double slit, which size is of the order of few centimeters, allows us to obtain a diffraction pattern in the focus plane of the telescope. Fluctuations in phase and amplitude of the complex field generate fluctuations in the diffracted intensity from which the wave structure function is deduced.

Comparison between the theoretical seeing, used to generate the phase screen, and the retrieved seeing showed the validity of this method. That comparison was done in the usual range of the seeing (0.2 -- 3 arcsec) and the altitude (0--20 km). In bad seeing conditions ($>$ 2 arcsec) we found that this approach over-estimates the seeing but the relative error remains within 10 per cent.

A measurement campaign is being held in order to compare the seeing measured with this approach and that measured by a DIMM.

9909-121, Session PMon2

Imaging exoplanets with TMT: from characterizing young jovians with NFIRAOS/IRIS to imaging rocky planets at 10 microns

Christian Marois, NRC-Dominion Astrophysical Observatory (Canada); Spencer Bialek, Univ. of Victoria (Canada)

The potential for 30m class telescopes is enormous, given the smaller inner working angle and D^4 advantage, opening a vast array of new science capabilities. I will discuss work-in-progress to develop a high-contrast imaging module for NFIRAOS and IRIS to allow first-light detailed characterization of known young gas giant planets. The ExAO coronagraphic system will pioneer a new “super-Nyquist” wavefront AO control scheme to achieve high-SNR detections of planet, even if they are located outside the central “dark hole”. New science capabilities

will include R-5000 J- to K-band spectroscopy with IRIS, the ability of high-SNR time-dependent spectroscopic/photometric analysis, and fiber-fed spectroscopy for the brightest planets to reach "extreme" spectral resolution. The much higher spectral resolution will enable a vast array of new science observations to be performed, including radial velocity to search for large moons, and Doppler imaging.

In addition, I will also review the TMT 10 microns rocky planet science case, and the remarkable potential of an ExAO would have operating at this wavelength. I will present the various challenges involved in designing such an instrument and the various possible solutions that we are planning to test in the coming few years.

9909-124, Session PMon2

A preliminary study for a visible MCAO system at VLT-AOF

Simone Esposito, Paolo Spanò, INAF - Osservatorio Astrofisico di Arcetri (Italy); Thierry Fusco, ONERA (France); Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Guido Agapito, Lorenzo Busoni, Alfio T. Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Jean-Luc Gach, First Light Imaging S.A.S. (France)

In this paper we present numerical simulations and an initial design for a visible MCAO system for the VLT-UT4 telescope. The proposed concept takes great advantage of the existing HW developed for the Adaptive Optics Facility (AOF) at the VLT-UT4, in particular the 4x20W Toptica lasers and the adaptive secondary mirror with 1170 actuators. The mentioned units makes the VLT-AOF a unique facility to develop a second generation AO system aiming to provide corrected FoV at short wavelength. In particular the flux provided by the four lasers steerable on sky and the high density of actuators (20cm equivalent on M1) provides the temporal bandwidth and the spatial sampling to push the correction down to the visible wavelengths. In addition to this the request of a reasonable size corrected FoV with uniform performance calls for an MCAO system. For such reason here we propose to complement the AOF with post-focal DMs that together with the VLT DSM can provide a corrected FoV of roughly 20/30 arcsec diameter size. An additional challenge for the system is the provided a large sky coverage. Such condition comes from the efficiency of LO wavefront sensors that use field NGS. The presented simulations give some first results for (a) the achieved performance at visible wavelength 0.4-0.9 um as a function of DMs and tip tilt NGSs characteristics (b) the achieved system sky coverage after. Pushing performance toward visible wavelengths calls for embedded and efficient post-processing methods. Being able to capture short-exposure science images (with the trade-off on noise and overheads), would allow retrieving the ultimate performance by compensating the residual turbulence aberrations left over by the AO system. Considerations about advanced analysis tools that may potentially relax the system constraints are discussed. Finally the paper presents a conceptual arrangement for the opto-mechanics of the considered AO module including the additional DMs and wavefront sensors.

9909-126, Session PMon2

SOUL: the single conjugated adaptive optics upgrade for LBT

Enrico Pinna, Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Philip M. Hinz, The Univ. of Arizona (United States); Guido Agapito, Marco Bonaglia, Luca Carbonaro, Alfio T. Puglisi, Marco Xompero, Armando Riccardi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Oscar Montoya, Olivier Durney, The Univ. of Arizona (United States)

We present here SOUL: the Single conjugated adaptive Optics Upgrade for LBT. Currently, there are 4 SCAO systems operating at LBT, all composed by an Adaptive Secondary Mirror (672 actuators) and a Pyramid Wavefront Sensor (30x30 sub-apertures). Two of these SCAO systems feed the interferometric focal stations of LBTI, while the remaining two provide the correction for the two LUCI spectro-imagers. Starting the on-sky operations in 2010, these systems provided the first high contrast images ever on 8m-class telescopes in the NIR. The use of state-of-the art devices is critical for the AO performances and, after about 10 years from the LBT SCAO design, the technological development made significant steps forward, especially in the visible detector field. SOUL will upgrade the two main AO system components: the wavefront sensor and the adaptive secondary. Replacing the current wavefront sensor CCD with an Electron Multiplied CCD, we will provide: a faster read out and framerate (2kHz instead of 1kHz) at lower noise (< 1e- instead of ? 10e-) for better rejection of disturbances, and a higher spatial sampling (40 instead of 30 sub-apertures on the pupil diameter) for improved reduction of aliasing error. The firmware of the adaptive secondary mirror will be upgraded allowing the full AO loop running at 2kHz and dealing with the increased number of sub-apertures.

Here we present the results of the preliminary design study of the SOUL project. This includes the error budget analysis, the design for the implementation of the new WFS camera, the adaptive secondary firmware upgrade and the end-to-end numerical simulations for the performance estimation. The simulations show that the higher spatial sampling and system frame rate allow correcting more modes with a larger control bandwidth, increasing so the Strehl Ratio (SR) in the case of bright guide stars and enabling operations at shorter wavelengths. The gain in magnitude (for a given SR) offered by SOUL is estimated to be around 1.5-2 magnitudes at all wavelengths in almost all the range of reference star brightness (7.5 < mR < 18). The gain in reference star magnitude implies a significant improvement of the sky-coverage that is currently the main limitations of the SCAO systems working with natural guide stars. SOUL will increase the sky coverage of the current systems up to a factor 10 at all wavelengths from R to M.

Upgrading all the 4 SCAO focal stations, SOUL will provide this benefit to the 2 LUCI NIR spectro-imagers, the LBTI interferometer and to the upcoming new generation instruments as the 2 SHARK IR and visible high resolution imagers and the planet-finding spectrometer iLocater. Moreover, it represents the first step toward the visible interferometry as proposed in the Live project.

9909-130, Session PMon2

Using tomographic AO for scintillation compensation in high-precision photometry of exoplanet transits

James Osborn, Timothy J. Morris, Durham Univ. (United Kingdom); Vik Dhillon, The Univ. of Sheffield (United Kingdom); Richard W. Wilson, Durham Univ. (United Kingdom)

As an exoplanet passes in front of its host star it blocks some of the light. This reduction in intensity is observable by telescopes and is used to deduce the presence of a planet orbiting a distant star and a wealth of information about it.

Transit photometry is a powerful technique for extrasolar planet detection and characterisation. By performing time-resolved photometry of exoplanet transits simultaneously in a number of different wavelength bands, it is possible to derive information about the temperature distribution, dynamics and composition of the exoplanet's atmosphere.

The difficulty with such observations is that although the targets are bright, the variation one needs to detect is very small (typically ?1%, ?0.1% and ?0.01% for Jupiter, Neptune and Earth sized planets respectively,

around a sun-like star). Although this is within the capabilities of modern detectors, when the light from the star passes through the Earth's atmosphere regions of turbulence cause intensity fluctuations (seen as twinkling by the naked eye), called scintillation.

Scintillation noise due to the Earth's turbulent atmosphere can be a dominant noise source in high-precision astronomical photometry when observing bright targets from the ground. Accurate knowledge of scintillation noise is important to enable performance assessment, calibration and optimisation of photometric instrumentation. It is also useful when fitting models to photometric data, for example, extrasolar planet eclipse light curves, and to help develop scintillation correction concepts.

Adaptive Optics (AO) is a mature technology which can be used to correct for the blurring of astronomical images by the Earth's atmosphere, however no adaptive technique currently exists for scintillation.

Conjugate Plane Photometry attempts to reduce scintillation noise from a single turbulent layer by a combination of pupil reconjugation and apodisation. This system is non-adaptive and is limited in the situations in which it will perform.

Here we describe an adaptive scintillation correction technique using a tomographic Adaptive Optics system to make a 3D model of the turbulent atmosphere and hence correct the intensity variations caused by all turbulent layers.

This technique, in combination with the large apertures of ground based telescopes, make them an ideal facility for very high-precision photometry, enhancing sensitivity for the detection and characterisation of extrasolar planets. Therefore, AO with scintillation correction could be competitive with the precision of space-based measurements and the larger collecting areas will enable fainter targets to be observed and higher spectral and time resolution photometry.

9909-131, Session PMon2

Utilizing simultaneous pupil plane and focal plane telemetry for exoplanet imaging

Richard A. Frazin, Univ. of Michigan (United States)

The coming generation of ELTs has the potential to provide unprecedented imaging and spectroscopy of exo-planetary systems, if the difficulties in achieving the extremely high dynamic range required to differentiate the planetary signal from the star can be overcome to a sufficient degree.

Fully utilizing the potential of ELTs for exoplanet imaging will likely require simultaneous and self-consistent determination both the planetary image and the unknown aberrations in multiple planes of the optical system, using statistical inference based on the wavefront sensor and science camera data streams.

It is demonstrated at a theoretical level that simultaneous millisecond telemetry has the potential to surpass current speckle suppression techniques such as ADI, SDI and electric field conjugation methods.

Simulations show that these methods can also effectively reduce the inner working angle, which is a critical parameter for the success of exoplanet searches.

9909-136, Session PMon2

Experimental results on using artificial neural networks for accurate centroiding in Shack-Hartmann wavefront sensors with elongated spots

Christian Dani Guzmán, Pontificia Univ. Católica de Chile (Chile); Alexandre T. Mello, Univ. Tecnológica Federal do Paraná (Brazil)

The use of adaptive optics in extremely large telescopes brings new challenges, one of which is the treatment of images from Shack–Hartmann wavefront sensors. When using this type of sensor in conjunction with laser guide stars to sample the pupils of telescopes with diameters of more than 30 m, it is necessary to compute the centroid of elongated spots, whose elongation angle and aspect ratio are changing across the telescope pupil. Existing techniques, such as the matched filter, have been considered as the best ways to compute the centroid of elongated spots, but these are not good at coping with the effect of a variation in the sodium profile. In a 2014 MNRAS article, we introduced a new technique for centroiding using artificial neural networks. This technique takes advantage of the neural network's ability to cope with changing conditions and can outperform existing algorithms. We developed comprehensive simulations to explore this technique and compare it with existing methods. For this paper, we implemented a laboratory setup to produce the spot elongation, emulating a changing Sodium profile as well as using a phase screen to generate turbulence. We compared the same techniques as in our original paper, confirming that artificial neural networks are an alternative for accurate centroiding, with similar complexity when compared to matched filter, in terms of computing capacity.

9909-137, Session PMon2

SRAO: the first southern robotic AO system

Carl Ziegler, Nicholas M. Law, The Univ. of North Carolina at Chapel Hill (United States)

The in-development SRAO will be the first Southern Robotic AO system, capable of confirming and characterizing planet candidates produced by major new transit surveys. SRAO is a moderate-order natural guide star AO system with an innovative photon-counting wavefront sensor, allowing guiding on faint stars with the 4.1m SOAR telescope. The system will deliver diffraction-limited imaging in the NIR on targets as faint as mV=16. With the proven robotic AO software developed for Robo-AO, SRAO will be capable of observing overheads on sub-minute scales, allowing at least 200 observations per night. SRAO will attain three times the angular resolution of the Palomar Robo-AO system, and with its NIR camera will attain much higher sensitivity to faint companions. In addition to exoplanet science, SRAO will compliment Robo-AO in a full-sky, stellar neighborhood multiplicity census. SRAO will also perform follow-ups to transient events discovered in large-sky-area surveys, such as stellar merger events and supernovae.

9909-140, Session PMon2

Dynamic modeling and analysis of adaptive optics system for CGST

Yichun Dai, Zhenyu Jin, Yunnan Observatories (China)

Chinese Giant Solar Telescope (CGST) is the next generation infrared and optical solar telescope of China, which is proposed and pushed by the solar astronomy community of China and listed into the National Plans of Major Science and Technology Infrastructures. CGST is currently proposed to be an 8 meter Ring Solar Telescope (RST) with width of 1 meter, the hollow and symmetric structure of such an annular aperture facilitates the thermo control and high precision magnetic field measurement for a solar telescope. RST has collecting area of 22 square meters, which equals to a 5 meter full aperture telescope, but its spatial resolution is 8 meter, thus it can observe the fine structure in near infrared bands as DKIST and EST do in visible bands, therefore it can relieve the stringent requirement of control systems, such as active control and adaptive optics (AO). AO is an indispensable tool of CGST to obtain diffraction limited observations. For RST, how to realize AO involved wavefront sensing and correcting, and the degree of compensating in a narrow ring aperture is the primary problem of AO implementation of CGST. Consequently, we investigate the whole dynamic wavefront reconstruction and control process based on Shack-Hartmann measurement in RST by an end to end modeling. Performances of AO in RST with different geometry of subaperture, measurement noise level and control bandwidth are simulated and analyzed. Error propagation of wavefront reconstruction is paid particular attention to, for there is a potential risk that the error propagation in an annular aperture is larger than that in a full aperture, which probably has the fatal effect on reconstruction precision. The results show that RST can realize diffraction-limited imaging in wavelength of 1 micrometer with the aid of AO system, which meets the demand of most science cases of CGST in near infrared waveband.

9909-142, Session PMon2

Adaptive optics for high-resolution spectroscopy

Uriel Conod, Univ. de Genève (Switzerland)

So far, High Resolution Spectrographs (HRSs) work in seeing limited-mode, i.e. the size of the slit/fiber projected to the sky is equal to the seeing (order of the arcsec). The linear size of the instruments is directly proportional to the entrance slit, while the cost of the instrument scales like D^2. In addition, his stability and his feasibility are also affected (for the grating element especially). Several paths are explored nowadays to mitigate this issue, that will increase with future ELTs instruments. One of them is to use an Adaptive Optics system to reduce the beam etendue, i.e. the size of such HRSs, without loosing in light collection capacity.

Except few attempts to couple light into single-mode fiber-fed HRSs, AO systems have been used and optimized for high angular resolution and high contrast imaging. The classical way to characterize their efficiency, the so called Strehl Ratio (SR), therefore not the most appropriate figure of merit for an instrument aiming at sensitive spectroscopy on faint targets.

In this work, we focus on the Encircled Energy (EE) to characterize the efficiency and design an AO system feeding an HRSs. We derive global parameters aiming at finding the best compromise between sensitivity and EE. We then present the preliminary design of the foreseen AO injection module of the future spectrograph NIRPS (Near Infra-Red Planet Searcher) for the 3.6m-ESO telescope at La Silla Observatory. The requirements to reach by this module are in one hand defined by the magnitude of the natural guide star, 12 in the I band in order to follow the brightest M-type stars of the TESS satellite candidates. And the other hand by the fact that NIRPS + HARPS can operated simultaneously which limits the wave-front sensor spectral range to the gap between NIRPS and HARPS: 0.7-0.9 micron. According to theses parameters, a deformable mirror of 14x14 actuators and a wave-front sensor Shack-Hartmann (SH) with 14x14 subapertures can reduce the diameter of the EE=50% to 0.3" (FOV) for all the NIRPS spectral domain. The optimal frequency of the control loop depends on the star magnitude, for faint stars (I>10) the system can operate at 250Hz and for bright stars at 500 Hz in order to maximize the EE.

A relatively simple AO module can reduce the size of the entrance slit by a factor 3 with the same collection capacity than a spectrograph working in seeing limited-mode.

Development of a novel three-dimensional deformable mirror with removable influence functions for high precision wavefront correction in adaptive optics system

Huang Lei, The Univ. of Arizona (United States) and Tsinghua Univ. (China); Chenlu Zhou, Tsinghua Univ. (China)

Deformable mirror is a widely used wavefront corrector in adaptive optics system, especially in astronomical, image and laser optics. Conventional DM has position-fixed actuators and corrects different aberrations with same actuator arrangement. In this paper, a new structure of DM is proposed, which has removable actuators and can correct different aberrations with different actuator arrangements. Compared to the one-dimensional motion of actuators in conventional DM, the new structure DM's have two more movement dimensions, so it can be named 3D DM. A 3D DM consists of several reflection mirrors, and every mirror has a single actuator and is independent of each other. Beam to be corrected reflected by these DM units in turn, and the aberration can be corrected with every DM units work together. The position of each DM units is changeable, so the system can be equivalent to a DM with removable influence function. Without consideration of the interval distance, more actuators can be achieved in 3D DM than conventional DM in a specific size, making a better correction result. In addition, as actuators' positions are removable, a specific aberration can be corrected more effectively with an appropriate influence function arrangement. Correspondingly, two kinds of actuator arrangement algorithm are proposed to calculate the proper actuator arrangement, which named random disturbance algorithm (RDA) and global arrangement algorithm (GAA). In RDA, each actuator has a small displacement from its original position, and it is restricted to a specific area near the original position. In GAA, actuators can move everywhere freely and influence functions can be at arbitrary position of the cross section of beam. In this paper, correction effects of these two algorithms are analyzed through numerical simulation. And there is also a comparison between the two algorithms and correction of conventional DM. The simulation results show that 3D DM with removable actuators can obviously improve the correction effects compared to conventional DM. As the two arrangement algorithms, actuator placement is more liberal in GAA than RDA, so GAA commonly has a better correction result. However, the algorithm of GAA is more complex and it takes more time to calculate. On the other hand, 3D DM can achieve a specific correction effect with fewer actuators than conventional DM, and significantly reduce the cost. Some other factors that will influence the correction result are also analyzed, such as the diameter of influence function, iterative steps and actuator displacement distance of the algorithm. Different from conventional DM, the diameter of influence function of 3D DM can be designed as any value we want, while that of conventional DM is determined by the coupling coefficient, which is hard to change. There is an appropriate size of influence function diameter for a given beam diameter to achieve the best correction result. A relevant experiment is also carried out to confirm the simulation result.

9909-145, Session PMon2

Development of narrow bandpass etalon for daytime AO observation using laser guide star in mid-infrared wavelength

Yutaka Hayano, National Astronomical Observatory of Japan (Japan); Mitsuhiko Honda, Kurume Univ. (Japan); Mark R. Chun, Univ. of Hawai'i (United States); Christopher Packham, The Univ. of Texas at San Antonio

(United States)

The use of laser guide star (LGS) in daytime expands the operational time of nighttime-based telescope for AO instruments. The background of this idea is proposed for an instrument for thermal infrared to mid infrared wavelength, because the sky brightness is not so different from night to daytime. The adaptive optics (AO) in thermal and mid infrared wavelength has a great advantage in performance of AO, which can reach almost diffraction limit of even if the extremely large telescope. The sky back ground in 589nm is about a million times brighter than bright night, though, the bandwidth of sodium return light is a few GHz. The narrow bandpass filter at this wavelength makes possible to use LGSs during the day.

We have manufactured prototype of narrow bandpass interference filters from Materion to test whether sodium laser guide star adaptive optics can be used during the day. Although the initial spectral bandwidth of filter just after the fabrication met the specification, which is 0.3nm in FWHM, the width of spectral bandwidth seemed to be degraded. Also the peak transmission was dropped from the initial condition at 70% down to 25 to 30%.

Based on this prototyping experience, we started to investigate the etalon technology to achieve the extreme narrow band filter. It is very challenging to realize both the high throughput at central wavelength and narrow bandwidth less than 0.1nm. Theoretically, we can specify the parameters of etalon, which has high transmission and extreme narrow band transmission, however, the surface quality of high reflective etalon, coating quality of high reflective surface, maximum size of diameter of etalon, integration and testing method, stability in central wavelength, bandwidth and peak transmission have to be confirmed by prototyping. In this paper, prototyping process and results will be presented.

9909-147, Session PMon2

Getting ready for the first on-sky experiment using an elongated sodium laser guide star

Lisa Bardou, Gérard Rousset, Damien Gratadour, Éric Gendron, Fabrice Vidal, Jean-Tristan M. Buey, Observatoire de Paris (France); Fanny Chemla, Observatoire de Paris à Meudon (France); Richard M. Myers, Timothy J. Morris, Alastair G. Basden, James Osborn, Andrew P. Reeves, Robert G. Talbot, Durham Univ. (United Kingdom); Domenico Bonaccini Calia, Thomas Pfrommer, European Southern Observatory (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Jean-Luc Gach, First Light Imaging S.A.S. (France) and LAM (France); Philippe Feautrier, Eric Stadler, Institut de Planétologie et d'Astrophysique de Grenoble (France) and First Light Imaging S.A.S (France)

The use of sodium Laser Guide Star (LGS) for Extremely Large Telescope (ELT) Adaptive Optics (AO) is a key concern due to the perspective effect that produces elongated images in the Shack-Hartmann pattern. In order to assess the feasibility of using an elongated sodium beacon at an ELT, an on-sky experiment reproducing the extreme off-axis launch conditions of the European ELT is scheduled for summer 2016. The experiment is made possible by the synergies between the teams of different ESO member states, using the demonstrator CANARY installed on the William Herschel Telescope (WHT), and the ESO transportable 20W CW fiber laser, embedded in the Wendelstein LGS unit (WLGSU). The laser will be launched 40m off-axis from the WHT pupil edge, to reproduce the E-ELT baseline configuration giving an LGS elongation of about 20''.

CANARY has been upgraded with an elongated sodium LGS Wavefront Sensor (WFS), to be able to compare the wavefronts from a Natural Guide Star (NGS) to the one from the superimposed LGS. In addition, a profiler system has been designed for the 2.50m Isaac Newton Telescope, located 426 meters away. It will be used to produce synchronised images of the sodium plume at an increased spatial resolution and at the frame rate of the WFS, so as to be able to measure the spatial and temporal characteristics of the sodium layer and to extract a reference function from it for feeding centroiding algorithms based on correlation-like methods. The WLGSU will provide the LGS and the photometry done on the LGS during the experiment, taken with the in-built photometric receiver. WLGSU will be tailored mostly in the aspect of the control software and local installations.

In order to prepare for this experiment, an error budget is computed to predict the performance of each centroiding algorithm depending on the sodium layer profile. The incidence of different sources of error such as spot undersampling and truncation, cone effect, laser jitter and noise is analysed. Furthermore, the use of reference function is investigated : it can either be obtained with the profile provided by the INT profiler, or retrieved directly from the spots observed on the Shack-Hartmann. In both cases, the question of adequate sampling and how to get reference slopes are the main concerns. In order to evaluate the sources of error in the experiment, the corresponding error budget is derived through end to end simulations using the AO simulation platform COMPASS. We will present the design and the integration tests of the sodium LGS WFS and the simulation results of the wavefront error analysis.

9909-150, Session PMon2

Last results from the 4RUNNER experiment at LBT

Fernando Pedichini, Mauro Centrone, Filippo Ambrosino, INAF - Osservatorio Astronomico di Roma (Italy); Luca Carbonaro, INAF - Osservatorio Astrofisico di Arcetri (Italy); Jacopo Farinato, INAF - Osservatorio Astronomico di Padova (Italy); Fabrizio Fiore, Emanuele Giallongo, INAF - Osservatorio Astronomico di Roma (Italy); Enrico Pinna, Alfio T. Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Marco Stangalini, INAF - Osservatorio Astronomico di Roma (Italy); Vanessa P. Bailey, The Univ. of Arizona (United States); Julian C. Christou, John M. Hill, Large Binocular Telescope Observatory (United States); Philip M. Hinz, The Univ. of Arizona (United States); Christian Veillet, Large Binocular Telescope Observatory (United States)

Over the last years the LBT (Large binocular telescope) extreme adaptive optics (ExAO) system has demonstrated very good performances at visible wavelengths. This capability is of paramount importance for the detection of cold giant planets orbiting nearby stars, for which the bulk of the emission is expected at these wavelengths, yet this represents a very challenging task due to the strong effects of the atmospheric turbulence in the visible. In this work we report on the first results obtained by 4RUNNER, the LBT high contrast imager forerunner recently tested on-sky at visible wavelengths. These results demonstrate once more the extremely good performances of the LBT ExAO system at these wavelengths, both in terms of achieved spatial resolution and contrast. To this regard, we used these data to quantitatively assess the contrast enhancement achieved by employing different post-processing techniques like ADI (Angular differential imaging) and PCA (Principal component analysis), after injecting several different synthetic faint sources into them. Our results show that a contrast of 11 mag is easily obtained in the visible. This is an extremely promising result, given the range of working wavelengths considered.

9909-152, Session PMon2

On-sky demonstration of the GMT dispersed fringe phasing sensor prototype on the Magellan Telescope

Derek A. Kopon, Brian McLeod, Smithsonian Astrophysical Observatory (United States); Marcos A. Van Dam, Flat Wavefronts (New Zealand); Antonin H. Bouchez, GMTO Corp. (United States); Kenneth McCracken, Daniel Catropa, William A. Podgorski, Stuart McMuldroch, Smithsonian Astrophysical Observatory (United States); Alan Conder, GMTO Corp. (United States); Laird M. Close, Jared R. Males, The Univ. of Arizona (United States); Timothy J. Norton, Smithsonian Astrophysical Observatory (United States)

The GMT is an aplanatic Gregorian telescope consisting of 7 primary and secondary mirror segments that must be phased to within a fraction of an imaging wavelength to allow the 25.4 meter telescope to reach its diffraction limit. When operating in Laser Tomographic Adaptive Optics (LTAO) mode, on-axis guide stars will not be available for segment phasing. In this mode, the GMT's Acquisition, Guiding, and Wavefront Sensing system (AGWS) will deploy four pickoff probes to acquire natural guide stars in a 6-10 arcmin annular FOV for guiding, active optics, and segment phasing using a dispersed fringe sensor (DFS). The phasing sensor will be able to measure piston phase differences between the seven primary/secondary pairs of up to 50 microns with an accuracy of 50 nm. Recent simulations by Van Dam, et al demonstrate that the highest sky coverage for the dispersed fringe sensor on the GMT can be obtained in the J-band. To test the dispersed fringe sensor design and validate the performance models, SAO has built and commissioned a prototype phasing sensor on the Magellan Clay 6.5 meter telescope. This prototype will use an aperture mask to overlay 6 GMT-size segment gap patterns over the Magellan 6.5 meter primary mirror. The six diffraction patterns created by these subaperture pairs will then be reimaged with a lenslet array and dispersed with a grism. The phasing prototype has two wavelength channels: an I-band channel that uses a Princeton EMCCD and a J-band channel that uses a Ninox 640 InGaAs camera. Each camera can be read at 100 Hz to "freeze" the atmospheric turbulence. A phase difference across the segment gap causes a shear in the fringes. In Fourier space this leads to a displacement of the location of the side lobes. By stacking the Fourier amplitude of multiple frames and measuring the location of the side lobes, we obtain an estimate of the phase difference. An on-board phase shifter has the ability to simulate an arbitrary phase shift within subaperture pairs. The prototype operates both on-axis and 6 arcmin off-axis either with AO on or off in order to replicate as closely as possible the conditions expected on the GMT.

9909-154, Session PMon2

A testing facility at the Asiago Copernico telescope in the framework of the ADaptive Optics National laboratory of INAF: ADONI

Simonetta Chinellato, Roberto Ragazzoni, Jacopo Farinato, Stefano Benetti, Maria Bergomi, Federico Biondi, Enrico Cappellaro, Elena Carolo, Venerio Chiomento, Marco Dima, Aldo Frigo, Davide Greggio, Marco Gullieuszik, Demetrio Magrin, Luca Marafatto, Giorgio Martorana, Elisa Portaluri, Mauro Rebeschini, Lina Tomasella, Luciano Traverso, Massimo Turatto, Daniele Vassallo, Valentina Viotto, INAF - Osservatorio Astronomico di Padova (Italy)

ADONI laboratory has been proposed in 2012 to better coordinate the activities in Adaptive Optics, gathering the INAF know-how in the AO world, to provide a larger momentum in the international collaborations and to realize a structure capable of managing large AO projects. In April 2015 the activity of ADONI has officially started, with the initial participation of three INAF institutes: Arcetri, Padova and Roma Monte Porzio. In the plan concerning the laboratory activity, it is also foreseen to set-up facilities accessible to the Italian and international AO community, with the purpose of facilitating the testing of critical sub-systems or components (which may be part of instruments under construction), or prototypes of innovative concepts which may require on-sky demonstrations.

In this framework, the largest telescope in Italy, located in Asiago, named Copernico and characterized by a primary mirror as large as 182cm, has been selected to be a suitable facility to accomplish this task. In fact, it is a Cassegrain telescope with a design that allows the possibility to redirect the light toward a Coudè focus, by rotating the tertiary mirror. The Copernico telescope requires to be refurbished in order to implement the Coudè optical train (initially foreseen but never implemented and used till today) and the Coudè laboratory may be properly setted-up to host an optical bench installed for specialized instrument set-ups, on which visiting multi-purpose instrumentation will be accommodated and where the testing activities will be conducted.

Possible examples of cost effectiveness of such a facility include, but are not limited to, the very fast implementation of novel concept of wavefront sensing, the comparison of different kinds or concepts of wavefront sensors, the implementation of new techniques in high angular resolution imaging like lucky imaging, speckle interferometry with phase retrieval, the adoption of specialized pupil planes aperture (like the double opening of LBT or the multiple apertures of GMT) and superresolution approaches. Although not primarily intended for such an use, this facility could also carry on experiments in novel kind of low resolution spectrograph using –for instance- volume phase holographic devices. In connection with a working AO system or with a severe pupil stop down it can also be used to experiment on the sky with various different approaches in coronographic devices.

In this paper we describe the opto-mechanical train at the Coudè focal station to be implemented for the laboratory set-up, and we sketch out the foreseen telescope refurbishing activities to implement a multi-purpose testing facility dedicated to AO related projects.

We also point out that such a facility may be used to host a permanent AO demonstrator system, which may serve both as an experimental setup and as a training system for young researchers approaching the AO community, being education and training of young astronomers also between the main tasks and interests of the newly constituted ADONI laboratory.

9909-155, Session PMon2

CHOUGH: implementation and performance of a high-order 4m AO demonstrator

Nazim A. Bharmal, Alastair G. Basden, Cyril J. Bourgenot, Durham Univ. (United Kingdom); Martin Black, UK Astronomy Technology Ctr. (United Kingdom); Cornelis M. Dubbeldam, Durham Univ. (United Kingdom); David M. Henry, UK Astronomy Technology Ctr. (United Kingdom); Daniel Hölck-Santibanez, Timothy J. Morris, David J. Robertson, Jürgen Schmoll, Robert G. Talbot, Eddy J. Younger, Richard M. Myers, Durham Univ. (United Kingdom)

CHOUGH is a small, fast project to provide an experimental on-sky high-order SCAO capability to the 4.2m WHT telescope. The basic goal has r_0-sized sub-apertures with the aim of achieving high-Strehl ratios (>0.5) in the visible (>640nm). It achieves this by utilizing existing high-performance equipment where possible and this includes the CANARY experiment: CHOUGH is mounted as a breadboard and intercepts the beam within CANARY via a periscope. In doing so, it takes advantage of the mature CANARY infrastructure but adds new AO capabilities. The key instruments that CHOUGH brings to CANARY are an atmospheric dispersion compensator, 32x32 (1000 actuator) MEMS deformable mirror, 31x31 wavefront sensor, and a complementary (narrow-field) imager. Together these are tied together with an optical relay (the backbone) which uses CotS optics where possible and is central to the breadboard. Correspondingly, CANARY provides a 241-actuator DM, tip/tilt mirror, and comprehensive off-sky alignment facilties together with a RTC. In this work, we describe the CHOUGH optical, mechanical, and electronic design from the perspective of the sub-systems: backbone, ADC, KDM, HOWFS, CAWS, and NFSI. We concentrate on these key sub-systems and their individual performance characterization in the laboratory, and then in the context of the integrated instrument. Included are the constraints which led to the optical design, including a discussion of all-metal diamond-machined mirrors. With an on-sky target date of mid-August, we review the integration of CHOUGH into CANARY as an on-sky instrument and associated tasks involved that allow it to operate (in a limited mode) as a standalone bench or integrated with CANARY. The complementary paper in these proceedings (#????) discusses the control strategy and associated algorithm development that can take advantage of CHOUGH.

9909-158, Session PMon2

On the verification of NFIRAOS algorithms and performance on the HeNOS bench

Matthias Rosensteiner, NRC - Herzberg Astronomy & Astrophysics (Canada); Paolo Turri, Univ. of Victoria (Canada); Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada); Etsuko Mieda, Dunlap Institute for Astronomy & Astrophysics (Canada); David R. Andersen, Glen Herriot, NRC - Herzberg Astronomy & Astrophysics (Canada)

NFIRAOS will be the first light MCAO system of TMT. HeNOS is a scaled down version of the instrument, which is designed to mimic its behavior. Its purpose is the verification of the performance predicted through simulations and the demonstration of calibration procedures. It implements four LGS with Shack-Hartmann WFS, aligned in a square asterism, and two deformable mirrors, conjugated to the same altitudes as in NFIRAOS. To obtain a comparable actuator spacing we simulate an 8m telescope with a turbulence generated with three phase screens at different altitudes. There is a large number of NGSs in the field of view (FoV) to evaluate the performance and HeNOS is designed in such a way that the expected degradation of the correction over the FoV matches that of the science field of NFIRAOS. Furthermore, it includes a Pyramid Truth WFS which can pick any star in the field, either for high or for low order measurements.

With this setup we run the MCAO correction including LGS effects like spot elongation, tip/tilt uncertainty and sodium layer variations using the algorithms considered to be used in NFIRAOS. The tests give valuable insight into the behavior of the methods and are compared to the predictions from the simulations. This helps gaining confidence in the simulations done for NFIRAOS and the design choices taken with respect to the update of the reconstruction matrix.

Several other methods are tested with HeNOS, which are necessary for the success of NFIRAOS. The identification of the turbulent layers is done with a SLODAR method, tomographic phase diversity identifies the non-common path aberration. Matched filters are used to compute the centroids for the LGS and the Pyramid Truth WFS keeps track of the varying sodium layer. Additionally, the algorithms proposed for PSF reconstruction on NFIRAOS are tested and evaluated.

We discuss the recent advances on the tests and the impact of the results on the control of NFIRAOS.

9909-160, Session PMon2

Distortion calibration unit for ‘imaka

Maxwell Service, Mark R. Chun, Institute for Astronomy (United States) and Univ. of Hawai'i (United States); Jessica R. Lu, Institute for Astronomy (United States); Christoph Baranec, Institute for Astronomy (United States) and Univ. of Hawai'i (United States); Douglas Toomey, Mauna Kea Infrared, LLC (United States)

The aim of the ‘imaka distortion calibration unit is to characterize the geometric optical distortion of the imaging system. It is designed to operate in at night or daytime, and will allow us to measure how the system changes as a function of the conditions, such as the gravity vector, temperature and humidity. Our calibration unit will limit the amount of calibrations that must be taken on sky by allowing us to replicate observing setups and calibrate during the daytime.

The current design utilizes a pinhole mask to directly measure the distortion of the instrument. The design considerations for such a system are complex. We use simulations and a lab experiment to understand how the physical attributes of a given pinhole mask correspond to errors in the measured distortion. The lab experiment consists of a light source, a pinhole mask on a translation stage, and a low-distortion lens. This setup allows us to measure our ability to centroid on pinhole images as well as measure the centroid error due to changes in hole shape and gradients in the light source. We will demonstrate how different dithering patterns of the mask map to different samplings of the optical distortion.

‘imaka's astrometric accuracy is critical to many of its science cases, including measuring the physical quantities of star forming regions in the galactic plane. These clusters have a high stellar density and are extended to radii greater than 5'. ‘imaka will be ideal for studying such regions; the large GLAO corrected field of view enables accurate astrometry on large scales which allows us to select cluster sources based on their common motion.

‘imaka's calibration unit will also be a demonstration of using a pinhole mask to measure and calibrate distortion in an astronomical instrument to the levels needed for 30-meter class telescopes. The relatively coarse plate scale of `imaka translates to an absolute distortion accuracy in the final focal plane similar to that of the 30-meter class instruments such as the TMT/IRIS instrument. We present the design and performance of the ‘imaka calibration unit.

9909-161, Session PMon2

DRAGON-NG: a configurable and capable AO test-bench

Nazim A. Bharmal, Urban Bitenc, David G. Bramall, Nigel A. Dipper, Cornelis M. Dubbeldam, Andrew P. Reeves, Colin Dunlop, Stephen Rolt, Eddy J. Younger, Richard M. Myers, Durham Univ. (United Kingdom)

An astronomical adaptive optics test-bench, designed to replicate the conditions of a 4m-class telescope with observatory-like astroclimatology, is presented. Named DRAGON-Next Generation, it is an evolution of CfAI's DRAGON test-bench which utilizes existing components together with an extensive in-house customized mechnical design work. In contrast, DRAGON-NG is constructed primarilyy from commercial off-the-shelf components with minimal customization (approximately a 90:10 ratio). This permits an optical design which is compact and truly modular: all sub-systems interface via a 18mm pupil conjugate. This permits the reconfiguration of sub-systems or the re-design of any one without affecting the other sub-systems. In other words, DRAGON-NG has been designed for operation for the following modes: (high-order) SCAO, (twin-DM) MOAO, and (twin-DM) MCAO. It is capable of open-loop or closed-loop operation, with natural and laser guide-star emulation (the latter including elongation effects), and with a large number of sub-apertures (upto 5000 slopes), at loop rates of upto 200Hz.

Field angles of upto (from a 4m telescope perspective) 2.4 arcmin can pass through the system and three NGS are available at 9 distinct off-axis field angles and one on-axis. Three LGS are also provided and this includes one on-axis, and are emulate a 90km altitude beacon (Na-layer). The design is dioptric and hardware interfaces are exclusively USB or Ethernet which permits long cable runs to a compact realtime control system and control server. The on-sky compatible real-time control software is open-source (C programming language) and permits experimental validation on DRAGON-NG before transfering to an on-sky system, which is a significant risk mitigation. Additional software developments carried out include a centralized supervisor which interfaces with a database to manage data collected. Together this makes DRAGON-NG both easy to use and flexible in configuration, both of which are pragmatic and therefore encourage a wide range of AO research use rather than specializing in one facet of the subject.

9909-164, Session PMon2

Analysis and verification of the error budget for HeNOS: the test bench for NFIRAOS

Paolo Turri, Univ. of Victoria (Canada) and NRC - Herzberg Astronomy & Astrophysics (Canada); David R. Andersen, Matthias Rosensteiner, Jean-Pierre Véran, Glen Herriot, NRC - Herzberg Astronomy & Astrophysics (Canada)

At NRC Herzberg we are developing the Herzberg NFIRAOS Optical Simulator (HeNOS), a test bench to support the development of NFIRAOS, the multi-conjugate adaptive optics (MCAO) system for the Thirty Meter Telescope.

On HeNOS, two ALPAO deformable mirrors are conjugated at the ground and at 11 km of altitude. The laser guide stars are generated by an asterism of four laser diodes and their elongation, caused by the thickness of the sodium layer, is simulated by defocusing in steps the ground deformable mirror during the exposure on the wavefront sensor. A single Shack-Hartmann wave front sensor measures the four laser guide stars, each lenslet having a large enough field of view to image the entire asterism. A grid of natural guide stars, created by a laser diode behind a lenslet array, can be used to measure the tip-tilt aberrations and to track the sodium layer's variation by a pyramid truth wavefront sensor. Three rotating phase screens introduce the atmospheric turbulence, conjugated to the ground, between the two deformable mirrors and at high altitude; turbulence "movies" can also be played by the deformable mirrors.

The purpose of our bench is to verify the performance predicted for NFIRAOS and to test algorithms like the tomographic reconstructor, SLODAR and the MCAO PSF reconstruction that will be used on TMT. To use them on HeNOS, we need first to measure its properties and to characterize its performance. Here we present the error budget analysis and verification for the single-conjugate mode, a necessary step to analyze the system behavior before starting MCAO operations.

9909-166, Session PMon2

Prototyping an ELT scale AO loop in the lab with a spatial light modulator and GPUs

Arnaud Sevin, Julien Bernard, Éric Gendron, Denis Perret, Maxime Lainé, Damien Gratadour, Fabrice Vidal, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France)

With Extremely Large Telescopes (ELT) under construction, studies on new strategies to control the waveform are becoming critical. To validate them in the laboratory, access to high density deformable mirrors with thousands of actuators is now mandatory. Several technologies are envisioned for ELTs with various actuators geometries and shape. In this paper, we will present an innovative approach to simulate such deformable mirrors using Liquid Crystal On Silicon Spatial Light Modulator (LCOS-SLM). Such devices provide tens of thousands of degrees of freedom and can be driven at framerates up to about 120Hz. To meet this challenge, GPUs appear as a solution of choice, since they natively support efficient DVI output, the standard interface used with SLMs. Additionally, GPUs provide high compute performance that can be leveraged to implement a variety of shaping models at relatively high framerates.

However, to emulate a complete AO loop, such system must be coupled to a high density wavefront sensor (WFS), of which the pixels data must be transferred efficiently to the GPU. We will present a lab demonstrator hosting multiple GPUs and an off-the-shelf FPGA development board on which an efficient GPU aware data transfer scheme has been implemented to provide adequate data transfer rates from the WFS camera to the GPUs. The latter are used to process the WFS pixels data, derive wavefront measurements, reconstruct the wavefront shape and project it to a given deformable mirror geometry simulated on the SLM. We will present the performance achieved for various system dimensioning from 5k and up to 20k actuators systems in the context of the E-ELT first light instruments.

9909-167, Session PMon2

An engineered design of a diffractive mask for high precision astrometry

Kaitlin Dennison, Univ. of Connecticut (United States); S. Mark Ammons, Lawrence Livermore National Lab. (United States)

We present an engineered design for GeMSDiM, a diffractive mask for the Gemini Multi-Conjugate Adaptive Optics System (GeMS). We: (1) used the optics modeling code ZEMAX to simulate the optical performance of the GeMSDim instrument; (2) engineered a CAD model of the instrument using AutoCAD; and (3) performed a high-fidelity Fresnel simulation of the instrument's optical performance using the IDL PROPER simulator.

9909-170, Session PMon2

Status of an extreme adaptive optics testbench using a self referenced Mach Zehnder sensor

Magali Loupias, Observatoire de Lyon (France) and Ctr. de Recherche Astronomique de Lyon (France); Maud P. Langlois, Éric M. Thiébaut, Michel Tallon, Ctr. de Recherche Astronomique de Lyon (France)

Extreme adaptive optics (XAO) has severe difficulties meeting the high

speed (>1kHz), accuracy and photon efficiency requirements. An innovative High order adaptive optics system using a self-referenced Mach-Zehnder wavefront sensor allows counteracting these limitations. This sensor estimates the wavefront phase by measuring intensity differences between two outputs, with a lambda/4 path length difference, but is limited by its dynamic range. During the past few years, such an XAO system has been studied by our team in the framework of 8-meter class telescopes. In this work, we report on our latest results with the XAO testbed recently installed in our lab, and dedicated to high contrast imaging with 30m-class telescopes (such as the E-ELT or the TMT). A woofer-tweeter architecture is used in order to deliver the required high Strehl ratio (>95%). It consists of a 12x12 deformable mirror and a 512x512 spatial light modulator, characterized using both mono- and polychromatic light. We present our latest simulation and laboratory demonstration results, including components characterization, close loop performance, and sensitivity to calibration errors. This work is carried out in synergy with the validation of fast iterative wavefront reconstruction algorithms, and the optimal treatment of phase ambiguities in order to mitigate the dynamical range limitation of such a wavefront sensor.

9909-27, Session 8

ESO 4LGSF: Integration in the VLT, Commissioning and on-sky results *(Invited Paper)*

Wolfgang K. Hackenberg, Domenico Bonaccini Calia, Jose Antonio Abbad, José Luis Alvarez, Juan Beltran, Bernard Buzzoni, Mauro Comin, Diego Del Valle, Philippe R. Duhoux, Christophe Dupuy, Gerhard Fischer, Fernando Gago Rodriguez, Ronald Guzman, Pierre Haguenauer, Andreas Haimerl, Ronald Holzlöhner, Stefan Huber, Lothar Kern, Arno van Kesteren, Jean Paul Kirchbauer, Harald Kuntschner, Steffan A. Lewis, Jean-Louis Lizon, Pierre-Yves Madec, Stewart McLay, Ivan Munoz, Juan Canos Palacio, Thomas Pfrommer, Jean-Francois Pirard, Dan Popovic, Marco Quattri, Jutta Quentin, Robert Ridings, Miguel Riquelme, European Southern Observatory (Germany)

The Four Laser Guide Star Facility (4LGSF) is part of the ESO Adaptive Optics Facility (AOF), in which one of the VLT unit telescopes, UT4, is transformed in an adaptive telescope - equipped with a deformable secondary mirror, two adaptive optics systems at the Nasmyth foci and four laser guide star modular units, side launched.

In this paper we present the key results of the acceptance tests performed on the 4LGSF in Europe and the on-sky commissioning results, obtained with the Four Laser Guide Star Unit in stand-alone operation.

The emphasis will be on the design choices, the experience cumulated so far with the lasers and other subsystems, the automatic pointing and focusing aided by the Laser Pointing Camera, the integration with the Telescope control system, the on-sky Commissioning process and results.

9909-28, Session 8

Four generations of sodium guide star lasers for adaptive optics in astronomy and space situational awareness

Celine d'Orgeville, The Australian National Univ. (Australia); Gregory J. Fetzer, Arete Associates (United States)

This presentation recalls the history of sodium guide star laser systems used in astronomy and space situational awareness adaptive optics, analysing the impact that sodium laser technology evolution has had on routine telescope operations. While it would not be practical to describe every single sodium guide star laser system developed to date, it is possible to characterize their evolution in broad technology terms. The first generation of sodium lasers used dye laser technology to create the first sodium laser guide stars in Hawaii, California, and Spain in the late 1980's and 1990's. These experimental systems were turned into the first laser guide star facilities to equip medium-to-large diameter adaptive optics telescopes, opening a new era of LGS AO-enabled diffraction-limited imaging from the ground. Although they produced exciting scientific results, these laser guide star facilities were large, power-hungry and messy. In the USA, a second-generation of sodium lasers was developed in the 2000's that used cleaner, yet still large and complex, solid-state laser technology. These are the systems in routine operation at the 8-10m class astronomical telescopes today. Meanwhile in Europe, a third generation of sodium lasers was being developed using inherently compact and efficient fiber laser technology, and resulting in the only commercially available sodium guide star laser system to date. Fiber-based sodium lasers have been deployed at two astronomical telescopes and at least one space debris tracking station last year (2015). Although highly promising, these systems remain significantly expensive and they have yet to demonstrate long-term, high performance in the field. We are proposing to develop a fourth generation of sodium lasers: based on semiconductor technology, these lasers could provide the final solution to the problem of sodium laser guide star adaptive optics for all astronomy and space situational awareness applications.

9909-29, Session 8

Keck II laser guide star AO system and performance with the TOPTICA/MPBC laser

Jason C. Chin, Peter L. Wizinowich, Edward Wetherell, Scott J. Lilley, Sylvain Cetre, Sam Ragland, Drew W. Medeiros, James E. Lyke, W. M. Keck Observatory (United States); Kai Wei, Matthias Schöck, Angel C. Otárola, Thirty Meter Telescope (United States)

The Keck II Laser Guide Star (LGS) Adaptive Optics (AO) System was upgraded from a dye laser to a TOPTICA/MPBC Raman-fiber amplifier (RFA) laser in December 2015. The W. M. Keck Observatory (WMKO) has been operating its AO system with an LGS for science since 2004 using a first generation 15 W dye laser. The dye laser was challenging to maintain and operate, requiring significant manpower and infrastructure resources. The advent of new technologies has significantly improved the efficiencies and operability of lasers, which are important qualities for facility class telescopes. In addition, much has been learned from operations at WMKO and other observatories on laser formats which can improve the coupling efficiency of sodium atoms in the mesosphere with lasers. This has led to higher sodium returns, improving the ability of LGS AO to correct for atmospheric turbulence.

Using diode pump lasers, Raman amplification and a well-tuned second harmonic generator, the TOPTICA laser is able to produce a highly stable 589 nm laser beam for power, wavelength, bandwidth and mode quality. The beam's linear polarization and continuous wave formats along with optical back pumping are expected to improve the coupling efficiencies by factors of 10 or more as compared to the dye laser. At the same time, the efficiency and operability of the laser are gained by reducing its input power and cooling requirement, and the manpower to operate and maintain it. The physical architecture of the laser and its smaller footprint reduce the negative impacts of a moving telescope which have plagued previous laser systems. Fibers are used to transport laser light on the telescope without a beam train to minimize the effects of a changing gravity vector. The system architecture allows the laser to be operated

remotely with continuous diagnostics to monitor its health. Unlike the dye laser, the new laser is ideal for time-domain astronomy as it can be started quickly and reaches its stable operational state in minutes versus hours.

The new laser has been implemented with a new Nasmyth sub-platform to house up to three lasers, a safety system to monitor the laser and the beam environment, an optical bench for diagnostics and steering of the beam, motion controllers, and supporting software. The laser and associated subsystems use the recently implemented Center Launch System (CLS) to further reduce the spot size and negative impacts from aniosoplanatism on larger aperture telescopes. The coupling efficiency of the new laser will be examined, based on its relative power, wavelength, optical repumping, polarization, and its alignment to the magnetic field (telescope azimuth and elevation) for the Maunakea site. This should further improve existing sodium models for lasers with this format. We will present the LGS system on the telescope, the on-sky results compared to existing models, the challenges and operations experience of the laser with the CLS, and the overall LGSAO performance using the NIRC2 science camera. We will also examine next steps for the Keck II LGSAO system allowed by the increase in sodium return.

9909-30, Session 8

LGS return flux: report on the Tenerife optimization experiments and comparison with the Toptica laser results at the VLT

Domenico Bonaccini Calia, European Southern Observatory (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Gianluca Lombardi, Gran Telescopio de Canarias, S.A. (Spain); Marcos Reyes Garcia-Talavera, Iciar Montilla Garcia, Instituto de Astrofísica de Canarias (Spain); Ivan M. Guidolin, European Southern Observatory (Germany); Fernando Pedichini, INAF - Osservatorio Astronomico di Roma (Italy); Thomas Pfrommer, Wolfgang K. Hackenberg, Ronald Holzlöhner, Steffan A. Lewis, European Southern Observatory (Germany)

We report on the Laser Guide Star return flux results and laser optimized parameters, obtained during the field observation campaigns at Observatorio de el Teide, Tenerife, using ESO's transportable 20W CW Wendelstein laser guide star unit, based on Raman fiber amplifiers.

We compare the return flux results of Tenerife with those obtained in Paranal with the Toptica lasers on the 4LGSF system.

The Tenerife campaign has involved six missions and has given LGS return flux measurements of unprecedented statistical significance for different seasons of the year.

To find the optimal laser format for the various ALT/AZ pointing directions, we have made scans in laser emitted power, polarization, linewidth, fraction of D2b repumping, frequency of the D2b repumping.

The work, which we report on, has been done in view of optimizing the laser format specifications for the EELT lasers.

9909-31, Session 8

The TIPC pulsed-laser based on sum-frequency-generation of 1319nm and 1064nm infrared lasers: results from laboratory tests of key performance parameters

Angel C. Otarola, Thirty Meter Telescope (United States); Lu Feng, National Astronomical Observatories (China); Yong Bo, Junwei Zuo, Qi Bian, Li Ming, Qinjun Peng, Zuyan Xu, Technical Institute of Physics and Chemistry (China)

The first light Thirty Meter (TMT) Telescope Multi Conjugate Adaptive Optics system NFIRAOS utilizes a six laser guide star (LGS) asterism, and room is available for a future upgrade to eight LGS in the telescope design. Since 2011 TMT has been exploring the potential of using a 589 nm wavelength pulsed laser, based on a quasi-continuous/sum frequency generation design, as an option for the LGS system. The laser pulse parameters include a pulse length in the order of 100 microseconds, and pulse repetition frequency adjustable in the range from 500 Hz to 800 Hz. The design, prototyping and testing of this pulsed-laser is being carried out by the Technical Institute of Physics and Chemistry (TIPC) in Beijing China, with the support of the National Astronomical Observatories of China (NAOC), both institutes sponsored by the Chinese Academy of Sciences (CAS).

In this talk we will summarize the results from laboratory tests of key performance parameters, such as: wavelength stability, power output and power stability, as well as pulse characteristics and laser beam quality, and will compare the test results with the TMT laser requirements. These performance tests are conducted under various environmental and dynamic conditions compatible with those expected during the operations at the TMT site.

9909-32, Session 9

SPHERE on-sky results: final performance, lesson learned, and possible upgrades *(Invited Paper)*

Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Jean-François Sauvage, ONERA (France) and Lab. d'Astrophysique de Marseille (France); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Markus E. Kasper, European Southern Observatory (Germany); Cyril Petit, ONERA (France); Kjetil Dohlen, Anne Costille, Lab. d'Astrophysique de Marseille (France); Julien H. V. Girard, European Southern Observatory (Chile); Marcos Suárez Valles, Christian Soenke, Norbert Hubin, European Southern Observatory (Germany); Julien Milli, European Southern Observatory (Chile); Arthur Vigan, European Southern Observatory (Germany); Andrea Baruffolo, Bernardo Salasnich, Istituto Nazionale di Astrofisica (Italy); Gérard Zins, European Southern Observatory (Chile); Denis Perret, Pierre Baudoz, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); François Wildi, Observatoire de Genève (Switzerland)

The objective of the Spectro-Polarimetric High-contrast Exoplanet Research (SPHERE) instrument is to detect extremely faint astronomical sources (i.e. giant extra-solar planets) in the vicinity of bright stars. The detection capabilities of an exoplanet hunter are largely controlled by its adaptive optics (AO) system. Better AO correction provides improved coronagraphic extinction and fewer residual defects. The challenging SPHERE science goals require a very high-order performance AO system to feed a quasi-perfect flat wave front, corrected for atmospheric turbulence and internal defects, to its focal instruments : differential imaging camera, integral field spectrograph, differential imaging polarimeter. The AO system

of the instrument, known as the Sphere AO for eXoplanet Observation (SAXO), is the 'heart' of the instrument, which 'beats' 1200 times per second to provide unprecedented image quality from a large ground-based telescope operating at optical/near-IR (NIR) wavelengths. As such, SPHERE presents tremendous potential for exoplanet discoveries.

In May 2014 SPHERE was installed on the Very Large Telescope in Chile. After six months and four commissioning runs of extensive and comprehensive tests (for robustness, performance, and ease of use), the instrument was made available first for successful science verification observations and now SPHERE is offered, since April 2015, to the ESO astrophysical community for general science programmes.

We present here an overview of the SAXO characteristics, on-sky performances, first astrophysical results, lessons learned during the commissioning and test periods as well as remaining issues.

9909-33, Session 9

Status and performance of the Gemini planet imager adaptive optics system

(Invited Paper)

Vanessa P. Bailey, Stanford Univ. (United States); Lisa A. Poyneer, Lawrence Livermore National Lab. (United States); Bruce A. Macintosh, Stanford Univ. (United States); Dmitry Savransky, Cornell Univ. (United States); Abhijith Rajan, Arizona State Univ. (United States); Jean-Baptiste Ruffio, Stanford Univ. (United States); Jason J. Wang, Univ. of California, Berkeley (United States)

The Gemini Planet Imager (GPI) and its natural guide star adaptive optics system have been optimized for high-contrast imaging of bright stars. GPI AO uses a woofer-tweeter setup, with a high-order MEMS deformable mirror and a Fourier modal basis set reconstructing more than 2000 modes. Advances in both hardware and control, such as WFS spatial filtering, vibration suppression with LQG control, and modal gain optimization improve GPI's contrast capabilities relative to previous generation systems. As a result, GPI achieves median H-band contrasts of 7E-5 and 2E-6 at 0.5" in a single unprocessed 60-second exposure and a fully-processed 60-minute sequence, respectively. With more than 150 stars observed as part of the GPIES campaign, we can now analyze the system's real-world performance under a variety of conditions. We detail performance quantified both by AO telemetry and by science data. In particular, we compare parameters such as guide star brightness, loop frequency and gains, and atmospheric coherence time with both single frame contrast and post-processed multiple-frame sequence contrast. Finally, we discuss how these performance analyses have informed recent and planned system updates.

9909-34, Session 9

The SCExAO high contrast imager: transitioning from commissioning to science

Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States) and Macquarie Univ. (Australia); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States) and The Univ. of Arizona (United States); Thayne Currie, Subaru Telescope, National Astronomical Observatory of Japan (United States); Janis Hagelberg, Univ. of Hawai'i (United States); Barnaby R. Norris, The Univ. of Sydney (Australia); Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States); Garima Singh, Jet Propulsion Lab. (United States); Prashant Pathak, Danielle Doughty, Subaru Telescope, National Astronomical Observatory of Japan (United States); Sean B. Goebel, Subaru Telescope, National Astronomical Observatory of Japan (United States) and Institute for Astronomy (United States); Jared R. Males, The Univ. of Arizona (United States); Jonas G. Kuhn, Jet Propulsion Lab. (United States) and ETH Zürich (Switzerland); Eugene Serabyn, Jet Propulsion Lab. (United States); Peter G. Tuthill, The Univ. of Sydney (Australia); Guillaume Schworer, Observatoire de Paris (France) and The Univ. of Sydney (Australia); Frantz Martinache, Observatoire de la Côte d'Azur (France); Tomoyuki Kudo, Subaru Telescope, National Astronomical Observatory of Japan (United States); Hajime Kawahara, The Univ. of Tokyo (Japan); Takayuki Kotani, National Astronomical Observatory of Japan (Japan); Michael J. Ireland, The Australian National Univ. (Australia); Tobias Feger, Macquarie Univ. (Australia); Adam D. Rains, The Australian National Univ. (Australia); Christian Schwab, David W. Coutts, Macquarie Univ. (Australia)

The Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) system is an instrument optimized for high-contrast imaging and characterization at <5 lambda/D from the host star. Unlike other similar platforms such as GPI and SPHERE, it is constantly evolving in order to incorporate the latest in state-of-the-art technologies. This makes it the ideal testbed for a high-contrast imager for an ELT.

SCExAO achieves high-contrast by first improving on the correction offered by the facility adaptive optics (AO) system. The Extreme AO loop consists of a pyramid wavefront sensor offering diffraction-limited wavefront sensing in the visible on the 8-m class Subaru telescope, combined with a 2000-element deformable mirror which is modified at >3 kHz in order to flatten the wavefront and offer >90% Strehls when fully commissioned. A Lyot based low-order wavefront sensor is used to track small, non-common path and chromatic fluctuations simultaneously in the near-IR in the coronagraphic focal plane in order to ensure sub-milliarcsecond pointing precision and minimal stellar leakage.

The suite of coronagraphs on SCExAO is extensive and includes, the PIAA, PIAACMC, vector vortex, 4 quadrant, 8 octant and shaped pupil versions. The PIAA, PIAACMC and vector vortex with pupil remapping optics are all optimized for small inner working angles at or below 1 lambda/D. These coronagraphs take full advantage of the flat wavefront and are unrivaled on any other ground-based high contrast imager.

For advanced calibration we can close the loop on the ADC in order to reduce residual chromatic dispersion to < 1 mas in the NIR. In addition we commonly utilize an adaptive grid of speckles which are run to calibrate photometry and astrometry. Unlike other systems however, SCExAO creates incoherent speckles which are far superior in stability and robustness compared to their coherent counter parts.

Making use of the discarded visible light are several visible modules including VAMPIRES, FIRST and RHEA. The VAMPIRES instrument offers diffraction-limited imaging capabilities in the visible thanks to the interferometric imaging technique known as aperture masking. Combined with polarimetry VAMPIRES is actively studying the dusty shells around giant stars with unprecedented fidelity and will begin to investigate the dust disks around young stellar objects. RHEA is a high-resolution Echelle-based spectrograph, which will be fed with a single-mode fiber IFU to spatially resolve the convection cells on the surfaces of giant stars and study their dynamics for the first time.

In addition we are currently developing a post-coronagraphic fiber injection unit to feed the light into the IR doppler instrument known as IRD soon to be installed at Subaru Telescope. This will reduce the photon-noise

from the star allowing for a higher signal-to-noise planet spectrum to be extracted.

In this paper we give an overview of SCExAO and outline the current commissioning status of each module. We present results for the AO-loop, pointing control and the coronagraph performance in the laboratory and on-sky. We then go on to demonstrate the preliminary ground-breaking results achieved to date from science operation in regards to imaging disks, faint companions and dust shells around giant stars.

9909-177, Session PTue1

Linear dark field control: simulation for implementation and testing on the UA wavefront control testbed

Kelsey L. Miller, The Univ. of Arizona (United States); Olivier Guyon, The Univ. of Arizona (United States) and Jet Propulsion Lab. (United States)

This paper presents the early-stage simulation results of linear dark field control (LDFC) as a new approach to maintaining a stable dark region within a stellar coronagraphic PSF. These results represent the first step in the implementation of LDFC in the UA Wavefront Control Lab as a new wavefront sensing and control technique to be tested. In practice, electric field conjugation (EFC) creates a dark region in the image, and LDFC maintains it by using information from the bright speckle field outside of the dark hole. In theory, LDFC is faster, more sensitive, and more robust than using EFC alone to maintain the dark hole. The concept utilizes the linear response of the bright speckle intensity to wavefront variations in the pupil, and therefore has many advantages as a method for stabilizing the dark hole. To make use of this linear relationship, the first step in the implementation and characterization of LDFC is to determine the limits within which the linear response holds. In this paper, the limits of the detector response's linear regime are presented as an initial step toward the deployment of LDFC on the UA Wavefront Control testbed in the coming year.

9909-180, Session PTue1

Natural guide-star processing for wide-field laser-assisted AO systems

Carlos M. Correia, Benoit Neichel, Lab. d'Astrophysique de Marseille (France); Jean-Marc Conan, Cyril Petit, Jean-François Sauvage, ONERA (France); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Joël D. R. Vernet, European Southern Observatory (Germany); Niranjan A. Thatte, Univ. of Oxford (United Kingdom)

We present the natural guide-star processing for wide-field laser tomography AO systems.

The approach is based on tailoring the spatio-angular approach whereby the wavefront is estimated directly in the pupil plane avoiding a cumbersome explicit layered estimation, to tilt modes on Extremely Large Telescopes.

Taking the case of Harmoni, the European-ELT's visible and near-infrared (0.47 to 2.45 μm) integral field spectrograph we cover the choice of wave-front sensors, the number and field location of guide-stars, the optimised algorithms to beat down angular anisoplanatism and the performance obtained with different temporal controllers under split high-order/low-order tomography or joint tomography. We consider both atmospheric and far greater telescope wind buffeting disturbances. In addition we provide the sky-coverage estimates thus obtained.

9909-183, Session PTue1

Green FLASH: energy efficient real-time control for AO

Damien Gratadour, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Nigel A. Dipper, Durham Univ. (United Kingdom); Roberto Biasi, Microgate S.r.l. (Italy); Hugues Deneux, PLDA (France)

Addressing the problem of the unprecedented computing power required to control AO systems coupled to the associated data rate is one of the major challenges identified in the phase A concept studies for the E-ELT instruments. Thus the simplest control law applied to a multi-laser guide stars system such as MAORY or MOSAIC require computing power of up to a TMAC/s (Tera Multiply Accumulate per second)and associated data rates of the order of several hundreds of Gb/s . While current designs of real-time control systems of most AO instruments are based on the use of specialized microprocessors (DSP) and / or reprogrammable logic chips (FPGA), the complexity and scale of future generation systems make the use of these technologies extremely expensive. In addition, due to the saturation of the power evolution of the X86 processors, the use of this technology requires the implementation of substantial structures, with low energy efficiency. Following the recent development of the high-performance computing market, the development of a new solution for AO RTC based on processors such as GPUs to replace DSP cards is an attractive option. This readily available hardware can potentially provide the computing power necessary at a limited cost and with more energy efficiency. Moreover, complete and optimized programming models are available, such as CUDA, OpenCL and OpenMP, and are compatible with traditional mathematical libraries. This is crucial to ensure the development of a scalable, standards-based RTC solution. In order to study this strategy as well as other technology options such as using reprogrammable logic (FPGA), we are starting a large research program, codenamed Green FLASH, gathering the efforts of academic partners (Observatoire de Paris and Durham University) and industrial partners (PLDA company in France and Microgate in Italy), to select and validate new concepts for real-time control for AO on the E-ELT. Over a period of three years (delivery of a prototype scheduled for the end of 2018) and a budget of about 4M€ mostly funded by the European program Horizon 2020, the goal of the Green FLASH project is to implement a full scale RTC prototype instrument for a tomographic system such as MAORY on the E-ELT. We will present the project goals, the roadmap and the results from the first year of prototypes development.

9909-188, Session PTue1

Kaczmarz and Cimmino: iterative and layer-oriented approaches to atmospheric tomography

Chiara Garbellotto, Michele Donini, Univ. degli Studi di Padova (Italy); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Carmelo Arcidiacono, INAF - Osservatorio Astronomico di Bologna (Italy); Andrea Baruffolo, Jacopo Farinato, INAF - Osservatorio Astronomico di Padova (Italy)

Multi Conjugated Adaptive Optics is based upon tomographic reconstruction of the atmospheric turbulence over the line of sight of a telescope, by means of reconstructing turbulence layers through measurements achieved at slightly different directions in the sky. Different approaches have been developed so far, notably the so called layer-oriented one, experienced with success at the VLT through MAD. Later it has been shown that the problem, once posed in terms of solving a set of linear equations describing the turbulence layers with respect to the

observables, can be solved in an iterative manner through a technique first proposed by Kaczmarz in 1937. While it was speculated that the layer-oriented would asymptotically converge to the same solution, we investigated the generalized problem and we found that the layer-oriented is basically a weighted form of an alternative technique for the same kind of problem (finding the solution of a set of linear equations) invented by Cimmino in 1938. We placed the two approaches in the same theoretical framework using the same notation, and we demonstrated the validity of the speculation. The finding can be used to further investigate the differences between the two methods. The first one iteratively forces the solution to achieve a perfect matching in one direction at a time while the second one privileges the results on the various layers. Although this has just a sort of historical perspective it is interesting to note that the second method, the layer-oriented, is better suited for a limited number of iterations. In fact, in its implementation in the sky the number of iterations performed before commands being applied is actually just one. This single-iteration approach would turn out to produce largely non uniform effects in the field of view when using Kaczmarz's method, which, however, has been introduced assuming a large number of iterations to be performed before the commands being applied. The finding can also be used to trace some preliminary conclusions in terms of speed of convergence, further to suggest that several other approaches invented almost a century ago could be of some practical interest.

9909-193, Session PTue1

The control switching adapter: a practical way to ensure bumpless switching between controllers while AO loop is engaged

Henri-François G. Raynaud, Lab. Charles Fabry (France); Rémy Juvénal, Lab. Charles Fabry (France) and ONERA (France); Caroline Kulcsár, Lab. Charles Fabry (France); Cyril Petit, ONERA (France)

In recent years, advanced control methods have gained significant ground in astronomical Adaptive Optics (AO) systems. In particular, the Linear Quadratic Gaussian (LQG) control has been implemented and tested on a full-scale AO system with the CANARY instrument in 2012 [1]. LQG has also been deployed as the default tip & tilt modes controller for SAXO, the Extreme AO system of the SPHERE planet imager [2], and for pointing and focus control on GPI [3]; LQG has also been included as a baseline algorithm for the low-order control loop of NFIRAOS, the first adaptive optics system of the future Thirty Meter Telescope [4].

Real-time implementation of LQG relies on the so-called state-space form, which enables to adjust its parameters by simply loading a different set of matrices in the system's Real Time Computer (RTC). On-line LQG re-tuning is crucial to obtain and maintain high performance and stability over long observation times, since gains need to be adapted at regular intervals to match changes in turbulence conditions and other disturbances (vibrations, windshake). However, switching from one LQG to another (or back and forth from LQG to integrator control) creates transient "bumps" in control trajectories which may have an adverse (if temporary) impact on the AO loop's stability and performance. One way to eliminate these "control bumps" is to exploit the fact that when the controller about to be switched on is implemented in state-state form, its internal state vector can be adjusted to mimic a fictitious scenario where the old and the new controllers would have operated alongside each other and generated the same control trajectory over a short overlapping period of time. This well-known control engineering trick [5] can be adapted to the special case of AO to manage the switch from LQG to (another) LQG, from LQG to integrator and from integrator to LQG.

In this work, we show how to implement this procedure in the special case of a tip and tilt AO control loop, using a "control switching adapter" – an additional piece of AO RTC software which would need to be activated a few milliseconds before the new controller is switched on to compute the appropriate value of its internal state vector. A simulation of controller switching between an integrator and two different LQG controllers settings is presented.

Dimensioning the MAORY real time computer

Laura Schreiber, Emiliano Diolaiti, Carmelo Arcidiacono, INAF - Osservatorio Astronomico di Bologna (Italy); Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Giovanni Bregoli, INAF - Osservatorio Astronomico di Bologna (Italy); Enrico Cascone, INAF - Osservatorio Astronomico di Capodimonte (Italy); Giuseppe Cosentino, Univ. degli Studi di Bologna (Italy); Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Corrado Felini, INAF - Osservatorio Astronomico di Capodimonte (Italy); Italo Foppiani, INAF - Osservatorio Astronomico di Bologna (Italy); Paolo Spanò, INAF - Osservatorio Astrofisico di Arcetri (Italy); Paolo Ciliegi, INAF - Osservatorio Astronomico di Bologna (Italy); Philippe Feautrier, Institut de Planétologie et d'Astrophysique de Grenoble (France)

The MAORY system is the Multi-Conjugate Adaptive Optics module for the European Extremely Large Telescope first light.

MAORY should provide high and homogeneous image quality over the MICADO field of view (about 1 arcmin diameter) and still an accettable correction up to the 2.6 arcmin technical Field of View.

The baseline of MAORY is therefore to rely upon the use of multiple Laser Guide Stars (6), multiple Natural Guide Stars (3) and multiple Deformable Mirrors (DM) correction (M4/M5, that are part of the telescope, and 2 post focal DMs).

The Real-Time Control is a key sub-system of MAORY.

It must collect the measurements from various sensing devices and drive the numerous actuators, that can be part of the telescope (like M4 and M5 mirrors) or part of MAORY itself. Many correction loops are forseen with different updates rates.

The main requirements concerning the system dimensioning and real-time performance depend on the sensors and on the actuators interface and on the Real-Time Data Processing.

In this paper we give a preliminar description of the MOARY Real-Time Control system functional requirements derived from the system baseline at the beginning of the instrument Phase B.

9909-197, Session PTue1

Bridging FPGA and GPU technologies for AO real-time control

Denis Perret, Maxime Lainé, Damien Gratadour, Arnaud Sevin, Observatoire de Paris (France)

Our team has developed a common environment for high performance simulations and real-time control of AO systems based on the use of Graphics Processors Units in the context of the COMPASS project. Such a solution, based on the ability of the real time core in the simulation to provide adequate computing performance, limits the cost of developing AO RTC systems and make them more scalable. A code developed and validated in the context of the simulation may be injected directly into the system and tested on sky. Furthermore, the use of relatively low cost components also offers significant advantages for the system hardware platform. However, the use of GPUs in an AO loop comes with drawbacks: the traditional way of offloading computation from CPU to GPUs, involving multiple copies and and resulting in unacceptable kernel launch overheads, is not well suited in a real time context. This last application requires the implementation of a solution enabling direct memory access (DMA) to the GPU memory from a third party device, bypassing the operating system. This allows this device to communicate directly with the real-time core of the simulation feeding it with the WFS camera pixel stream. We show that DMA between a custom FPGA-based frame-grabber and a computation unit (GPU, FPGA, or Coprocessor such as Xeon-phi) across PCIe allows us to get latencies compatible with what will be needed on ELTs. As a fine-grained synchronisation mechanism is not yet made available by GPU vendors, we propose the use of memory polling to avoid interrupts handling and involvement of a CPU. Network and vision protocols are handled by the FPGA-based Network Interface Card (NIC). We present the results we obtained on a complete AO loop using camera and deformable mirror simulators.

9909-202, Session PTue1

Thirty Meter Telescope narrow-field infrared adaptive optics system (NFIRAOS) real-time controller prototyping results

Malcolm Smith, Daniel A. Kerley, Jennifer S. Dunn, Jean-Pierre Véran, Glen Herriot, NRC - Herzberg Astronomy & Astrophysics (Canada); Luc Gilles, Corinne Boyer, Lianqi Wang, Brent L. Ellerbroek, Thirty Meter Telescope (United States)

Prototyping and benchmarking was performed for the Real-Time Controller (RTC) of the Narrow Field Infrared Adaptive Optics System (NFIRAOS). NFIRAOS utilizes two deformable mirrors (DM) and one tip/tilt stage (TTS) to perform wavefront correction. The RTC receives wavefront information from six Laser Guide Star Shack-Hartmann WaveFront Sensors (LGS WFS) and one high order Natural Guide Star Pyramid WaveFront Sensor (PWFS) and uses this information to determine the commands to send to the wavefront correctors. NFIRAOS is the first light AO system for the Thirty Meter Telescope (TMT).

The prototyping was performed using dual-socket high performance Linux servers with the real-time (PREEMPT_RT) patch and demonstrated the viability of a commercial off-the-self (COTS) hardware approach to large scale AO reconstruction. In particular, a large custom matrix vector multiplication was benchmarked which met the required latency requirements, all major inter-machine communication was verified to be adequate using 10Gb and 40Gb Ethernet, and standard browser-based technologies were used to implement high performance AO displays. The results of this prototyping has enabled a CPU based NFIRAOS RTC design to proceed with confidence that COTS hardware can be used to meet the demanding performance requirements

9909-203, Session PTue1

Comparison of layer compression methods and joint optimization

Daniela Saxenhuber, Johannes Kepler Univ. Linz (Austria); Günter Auzinger, Johann Radon Institute for Computational and Applied Mathematics (Austria); Tapio Helin, Univ. of Helsinki (Finland); Miska Le Louarn, European Southern Observatory (Germany)

In wide-field atmospheric tomography applications of adaptive optics (AO) systems, tomographic solvers cannot always perform phase delay reconstructions on the full number of layers defined in established statistical atmosphere models (mainly due to restrictions on run-time and stability). Hence, a smaller number of reconstruction layers has to be used. In this poster we investigate the crucial question how to choose appropriate reconstruction layer profiles (heights and cn2-weights) with given small numbers of layers, in order to enable tomographic solvers to achieve acceptable small residuals. A special focus is put on two new and promising approaches for automatic generation of such profiles - namely the a-priori compression method optimal grouping and joint optimization, a method for optimizing the profile during solution of the tomography problem without knowing the exact profile.

We will show comparisons of AO simulations for several tomographic solvers running on different reconstruction layer profiles. The simulations are performed for an ELT setting with realistic atmospheric models on the ESO end-to-end AO simulation tool, OCTOPUS.

9909-206, Session PTue1

Novel technology for reducing wavefront image processing latency

David T. Barr, UK Astronomy Technology Ctr. (United Kingdom) and Heriot-Watt Univ. (United Kingdom); Alastair G. Basden, Nigel A. Dipper, Durham Univ. (United Kingdom); Noah Schwartz, Hermine Schnetler, UK Astronomy Technology Ctr. (United Kingdom)

Adaptive optics is a crucial system for the future extremely large telescopes. The instrument real-time control of these planned AO systems offer an interesting computational challenge which cannot easily be solved with current technologies.

Large amounts of work have been done on reducing the overall AO latency. The majority of this work is aimed at reducing the wavefront reconstruction latency by using many-core hardware accelerators such as Xeon Phis and GPUs. These modern hardware solutions have large numbers of cores and high memory bandwidths while having restrictive I/O capability. This lack of I/O inhibits the efficient data processing needed to be performed by these systems. A single camera for an ELT scale adaptive optics system can produce hundreds of millions of pixels per second that need to be processed. Passing all this data though a CPU and into GPUs or Xeon Phis is inefficient.

The Tilera multi-core processor is a novel technology combining a high number of cores and multiple 10 Gbps Ethernet I/O ports. In this paper, we present performance results of using the Tilera Tile GX36 to process pixel data streaming from a wavefront camera. We describe our testing strategy and show that this hardware is a suitable candidate for E-ELT scale AO systems, offering both high performance and very high stability. Finally, we describe how it could be implemented in a real-time control system to reduce the amount of data needing to be transferred to the wavefront reconstruction hardware.

9909-212, Session PTue1

EDiFiSE full-FPGA adaptive optics: first laboratory results using the IACAT (IAC Atmosphere and Telescope) optical ground support equipment

Haresh M. Chulani, Yolanda Martín-Hernando, Jesús J. Fuensalida, Instituto de Astrofísica de Canarias (Spain); Carlos Echeandía, Orbital Aerospace (Spain); Luis Fernando Rodríguez-Ramos, Angel Alonso-Sánchez, Instituto de Astrofísica de Canarias (Spain)

This paper presents the EDiFiSE Equalized and Diffraction-limited Field Spectograph Experiment full-FPGA AO system and its first laboratory results. EDiFiSE is a prototype Equalized Integral Field Unit (EIFU) Spectrograph for the observation of high-contrast systems in the Willian Herschel Telescope (WHT). Its Adaptive Optics (AO) system comprises two independent parallel full-FPGA control loops, one for tip-tilt and one for higher order aberrations. Xilinx's Virtex-4 and Virtex-5 FPGA's fixed point arithmetic and their interfacing with the rest of AO components and the user have been adequately dealt with, and a very deterministic system with a negligible computational delay has been obtained. The AO system has been recently integrated in laboratory and verified using the IACAT (IAC Atmosphere and Telescope) optical ground support equipment. About 0.25 Strehl ratio is obtained in the visible range for the WHT with a 9 x 9 subpupil configuration, low star magnitude, wind speeds up to 10 m/s and Fried parameter down to 18 cm.

9909-215, Session PTue1

Novel algorithm implementations in DARC: the Durham AO real-time controller

Alastair G. Basden, David Jenkins, Durham Univ. (United Kingdom)

The Durham AO Real-time Controller has been used on-sky with the CANARY AO demonstrator instrument since 2010. Over this period, many new real-time algorithms have been developed, implemented and demonstrated, leading to performance improvements for CANARY.

Additionally, the computational performance of this real-time system has continued to improve. Here, we provide details about recent updates and changes made to DARC, and the relevance of these updates, including new algorithms, to forthcoming AO systems. We present the computational performance of DARC when used on different hardware platforms, including hardware accelerators, and determine the relevance and potential for ELT scale systems.

Recent updates to DARC have included algorithms to handle elongated laser guide star images, including correlation wavefront sensing, with options to update references during AO loop operation. Additionally, sub-aperture masking options have been developed to increase signal to noise ratio when operating with non-symmetrical wavefront sensor images. The development of end-user tools has progressed with new options for configuration and control of the system. New wavefront sensor camera models and DM models have been integrated with the system, increasing the number of possible hardware configurations available, and a fully open-source AO system is now a reality, including drivers necessary for cameras and DMs.

The computational performance of DARC makes it suitable for ELT scale systems when implemented on suitable hardware. We present tests made on different hardware platforms, along with the strategies taken to optimise DARC for these systems.

9909-217, Session PTue1

Demonstration of the suitability of GPUs for AO real-time control at ELT scales

Urban Bitenc, Alastair G. Basden, Nigel A. Dipper, Richard M. Myers, Durham Univ. (United Kingdom)

The computational demands on the real-time control system to be used for Extremely Large Telescopes will be challenging. Different hardware is available for this task: CPU (computer), FPGA (Field Programmable Gate Array), Graphics Processing Units (GPU) and specialized components like Xeon-Phi. Several different architectures (including hybrids) are being investigated to assess which solution is the best compromise in terms of performance, development time, software maintenance and cost of hardware.

Durham AO Real-time Controller (DARC) is a modular, flexible and configurable CPU-based real-time control system designed with ELT performance in mind. Its modular approach and flexibility allow the simple addition of hardware acceleration, and also facilitates operation with any camera or deformable mirror type.

In this contribution we present an implementation of DARC where the entire data processing pipeline is executed on one or more GPUs. The pixel data from a camera are retrieved by the CPU and copied to GPU. There they are calibrated (with inclusion of several advanced algorithms), then wavefront slopes are calculated and the wavefront is reconstructed with the traditional matrix-vector-multiplication method. Finally the actuator commands are copied back to CPU to be delivered to the Deformable Mirror.

With dummy data on the scale of an ELT instrument, we have demonstrated that the required frame rates for a single DM can be achieved using a small number of current generation GPUs. We have confirmed this result using pixel data from a real camera.

We have addressed the issue of copying data between CPU memory and the GPUs and present a method of minimising the impact on the system latency resulting from this overhead. This is achieved by copying new data to/from GPU in parallel to processing data that has been copied earlier. We also investigated the limitations of this approach.

As well as using the standard centre-of-gravity centroiding, we have implemented several advanced slope estimation algorithms which will be crucial for the on-sky performance of an ELT. These algorithms are computationally intensive but highly parallelizable so there is a significant benefit from implementation on GPU. We show that the impact of these algorithms on system latency can be minimised by implementation on GPU technology, making their use at ELT scales practical.

9909-218, Session PTue1

Model predictive control for laser shaping

José Luis Marchioni Clavería, Pedro Escárate, Sebastián Zúñiga Fernández, Mario A. Castro R., Diego A. Rojas Zagals, Javier Garcés, Univ. Técnica Federico Santa María (Chile)

Laser Guide Star (LGS) are widely used in telescopes with mirrors diameter greater than 4 meter, observatories as Gemini, Paranal and Keck, just to mention a few, have developed and apply Adaptive Optics (AO) systems to improve resolution considerably into observations. Due to remarkably results in AO systems, this technology keeps evolving in order to affront new challenges as TMT and E-ELT. This work aim at optimize quality and speed-up calibration of laser beam, so that to increase the availability telescopes.

First stage consists in simulations to validate the lineal model of the system, corresponding to Fresnel Propagation in near field, which is part of iterative phase-retrieval method. This work aim to achieve a determined

propagation shape of laser beam, the closed loop should be capable to counteract the disturbances that cause distortion on the beam path. Then, second stage, should generate an algorithm of closed loop based in Model predictive Control (MPC) and through simulations corroborate a good performance. Finally, third stage considers validation in a laboratory environment in order to analyze the hardware limitations.

Currently, the first and second stage finished successfully, where has verified that MPC is an appropriated method to solver this kind problem with fast dynamics. In order to obtain convincing result the algorithm are tests for different distribution of amplitude to classic super Gaussian shape, also achieved successfully. Other variable considered are: the computing time; error reference of amplitude; and the convergence solution speed. In addition, ratios are used by evaluate performance of algorithm.

The experimental stage is been implemented rigorously on a laboratory bench in order to validate the algorithm of control. If we got successful results, will mean a huge simplification to calibrate LGS due to the closed loop allow a little error to propagation model, thus, the advantage now consisting in not to have a so complex model that require too much computing time. Instead to its allowing to increase a larger number of actuator of DM, meaning, controlling a mirror bigger with improved resolution.

The relevance to continue development AO system generate great impact at telescope due to this technique tip the balance toward the facility the telescopes on surface ground and not in space by its high cost and limited size. The weakness of this work corresponding to not prove the system in a real telescope to test the performance of control over a bigger system with a larger number of actuator and better computing power, this way test the ultimate performance of algorithm.

9909-219, Session PTue1

Control of tip-tilt mirror: a LMI based anti-windup approach

Jean-Pierre Folcher, Univ. de Nice Sophia Antipolis (France)

This paper adresses the application of LMI-based approach for the control of tip-tilt modes. We focused our attention on saturation phenomena which can occur in a strong turbulence context and in the presence of structural vibration of the telescope. This phenomena can degrade the performance or even destabilize the feedback system that is denoted the “windup” effects. We propose an anti-windup two-step approach which guarantees stability and levels of performance. A controller is first designed to work well in the absense of input saturations. Then, it is modified by an anti-windup block which would modify the control signal when saturations are present. The advantages of the proposed approach are shown through numerical experiments.

9909-221, Session PTue1

Location-grouping algorithm based on limited actuators deformable mirror for high precision wavefront aberration correction in adaptive optics system

Meng Yan, Tsinghua Univ. (China); Huang Lei, Tsinghua Univ. (China) and College of Optical Sciences, The Univ. of Arizona (United States); Qi Bian, Chenlu Zhou, Xingkun Ma, Tsinghua Univ. (China); Mali Gong, College of Optical Sciences, The Univ. of Arizona (United States)

The aberration in the center position of wavefront can be corrected well when the deformable mirrors (DM) used in high-resolution adaptive optics system of telescope. However, for the defocus and spherical aberration of telescope, the four corners of the wavefront cannot be corrected well. At two levels of wave front correction based on the LS (least squares) algorithm and the SPGD (stochastic parallel gradient descent) algorithm, the control elements of wave front corrector of deformable mirrors are subdivided into four parts depending the location.

In wavefront sensor adaptive system, there are several frequently-used control methods. The LS algorithm is fast but suffers from low relatively accuracy. And the SPGD algorithm, simulated annealing algorithm, genetic algorithm, have low correction efficiency. To solve this problem, hybrid LS-SPGD algorithm is proposed, which can get correction effect and improve correction efficiency. The mathematical model for the hybrid LS-SPGD algorithm is established, and numerical simulations and spot correction experiments will be conducted. The probable aspects when it is applied to the practice are analyzed specifically. Judging from the results of the correction, the new method can improve correction effect. At the same time, the four corners of the corrected wave front cannot get a good consistency. Especially the defocus and spherical aberration have great influence on the correction of the four corners of wavefront. To solve this problem, the aberration correction procedure can be divided into two steps.

A novel correction method at different levels and regions of deformable mirror is proposed. At first, the wavefront is corrected by the LS-SPGD algorithm. And then the control elements of wave front correctors in four corners are divided, and every four or five DM units in a corner is a group. Then hill-climbing algorithm is used to correct aberration of four corners of the wavefront, and the local root mean square (RMS) of residual wavefront of every corner is considered as a standard to evaluate the effectiveness of the correction. The control elements in each cluster are driven by the different control voltage which is treated as a control variable in correction process.

The novel hybrid algorithm adaptive optics system corrects the distorted wavefront in the sequence from the center parts to the four corners. Aiming at the random aberration, a 49-element AO model based on the method mentioned in this paper is set up, and a group of phase aberration is simulated to research the effect on correct process.

The results reveal that there is a promising prospect for the novel method to be used in corrections of static aberrations, and showed significant advantages in correction of high order aberration. Numerical simulations and spot correction experiments were conducted, and the results indicated this method can get a high efficiency.

9909-222, Session PTue1

Prediction control method to improve the dynamic performance of a close-loop adaptive optics system

Xinyang Li, Qi Luo, Zhao-jun Yan, Institute of Optics and Electronics (China)

The prediction control method can be used to reduce the dynamic performance of an adaptive optics system (AOS) used for correcting the wavefront distortion of atmosphere turbulence. Some researchers have proved this idea but usually in open-loop condition, which predicts the change of wavefront distortion without corrected by deformable mirror (DM). Those open-loop prediction methods often based on the wavefront or sub-aperture gradients of Hartmann-Shack (HS) wavefront sensors. But in practice nearly all AOS are running in close-loop to reduce the nonlinear error of wavefront sensor and DM. It is difficult to predict wavefront distortion in close-loop. In this paper, prediction methods were proposed to improve the dynamic performance of an AOS running with HS and DM in close-loop. In one method, prediction on reconstructed voltages of DM was added to normal close-loop AOS after parallel-integration control calculation. In another method, the prediction process on reconstructed voltages of DM was joined with the reconstruction process and the integration control process. The Recursive Least-Square (RLS) algorithm was used to calculate the wind speed and control parameters of an AOS

based on the voltages of DM. Both methods can be used to practice close-loop AOS with less modification on control algorithm. Calculations were carried out with measured atmosphere turbulence data from a telescope with an AOS to validate the predict method in different atmosphere turbulence condition. There are 127 actuators in the DM of the AOS. The residual wave-front error, the Strehl Ratio of far-field spot, and the power spectrum densities were calculated and compared between an AOS with and without the prediction method. The results show that the dynamic control performances of an AOS will be improved significantly by using both prediction methods, but the second method will be better for more atmosphere conditions.

9909-223, Session PTue1

Spiders: a problem for the DM control?

Andreas Obereder, Johann Radon Institute for Computational and Applied Mathematics (Austria)

All reflecting telescopes need support structures to hold the secondary mirror.

To cope with the weight of the secondary mirror in the planned ELTs, large support structures must be used.

Inadvertently, these support structures will obstruct several wavefront sensor subapertures fully or at least partly.

These effects, also known as spiders, manifest in the WFS measurements as higher measuring inaccuracies or even missing measurements from completely obstructed WFS subapertures.

Subsequently effects of spiders appear as a set of disconnected domains with valid measurements on the wavefront sensor.

This may, if no proper regularization is used, result in separate piston modes in the DM shape on each disconnected domain.

As the piston mode is in the null-space of, e.g., the SH-WFS, those constant shifts may evolve slowly over time and lead to decreasing Strehl ratios.

In order to overcome this problems we will introduce new ways to control the DM shape.

To avoid those piston modes three different methods are implemented and compared.

Method A: The piston in each DM segment is derived using a lower order Wavelet reconstruction using the FEWHA reconstructor. The so calculated piston is applied to a higher order reconstruction on each DM segment obtained with the CuReD (Cumulative Reconstructor with Domain Decomposition).

Method B: The piston is derived, such that he jumps between the segment are minimized using line integrals on the borders of the segments. This is equivalent to the assumption that “nothing” happens under the spider. This method is more stable then assuming zero measurements on the obstructed sensor subapertures and leads thus to higher Strehl Ratios.

Method C: Use a regularization method to derive the piston on each segment, such that the wavefront statistics are fulfilled.

In this talk we focus this methods for a stable DM control using the CuReD and will compare the obtained results with existing algorithms, namely FrIM and FEWHA using all Wavelet Scales. Both methods use statistical regularization to get an optimal reconstruction quality.

Major focus is as well put on real life simulations using the planned E-ELT spider structures and realistic AO-settings. The results presented have been obtained utilizing Octopus, the ESO end-to-end simulation tool and YAO.

9909-22, Session PTue2

On-sky performance using an LQG controller for tip-tilt correction in regular science observation on GeMS

Gaetano Sivo, Gemini Observatory (Chile); Rémy Juvénal, Institut d’Optique Graduate School (France) and ONERA (France); Caroline Kulcsár, Institut d’Optique Graduate School (France); Vincent Garrel, Pedro Gigoux, Gemini Observatory (Chile); Henri-François G. Raynaud, Institut d’Optique Graduate School (France); Eduardo Marin, Gemini Observatory (Chile); Jean-Marc Conan, Cyril Petit, ONERA (France); William N. Rambold, Vanessa Montes, Cristian Moreno, Gemini Observatory (Chile); Jeff Donahue, Gemini Observatory (United States); Eleazar R. Carrasco Damele, Gemini Observatory (Chile); Marcos A. Van Dam, Flat Wavefronts (New Zealand); Benoît Neichel, Lab. d’Astrophysique de Marseille (France); Chadwick A. Trujillo, Gemini Observatory (United States)

AO systems aim at detecting and correcting for optical distortions induced by atmospheric turbulences. They are also extremely sensitive to extraneous sources of perturbation such as vibrations, which degrade their performance. The Gemini South telescope has currently 2 main AO systems: the Gemini Multi-Conjugated AO System GeMS and the Gemini Planet Imager GPI. GeMS is operational and regularly used for science observation delivering close to diffraction limit resolution over a large field of view (85x85 arcsec2). Performance limitation due to the use of an integrator for Tip-Tilt control is here explored. In particular, this type of controller does not allow for the mitigation of vibrations with an arbitrary natural frequency. We have thus implemented a Tip-Tilt Linear Quadratic Gaussian (LQG) controller with different underlying perturbation models: (i) a sum of auto-regressive models of order 2 identified from an estimated power spectrum density (s-AR2) of the perturbation (Meimon et al., JOSA A 2010), already tested on CANARY (Sivo et al., Opt. Exp. 2014) and routinely used on SPHERE (Petit et al., SPIE 2014); (ii) cascaded ARMA models of order 2 identified using prediction error minimization (c-PEM) as proposed in (Massioni et al., SPIE 2012, Juvénal et al., AO4ELT4 2015). Both s-AR2 and c-PEM were parameterized to produce tip or tilt state-space models up to order 20 and up to order 30 respectively.

We present in this paper the results obtained on-sky using these LQG controllers and compare their performance to what GeMS is currently delivering using the classic integral controller. We also discuss the parallelized implementation in the real-time computer and give the strategy adopted to commission this controller in regular operation for GeMS.

9909-174, Session PTue2

Speckle lifetime in XAO coronagraphic images: temporal evolution of the SPHERE point spread function

Julien Milli, European Southern Observatory (Chile); David Mouillet, Institut de Planétologie et d’Astrophysique de Grenoble (France); Dimitri Mawet, California Institute of Technology (United States); Julien H. V. Girard, Zahed Wahhaj, European Southern Observatory (Chile); Tyler Banner, European Southern Observatory (Germany); Thierry Fusco, Jean-François Sauvage, ONERA (France); Raphaël Galicher, Lab. d’Etudes Spatiales et d’Instrumentation en Astrophysique (France)

The major source of noise in high-contrast imaging is the presence of slowly evolving speckles that do not average with time. The temporal stability of the point-spread-function (PSF) is critical to reach a high contrast with extreme adaptive optics (XAO) instruments. Understanding on which timescales the PSF evolves and what are the critical parameters driving the speckle variability allow to design an optimal observing strategy and data reduction technique to calibrate instrumental aberrations and reveal faint astrophysical sources. In this talk, I will analyze the evolution of the PSF of the XAO instrument SPHERE on the VLT, based on on-sky coronagraphic observations from the first year of operations of SPHERE. I retrieve the timescales of the different sources of aberrations. We show that residuals from the atmospheric turbulence induce a fast, partial decorrelation of the PSF over a few seconds, before a transition to a regime with a linear decorrelation with time, at a rate of a few tens parts per million per second. We analyze the spatial dependence of this decorrelation, within the well-corrected radius of the adaptive optics system. We show the impact on the contrast and show that the meridian passage corresponds to the most stable configuration with the smallest PSF decorrelation rate for an instrument such as SPHERE sitting on the Nasmith platform of the VLT.

9909-176, Session PTue2

High contrast imaging of exoplanets on ELTs using a super-Nyquist wavefront control scheme

Benjamin L. Gerard, Univ. of Victoria (Canada); Christian Marois, NRC-Dominion Astrophysical Observatory (Canada)

One of the key science goals for extremely large telescopes (ELTs) is the detailed characterization of already known directly imaged exoplanets. The typical adaptive optics (AO) Nyquist control region for ELTs is ?0.4 arcseconds, placing many already known directly imaged planets outside the DM control region and not allowing any standard wavefront control scheme to remove speckles that would allow higher SNR images/spectra to be acquired. This can be fixed with super-Nyquist wavefront control (SNWFC), using a sine wave phase plate to allow for wavefront control outside the central DM Nyquist region. We demonstrate that SNWFC is feasible through a simple, deterministic, non-coronagraphic, super-Nyquist speckle nulling technique in the adaptive optics laboratory at the National Research Council of Canada. We also present results in simulation of how SNWFC using the self coherent camera (SCC) can be used for high contrast imaging. This technique could be implemented on future high contrast imaging instruments to improve contrast outside the standard central dark hole for higher SNR characterization of exoplanets.

9909-181, Session PTue2

High-precision wavefront control using multiple wavefront sensors: the SCExAO experience

Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States) and The Univ. of Arizona (United States); Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Jared R. Males, The Univ. of Arizona (United States); Frantz Martinache, Observatoire de la Côte d'Azur (France); Garima Singh, Jet Propulsion Lab. (United States); Prashant Pathak, Subaru Telescope, National Astronomical Observatory of Japan (United States); Sean B. Goebel, Institute for Astronomy (United States)

The Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) instrument, currently under development for the Subaru Telescope, optimally combines state-of-the-art technologies to study exoplanets and stellar environments at the diffraction limit, both in visible and infrared light (0.6 to 2.4 um). The instrument integrates efficiently an ultra-fast visible Pyramid Wavefront Sensor (PyWFS) operating at 3.5 kHz with a latency below 1 ms (3 times faster than any system currently on-sky), a fast speckle nulling loop at 1 kHz, an asymmetric pupil Fourier wavefront sensor (APFWFS) and a Lyot-based low-order wavefront sensor (LLOWFS) at 170 Hz. All these loops use the same 2k-actuator MEMs deformable mirror to perform their correction.

Using all these wavefront sensors at the same time is essential to achieve the best contrast at about 1 lambda/D: the extreme AO loop cleans the wavefront in visible, the APFWFS corrects residual static low-order aberrations in IR, the speckle nulling loop optimizes the contrast by removing quasi-static speckles on one half of the image plane, and the LLOWFS corrects non-common path low-order aberrations behind the coronagraphic masks.

Combining all these loops together with the same correcting device requires a complex real-time architecture, using both CPUs and a bank of GPUs for speed. The PyWFS is considered as the main loop, while the other wavefront control loops are sending it zero-offset commands. This paper will describe how this system was implemented on SCExAO, its advantage and limitations, and how we will soon reach a loop speed of 10 kHz, necessary for SCExAO's operation on TMT.

9909-184, Session PTue2

The path to visible extreme adaptive optics with MagAO

Jared R. Males, Laird M. Close, Katie M. Morzinski, Olivier Guyon, Philip M. Hinz, The Univ. of Arizona (United States)

The next generation extremely large telescopes (ELTs) have the potential to image habitable rocky planets in the visible, if suitably optimized. This will require the development of fast high order ``extreme'' adaptive optics systems for the ELTs. Located near the excellent site of the future GMT, the Magellan AO system (MagAO) is an ideal on-sky testbed for visible high contrast imaging development. Here we will review some highlights of exoplanet imaging with MagAO's VisAO camera. We will then discuss planned upgrades to MagAO. These include improvements in WFS sampling (enabling correction of more modes) and an increase in speed to 2000 Hz, as well as an H2RG detector upgrade for the Clio infrared camera. This NSF funded project, MagAO-2K, will be on-sky in the Fall of 2016 and will significantly improve the performance of MagAO at short wavelengths. Finally, we describe MagAO-X, a visible-wavelength extreme-AO "afterburner" system under development. MagAO-X will deliver Strehl ratios of over 80% in the optical and is optimized for visible light coronagraphy.

9909-185, Session PTue2

High frame-rate detectivity methods with SPHERE ZIMPOL instrument

Jean-François Sauvage, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Hans Martin Schmid, ETH Zürich (Switzerland); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Thierry Fusco, ONERA (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France)

The direct imaging of exoplanet is a leading field of astronomy today. Capturing the few photons coming from a planet witnesses for the chemical composition of its atmosphere. The second-generation instrument SPHERE, dedicated to exoplanet imaging of Jovian-like planets, is now in operation on the European Very Large Telescope [VLT]. Such an instrument relies on an extreme adaptive optics (AO) system to compensate for atmospheric turbulence as well as internal system defects with an unprecedented accuracy.

We propose in this paper to develop new detection methods, based on temporal statistics at high framerate, on visible imaging data already acquired with SPHERE instrument. These data, acquired at high framerate, are a unique opportunity to finely understand the physics of coronagraphic image formation in the particular regime where the temporal behavior of Speckle light residual is frozen. The numerical model of image formation is therefore compared to sky data, and a first analysis is proposed.

9909-189, Session PTue2

SCExAO: on-sky performance of the asymmetric pupil Fourier wavefront sensor

Frantz Martinache, Observatoire de la Côte d'Azur (France); Nemanja Jovanovic, Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States)

Contrast detection limits for the direct imaging of extrasolar planets from ground based adaptive optics (AO) observations are mostly driven by the presence of residual static and slow-varying aberrations in the optical path that leads to the science instrument, and that are not sensed by the upstream wavefront sensor.

To measure and compensate for this non-common path error, the Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) instrument relies on a technique known as the asymmetric pupil Fourier wavefront sensor (APF-WFS). This technique uses the Fourier analysis of conventional focal images. This phase retrival problem, known to be degenerate can actually be solved quite simply when some asymmetry is introduced in the system. The insertion of a simple asymmetric pupil stop has proven sufficient to achieve this goal. Assuming reasonable upstream AO correction, a typical 30-second close-loop APF-WFS sequence suffices to compensate the non-common path error experienced by SCExAO after each new telescope pointing. APF-WFS is a powerful tool that senses the true wavefront at the level of the science detector, and leads to unbiased wavefront estimates. Although it introduces additional diffraction spikes to the instrument PSF, the asymmetry is mild enough to be considered as negligible for general purpose imaging.

This paper presents the latest status, linearity properties and reports on the on-sky performance of the APF-WFS sensor, as it is currently implemented on SCExAO, to control low-order Zernike modes in a close-loop system, desiged to offset the zero-point of SCExAO's main pyramid-based AO loop. The paper also shows how the sensor can be used to characterize the so-called low-wind effect experienced by SCExAO.

9909-192, Session PTue2

Speckle nulling wavefront control for Palomar and Keck

Michael Bottom, California Institute of Technology (United States); Bruno Femenia-Castella, W. M. Keck Observatory (United States); Elsa Huby, Univ. de Liège (Belgium); Dimitri Mawet, California Institute of Technology (United States); Eugene Serabyn, Jet Propulsion Lab. (United States)

The main requirements for high contrast imaging are an adaptive optics system to sharpen the point spread function by removing atmospheric turbulence, a coronagraph to control diffraction, and image post-processing to remove residual "speckles". Speckle-type errors, caused by optical aberrations after the wavefront sensor of the adaptive optics system (and hence invisible to it) are the dominant source of non-common-path aberrations. These are the most serious current barrier to imaging planets and other faint sources, as they are typically tens to thousands of times brighter than these sources of interest.

"Speckle nulling" is a way to remove speckles optically, rather than in post processing. The technique uses the deformable mirror to put "probe" speckles at the same locations in the focal plane as the offending speckles, then changes the phase of the light to modify the interference pattern. By analyzing the interference intensity on the science camera, it is possible to measure the electric field phase of the offending speckles. Knowledge of the electric field phase allows for speckle removal by putting the opposite phase on the deformable mirror, allowing for large improvements in raw contrast.

We present a speckle nulling code that is currently being used on a number of instruments at Palomar and Keck. The code is self-calibrating, requiring no system model or tuned parameters, and thus can be used with a wide variety of different instruments---current implementations range from fast optical imagers to thermal-infrared coronagraphs. It can operate in open loop or closed loop, though closed loop operation presents some additional challenges that we discuss. We present measured contrast curves demonstrating consistent improvements of 5-10 over the controllable area in the focal plane.

The speckle nulling code is written in a modular fashion, which makes it straightforward to port to different systems. It also allows for high-level scripting of wavefront manipulation and calibration routines. We intend to release it to the general public in the near future.

9909-196, Session PTue2

First on-sky closed loop measurement and correction of atmospheric dispersion

Prashant Pathak, Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States) and College of Optical Sciences, The Univ. of Arizona (United States); Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States); Frantz Martinache, Observatoire de la Côte d'Azur (France); Yosuke Minowa, Subaru Telescope, National Astronomical Observatory of Japan (United States); Hideki Takami, Yutaka Hayano, National Astronomical Observatory of Japan (Japan)

In the field of exoplanetary sciences, high contrast imaging is crucial for the direct detection of, and answering questions about habitability of exoplanets. For the direct imaging of habitable exoplanets, it is important to employ low inner working angle (IWA) coronagraphs, which can image exoplanets close to the PSF. To achieve the full performance of such coronagraphs, it is crucial to correct for atmospheric dispersion to the highest degree, as any leakage will limit the contrast. To achieve the highest contrast with the state-of-the-art coronagraphs in the SCExAO instrument, the spread in the point-spread function due to residual atmospheric dispersion shouldn't be more than 1 mas in the science band. In a traditional approach, atmospheric dispersion is compensated by an atmospheric dispersion compensator (ADC), which is simply based on model which only takes into account the elevation of telescope and hence results in imperfect correction of dispersion. In this paper we present the first on-sky closed-loop measurement and correction of residual

atmospheric dispersion. Exploiting the elongated nature of chromatic speckles, we can precisely measure the presence of atmospheric dispersion and by driving the ADC, we can do real-time correction. With the above approach, in broadband operation (y-H band) we achieved a residual of 4.6 mas from an initial 17.7 mas and as low as 1.2 mas in H-band only after correction, which is close to our science requirement. This work will be valuable in the field of high contrast imaging of habitable exoplanets in the era of the ELTs.

9909-199, Session PTue2

Robust exo-planet detection in multi-spectral multi-temporal data

Éric M. Thiébaut, Ctr. de Recherche Astrophysique de Lyon (France); Loïc Dénis, Lab. Hubert Curien (France); Laurent M. Mugnier, ONERA (France); Andréa Ferrari, David Mary, Lab. J.L. Lagrange (France) and Observatoire de la Côte d'Azur (France); Maud P. Langlois, Ctr. de Recherche Astrophysique de Lyon (France); Faustine Cantelou, ONERA (France) and Institut de Planétologie et d'Astrophysique de Grenoble (France); Nicholas Devaney, National Univ. of Ireland, Galway (Ireland)

The detection of exo-planets in coronographic images is one of the most challenging data processing task for new instruments like SPHERE and GPI. The difficulty is that the planets must be sought in images where the stellar leakage forms speckles which largely dominate the planetary signal. In this context, robust detection methods may be more suitable as they can take into account the imperfect speckle suppression achieved by image processing methods based on image differences (ADI, SDI) or principal component analysis (PCA) for instance. We recently (Denis & Thiébaut, GRETSI 2015) proposed to use Cauchy distributions (rather than Gaussian ones) to achieve robust detection and show that the corresponding Locally Most Powerful test (LMP) can then be computed on large images by means of FFT's. In this contribution, we first show how to generalize the LMP test to multi-spectral and multi-temporal data. The computations involved by the LMP test are carried out in the limit of a negligibly faint planet, thus the nuisance parameters (such as the speckles) only have to be estimated assuming that there are no planets. This makes the proposed method a perfect post-processing detection device which can be applied to the output of various speckle suppression methods. We demonstrate the improved robustness achieved by the generalized method on simulated and real SPHERE data.

9909-200, Session PTue2

Correlated PSF subtraction using an archive

Benjamin L. Gerard, Univ. of Victoria (Canada); Christian Marois, NRC - Herzberg Astronomy & Astrophysics (Canada)

Current high contrast imaging PSF subtraction algorithms all use some form of a least-squares minimization to find planets hidden below the speckle noise. Generally, a set of reference images is constructed from the target image sequence using Angular and/or Simultaneous Spectral Differential Imaging (ADI, SSDI, respectively). These techniques alone limit the available number of reference images at separations close to the focal plane mask, therefore limiting the performance of the least-squares (i.e., sensitivity to closer-orbiting planets) vs. performance at wider separations. The solution is to use additional reference images over a longer baseline and/or different spectral window from either the same and/or different target. But, this Reference Star Differential Imaging (RSDI) technique has been mostly ineffective in previous high contrast imaging surveys due to the unknown nature of PSF stability across time and wavelength, until now. The now >200 target reference library from the Gemini Planet Imager Exoplanet Survey (GPIES) allows for a detailed characterization of the GPI PSF stability, which we determine is suitable for RSDI GPI PSF subtraction. We present the results of work to optimize PSF subtraction with the GPIES reference library using an adaptation of the least-squares SOSIE algorithm, designed to minimize speckle noise and also maximize planet throughput. We find that using a reference library is more effective on target datasets with less FOV rotation (i.e., where ADI is less effective) and that the optimal number of the most correlated archival reference images to include in our SOSIE algorithm varies with observing conditions in time and wavelength. Our work is also more generally applicable to any current or future high contrast imaging survey instrument, such as WFIRST or a second generation ELT planet finder.

9909-204, Session PTue2

Focal-plane electric field sensing with pupil-plane holograms

Emiel Por, Christoph U. Keller, Leiden Observatory (Netherlands)

For direct detection and spectral characterization of exoplanets, a coronagraph is used to suppress the star light. Amplitude and phase aberrations in the optical train fill the dark zone of the coronagraph with quasi-static speckles, limiting the achievable contrast. Focal plane electric field sensing, such as phase diversity introduced by a deformable mirror (DM), provides a powerful tool for correcting this residual star light. Phase probes applied sequentially on the DM inject star light with a well-known amplitude and phase into the dark zone and the resulting intensity images are combined to estimate the residual electric field. The DM can then be used to add light with the same amplitude but opposite phase to destructively interfere with this residual star light.

Using a static phase-only pupil-plane element we create holographic copies of the point spread function (PSF), each superimposed with a certain pupil-plane phase probe. We therefore obtain all intensity images simultaneously, while still retaining a central, unaltered science PSF. The electric field sensing method only makes use of the holographic copies, allowing for correction of the residual electric field while retaining the central PSF for uninterrupted science data collection. In this paper we discuss the feasibility of this method through numerical simulations.

9909-208, Session PTue2

Extreme adaptive optics wavefront control towards high-contrast and extra-solar planet imaging with ELTs

Maud P. Langlois, Magali Loupias, Éric M. Thiébaut, Michel Tallon, Gilberto Moretto, Christian Delacroix, Ctr. de Recherche Astronomique de Lyon (France)

In order to allow the discovery of other Earths, different teams around the world are conceiving a new generation of instruments and telescopes. These new discoveries will rely on high contrast imaging that requires near perfect wavefront so that speckles of starlight, created by subtle aberrations caused by atmospheric turbulence and by the telescope optics, will not create a glare that would obscure the presence of very faint planets. In our presentation we propose real time wavefront control strategies and a WFS concepts to push the performances. Our main goal is the development of adaptive optics (AO) systems to enable ultra-high-contrast astronomical observations to allow such achievements. From the ground, the core of any high contrast instrument is an extreme adaptive optics (ExAO) system correcting both for atmospheric turbulence and for

internal aberrations of the instrument itself. There are currently several high contrast instruments equipped with ExAO under development around the world (Macintosh, 2006 and Beuzit, 2007) on 8 m class telescopes. For E-ELTs. it is extremely difficult, with the current technology, to achieve ExAO on such large telescopes. To address this difficulty, we have dedicated efforts in R&D for demonstrating the feasibility of the required high-order, high-speed wavefront control despite the increase of the number of actuators for the E-ELT. In this context, we present results obtained with a new wavefront sensor concept, based on the Mach-Zehnder wavefront sensor (MZWFS), allowing to achieve better performances and increased robustness to gaps and discontinuities in the telescope pupil. Thanks to a better sensitivity at high spatial frequencies, such WFS favors a clean correction of the starlight halo at small angular separations where the most demanding contrast is required. We present the latest closed loop performances we obtained with the MZWFS by using numerical simulations and the ExAO bench available at CRAL/CNRS.

9909-209, Session PTue2

Precise wavefront control for stellar coronagraphy: possibilities by a common-path extremely unbalanced interferometer

Ilya Dziuban, Inna Shashkova, Pavel Frolov, Yuliya Bezymyannikova, Alexander Tavrov, Space Research Institute (Russian Federation)

Direct exoplanet observations in the visible wavelength range using a stellar coronagraph entail a raw (coronagraphic) contrast of 10e10, which requires a ?/10000 rms wavefront control. In communication, we demonstrate a possibility to effectively increase the accuracy of phase control because of the coherent summation within an amplitude imbalanced interferometer. Such an extremely unbalanced interferometer (EUI) is made mechanically stable due to a common-path schematic.

Despite of existing coronagraphs lab demos have already achieved a 10e10 level of the coronagraphic contrast without the proposed technique, the later can still be considered as an alternative to existing solutions, as having several attractive perspectives. The UV spectral range may be one of the featuring EUI applications: in UV range the AO error remains too large. Another potential EUI application seems to be for wavefront correctors with the larger number of active pixels rather than by deformable mirrors: liquid crystals displays (LCDs), digital micromirror device (DMD)... Their general drawbacks are of a lower accuracy compare to the best quality DMs and the raster (gratings of pixel), which causes a strong diffraction- and scattering effects. Principally, the wavefront control error can be reduced in an unbalanced interferometer which mixes into the wavefront a small fraction of itself, where this small fraction is further adjusted in phase by an AO, however the control error here is effectively reduced because the mixing ratio is a small number.

By interference, the amplitude imbalance ratio is set about 1/0.1 between the arms of EUI which explains the abbreviation of a proposed technique having an extreme amplitude imbalance. The EUI schematic has a DM inserted in an interferometer arm or in a loop if interferometer has common-path. EUI is not a nulling interferometer because it does not aim to attenuate the stellar light, for other uses, such as a telescope guiding, and FOV pointing by a nulled star, etc.

Consider a DM pixel performing a ?/500 rms wavefront modulation step (minimum incremental motion which is under control) and that DM is inserted in the interferometer arm with lower amplitude. After the unbalanced interferometer, the wave becomes phase modulated, within a range that can be much smaller than the initial DM modulation, e. g. of about ?/8000 rms. An amplitude error was treated in a manner similar to the phase error and shows the accurate correction.

We start to test the proposed EUI wavefront control technique in a simple experiment with a common-path interferometer scheme. Fresnel reflection and transmission on beamsplitter (or PBS) introduce chromatic phase-amplitude coefficients, which can be effectively compensated by EUI common-path schematic, similar to the common-path achromatic interfero-coronagraph CP-AIC.

An AO control shows an increased accuracy in wavefront control, if an initial wavefront quality before the EUI unit is better than ?/200 rms, then that wavefront quality can be enhanced in more than one order of magnitude. The EUI with DM shows a wide achromaticity towards larger wavelengths. We hope that the EUI method can be a useful addition for future Earth-like planet observations.

9909-214, Session PTue2

SHARK-NIR coronagraphic trade-offs study

Alexis Carlotti, Christophe Vérinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France); Daniele Vassallo, Jacopo Farinato, INAF - Osservatorio Astronomico di Padova (Italy); Mamadou N'Diaye, Space Telescope Science Institute (United States); Davide Greggio, Valentina D'Orazi, Elena Carolo, INAF - Osservatorio Astronomico di Padova (Italy)

SHARK-NIR is one of the two coronagraphic instruments proposed for the Large Binocular Telescope (LBT), in the framework of the call for second generation instruments, issued in 2014. Together with the SHARK-VIS, it will offer a few observing modes (direct imaging, coronagraphic imaging and coronagraphic low resolution spectroscopy) covering a wide wavelength domain, going from 0.6μm to 1.65μm.

SHARK-NIR has been undergoing the conceptual design review at the end of 2015 and it has been approved to proceed to the final design phase, receiving the green light for successive construction and installation at LBT.

The current design makes it possible to use two pupil planes and one image plane where apodizers, focal plane masks, and Lyot stops can be used to create high-contrast.

We present the results of the trade-offs study of the coronagraphs that we have designed for SHARK-NIR while taking into account the specifications of the LBT aperture, and of the LBT AO system.

The aperture of the LBT is characterized by a smaller central obscuration (11%) than of most telescope apertures, which is good for high-contrast imaging.

The secondary support structure, however, is asymmetric, and it covers a relatively large fraction of the aperture. This is a potential problem for high-contrast imaging, especially since pupil shifts during the observation must be taken into account.

We review the respective advantages and weaknesses of several types of coronagraphs that we have designed for this aperture, and in particular we give an exhaustive description of the shaped pupils, apodized phase plates, apodized pupil Lyot coronagraphs, and apodized vortex coronagraphs.

9909-173, Session PTue3

On-sky results of the TOPTICA guide star laser

Martin Enderlein, Bernhard Ernstberger, TOPTICA Photonics AG (Germany); Daoping Wei, Wallace R. L. Clements, MPB Communications Inc. (Canada); Wilhelm G. Kaenders, TOPTICA Photonics AG (Germany)

TOPTICA Photonics AG and partner MPB Communications Inc. have completed the first production batch of ten next-generation sodium guide star lasers. The optical concept of this third-generation sodium laser was first demonstrated in technology demonstrators (2009-2011),

followed by a pre-production unit in 2012. A master oscillator signal from a robust linearly-polarized 1178-nm continuous-wave diode laser with stabilized emission frequency and linewidth of 1-2 MHz, is amplified in a polarization-maintaining (PM) Raman fiber amplifier (RFA) pumped by a high-power 1120-nm PM fiber laser. With efficient suppression of stimulated Brillouin scattering, an unprecedented 40 W of narrow-band RFA output is obtained. The RFA output is mode-matched into a resonant frequency-doubling cavity with a free spectral range matching the sodium D2a to D2b separation, allowing simultaneous generation of an additional frequency component (D2b line) to re-pump the sodium atom electronic population from the F=1 hyperfine ground state. Using a direct diode modulation technique, the return flux can be increased without introducing optical wave front distortions or compromising spatial beam overlap. With demonstrated doubling efficiencies >85%, output powers at 589 nm easily exceed the 18+2W design goal. A detuning option allows for measuring and subtracting the Rayleigh scattering background.

A major effort has been dedicated to integrating all optical components into a ruggedized and reliable system design, providing a maximum of convenience for astronomers. With a cooling-water flow of 5 l/min and an overall power consumption of 700 W, the infrastructure demands on site are minimal. Each system is built in a modular way, based on the concept of line-replaceable units (LRU). A comprehensive system software, as well as an intuitive service GUI, allow for remote control and error tracking down to the LRU level. In case of a failure, any LRU can be replaced within less than four hours. With the remote pumping option, the small 80-kg laser head consisting of RFA and second-harmonic generation stage can be separated by up to 27 m from the larger (600 kg) electronics cabinet. This minimizes the effort for integration with existing telescope infrastructures. The end result is a system designed throughout to provide convenient, turn-key operation at the remote and harsh locations of major optical telescopes. By March 2016 and after rigorous testing by the customers, eight TOPTICA lasers (including a prototype system) will be on-sky at four different major telescopes sites worldwide. This allows us to present a comparative survey of return flux and long-term performance results.

9909-178, Session PTue3

Comparison between observation and simulation of sodium LGS return flux with a 20W CW laser on Tenerife

Ronald Holzlöhner, Domenico Bonaccini Calia, European Southern Observatory (Germany); Dmitry Budker, Johannes Gutenberg Univ. Mainz (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Felipe Pedreros Bustos, Johannes Gutenberg Univ. Mainz (Germany); Simon Rochester, Rochester Scientific, LLC (United States)

We report on the comparison of sodium fluorescence models with observations at Observatorio del Teide, Tenerife (28°N), using ESO's transportable 20W CW Wendelstein sodium laser guide star (LGS) system. This campaign has provided return flux measurements of unprecedented detail regarding Alt/Az laser pointing direction, variation of laser power and linewidth, polarization and D2b repumping. With this extensive set of data we can compare the observed flux with numerical simulations using the open source LGSBloch density matrix simulation code. The physical insight validates our simulation tools and enables us to predict/optimize the performance of the various types of lasers in sodium LGS operation.

9909-179, Session PTue3

Polarization switching of sodium guide star laser for brightness enhancement

Tingwei Fan, Shanghai Institute of Optics and Fine Mechanics (China) and Univ. of Chinese Academy of Sciences (China); Yan Feng, Tianhua Zhou, Shanghai Institute of Optics and Fine Mechanics (China)

The brightness of the sodium laser guide star is one of the key parameters determining the performance of adaptive optics, which allows ground-based large-aperture telescopes to explore the deep Universe. Improving sodium excitation efficiency by optimizing the spectral, temporal and polarization characteristics of the 589 nm laser beam has been a focus of study in the astronomical community. The use of circularly polarized laser was proposed to have brighter guide star utilizing the optical pumping process. However, the benefits of optical pumping are substantially reduced with the presence of geomagnetic field, since the sodium atoms precess along the magnetic field. The precessing atoms are reoriented faster than the time it takes to establish a beneficial distribution. Precession of the angular momentum does not occur when the laser beam is parallel to the magnetic field, but is maximized for the perpendicular case. Unfortunately, large angles are more typical in astronomical observing. Thomas J. Kane et al. proposed to use a laser source pulsed at the Larmor frequency for improving the brightness of sodium LGS. It works because it allows the laser light to interact with the atoms at a fixed point in the precession cycle. Their simulation shows a photon return double that of an optimized cw laser at the same average power for large angles between laser beam and geomagnetic field. But sodium guide star lasers pulsed at this frequency range are not available and technically challenging to develop.

In this paper, we propose a method of "magnetically resonant pumping" with currently available cw laser to overcome the problem induced by the magnetic field. Magnetically resonant pumping is achieved by switching the polarization of the cw guide star laser between left and right circular polarization at a rate of Larmor frequency.

Our simulation is based on the open-source LGSBloch package for Mathematica. Program for the polarization switching is implemented to carry out the calculation. Program for the polarization switching is implemented to carry out the calculation. A piecewise function is used to define the polarization switching as instantaneous square-wave switching. Similar results are expected for square wave switching with nanosecond leading and falling edges. Sine-wave modulation of polarization is also simulated, although the improvement in the return flux is not obvious. Numerical simulation with ESO's laser guide star system at Paranal as example shows that the return flux can be increased when the angle between geomagnetic field and laser beam is larger than 60°, as much as 50% at 90°. The proposal is significant since most astronomical observation is at angle between 60° and 90°, and it only requires a minor modification to the optics after the current installed cw laser.

The influence of laser irradiance, polarization states, angle between laser beam and geomagnetic field, and repumping fraction on return flux and populations dynamics are investigated to understand the mechanism of return flux improvement in the polarization switching method. The practical implementation of the polarization switching method is discussed. Furthermore, the dependence of return flux on the polarization switching frequency is calculated, based on which an alternative method is proposed for remote measurement of magnetic field.

9909-182, Session PTue3

LGS adaptive optics system with long-pulsed sodium laser on Lijiang 1.8 meter telescope 2014-2016 observation campaign

Kai Wei, Min Li, Changchun Jiang, Kai Jin, Ling Wei, Xiaoyu Ma, Luchun Zhou, Wenjia Zheng, Wenru Li, Institute of Optics and Electronics (China); Yong Bo, Technical Institute of Physics and Chemistry (China); Xianghui Xue, Univ. of Science and Technology of China (China); Xianmei Qian, Anhui Institute of Optics and Fine Mechanics (China); Junwei Zuo, Pengyuan Wang, Technical Institute of Physics and Chemistry (China); Feng Cheng, Xiaojun Zhang, Xinlong Fan, Donghong Chen, Jijiang Deng, Yang Gao, Institute of Optics and Electronics (China); Yu Shen, Qi Bian, Ji Yao, Technical Institute of Physics and Chemistry (China); Jiang Huang, Ruoxi Dong, Keran Deng, Institute of Optics and Electronics (China); Qinjun Peng, Technical Institute of Physics and Chemistry (China); Changhui Rao, Institute of Optics and Electronics (China); Zuyan Xu, Technical Institute of Physics and Chemistry (China); Yudong Zhang, Institute of Optics and Electronics (China)

During 2014~2016, the Laser guide star (LGS) adaptive optics (AO) system observation campaign has been carried out on Lijiang 1.8 meter telescope Yunnan observatory. During the campaign, two generation LGS AO systems have been developed and installed. In 2014, a long-pulsed solid Sodium prototype laser with 20W@400Hz, a beam transfer optical (BTO) system, and a laser launch telescope (LLT) with 300mm diameter were mounted onto the telescope and moved with telescope azimuth journal. At the same time, a 37-elements compact LGS AO system had been mounted on the Bent-Cassegrain focus and got its first light on observing HIP43963 (mV= 8.18mv) and reached Sr=0.27 in J Band after LGS AO compensation. In 2015, the solid Sodium laser has been upgrade to stable 25W@800Hz while D2a plus D2b repumping is used to increase the photon return, and a totally new LGS AO system with 61-elements Deformable Mirror, 9x9 Shark Hartman wavefront sensor, Real Time Controller based on Linux system, two Tip/tilt mirrors with inner closed loop, Multiple-Photomultiplier Tube (MPMT) tracking detector is established and installed on the telescope. And the throughput for the BTO/LLT is improved nearly 20%. The campaign process, the performance of the two LGS AO systems especially the latter one, the characteristics of the BTO/LLT system and the result are present in this paper.

9909-186, Session PTue3

LGS-AO in daytime: experimental results in detecting the LGS with narrow band filters

Domenico Bonaccini Calia, European Southern Observatory (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Joachim Staiger, Kiepenheuer-Institut für Sonnenphysik (Germany); Marco Stangalini, INAF - Osservatorio Astronomico di Roma (Italy)

The detection of the Laser Guide Stars (LGS) seen against the sky background, is theoretically possible.

It allows daytime LGS-AO for the thermal infrared instruments, potentially more than doubling the observing time availability of thermal infrared instrument on large and extremely large telescopes., e.g. on ELTs. Also for large solar telescopes, LGS-AO in the solar corona opens new research areas in trying to understand e.g. the processes occurring before and during a solar flare.

In this paper we present the experimental results obtained with an extremely elongated LGS in a joint experiment using the 20W CW fiber laser of the ESO Wendelstein Laser Guide Star Unit and the Vacuum Tower Telescope of the Kiepenheuer Institute für Sonnenphysik, located at Izaña, Tenerife, Canary islands. The VTT is equipped with the 30 milli-Angstrøm tunable filter Hellride.

9909-190, Session PTue3

Back to the optical: a new dawn for LGS AO at shorter wavelengths

David F. Buscher, Univ. of Cambridge (United Kingdom); Richard M. Myers, Nazim A. Bharmal, Huizhe Yang, Durham Univ. (United Kingdom)

Laser tomography AO (LTAO) is the accepted technology for providing wavefront correction on ELTs at infrared wavelengths, but scientific demand is never static. There are many ELT science cases which require high-sky-coverage wavefront correction at optical wavelengths and this represents the new frontier for AO. Pushing towards shorter wavelengths requires substantial increases in the correction frequency and the modal order of AO, but neither of these present a fundamental limitation to optical-wavelength correction. Instead it is the deficiencies of the tomography itself which come to the fore as wavefront correction at shorter wavelengths is persued. The main limitation for LTAO is that it requires a model for the vertical structure of C_n^2, and this model must be updated to keep up with the changes in the vertical structure of the atmosphere, which are now known to be rapid and substantial.

We argue that the high wavefront accuracy required at optical wavelengths means that the rate at which the model must be updated becomes impracticable and an alternative strategy is required. We propose instead the use of projected pupil plane patterns (P^4) to directly measure wavefront distortions without requiring a model for the vertical structure. We describe how advances in detector technology mean that problems with fluorescence in the monostatic laser launch required with this method can now be straightforwardly overcome, and describe progress towards a future optical-wavelength capability for ELTs. We describe how extra Ps may be added to P^4 techniques to improve its power, up to P^n.

9909-191, Session PTue3

Laser traffic control system upgrades for Maunakea

Paul J. Stomski Jr., Randall D. Campbell, W. M. Keck Observatory (United States); Tom Cumming, Gemini Observatory (United States); Russell D. Kackley, Subaru Telescope, National Astronomical Observatory of Japan (United States); Shui Hung Kwok, W. M. Keck Observatory (United States); Jim Thomas, Canada-France-Hawaii Telescope (United States)

The Maunakea Laser Traffic Control System (LTCS) has been in use since 2002 providing a mechanism to prevent the laser guide star or Rayleigh scatter from a laser propagated from one telescope from interfering with science observations at any of the other telescopes that share the mountain. The LTCS has also been adopted at several other astronomical sites around the world to address that same need. In 2014 the stakeholders

on Maunakea began the process of improving LTCS capability to support common observing techniques with enhanced First On Target (FoT) equity. The planned improvements include support for non-sidereal observing, laser checkout at zenith, dynamic field of view size, dithering, collision calculations even when a facility is not laser impacted, multiple alert severity levels, and software refactoring. The design of these improvements was completed in early 2015, and implementation is expected to be completed in 2016. This paper describes the Maunakea LTCS collaboration and the design of these planned improvements.

9909-195, Session PTue3

Laser beam shaping simulations for generation of artificial stars constellations

Héctor González-Núñez, Clémentine Béchet, Andrés Guesalaga, Pontificia Univ. Católica de Chile (Chile)

Laser guide stars (LGS) technology significantly enlarge the portion of the sky covered by adaptive optics (AO) on optical telescopes, having a large impact on astrophysical and science capabilities in the world's largest observatories. Furthermore all the future visible or near-infrared ground-based telescopes are being designed to use some kind of LGS AO system. Because AO correction is typically limited to a relatively small field of view around a single guidestar, artificial light patterns with multiple reference sources, known as LGS asterisms, are being used. With more than one reference source, it is possible to have more accurate observations (astrometry), better observations in deep space and high-resolution observations over large fields, among others. Despite all the benefits, high power and quality lasers and projection optics are required, increasing the complexity of the LGS AO systems.

Nowadays, the generation of the LGS asterisms is usually carried out with sophisticated layouts by using beam splitters and mirrors or multiple laser sources. The concept of a beam shaping system with deformable mirrors and its potential benefit for laser-based astronomical AO has been recently proposed.

In this work we report the study and analysis of different methods to generate arbitrary patterns of LGS asterisms starting from a single laser beam and optically processes by continuous face-sheet deformable mirrors. The potential benefits of beam shaping for generation of artificial constellations are based on the actual and expected progress in the development of better deformable mirrors along with improvements in laser technology. Some of these potential benefits are: to enhance the quality of the LGS beacons, to precompensate atmospheric turbulence effects, to reduce the number of elements in the beam transfer optics and to minimize the alignment and calibration time before observations. We carried out detailed numerical simulations of optical propagation with novel beam shaping algorithms applied to the generation of astronomical LGS asterisms. The possibility of using multiple DMs to accomplish this task and the differences between near-field and far-field beam shaping algorithms are presented. Parameters like the diameter of the launch telescope, the number of actuators of the DMs and the influence function of the actuators are also evaluated.

9909-198, Session PTue3

Laser pointing camera: a valuable tool for the LGS-AO operations

Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Domenico Bonaccini Calia, European Southern Observatory (Germany); Fernando Pedichini, INAF - Osservatorio Astronomico di Roma (Italy); Antonio Cerruto, Andrea Ricciardi, Astrel Instruments (Italy); Filippo Ambrosino, INAF - Osservatorio Astronomico di Roma (Italy)

In this poster we describe the design, functionalities and full commissioning performance of the Laser Pointing Camera, developed for the ESO Adaptive Optics Facility.

The LPC allows having a fast pointing of the multiple LGS on the AO WFS during the initial acquisition phase of the telescope preset, thus reducing considerably the overheads currently experienced in most LGS-AO systems in operation. By recognizing the field stars as well as the multiple LGS, LPC is insensitive to flexures of the laser launch telescope or of the receiver telescope opto-mechanics.

Moreover, LPC gives regularly the photometry and fwhm of the LGS, as well as the scattering of the uplink beams at the height of 10-15km, thus monitoring the presence and evolution of cirrus clouds.

We will present the Commissioning results of the Laser Pointing Camera, obtained at the ESO VLT during the full 4LGSF Commissioning, and will discuss its possible extension for the ELT operations.

9909-201, Session PTue3

Closed-loop control for laser beam shaping system before guide star projection

Pedro Escárate, Sebastían Zúñiga Fernández, Mario A. Castro R., Javier Garcés, Diego A. Rojas Zagals, José Luis Marchioni Clavería, Univ. Técnica Federico Santa María (Chile)

Despite the significant advances in laser guide star for astronomy, the laser beam system usually requires constant and complex system alignments in order to achieve a satisfactory performance in terms of power and quality. During operations, efforts to adjust the laser system can cost an important part of the observation time, even some of the laser systems have been available less than 50% of the time.

The scintillation arises when the phase aberrations induced by turbulence are converted in amplitude fluctuations in the target (receiver, satellite or sodium layer). In the case of laser guide stars formed in the atmosphere, this scintillation not only reduces the energy density applied at the desired point, can also extend the spread to the point that cannot be resolved with sufficient resolution due to the low SNR in the subaperture of the wavefront sensors. The performance of laser projection systems can be improved compensating the effects of scintillation caused by aberrations in the laser source or misalignment in the transfer optics before the laser beam propagating through the aperture.

In case of laser beam shaping, the goal is to maximize the available energy in the focused spot. One of the first approaches to reach phase and amplitude correction simultaneously was proposed by Roggermann and Lee. This configuration has two deformable mirrors, using a phase retrieval method process amplitude and phase measurements to determine the deformation to be applied to each deformable mirror. Systems with two DMs have been intensively used during the past three decades in military and space communications. In case of astronomical field challenges, optical field conjugation has been proposed for applications such as high-contrast detection of planets but without significant efforts regarding laser beam shaping.

Regarding laser system for astronomical AO, laser beam shaping using 2 DMs have been presented for only phase correction where the second mirror is conjugated to the first in order to increase the stroke of overall system and spatial frequency of the correction. Another project use DMs for laser beam shaping but again is focused in only phase correction before laser guide star projection. More recently a novel 2-DM concept for amplitude and phase correction based on phase retrieval techniques was presented by Bechet et al. including a laboratory validation for this method. The studies of both amplitude and phase correction before guide star projection is still new in AO for astronomy.

In this project, we aim to improve the 2-DM concept for amplitude and phase correction through a closed loop configuration using the Linear Quadratic Regulator (LQR). In Sect. 2 LQR and feedback controller design are detailed. In Sect. 3 simulation, numerical results and comparisons are presented. Finally in Sect. 4 conclusions and future work are discussed.

9909-205, Session PTue3

Daylight operation of a sodium laser guide star

Michael Hart, The Univ. of Arizona (United States); Stuart M. Jefferies, Georgia State Univ. (United States)

We report contrast measurements of a sodium resonance guide star against the daylight sky when observed through a tuned magneto-optical filter (MOF). The MOF includes an interference filter with 2.88 nm equivalent width and a sodium vapor cell in a magnetic field between crossed polarizers.

The filter has a very narrow transmission profile of approximately 0.008 nm. Our observations were made with the 1.5 m Kuiper telescope on Mt. Bigelow, AZ, which has a separately mounted guide star laser projecting a circularly polarized single-frequency beam of approximately 3.5 W at 589.16 nm. Both the beam projector and the 1.5 m telescope were pointed at zenith; the baseline between them is approximately 5 m. Contrast measurements of the resonance beacon were made on the morning of 2015 November 3 using an imaging camera focused on the beacon and looking through the full aperture of the telescope. The guide star had a V magnitude of 9.8, and we estimate the unfiltered V-band sky surface brightness at 07:15 local time (14:15 UTC) to be magnitude 4.2 per square arcsecond. Assuming a solid angle of 2x2 arcsecond, typical for the field of view of the subapertures of a Shack-Hartmann wave-front sensor, we show that the beacon contrast is improved from 0.17, when looking through the interference filter alone, to 10.0 with the MOF. We interpret our results in terms of the performance of adaptive optics systems for astronomy, with particular emphasis on the thermal infrared wavebands at the coming generation of extremely large telescopes.

9909-207, Session PTue3

Vapor-cell based sodium laser guide star mechanism study lab-bench

Hongyan Wang, National Univ. of Defense Technology (China)

Sodium laser guide star (SLGS) is the key for the success of modern adaptive optics (AO) supported large ground based telescopes, however, for many field applications, SLGS's brightness is still a limited factor. Large amounts of theoretical efforts have been paid to optimize SLGS exciting parameters, that is, to fully discover potential of harsh environment surrounding mesospheric extreme thin sodium atoms under resonant excitation, whether quantum or Monte Carlo based. But till to now, only limited proposals are demonstrated with on-sky test due to the high cost and engineering complexities. To bridge the gap between theoretical modeling and on-sky test, we built a magnetic field controllable sodium cell based lab-bench, which includes a small scale sum-frequency single mode 589nm laser, with added amplitude, polarization, and phase modulators. We could perform quantitative resonant fluorescence study under single, multi-frequency, side-band optical re-pumping exciting with different polarization, also we could perform optical field modulation to study Larmor precession which is considered as one of devils of SLGS, and we have the ability to generate beams contain orbital angular moment. Our preliminary sodium cell based optical re-pumping experiments have shown excellent consistence with Bloch equation predicted results, other experimental results will also be presented in the report, and these results will give a direct support that sodium cell based lab-bench study could help a SLGS scientists a lot before their on-sky test.

9909-210, Session PTue3

Sodium vapor cell laser guide star experiments for continuous wave model validation

Felipe Pedreros Bustos, Johannes Gutenberg Univ. Mainz (Germany); Ronald Holzlöhner, European Southern Observatory (Germany); Dmitry Budker, Johannes Gutenberg Univ. Mainz (Germany); Steffan A. Lewis, European Southern Observatory (Germany)

Recent numerical simulations and experiments on sodium Laser Guide Star (LGS) have shown that a continuous wave (CW) laser with circular polarization and D2b re-pumping should maximize the fluorescent photon return flux to the wavefront sensor for adaptive optics applications. The orientation and strength of the geomagnetic field in the sodium layer also play an important role affecting the LGS return flux. Field measurements of the LGS return flux show agreement with the CW LGS model, however, fluctuations in the sodium column abundance and geomagnetic field intensity, as well as atmospheric turbulence, induce experimental uncertainties and errors.

We describe a laboratory experiment to measure the photon return flux from a sodium vapor cell illuminated with a 589 nm CW laser beam, designed to approximately emulate a LGS under controlled conditions. Return flux measurements are carried out adjusting polarization, power density, re-pumping with about 12% of the power in the D2b at 1713 MHz offset, laser linewidth, and magnetic field intensity and orientation. Comparison with the numerical CW simulation package Atomic Density Matrix are presented and discussed.

9909-213, Session PTue3

The progress of TMT Laser Guide Star Facility

Min Li, Kai Wei, Jinlong Tang, Changchun Jiang, Muwen Fan, Feng Cheng, Daoman Rui, Xiqi Li, Institute of Optics and Electronics (China); Corinne Boyer, Brent L. Ellerbroek, Lianqi Wang, Fengchuan Liu, Thirty Meter Telescope (United States); Hao Xian, Changhui Rao, Yudong Zhang, Institute of Optics and Electronics (China)

The Laser Guide Star Facility (LGSF) is one of the first light AO systems of TMT. Its design, manufacturing, testing and integration work is managed and carried out by the Institute of Optics and Electronics (IOE) in Chengdu (China). The LGSF uses multiple sodium lasers to generate and project several LGS asterisms from a laser launch telescope located behind the TMT secondary mirror. The LGSF includes 3 main sub-systems: (1) the laser system, (2) the beam transfer optics and laser launch telescope (BTO/LLT) system, (3) the associated laser safety system. In particular, the BTO/LLT system consists of two components: one is the beam transfer optical path, which includes conventional (mirror-based) beam transfer optics system; the other is the LGSF Top End. The latter includes the Diagnostic system, the Asterism Generator (AG), the Laser Launch Telescope Assembly (LTA) and the Laser Guide Star Acquisition System.

At present, the LGSF is at the preliminary design phase. During this phase, the laser launch telescope trade study, Beam transfer optical path trade study are compared carefully, and some critical components prototypes have been carried out to verify the requirements, such as the polarization status control along the BTO analysis and test, the Fast Steer Mirror (FSM)

prototype test. Finally the optical performance, the displacement budget are discussed in the paper.

The optical performance is mainly related with the laser system, the BTO and LLT. Here, the LLT design is focused on, which is a pivotal subsystem in the LGSF. It is a reflective off-axis structure with a clear aperture diameter of 0.4 m. The design of first mirror is paraboloid and the second mirror is hyperboloid. The LTA Field of View (FoV) shall be circular with a 510arcsec radius without vignetting and shall be focused at an adjustable range between 85 and 235 km. The tolerance analysis of the LTA has been done and the detailed structure has been designed to meet the requirement.

Displacement budget is about the error budgets for the beam centering and pointing errors of the LGSF. The alignment of the LGSF laser beams is defined in terms of (1) the apparent position error of the laser guide star as measured on the NFIRAOS wavefront sensor, and (2) the beam centering error on the laser launch telescope primary mirror and as many other surfaces as we care to monitor (which could be all of them), (3) the active mirrors which are used to compensate the displacement. And then, all these displacements can be divided into contributions from (i) internal misalignments of the LGSF optics and (ii) misalignment of the TMT structure itself. Each of these could be broken down further into flexure, thermal, vibration ..... The displacement budget will be discussed well in the paper.

9909-216, Session PTue3

Development of vertical external cavity surface emitting lasers (VECSELs) for use as monochromatic and polychromatic sodium guidestars

Shawn W. Hackett, Air Force Institute of Technology (United States); Alexander R. Albrecht, Zhou Yang, The Univ. of New Mexico (United States); Jeffrey G. Cederberg, Sandia National Labs. (United States); Mansoor Sheik-Bahae, The Univ. of New Mexico (United States); Robert L. Johnson, Jeff Richey, Air Force Research Lab. (United States)

To date, three types of laser sources have been used to excite mesospheric sodium atoms to use as a sodium guidestar for adaptive optics (AO). All these sources have inherent challenges and a possible fourth source is to utilize a frequency-doubled Vertical External Cavity Surface Emitting Laser (VECSEL). A design for 1178 nm VECSEL to be frequency doubled to be utilized as a sodium guidestar at 589 nm is presented. An 1141 nm VECSEL device is shown to provide a suitable source for simultaneous two wavelength excitation of sodium to provide a polychromatic guidestar. Such VECSELs are shown to present output efficiency above 20% with power in excess of 20 W. Modeling is also presented to validate the efficacy of developing VECSEL guidestar systems for use with current guidestar systems or as a stand-alone guidestar. The model agrees with the data collected with the 3.5 m telescope and narrowband laser guidestar at Starfire Optical Range.

9909-35, Session 10

Review of solar adaptive optics *(Invited Paper)*

Dirk Schmidt, National Solar Observatory (United States)

Adaptive optics is essential for ground-based high-resolution observations of the Sun in the visible wavelength regime. Classical solar AO (CAO) - first introduced at sub-meter class telescopes - is well established for about 15 years. CAO is the enabling technology of the current 1.5-meter class telescopes, and even more for the upcoming 4-meter solar telescopes. MCAO is highly interessting for observations of large active solar regions, and being developed at various institutes.

The latest trend of solar AO development is dedicating systems for observations off the solar limb, using very weak prominences for wavefront sensing.

We will summarize solar AO techniques, current developments and difficulties being encountered.

9909-36, Session 10

Status of the DKIST system for solar adaptive optics

Luke C. Johnson, Keith Cummings, Mark Drobilek, B. Scott Gregory, Steve L. Hegwer, Erik M. Johansson, José Marino, Kit Richards, Thomas R. Rimmele, Predrag Sekulic, Friedrich Wöger, National Solar Observatory (United States)

When the Daniel K. Inouye Solar Telescope (DKIST) achieves first light in 2019, it will deliver the highest spatial resolution images of the solar atmosphere ever recorded. Additionally, the DKIST will observe the Sun with unprecedented polarimetric sensitivity and spectral resolution, spurring a leap forward in our understanding of the physical processes occurring on the Sun.

The DKIST wavefront correction system will provide active alignment control and jitter compensation for all six of the DKIST science instruments. Five of the instruments will also be fed by a conventional adaptive optics (AO) system, which corrects for high frequency jitter and atmospheric wavefront disturbances. The adaptive optics system is built around an extended-source correlating Shack-Hartmann wavefront sensor, a PI fast tip-tilt mirror (FTTM) and a Xinetics 1600-actuator deformable mirror (DM), both of which are controlled by an FPGA-based real-time system running at 1975 Hz. It is designed to achieve on-axis Strehl of 0.3 at 500 nm in median seeing ($r0 = 7$ cm) and Strehl of 0.6 at 630 nm in excellent seeing ($r0 = 20$ cm).

The DKIST wavefront correction team has completed the design phase and is well into the fabrication phase. The FTTM and DM have both been delivered to the DKIST laboratory in Boulder, CO. The real-time controller has been completed and is able to read out the camera and deliver commands to the DM with a total latency of approximately 620 microseconds. All optics and optomechanics, including many high-precision custom optics, mounts, and stages, are completed or nearing the end of the fabrication process and will soon undergo rigorous factory acceptance testing.

Before installing the wavefront correction system at the telescope, it will be assembled as a testbed in the laboratory. In the lab, performance tests beginning with component-level testing and continuing to full-system testing will ensure that the wavefront correction system meets all performance requirements. Further work in the lab will focus on fine-tuning our alignment and calibration procedures so that installation and alignment on the summit will proceed as efficiently as possible.

9909-37, Session 10

Adaptive Optics Facility: control strategy and first on-sky results of the acquisition sequence

Pierre-Yves Madec, Johann Kolb, Sylvain Oberti, Jérôme Paufique, Paolo La Penna, Wolfgang K. Hackenberg, Harald Kuntschner, Javier Argomedo, Mario J. Kiekebusch, Robert H. Donaldson, Marcos Suárez Valles, Robin Arsenault, European Southern Observatory (Germany)

Adaptive Optics Facility is an ESO project aiming at converting Yepun, one of the four 8m telescopes in Paranal, into an adaptive telescope. This is done by replacing the current conventional secondary mirror of Yepun by a Deformable Secondary Mirror (DSM) and attaching four Laser Guide Star (LGS) Units to its centerpiece. In the meantime, two Adaptive Optics (AO) modules have been developed incorporating each four LGS WaveFront Sensors (WFS) and one tip-tilt sensor used to control the DSM at 1 kHz frame rate. The four LGS Units and one AO module (GRAAL) have already been assembled on Yepun.

Besides the technological challenge itself, one critical area of AOF is the AO control strategy and its link with the telescope control, including Active Optics used to shape M1. Another challenge is the request to minimize the overhead due to AOF during the acquisition phase of the observation.

This paper presents the control strategy of AOF. The current control of the telescope is first recalled, and then the way the AO control makes the link with the Active Optics is detailed. Lab results are used to illustrate the expected performance. Finally, the overall AOF acquisition sequence is presented as well as first results obtained on sky with GRAAL.

9909-38, Session 10

On-sky MOAO performance evaluation of RAVEN

Yoshito H. Ono, Tohoku Univ. (Japan); Olivier Lardiere, David R. Andersen, NRC - Herzberg Astronomy & Astrophysics (Canada); Carlos M. Correia, Lab. d'Astrophysique de Marseille (France); Kathryn Jackson, California Institute of Technology (United States); Darryl Gamroth, Univ. of Victoria (Canada); Shin Oya, Subaru Telescope, National Astronomical Observatory of Japan (Japan); Masayuki Akiyama, Tohoku Univ. (Japan); Colin Bradley, Univ. of Victoria (Canada)

This paper presents the AO performance we got on-sky with RAVEN, a Multi-Object Adaptive Optics (MOAO) technical and science demonstrator installed and tested at the Subaru telescope. RAVEN performs astronomic tomography with four guide stars and provides MOAO corrections simultaneously to the two independent science targets. RAVEN also supports ground-layer AO correction and single-conjugate AO correction. We have successfully completed on May and August 2014 and June 2015 both the engineering and science observations.

We now report Strehl-ratio, Ensquared-Energy, full width at half maximum, and wave-front error from science images on Subaru's IRCS and wave-front sensors telemetry taken during all on-sky observations. We show these metrics as function of different AO modes, atmospheric conditions, guide-star configurations and magnitudes and discuss dependencies of AO performance of RAVEN on these environments. We discuss how our results can be scaled to ELT-sized MOAO systems.

9909-39, Session 10

AO corrected satellite imaging from Mount Stromlo

Francis Bennet, Francois Rigaut, Ian Price, Nick Herrald, The Australian National Univ. (Australia); Ian T. Ritchie, Craig H. Smith, EOS Space Systems Pty. Ltd. (Australia)

Space situational awareness (SSA) is a rapidly growing field for optical telescopes. The goal of SSA is to track as many orbiting objects as possible, both active satellites and debris. These tracked objects are accumulated into a precise catalogue which contains up to date and highly accurate data needed to predict any possible conjuncture. Active satellites can be warned to perform debris avoidance manoeuvres, and possible collisions between debris objects determined in advance.

Orbiting objects need to be precisely tracked and categorised in order to have good orbital data and conjuncture assessment. The most precise way to determine an orbit in low Earth orbit is optically with satellite laser ranging (SLR). SLR operates by propagating a laser pulse from the ground to the target, and collecting returned photons. A precise range can be calculated by timing the laser pulse. Cooperative targets (those with retroreflectors) and uncooperative targets (those without retroreflectors) can be tracked in this manner, with higher power lasers required for tracking uncooperative targets. We plan to improve SLR by adding an adaptive optic (AO) system to compensate for atmospheric turbulence which spreads the laser beam on-sky (ref last SPIE).

Information on the size and shape of the object is also important for orbit propagation. This information when combined with the precise orbit determined with SLR the orbit prediction can reach unprecedented accuracy. We present the development and first results of a satellite imaging AO system for small (1-2m) telescopes. We focused on making a compact and high performance system using modern high stroke deformable mirror (DM) and low noise high rate EMCCD cameras for imaging and wavefront sensing. We are able to track satellites down to magnitude 10 with a Strehl in excess of 20% in median seeing.

We use the satellite as a natural guide star (NGS) on a Shack-Hartmann wavefront sensor with a closed loop rate of 2 kHz. Our system meets the performance requirement of 20% Strehl at a nominal orbiting altitude of 1000 km, but will also operate on objects down to 600 km. Below this altitude the telescope slew rate is so great that even at 2 kHz the AO system does not have the bandwidth to provide enough correction. We have developed a system for processing imaging data in real time to remove the need for derogating optics and large stroke tip-tilt correction.

We have demonstrated this AO system on a 1 m SLR telescope at Mount Stromlo Observatory in Canberra, Australia. We present the demonstration results here and plans to further develop the system for a 1.8 m telescope also located in Mount Stromlo. This next AO system will also be capable of providing orbital information out to geosynchronous orbit using high precision astrometry.

9909-40, Session 11

Development of the near-infrared eAPD array SAPHIRA achieving sub-electron read noise at millisecond full-frame readout *(Invited Paper)*

Gert Finger, European Southern Observatory (Germany); Ian M. Baker, SELEX ES Infrared Ltd. (United Kingdom); Domingo Alvarez, Derek J. Ives, Leander H. Mehrgan, Jörg Stegmeier, European Southern Observatory (Germany); Donald N. B. Hall, Univ. of Hawai'i (United States)

In 2007 ESO started a program at SELEX to develop near infrared detectors for wavefront sensing and fringe tracking. The growth technology was liquid phase epitaxy. The arrays required deep cooling to 40K to get acceptable cosmetic performance at high APD gain. The second step was to develop a specific multiplexer tailored to the application of the GRAVITY wavefront sensors and the fringe tracker. The pixel format is 320x256 pixels. The array has 32 parallel video outputs which are arranged in such a way that the full multiplex advantage is available also for small subwindows. Nondestructive readout schemes with subpixel sampling are possible. This reduces the readout noise at high APD gain well below the subelectron level at frame rates of 1 KHz. The third step was the change of the growth technology from liquid phase epitaxy to metal organic vapour phase epitaxy (MOVPE). This growth technology allows the band

structure and doping to be controlled on a 0.1μm scale and to apply solid state engineering techniques. Heterostructures can be designed with the bandgap varying across the diode structure. This generation HgCdTe eAPD arrays has matured and offers an unmatched combination of sub-electron read noise and millisecond full-frame readout at operating temperatures of T=85K. These arrays are sensitive in H and K-band.

First on-sky results have been obtained with the SAPHIRA array at the Palomar Robo-AO adaptive optics system and further applications are planned at the SUBARU and KECKII telescopes. The SAPHIRA arrays have also been deployed in the wavefront sensors and in the fringe tracker of the VLTI instrument GRAVITY. First results with the four auxiliary telescopes of the VLTI have demonstrated stabilized fringes at magnitudes >8 in K-band, which is a major improvement in comparison to previous fringe trackers based on conventional NIR arrays. The SAPHIRA array is also an ideal device for pyramid wavefront sensors. With subelectron readout noise the spatial sampling of the wavefront can be optimized for faint targets. The fast frame rates match the needs of extreme adaptive optics.

With a high temperature anneal it was possible to increases the diffusion length from 2 μm to 30 μm. Due to the long diffusion length the ?c=2.5 μm the HgCdTe absorber layer can be directly grown on a CdTe substrate without a wide bandgap HgCdTe buffer layer using a "pauseless growth" technique. This allows a smooth transition from CdTe to HgCdTe. Due to the large diffusion length the absorber layer can be made thicker. With the removal of the wide bandgap buffer layer limiting the sensitive range to H band on the short wavelength side, the devices now show flat response from 0.8 to 2.5 um. Results obtained with this new diode structure called Mark14 will be presented. In a further development step the CdTe substrate can be removed by a chemical etch to obtain eAPD arrays with panchromatic response. These arrays could also be operated at the wavelength of 598 nm and used for laser guide stars.

For AO systems of extremely large telescopes larger formats are needed. Therefore, a 1Kx1K SAPHIRA array is planned which has 64 outputs operating at 20 Mpixel/s. This corresponds to frame rates of 1.2 kframes/s for a full 1Kx1K single frame readout. The development will be carried out in two steps. First, a 1Kx1K ROIC with a pixel pitch of 12 ?m will be designed and manufactured. A 512x512 pixel eAPD array with the current pixel pitch of 24 ?m will then be hybridized to this ROIC connecting pixels only to every second row and column of the ROIC. This yields a 512x512 pixel array with 24 ?m pixel pitch. In parallel the mesa structure of the HgCdTe eAPD layers for the smaller pixel pitch of 12 ?m will be developed to extend the format to 1024x1024 pixels without the need of developing new ROIC.

9909-41, Session 11

C-RED one: ultra high speed wavefront sensing in the infrared made possible

Jean-Luc Gach, Philippe Feautrier, Eric Stadler, Timothée Greffe, Stéphane Lemarchand, Fabien Clop, David Boutolleau, First Light Imaging S.A.S. (France); Ian M. Baker, SELEX ES Infrared Ltd. (United Kingdom)

While in the visible Electron multiplying CCDs (EMCCDs) improved imaging techniques and permitted a leap especially in life science imaging, no important breakthrough has been made in the infrared imagery since the hybridization of III-V or II-VI semiconductors with low bandgap on CMOS read-out circuitry (ROICs). The EMCCD technology permitted wide readout bandwidths while maintaining ultra low readout noise. For instance the OCAM2 camera has to now the fastest readout speed combined with the lowest readout noise at the same time: it exhibits a readout rate in excess of 132 Mpixels/s while maintaining a readout noise down to 0.1 electron (Feautrier et al. 2010). No equivalent imagers to EMCCDs with embedded carrier amplification were existing up to now in the infrared, neither for short wave imaging (SWIR), nor for mid wave or long wave imaging (MWIR & LWIR).

During the last few years, HgCdTe avalanche photodiodes (APDs) have been demonstrated to be one of the most promising path to build focal plane arrays (FPA) for Infrared low flux and high speed applications such as active and hyper spectral imaging. Several groups (Beck 2001,2004,2006, Kinch 2004, Vaidyanathan 2004, Hall 2005, Reine 2006,2007, Perrais 2007, Rothman 2007) have reported multiplication gains of 100-1000 for low values of reverse bias, around 10V, associated with a quasi-deterministic multiplication yielding a close to conserved signal to noise ratio (SNR) by measuring an excess noise factor F from 1 to 1.2.

First light imaging has decided to make this technology available to everybody with its C-Red one camera which is the first camera ever using an e-APD infrared array. Based on a 320x256, 2.5 ?m cutoff HgCdTe e-APD array deeply cooled to 80K with a high reliability pulse tube cryocooler (MTBF ~ 90 000 hrs), the camera can exhibit a huge readout speed of ~2000 fps full frame while having a readout noise below one electron, thanks to the APD gain in the range of 1 to 60. These unprecedented performances will open a new era for infrared imagery. In addition to the outstanding performances of the detector, First Light Imaging provides a fully integrated system that can be used in demanding environments and requires only an electric power supply and water cooling. No liquid nitrogen or vacuum pumping is needed for the camera operation allowing the continuous use of the camera in a remote environment without any human operator and allowing also a full remote control of the system.

The main application of such a camera is wavefront sensing and we will show solutions to make them and compare its performance with various wavefront sensors in the infrared and also in the visible.

9909-42, Session 11

AO WFS detector developments at ESO to prepare for the E-ELT

Mark Downing, Mark M. Casali, Gert Finger, Derek J. Ives, Enrico Marchetti, Suzanne K. Ramsay, Javier Reyes-Moreno, European Southern Observatory (Germany)

ESO has a very active on-going AO WFS detector development program to not only meet the needs of the current crop of instruments for the VLT, but also has been actively involved in gathering requirements, planning, and developing detectors and controllers/cameras for the challenging instruments in design and being proposed for the E-ELT.

This paper provides an overall summary of the AO WFS sensor requirements of the various E-ELT instruments and AO Adapters. This is followed by a description of the many interesting detector, controller and camera developments underway at ESO to meet these needs; a) the rationale behind and plan to upgrade the 240x240 pixels, 2000fps, "zero noise", L3Vision CCD220 sensor based AONGC camera; b) status of the LGSD/NGSD High QE, 3e- RoN, fast 700fps, 1760x1680 pixels, AO LGS CMOS Imager and camera development; c) status of and development plans for the Selex SAPHIRA IR eAPD and controller.

Most of the instruments and detector developments are described in more detail in other papers at this conference.

9909-43, Session 11

Near infrared wavefront sensing

Peter L. Wizinowich, W. M. Keck Observatory (United States); Mark R. Chun, Institute for Astronomy (United States); Dimitri Mawet, California Institute of Technology (United States); Christoph Baranec, Institute for Astronomy (United States); Richard G. Dekany, California Institute of Technology (United States); Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Thierry

Fusco, Lab. d'Astrophysique de Marseille (France); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States); Donald N. B. Hall, Institute for Astronomy (United States); Cedric Plantet, Lab. d'Astrophysique de Marseille (France); Francois Rigaut, The Australian National Univ. (Australia)

We discuss the advantages of wavefront sensing at near-infrared wavelengths, from low order sensing with laser guide star (LGS) adaptive optics (AO) to high order sensing with natural guide star (NGS) AO. We then turn to the application of near-infrared sensing with the Keck AO systems as a demonstrator for similar systems on extremely large telescopes (ELTs).

Near-infrared wavefront sensing is a critical enabling technology for science with adaptive optics (AO) on current and future telescopes. It will enable high contrast science of exoplanets around low-mass stars and dust obscured regions (e.g. star-forming regions and the Galactic Center), and high sky coverage for extragalactic science. It can be used to extend the performance of NGS AO to fainter (i.e. redder) targets and to increase the sky coverage of LGS AO. Furthermore, it allows the application of optimal wavefront sensing approaches (e.g. pyramid and Zernike wavefront sensing) due to the AO correction at near-infrared wavelengths. All of the extremely large telescopes (ELTs) are planning to use infrared wavefront sensing as part of their AO facilities. The development and on-sky demonstration of near-infrared wavefront sensing represents considerable risk reduction for these projects. Furthermore all of the ELTs are segmented telescopes and the Keck telescopes with their AO systems are the only viable platform to evaluate any interaction issues between a segmented mirror and high order infrared wavefront sensing.

Game-changing sub-electron readout noise near-infrared detector technologies have recently become available; specifically the Selex SAPHIRA, and potentially the CEA/Sofradir RAPID, avalanche photo-diode arrays for high or low order sensing, and multiple reads of the Teledyne Hawaii (HxRG) detectors for low order sensing. We will report on our collaborative efforts to demonstrate both low and high order wavefront sensing using these technologies. These efforts include:

• University of Hawaii's work with Selex to develop and characterize the SAPHIRA array and the implementation of a traveling test camera.

• French (i.e. First Light Inc. (FLI), Institut d'Astrophysique et Planetologie a Grenoble (IPAG), Laboratoire d'Astrophysique de Marseille (LAM) and ONERA) work on detector and camera development.

• The extension of the pyramid wavefront sensor (PWFS) expertise at Arcetri and Subaru, including the real-time software used with the SCExAO's visible PWFS, to near-infrared PWFS.

• Implementation of a H2RG based tip-tilt sensor with the Keck I LGS AO system and enhancements to this system, including multiple tip-tilt stars.

• Application of a low order (e.g. focus) sensing algorithm (i.e. LIFT) to a near-infrared tip-tilt sensor system.

• Simulations and modeling of both low and high order near-infrared wavefront sensing.

• The proposed development of a near-infrared PWFS for on-sky demonstration with the Keck II AO system. The demonstration would include a pilot L-band coronagraphic imaging survey of 150 M dwarfs to identify exoplanet candidates around these host stars for the first time, followed by spectroscopy of these exoplanet candidates.

9909-44, Session 12

Tackling down the low-wind effect with SAXO, the SPHERE eXtreme Adaptive Optics system

Jean-François Sauvage, Thierry Fusco, ONERA (France); Julien H. V. Girard, Julien Milli, Pierre Bourget, European Southern Observatory (Chile); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France)

SPHERE is the VLT second generation planet hunter instrument. Installed since may 2014 on UT3, the system has been commissionned and verified for more than one year now and routinely delivers unprecedented images of star surroundings, exoplanets and dust disks. The exceptionnal performance required for this kind of observation makes the appointment: a repeatable Strehl Ratio of 90% in H band, a rough contrast level of 10-5@0.5 arcsec, and reaches 10-6 at the same separation after differential imaging (SDI, ADI). The instrument also presents high contrast levels in the visible and an unprecedented 17mas diffraction-limited resolution at 0.65 microns wavelength. SAXO is the SPHERE XAO system, allowing the system to reach its final detectivity. Its high performance and therefore highly sensitive capacities turns a new eye on telescope environement.

SAXO and SPHERE allowed to diagnose an effect called "Low Wind Effect", degrading strongly the performance of the SPHERE instrument during low wind atmospherical conditions. Some wave-front aberrations have been identified, composed of strong segmented contributions and deviating from kolmogorov statistics, and therefore not easily seen and compensated for by the XAO system. Solutions are developped and tested on sky to propose a new operation procedure reducing this limitation. The measurement of these particular aberrations is made with a dedicated phase diversity algorithm, while the compensation is proposed to be made with the SAXO loop as a classical Non Common Path aberration. The performance of this solution is studied in simulation, we present the first on-sky implementation of the method.

9909-45, Session 12

Coronagraphic imaging of habitable exoplanets with large ground-based telescopes: fundamental limits and system architecture

Olivier Guyon, The Univ. of Arizona (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States); Johanan L. Codona, The Univ. of Arizona (United States); Michael P. Fitzgerald, Univ. of California, Los Angeles (United States); Bruce A. Macintosh, Stanford Univ. (United States); Jared R. Males, The Univ. of Arizona (United States); Dimitri Mawet, California Institute of Technology (United States); Benjamin A. Mazin, Univ. of California, Santa Barbara (United States)

Thanks to recent advances in coronagraphy, detector technology, deformable mirrors and wavefront sensing techniques, we show that direct imaging and spectroscopic characterization of rocky planets in the habitable zones of nearby stars will be within reach of future 25-40-m extremely-large telescopes (ELTs). High throughput coronagraph designs compatible with segmented apertures enable efficient broadband imaging as close as 1 l/D from the star, and can be optimized to operate on partially resolved targets (nearby stars). New wavefront sensing approaches, such as unmodulated pyramid WFS, operate at the diffraction limit of the telescope and offer several order magnitude improvements in sensitivity over current seeing-limited sensors. Focal-plane wavefront sensing can provide immunity from non-common path errors limiting current systems, together with the ability to separate coherent speckles from incoherent planet light. These approaches are benefiting from high speed high efficiency photon-counting detectors now or soon available at visible and near-infrared wavelengths. Laboratory and on-sky demonstrations of these key techniques are being conducted, and will be reviewed.

We quantitatively derive the high contrast imaging performance of large ground-based telescope, and explore/compare several system architectures. We start with a physical model of atmospheric turbulence, capturing the temporal and chromatic dependency of incoming wavefronts. The model takes into account atmospheric composition, chromatic refraction, scintillations and diffraction propagation. We then evaluate how combinations of wavefront sensors operating at multiple wavelengths and at multiple locations in the instrument can simultaneously drive a fast extreme-AO correction and maintain a high contrast area in the focal plane image. We also evaluate the sensitivity gain offered by predictive control of atmospheric wavefronts. Finally, we explore how focal plane speckle sensing and modulation can calibrate residual speckles to better uncover planet light, which is incoherent with the central star.

We identify science targets and instrument system architectures suitable for reflected light imaging and spectroscopy of habitable planets around nearby stars in visible and near-IR. We conclude that ELTs can reach the sensitivity to image and characterize habitable planets around approximately 50 stars. We discuss how the technology gap between our assumptions and the current state of the art can be filled over the next few years, and possible future enhancements to our proposed approach.

9909-46, Session 12

Evolutionary timescales of AO-produced speckles at NIR wavelengths

Sean B. Goebel, Institute for Astronomy (United States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States); Donald N. B. Hall, Institute for Astronomy (United States); Nemanja Jovanovic, Subaru Telescope, National Astronomical Observatory of Japan (United States); Dani E. Atkinson, Institute for Astronomy (United States)

In order to observe in reflected light potentially habitable exoplanets, advanced wavefront control techniques must be developed and implemented. Effects such as imperfect AO correction of atmospheric turbulence, diffraction within the optical system, etc. produce a “speckle halo” around the PSF. These speckles, which have intensities up to a few 10^-3 times that of the PSF core, evolve with timescales that have not previously been characterized at near-infrared (NIR) wavelengths. Because speckles can appear indistinguishable from stellar companions such as exoplanets, they must be understood and removed. In order to better understand the behavior of these speckles and make informed decisions about future speckle control loops, we present measurements of the evolutionary timescales of speckles around adaptive optics-corrected PSFs. We placed a SELEX SAPHIRA 320x256 HgCdTe infrared APD detector behind the SCExAO instrument at Subaru Telescope atop Mauna Kea, Hawaii. SCExAO provides a 2000-element deformable mirror updating at 3.5 kHz for extreme adaptive optics corrections (NIR Strehls > 80%). We observed unresolved stars and analyzed the behavior of speckles at 1-10 ?/D from the PSF core in H-band (~1.6 ?m) SAPHIRA images collected at a frame rate of ~1 kHz. Ultimately we would like to image in reflected light potentially habitable exoplanets around nearby stars. These have typical contrasts ranging from 10^-7 (a rocky planet around an M-type star, potentially accessible with 30m-class telescopes) to 10^-10 (Earth around Sun-like star), independent of wavelength. Achieving this ambitious goal necessitates a fast speckle control loop that is able to (1) reduce speckle raw intensities, and (2) calibrate in post-processing residual speckles in order to separate them from incoherent planet light. We apply our measured speckle evolutionary timescales to derive the performance parameters of a speckle control loop optimized for this application. On Subaru Telescope, this activity will lead to direct imaging in reflected light of giant planets, in preparation for habitable planet imaging and spectroscopic characterization with 30m-class telescopes.

9909-224, Session PWed1

Precision astrometry with adaptive optics: towards exoplanet mass measurement from the ground

S. Mark Ammons, Lawrence Livermore National Lab. (United States); Bruce A. Macintosh, Stanford Univ. (United States); Dominic Ryan, Univ. of California, Berkeley (United States); Christian Marois, NRC - Herzberg Astronomy & Astrophysics (Canada); Jessica R. Lu, Maxwell Service, Maissa Salama, Univ. of Hawai’i (United States); Eduardo Marin, Gaetano Sivo, Vincent Garrel, Gemini Observatory (Chile); Eric Nielsen, Stanford Univ. (United States); Rob de Rosa, Univ. of California, Berkeley (United States); Olivier Guyon, The Univ. of Arizona (United States); Eduardo A. Bendek, NASA Ames Research Ctr. (United States); Donald T. Gavel, Univ. of California, Santa Cruz (United States); Kaitlin Dennison, Univ. of Connecticut (United States); Benoît Neichel, Lab. d’Astrophysique de Marseille (France); Quinn M. Konopacky, Univ. of California, San Diego (United States)

ELTs equipped with MCAO systems will be powerful astrometric tools in the next two decades. With sparse-field precisions exceeding 30 uas for V > 18, the ELTs will surpass even GAIA’s per-epoch precision for faint stars (V > 12). We present results from three ongoing astrometry programs with Keck NIRC2, Gemini GeMS, and ShaneAO and discuss synergies with WFIRST and GAIA. We present the first direct mass measurements of the individual L/T components of Luhman16 AB, the nearest brown dwarf binary known. Exploiting GeMS’ wide field of view to image reference stars, we are able to track the barycenter motion to better than 0.5 mas and derive the stellar masses with 3% precision, enabling a rigorous calibration of evolutionary models. We find that a mutual Keplerian orbit with no perturbing planets fits the binary separation to within the measurement errors, ruling out companions down to 14 earth masses for certain orbits.

We also present results from 2 years of astrometric monitoring of 15 T dwarfs with Keck NIRC2 and ShaneAO. With astrometric precisions of ~0.3 mas, we probe the brown dwarfs for companions as small as Saturn over 0.3- 2.0 year periods. The resulting limit on the giant planet occurrence rate independently checks planet formation models at the extreme low-mass end of the stellar main sequence.

Third, we show on-sky results with a lithographically-imprinted diffractive mask installed in the ShaneAO adaptive optics system. We verify that the diffractive mask allows us to recover astrometry of otherwise saturated bright stars at the ~0.3 mas level while simultaneously imaging field reference stars with high precision. Such a capability will be important for directly measuring masses of exoplanets discovered with GPI/SPHERE such as 51 Eri, independently calibrating planet formation models.

9909-226, Session PWed1

The Robo-AO KOI survey: laser adaptive optics imaging of every Kepler exoplanet candidate

Carl Ziegler, Nicholas M. Law, The Univ. of North Carolina at Chapel Hill (United States); Christoph Baranec, Univ. of Hawai’i at Manoa (United States); Reed L. Riddle, California Institute of Technology (United States); Timothy D. Morton, Princenton Univ. (United States)

The Robo-AO Kepler Planetary Candidate Survey is observing every Kepler

planet candidate host star (KOI) with laser adaptive optics imaging to hunt for blended nearby stars which may be physically associated companions. With the unparalleled efficiency provided by the first fully robotic adaptive optics system, we perform the critical search for nearby stars (0.15" to 4.0" separation with contrasts up to 6 magnitudes) that dilute the observed planetary transit signal, contributing to inaccurate planetary characteristics or astrophysical false positives. We present approximately 3300 high resolution observations of Kepler planetary hosts from 2012-2015, with ~500 observed nearby stars. We measure an overall nearby star probability rate of 16.2±0.8%. With this large data set, we are uniquely able to explore broad correlations between multiple star systems and the properties of the planets which they host, providing insight into the formation and evolution of planetary systems in our galaxy. Several KOIs of particular interest will be discussed, including possible quadruple star systems hosting planets and updated properties for possible rocky planets orbiting with in their star's habitable zone. Other Robo-AO surveys will also be presented.

9909-228, Session PWed1

GeMS/GSAOI photometric performances from an user perspective

Emanuele Dalessandro, Sara Saracino, Univ. degli Studi di Bologna (Italy); Livia Origlia, INAF - Osservatorio Astronomico di Bologna (Italy); Enrico Marchetti, European Southern Observatory (Germany); Francesco R. Ferraro, Barbara Lanzoni, Univ. degli Studi di Bologna (Italy); Doug Geisler, Francesco Mauro, Univ. de Concepción (Chile)

Ground-based near-IR imagers assisted by MCAO systems are the technological frontier to obtain high-quality stellar photometry in crowded fields at the highest possible spatial resolution. GeMS/GSAOI is the only MCAO system currently offered to the astronomical community.

We used a large sample of globular cluster images obtained in the J and Ks bands with GeMS/GSAOI under significantly different atmospheric conditions, to characterize the properties of the PSF (Full Width Half Maximum, Strehl Ratio, Encircled Energy) across the field of view as a function of the seeing.

We also performed some comparisons with images of the same targets obtained with ACS/WFC onboard HST.

9909-230, Session PWed1

Combining high-angular resolution imaging with state of the art 3D observations of distant galaxies

Benoît Neichel, Benoit Epinat, Lab. d'Astrophysique de Marseille (France); Thierry Contini, Institut de Recherche en Astrophysique et Planétologie (France); Anais Bernard, Lab. d'Astrophysique de Marseille (France); Markus Kissler-Patig, Gemini Observatory (United States); Jarle Brinchmann, David Carton, Leiden Univ. (Netherlands); Hayley Finley, Institut de Recherche en Astrophysique et Planétologie (France); Léo Michel-Dansac, Ctr. de Recherche Astrophysique de Lyon (France); Mieke Paalvast, Leiden Univ. (Netherlands)

In this paper we present first results on observations of a galaxy group at z~0.7, dissected both with high-angular resolution Near-Infrared images and 3D spectroscopy. The imaging part has been acquired with the newly GeMS/GSAOI instrument at Gemini South. This instrument provides high-angular resolution images in the NIR. For our observations, we obtained deep K-band images with a resolution of ~70mas. The unique performance and Field of View (FoV) provided by GeMS/GSAOI is used to derive an accurate and unprecedented morphological analysis of the group's galaxies. At these redshifts the GeMS/GSAOI NIR images are critical to determine the morphologies as they probe the old, underlying stellar populations that trace the bulk of the galaxy stellar mass and avoid bias due to young stellar formation. This unique morphological information is then combined with resolved internal derived from 3D spectroscopy. Two galaxies of the field already benefit from VLT/SINFONI observations, and the whole field has been observed with the MUSE instrument, a new generation 3D spectrograph at the ESO-VLT. By combining high resolution morphology, and kinematics, we will establish a complete description and understanding on the process at work in each individual galaxy studied, and investigate in great details how galaxies transform in specific group environments.

9909-232, Session PWed1

Astrometry with spatially variable PSFs: instrumental field-dependent aberrations

Breann N. Sitarski, Gunther Witzel, Michael P. Fitzgerald, Univ. of California, Los Angeles (United States); Jessica R. Lu, Institute for Astronomy (United States); Tuan Do, Andrea M. Ghez, Univ. of California, Los Angeles (United States); Gregory W. Doppmann, James E. Lyke, Randall D. Campbell, Marc Kassis, Luca Rizzi, W. M. Keck Observatory (United States); Keith Y. Matthews, California Institute of Technology (United States); Scott J. Lilley, Rachel Rampy, W. M. Keck Observatory (United States); Maxwell Service, Institute for Astronomy (United States); Matthew C. Britton, The Aerospace Corp. (United States); Mark R. Morris, Univ. of California, Los Angeles (United States); Eric E. Becklin, Univ. of California, Los Angeles (United States) and NASA Ames Research Ctr. (United States); Peter L. Wizinowich, Sam Ragland, W. M. Keck Observatory (United States)

Near infrared adaptive optics observations of the Galactic Center with the Keck Telescopes have revealed the presence of a supermassive black hole by tracing the orbits of the stars in the innermost arcsecond. The closest approach of S0-2--a bright, well-studied star that is expected to get within 130 mas of Sgr A*—in 2018 provides us with a unique opportunity to test General Relativity in the strong-gravity regime. Our current astrometry extraction techniques utilize StarFinder (Diolaiti et al. 2000), but this software does not take into account instrumental aberrations or atmospheric anisoplanatism that may affect spatial variability of the PSF. The Galactic Center Group at UCLA is in the final year of developing a software package that works with existing StarFinder modules to predict how the PSF varies off-axis and takes into account both instrumental and atmospheric anisoplanatic aberrations.

We present a model for 21 Zernike terms of field-dependent aberrations arising in the NIRC2 and OSIRIS infrared imagers on the W. M. Keck Telescopes. We use high signal-to-noise ratio phase diversity data employing a lit fiber source in the Nasmyth focal plane for each instrument to construct models of the optical path difference as a function of field position across the detector. With a differential wavefront error of up to 220 nm in NIRC2 and 100 nm in OSIRIS, this effect is a main contributor to astrometric and photometric measurement uncertainties, and can affect the astrometry up to 2 mas, which is large compared to our overall astrometric error of ~3 mas. The stability over a two-year period of our grid was 60 nm RMS, still significantly less than the overall wavefront error. The sampling error, measured from looking at the differences between adjacent maps, is highest at distances furthest from the optical axis (up to 87 nm

RMS), and has an average wavefront error difference of 43 nm RMS.

To apply a continuous model of the instrumental aberrations, we construct a third-order spline interpolated model constructed for the first 21 Zernike coefficients across the field of view of the detector. The difference between the model and measured phase maps at various points across our detector is at most 40 nm RMS. This model has been incorporated into the AIROPA (Anisoplanatic and Instrumental Reconstruction of Off-axis PSFs for AO) software package, and the details on the algorithms, data acquisition, and data reduction techniques are incorporated and can be applied on most systems that have tools (i.e., a moveable lit fiber) similar to NIRC2 and OSIRIS.

9909-234, Session PWed1

High-z galaxies simulations: a benchmark for GMCAO

Elisa Portaluri, Valentina Viotto, Maria Bergomi, Federico Biondi, Marco Dima, Jacopo Farinato, INAF - Osservatorio Astronomico di Padova (Italy); Davide Greggio, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli Studi di Padova (Italy); Marco Gullieuszik, Demetrio Magrin, Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy)

The superb spatial resolution of next generation ELTs gives the possibility to study far objects and to puzzle over the complexities of one of the key questions of the extragalactic research in the last years: how galaxies formed and evolved. The paramount controversy is about which scenario is more eligible between the “monolithic” process, in which large proto-galaxies formed early through a dissipational collapse, and the “hierarchical” one, in which galaxies are the result of successive mergers between small structures.

Several astronomical surveys that investigate the galactic structures over a wide range of morphologies were carried out in order to discriminate between the two scenarios. This kind of study needs an excellent level of details, possible only with space telescopes or with the application of adaptive optics techniques for ground-based ELTs.

In this work we supported the innovative idea of a Global-MCAO system that maximizes the chance to find suitable reference stars in a wide field of view, a fundamental issue for the forthcoming E-ELT. Therefore GMCAO allows the development of extragalactic research with ground-based instrumentation, often frozen out because of the small sky coverage. An estimation of the gain of this approach is given for several scientific results, and a thorough discussion is provided in order to assess the actual ability of GMCAO to deal with these classes of astrophysical problematic.

Moreover, using a tomographic simulation tool we compute a map of the Strehl Ratio simulating an observation of the Chandra Deep Field South with an ELT that makes use of the GMCAO. We take the E-ELT specifications as a reference and used them to build a mock image of a set of galaxies, assuming the estimated Strehl Ratio. The morphology and photometric properties of the sample galaxies were examined performing the source detection and two-dimensional light-profile modeling.

The good agreement we found between the recovered and the intrinsic parameters depicts GMCAO as a reliable challenging approach that can rebuild the AO skills and can cross the extragalactic frontiers to new unforeseen results.

9909-225, Session PWed2

Optical solutions for accommodating ELT LGS wavefront sensing to small format detectors

Éric Gendron, Lab. d’Etudes Spatiales et d’Instrumentation en Astrophysique (France)

Sodium laser guide stars (LGS) will be used on extremely large telescopes (ELT) for increasing the sky coverage of adaptive optics systems. The thickness of the sodium layer together with a perspective effect makes the laser beacon to appear as an elongated plume when observed from a pupil location distant from the laser launch telescope. The wave-front sensing with a Shack-Hartmann on such a peculiar object then requires a large number of pixels per sub-aperture in order to cope with the required field of view. As a large number of sub-apertures is required on an ELT, this results in the need for detector formats exceeding 1500x1500 pixels. It is worth noticing however that most of these numerous pixels are useless, as many of them won’t receive any light due to the arrangement of the pattern of spots.

We present in this article some potential optical solutions for reducing the requirements of the detector format by a significant amount. This is obtained by re-arranging the pattern of the elongated spots in order to avoid any loss of space between them. Depending on the geometry of the system, a factor of ≈2 on the pixel count can be gained along both directions.

9909-227, Session PWed2

A general formalism for Fourier-based wavefront sensing: application to the pyramid wavefront sensors

Olivier Fauvarque, Benoît Neichel, Lab. d’Astrophysique de Marseille (France); Thierry Fusco, Jean-François Sauvage, Lab. d’Astrophysique de Marseille (France) and ONERA (France)

In the article, we compare a set of Wave Front sensors based on Fourier filtering technique. In particular, this study explores the “class of pyramidal WFS” defined as the 4 faces pyramid WFS, all its recent variations (6, 8 faces, the flattened PWFS, etc.) and also some new WFSs as the flattened cone WFS or the 3 faces pyramid WFS.

In the first part, we introduce an analytic mathematical formalism based on Fresnel optics, which allows, among other things, to define a rigorous criterion about the chromaticity of a WFS. Secondly, we define an unified numerical post-imaging process which allows to avoid the constraining definition of the usual slopes maps computations (only valid for the PWFS).

We finally compare the WFSs of the Pyramidal class following a large set of criteria: efficiency of incoming flux, sensitivity, linear range, capacity to close a basic Adaptive Optics loop and chromaticity when the optical parameters of the Fourier filtering mask (number of faces, angle of the apex) change.

We show that the 3 faces pyramid has a very similar behavior compared with the 4 faces version.

We also show that the shape of the mask does not really matter on the performance when the angle of the apex is small, showing that the ease manufacturing may be the only relevant criterion to choose between these WFSs.

9909-229, Session PWed2

Sensing wavefronts on resolved sources with pyramids on ELTs

Markus Feldt, Stefan Hippler, Max-Planck-Institut für Astronomie (Germany); Andreas Obereder, Industrial Mathematics Competence Ctr. (Austria); Remko Stuik, Leiden Observatory (Netherlands); Thomas Bertram, Max-Planck-Institut für Astronomie (Germany)

The discussion about the advantages of Pyramid-type wavefront sensors (PWFS) with respect to Hartmann-Shack systems (SHS) is entering its second decade. It is nowadays widely recognized that Pyramid sensors do have an advantage at the faint end, being able to maintain peak performance on fainter stars than SHSs can. While this might render a choice between the two types for usage on ELT single-conjugate AO (SCAO) systems easy at first glance, particular concerns do exist: It is widely believed that PWFSs do require modulation to achieve optimal performance, something not necessarily easy to achieve in a cryogenic environment. On the other hand, SHSs require more pixels and thus larger detectors to optimally analyze a wavefront. A new concern arises however particularly on ELTs: This novel class of telescopes will, unsurprisingly, provide unprecedented resolution. Since much of the PWFSs advantages arises from the usage of the full telescope aperture, and thus its unrivaled resolution limit, it will now be confronted with an also unprecedented number of resolved reference sources.

While it is generally agreed that when using a resolved object for wavefront sensing, the PWFS' performance becomes equivalent to that of a SHS, systematic research on the behavior of a PWFS operating on extended sources is lacking to date. While observational proof exists that PWFSs do still work on extended targets, and performance roughly as expected, simulations of the subject are hard to come by. In observational data, the resulting Strehl ratio (SR) of an observation is not easy to measure correctly on an extended source. Objects that would provide an extened or even simply binary target as reference star with a suitably nearby point source to measure the resulting SR are also not abundant in the sky. Simulations are difficult, as tezhy require alrge amounts of computation time when each "pixel" of an extended source is propagated through the simulated WFS individually.

Nevertheless, in the course of a trade-off study for the METIS instrument for the E-ELT, we are conducting a large set of simulations of the performance of the PWFS option on multiple and extended sources. In this presentation, we will summarize the results and, for the first time, show quantitatively how a simulated yet real-world system is expected to behave on this class of reference objects.

9909-231, Session PWed2

ESO adaptive optics NGSD/LGSD detector and camera controller for the E-ELT

Javier Reyes-Moreno, Mark Downing, Nicola Di Lieto, European Southern Observatory (Germany)

This paper presents the details of the design of the first ESO Adaptive Optics (AO) camera and controller for the E-ELT which is based on the e2v large format CMOS imager Natural Guide Star Detector (NGSD) and Laser Guide Star Detector. NGSD is a 880x840 pixel CMOS array organized as 44x42 sub-apertures of 20x20 pixel each. NGSD is exactly 1/4 of the LGSD and therefore it is considered a scaled down demonstrator for the LGSD (1760x1680 pixels).

The detector controller requirements present numerous challenges in the design of the electronics due to the low-power, low-noise and high parallel data rate of the detectors involved.

The general architecture of the controller along with the front-end electronics to drive and read-out the detector are based on Xilinx Virtex-7 FPGAs and its advanced features as skew clock compensation, embedded CPUs and high-speed XAUI and 10 GbE interfaces, to name a few.

In addition, the work presented here describes both the modular and compact mechanical design approach, its built-in TEC controller, the environmental sensors and more importantly, the design roadmap for the future E-ELT AO camera based on this first version.

First tests results obtained with the camera and Rev. B of NGSD imager are here reported.

9909-233, Session PWed2

LIFT on Keck: analysis of performance and first experimental results

Cedric Plantet, Lab. d'Astrophysique de Marseille (France) and ONERA (France) and Institut de Planétologie et d'Astrophysique de Grenoble (France); Peter L. Wizinowich, W. M. Keck Observatory (United States); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Sam Ragland, Rachel Rampy, W. M. Keck Observatory (United States)

Laser-assisted adaptive optics relies on natural guide stars for the estimation of low orders. Infrared wavefront sensors, compared to visible ones, provide some advantages for this application: lower wavefront distorsion, hence better sensitivity, and access to colder stars or stars behind dust clouds, hence higher sky coverage. Moreover, cold stars of type K or M, which emit more in the near infrared than in visible light (2 to 3 magnitudes difference), represent a great majority of main-sequence stars. However, visible wavefront sensors have been preferred until now because of the difference in noise level between visible and infrared detectors.

Recently, a H2RG-based camera was implemented with the Keck I laser guide star adaptive optics system to work as a near-infrared (H and/or Ks band) tip-tilt sensor. Low noise is achieved by multiple reads of small regions of interest. The on-sky results have been excellent and have motivated a proposal to implement a near-infrared low-order wavefront sensor on Keck II. The Keck II sensor will be based on the recent advances with HgCdTe avalanche photodiodes arrays, such as the SAPHIRA (Selex) and RAPID (CEA LETI/Sofradir) detectors, which offer very low noise (1 to few electrons), and thus wavefront sensing at low flux in the near infrared.

The recently developed low-order wavefront sensor algorithm LIFT is considered for this application. It is very simple to set up, as it makes its estimation from a single astigmatic focal image. Previous studies have shown that LIFT has good noise propagation properties, comparable to a non-modulated pyramid, for the estimation of tip/tilt and focus. It was validated in the lab and in open loop on sky with the Gemini South MCAO system GeMS.

We will report on tests performed to prepare an implementation of LIFT on the Keck telescopes. Astigmatic images of calibration sources were acquired on the H2RG camera in Ks band. In this configuration, the sampling is 0.45 times the Nyquist sampling. LIFT had only been validated at Nyquist sampling before, and the extension to strongly undersampled images is a key operational aspect. With these tests, we have demonstrated the successful estimation of focus and astigmatism ramps at such a low sampling. The next steps will be to verify LIFT's performance in the presence of simulated turbulence, and finally to demonstrate the first pseudo-closed loop operation of LIFT on sky.

In parallel with these experiments, we will evaluate LIFT's behavior on a Keck-like system with end-to-end simulations and compare these with experimental results. We will also compare the outcome of these simulations with similar work previously for a different configuration (Gemini-like system, Nyquist sampling) and discuss the utility of using LIFT at low sampling.

9909-235, Session PWed2

Experimental study of an optimised Pyramid wavefront sensor for extremely large telescopes

Charlotte Z. Bond, Kacem El Hadi, Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, Lab. d'Astrophysique de Marseille (France) and ONERA (France); Carlos M. Correia, Olivier Fauvarque, Lab. d'Astrophysique de Marseille (France); Didier Rabaud, Innovation Network (France); Rodolphe Conan, GMTO Corp. (United States); Benoit Neichel, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, Lab. d'Astrophysique de Marseille (France) and ONERA (France)

Over the last few years the Laboratoire d'Astrophysique de Marseille (LAM) has been heavily involved in R&D for adaptive optics systems dedicated to future large telescopes, particularly in preparation for the European Extremely Large Telescope (E-ELT). Within this framework an investigation into a Pyramid wave-front sensor is underway. The Pyramid sensor is at the cutting edge of high order, high precision wave-front sensing for ground based telescopes. Investigations have demonstrated the ability to achieve a greater sensitivity than the standard Shack-Hartmann wave-front sensor whilst the implementation of a Pyramid sensor on the Large Binocular Telescope (LBT) has provided compelling results.

The Pyramid now forms part of the baseline for several next generation Extremely Large Telescopes (ELTs). As such its behaviour under realistic operating conditions must be further understood in order to optimise performance. At LAM a detailed investigation into the performance of the Pyramid aims to fully characterise the behaviour of this wave-front sensor in terms of linearity, sensitivity and dynamic range. We have implemented a Pyramid sensor using a high speed OCAM2 camera (incorporating close to 0 readout noise with a high frame rate of 1.5kHz), with which we carry out a study of the performance in a full closed loop adaptive optics system. This investigation involves tests on all fronts: from theoretical models and numerical simulations; to experimental tests under controlled laboratory conditions, with an aim to fully understand the Pyramid sensor in both modulated and non-modulated configurations. We include results demonstrating the linearity of the Pyramid signals; compare measured interaction matrices for different methods of calculating the 'meta-intensities'; and compare the Pyramid performance under modal and zonal control. The final goal is to provide an on sky comparison between the Pyramid and a Shack-Hartmann wave-front sensor, at Observatoire de la Côte d'Azur (ONERA-ODISSEE bench) during the first half of 2016. Here we present our setup and latest experimental and modelling results.

9909-236, Session PWed2

Novel tip-tilt sensing strategies for the laser tomography adaptive optics system of the GMT

Marcos A. Van Dam, Flat Wavefronts (New Zealand); Antonin H. Bouchez, Rodolphe Conan, GMTO Corp. (United States)

The availability of suitable tip-tilt guide stars is usually limits both the Strehl ratio and the sky coverage of laser guide star adaptive optics systems. The emergence of infrared eAPD arrays allows fast, low-noise tip-tilt sensing at wavelengths where the wavefront is partially corrected. For off-axis tip-tilt sensing, we show that the centroid estimator produces large errors even when there is no noise. Instead, we demonstrate that a peak finding algorithm, such as the correlation algorithm, leads to Strehl maximimizing tip-tilt estimates. In the case of the GMT, the sky coverage can be increased by supplementing low frame rate infrared tip-tilt measurements on a faint, near on-axis star with fast visible light measurements on bright guide stars 6 to 10 arcminutes off-axis.

9909-237, Session PWed2

Comparative study of infrared wavefront sensing solutions for adaptive optics

Cedric Plantet, Lab. d'Astrophysique de Marseille (France) and ONERA (France) and Institut de Planétologie et d'Astrophysique de Grenoble (France); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Nicolas Guerineau, Sophie Derelle, Clélia Robert, ONERA (France)

Adaptive optics systems in astronomy mostly rely on visible wavefront sensing for the analysis on natural guide stars, although infrared sensing would provide some advantages: lower wavefront distorsion, hence better sensitivity, and access to colder stars or stars behind dust clouds, hence higher sky coverage. This choice has been driven by the detectors technology: current visible detectors are almost noiseless, while classical infrared detectors suffer from high noise levels. The development of new infrared detectors based on HgCdTe avalanche photodiodes, such as RAPID (CEA LETI/Sofradir) or SAPHIRA (Selex), has given the possibility to detect infrared light with a detector noise low enough (1 to few electrons) to consider wavefront sensing at low flux.

On the other hand, whereas the Shack-Hartmann sensor can be found in almost every adaptive optics system, recent and promising wavefront sensing concepts, such as the pyramid sensor or the quadri-wave lateral shearing interferometer, are rarely used. It has been shown that the pyramid has a better behavior than the Shack-Hartmann in terms of noise propagation and aliasing. The quadri-wave lateral shearing interferometer has not been studied thoroughly yet in this context, but it also has the potential to overperform the Shack-Hartmann, while offering the possibility of a trade-off between sensitivity and dynamic range, as the pyramid does.

We propose here a comparative study of near infrared (J and H bands) wavefront sensing concepts using the RAPID camera, for mid and high orders estimation on an 8m-class telescope. These concepts rely on the three previously cited wavefront sensors: the Shack-Hartmann sensor, the pyramid sensor and the quadri-wave lateral shearing interferometer. All three of them rely on a simple optical element (microlens array, pyramid or self-imaging grating) that could be integrated in a DDCA (Detector Dewar Cooler Assembly), i.e. the cryogenic environment of the detector, for an optimal limitation of background and straylight.

An important point of this study is the trade-off between the noise level, linked to the background flux, and the compactness/realization difficulty of the DDCA. We present several preliminary designs, with optical elements being inside or outside the DDCA, and discuss on the main parameters that have an impact on background flux and on the DDCA itself.

To better evaluate the impact of background flux, and compare the relative performance of the different concepts, we also determine their respective noise propagation. This is done thanks to previous works relying on precise diffractive models.

Finally, we conclude on the main points that have to be considered for future infrared wavefront sensor designs, and propose a design basis that will be developed in future works.

9909-238, Session PWed2

Pupil phase discontinuity measurement: WFS sensing approach

Kacem El Hadi, Kjetil Dohlen, Aix-Marseille Univ. (France);

Jean-François Sauvage, Thierry Fusco, ONERA (France); Franck Marchis, Iris AO, Inc. (United States); Mamadou N'Diaye, Space Telescope Science Institute (United States)

Segmented deformable mirrors are widely used today in several domains: fiber bundle coupling, laser beam shaping, microscopy, retina imaging and many other applications such as wavefront control of LGS beam, Fibered Imager for Single Telescope.

In astronomy, and more particularly in the era of the giant telescopes, segmented deformable mirrors are mainly used to simulate bigger mirror sizes but also offer solutions for other questions related to fabrication, optics replacement and transport. In all its appliactions, they raise the problem of segment cophasing, characterization and measurement of phase discontinuities between segments.

In the E-ELT frame work, the Laboratoire d'Astrophysique de Marseille (LAM) is developing several R&D activities for active and adaptive optics instrumentation. Indeed, besides being at the origin of the development of the OCAM2 camera, a state of the art detector (up to 2.2 kHz frame rate and RON close to zero) and the demonstration of an ESO-EELT M1 mirror segment (1.5 m), our institute is deeply involved in the design of SCAO (Single Conjugated Adaptive Optics) and LTAO (Laser Tomography Adaptive Optics) systems for the HARMONI first light instrument.. We also develop since several years different wavefront sensing concepts such as the Pyramis sensor (OCAM2-Pyramid), the Zernike phase mask sensor (ZELDA), Phase diversity and NL Curvature.

In the present work, we couple a segmented mirror from Iris AO (PTT111, three degrees of freedom per segment) with different wavefront sensors: Shack-Hartmann, Pyramid and ZELDA. We aim to study their sensitivity to a segmented pupil and propose a suitable wavefront sensing approach for phase discontinuity measurements: segment phasing, stability, saturation, flat. Different addressing modes are then tested.

Correction of NIRI/ Altair non-common path aberrations using focal plane sharpening

Jesse Ball, Olivier Lai, Chadwick A. Trujillo, John White, Gemini Observatory (United States)

Adaptive optics, in astronomy, have been developed over the last 60+ years to help mitigate the degradational effects of turbulence in the atmosphere on image quality. As the index of refraction in earth's atmosphere changes spatially and temporally with temperature and wind speed variations, the wavefronts of light traversing through the atmosphere are blurred. In principle, a deformable optical element is used in conjunction with a wavefront sensor to provide near real-time corrections to the wavefront and output an un-aberrated phase to the science instrument(s). However, since the science instruments themselves inevitably introduce their own optical aberrations, there is a need for the deformable element to output a wavefront that is not necessarily aberration free, but rather inverse in phase to the aberrations inherent to the instrument. At the Gemini North Observatory, on the adaptive optics facility ALTAIR, accounting for these static non-common path aberrations could improve the K-band strehl ratio by as much as 30% on the near-infrared imaging instrument, NIRI. A technique known as focal plane sharpening is employed to correct for these non-common light path aberrations in NIRI. Small changes in the shape of the deformable mirror are made iteratively via a simplex algorithm as images of a light source in the shared light path are taken and analyzed in order to determine the best delivered image quality and therefore correct for the non-common path aberrations.

9909-240, Session PWed2

Wavefront sensing using a photonic lantern

Mark Corrigan, Jeremy R. Allington-Smith, Timothy J. Morris, Durham Univ. (United Kingdom); Robert J. Harris, Landessternwarte Heidelberg (Germany); Robert R. Thomson, David G. MacLachlan, Heriot-Watt Univ. (United Kingdom)

The need for high speed wavefront sensing within astronomical adaptive optics (AO) is growing, especially with the coming Extremely Large Telescope (ELT) scales. Wavefront sensors (WFSs), such as the Shack-Hartmann, typically rely on using a large 2D detector array to sample sufficient spatial frequencies at rates that can allow AO correction. At ELT scales these detectors must be developed specifically for wavefront sensing, greatly increasing system cost. In addition, handling the large data rates and processing pixel data in real time introduces a large computational overhead to the system. One potential solution to this problem could be made possible by using a photonic lantern (PL) as a WFS. The PL efficiently reformats a multi-moded input fibre to a set of single modes, all guided within individual fibres. The intensity output from each single mode fibre provides an optical modal decomposition of the PSF coupled into the input multi-mode fibre. A final design of a PL will therefore only require a 1D CCD array or individual low-noise photodiodes to measure the intensity distribution of each single mode output of the lantern. Not only could wavefront sensing with a PL remove the requirement for a large CCD array, but the read out speeds of a 1D array are much faster (by roughly an order of magnitude) and suitable low read noise devices already exist. In addition, without the need for complex centroiding such as in a Shack-Hartmann, the PL WFS only relies on the output intensities and could be relatively computationally inexpensive. We have developed an experimental set up using a 32-actuator Boston Mini-DM and an ultra-fast laser inscribed PL provided by Heriot-Watt University. Here we present results investigating the coupling between low-order aberrated wavefronts and the multimode input of the PL by analysing output of the separated single mode cores to investigate the suitability of a PL as an integrated wavefront sensing device. We also discuss the orthogonality of input wavefront and PL propagated modes.

9909-242, Session PWed2

High order dark wavefront sensing simulations

Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Carmelo Arcidiacono, INAF - Osservatorio Astrofisico di Arcetri (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Jacopo Farinato, Valentina Viotto, Maria Bergomi, Marco Dima, Demetrio Magrin, Luca Marafatto, INAF - Osservatorio Astronomico di Padova (Italy)

Dark wavefront sensing takes shape following quantum mechanics concepts in which one is able to "see" an object in one path of a two arm interferometer using an as low as desired amount of light actually "hitting" the occulting object. A theoretical way to achieve such a goal is represented by a combination of two unequal beams interferometer sharing the same incoming light, and whose difference in path length is continuously adjusted in order to show different signals for different signs of the incoming perturbation. Furthermore, in order to obtain this in white light, the path difference should be properly adjusted vs the wavelength used. While we incidentally describe how this could be achieved in a true opto-mechanical setup, we focus our attention to the simulation of an hypothetical "perfect" dark wavefront sensor of this kind in which white

light compensation is accomplished in a perfect manner and the gain is automatically tuned to the very best. Although this would represent a sort of idealized dark wavefront sensor that would probably be hard to match in real glass and metal, it would also give a firm indication of the maximum achievable gain or, in other words, of the prize for achieving such device. We compare this dark sensor to a conventional one in closed loop performing numerical simulation of both analyzing the behaviors and the performance on a common conventional adaptive optics system and a Kolmogorov turbulence evolving with time.

9909-243, Session PWed2

LGS wavefront sensing: pyramid and SH sensor comparison

Simone Esposito, Enrico Pinna, Guido Agapito, Christophe Giordano, Alfio T. Puglisi, Célia Blain, INAF - Osservatorio Astrofisico di Arcetri (Italy)

Laser Guide Star (LGS) reference sources, artificially generated at an altitude of 90 km at the atmospheric sodium layer, are mandatory to ensure large sky coverage of astronomical Adaptive Optics (AO) systems developed for 8m and Extremely Large Telescope (ELT). As a result of the projection effect, being the laser spots located at a finite distance from the telescope, the AO wavefront sensors perceive the LGSs as elongated. This elongation is a few arcseconds for the 8m class telescopes and can be more than 15 arcseconds for the ELTs. This can pose several challenges when using a Shack-Hartmann (SH) sensor such as truncation effects, the requirement for large detectors, and/or the requirement for detectors with geometry that corresponds to the source shape. In this work, we report the results of numerical simulations focused on the use of a Pyramid sensor with LGS. In particular the simulations will take into account the extension in altitude of the reference star and its effects on the sensor behavior. A first part of the work is dedicated to the study of Noise Propagation Coefficients of an LGS based Pyramid WaveFront Sensor. Informations from such study are used to optimize the sensor configuration. A second part reports performance comparison of AO correction when PWFS or SHS are used with LGS under the same conditions for an 8m class telescope. Finally some example cases are shown for the AO correction of an ELT class telescope.

9909-245, Session PWed2

A fast and furious solution to the low-wind effect at SPHERE

Michael J. Wilby, Christoph U. Keller, Leiden Observatory (Netherlands); Jean-François Sauvage, Thierry Fusco, ONERA (France); David Mouillet, Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France)

The SPHERE high-contrast imager for the VLT has recently finished its commissioning phase and is already providing exceptional results in the field of direct exoplanet and circumstellar disk imaging. Instrument performance is sometimes limited under the best seeing conditions by the so-called Low-Wind Effect (LWE), whereby the un-occulted stellar PSF gains two or more sidelobes (a.k.a. "Mickey Mouse ears") on spatial scales of 1 to 4 lambda/D and contrasts of 0.1 or greater, thus degrading the final coronagraph performance. In the pupil-plane this effect manifests itself as strong phase discontinuities and differential tip-tilt wavefront components within each pupil quadrant, which may reach 800nm in amplitude and are invisible to the filtered Shack-Hartmann Wavefront Sensor.

We present a potential noninvasive solution to sensing of the LWE wavefront, based on the "Fast and Furious" (F&F) sequential phase diversity wavefront reconstruction algorithm (Keller et al. 2014, Korkiakoski et al. 2014). This uses noncoronagraphic focal-plane images available from the NIR Differential Tip-Tilt Sensor and closed-loop DM update cycle telemetry to reconstruct the complex wavefront. Crucially, this removes the need for artificial phase probes on the DM itself as is the case for standard phase diversity approaches, allowing the technique to be performed as part of the AO closed-loop. Preliminary simulations indicate accurate recovery of the LWE wavefront shape and effective removal of LWE PSF lobes within a small number of F&F iterations. We will present the results of efforts to optimise this algorithm to the LWE on SPHERE, with the ultimate goal of integration within the SAXO closed-loop environment to detect and eliminate the LWE as it arises.

9909-246, Session PWed2

Focal plane wave-front sensing on phase discontinuities: from SPHERE to ELT high-contrast imagers

Masen P. Lamb, NRC - Herzberg Astronomy & Astrophysics (Canada); Jean-François Sauvage, ONERA (France); Carlos M. Correia, Thierry Fusco, Lab. d'Astrophysique de Marseille (France)

Classic adaptive optics (AO) has evolved considerably over the past few decades, driving the development for complex technologies such as high-contrast imaging; the recent commissioning of the SPHERE and GPI instruments on the VLT and Gemini telescopes have delivered the first top level instruments dedicated to this technology. Most future ground based telescopes (E-ELT, TMT, GMT) and space telescopes (JWST) will utilize segmented pupil shapes, which is a deflection from the plain pupils of the current telescopes that employ high-contrast imagers.

Among the limitations of high-contrast imagers are non-common path aberrations (NCPA), which result from the inability of the wavefront sensor to detect minute variations in the internal PSF of the imaging system. If these aberrations are not compensated, the AO loop cannot provide a correction and the focal plane is contaminated with NCPA residuals. We present new results on the calibration of NCPA for a coronographic (high-contrast imaging) system, in particular advances on the traditional NCPA correction techniques (i.e. phase diversity), which can be subject to errors when considering a segmented pupil instead of the traditional uniform case due to the phase discontinuities between each segment. We present new ideas and laboratory work on the calibration of aberrations resulting from a segmented pupil; in particular we examine these aberrations in both the coronographic and classical scenario, extending well known techniques such as phase diversity and focal plane sharpening.

9909-247, Session PWed2

Noncommon path aberration correction techniques and performances: handling multiple configuration AO systems

Masen P. Lamb, NRC - Herzberg Astronomy & Astrophysics (Canada) and Univ. of Victoria (Canada); David R. Andersen, Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada); Carlos M. Correia, Lab. d'Astrophysique de Marseille (France)

Non-common path aberrations (NCPA) arise from optical path differences between the science camera and the wavefront sensor, resulting in focal plane residuals after the loop is closed on an AO system. We have established two methods of NCPA compensation techniques, and successfully demonstrated their qualities on an experimental bench at NRC-Herzberg (in Victoria, Canada). The advantages and disadvantages of each method are explored quantitatively, with the goal to determine if

there is a synergic combination between the methods to yield the most efficient NCPA calibration possible. The quantitative analysis includes an assessment (for a given AO system), of how many modes can be corrected, what initial conditions (i.e. starting wavefront error) work best with each method, and what combination of the two methods yields a correction with the lowest RMS wavefront error.

AO systems such as TMT's NFIRAOS will provide AO-corrected light to several instruments, with each configuration containing their own respective NCPA. We present a novel technique where an NCPA 'lookup' table is constructed in order to correct errors that reoccur when AO systems cycle through different configurations. This technique is explored on our experimental bench, where the reoccurring NCPA are created using two phase screens in the non-common pupil plane: one stationary and the other with rotation capabilities. The goal is to use our NCPA estimation methods to construct a table with estimations at various phase screen positions and demonstrate the table can be used to provide correction at any desired phase screen configuration.

9909-248, Session PWed2

A new look at the laser propagation delay as a tool to retrieve tipt-tilt information from a laser guide star

Roberto Ragazzoni, Jacopo Farinato, INAF - Osservatorio Astronomico di Padova (Italy); Fernando Pedichini, INAF - Osservatorio Astronomico di Roma (Italy); Domenico Bonaccini Calia, European Southern Observatory (Germany); Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy)

As it is very well known nowadays Laser Guide Stars (LGS) are not useful to retrieve tip-tilt information. It seems to be general consensus that the onlypractical way to retrieve tipt-tilt in the Field of View of a telescope using LGS-assisted Adaptive Optics. However, there is been a time where such a resignation was fighted against by a large amount of ideas, concept, and actual true on-sky experiments. While some of the further studies in fact points toward the pragmatic –but not necessarily optimum- choice of simply look for enough bright natural references, we believe that one of the technique that has not been the subject of any further investigation could turn out of some relevance. We specifically refer to the so-called propagation delay in which the LGS is observed through the same aperture used to propagate. This would translates into nil jitter, but in fact it is easy to show that it would exhibits a small, but not negligible, finite difference with respect ot the time of traveling upward and backward. This difference can be integrated and used, till the accumulating error become below a certain threeshold, to guide an high frequency correction, and then being offset at low temporal frequency, by a true natural guide star. Once can see this as a multiplicator of bandwidth and in fact obtaining, for istance, 100Hz information from a natural star sampled at 1Hz –following the example given in the first and only paper on the subject) achieving a gain of 5 magnitude in limiting magnitude. The approach, in fact, continue to also use the advantages of the other technique for achieving high quality tip-tilt sensing (like the dark one). We revise the concept decribing its performance in a more detailed form, with a first order simulation and describing possible experimental setup to validate the approach with existing Sodium layer sounding facility.

9909-249, Session PWed2

Fast modulation and dithering on a pyramid wavefront sensor bench

Maaike van Kooten, Colin Bradley, Univ. of Victoria (Canada); Jean-Pierre Véran, Glen Herriot, Olivier Lardiere, NRC - Herzberg Astronomy & Astrophysics (Canada)

A pyramid wavefront sensor bench has been setup at NRC Herzberg (Victoria, Canada) to investigate, first, the feasibility of a lenslet-based pyramid wavefront sensor, and second, the proposed methodology for pyramid wavefront sensing to be used in NFIRAOS for the Thirty Meter Telescope. Traditional pyramid wavefront sensors require shallow angles and strict apex tolerances, making them difficult to manufacture. Lenslet arrays, on the other hand, are common optical components that can be made to the desired specifications, thus making them readily available. Understanding the differences between the two will allow for the lenslet-based pyramid wavefront sensor to become more widely used as an alternative to the standard pyramid, especially in a laboratory setting. In this work, the response of the SUSS microOptics 300-4.7 array, as the amount of modulation is changed, is compared to an ideal pyramid wavefront sensor modelled using the adaptive optics toolbox, OOMAO in MATLAB. The object oriented toolbox uses physical optics to model complete AO systems. Fast modulation and dithering using a PI fast steering mirror has been implemented using an Atmel mirco-controller to drive the mirror and trigger the camera exposure. This scheme allows for synchronization of the camera with the modulation, allowing for the linearity of the wavefront sensor to be increased. Applying a dithering signal, at a frequency of ? the modulation frequency, on top of the modulation signal allows for the optical gain to be tracked in real time, bettering the non-common path corrections. The various trade offs of this scheme, in a controlled laboratory environment, are studied and reported.

9909-250, Session PWed2

PWFSs on GMCAO: a different approach to the non-linearity issue

Valentina Viotto, Maria Bergomi, Marco Dima, Jacopo Farinato, INAF - Osservatorio Astronomico di Padova (Italy); Roberto Ragazzoni, Demetrio Magrin, INAF - Osservatorio Astronomico di Padova (Italy); Davide Greggio, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli Studi di Padova (Italy); Enrico Pinna, Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy)

In the last years, the Pyramid WFS (P-WFS) finally proved itself to be a very powerful tool for wavefront retrieval, in different applications, inside and outside astronomy, often showing outstanding results. However, being intrinsically a non-linear WFS, the P-WFS non-linearity error starts to play a role when the AO loop is not closed on the sensor zero-WFE point. This led to the need to elaborate new concepts when trying to apply the P-WFS to open (or partially open) loop based techniques, not to trade sensitivity for linearity. This was the case for Global MCAO, in which the reference stars are selected on a wide technical area of the sky, outside the FoV to be optimized, limiting the correction experienced by the WFSs to poor Strehl Ratio regime. While, in the recent past, we proposed a solution based on the Very Linear WFS, a sub-system that locally closes the loop on the Pyramid pin to let the sensor operate in its best regime, we now explore a different approach in which the PWFS non-linearity is continuously measured, injecting a known aberration onto the sensor. In particular, we evaluate in this paper the possibility to apply basic PWFSs to the GMCAO technique, measuring the non-linearity of the sensor and taking it into account in the wavefront computation, with an approach similar to what already proposed in the LBT AO facility FLAO for the non-common path aberrations correction.

9909-251, Session PWed2

An achromatic low-order wavefront sensor

Denis Brousseau, Simon Thibault, Univ. Laval (Canada); Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada)

We propose an innovative Low-Order Wave-front Sensor (LOWFS) design based on the pyramidal wave-front sensor (PWFS). The four facets of a glass pyramid are equivalent to the intersection of four micro-lenses having the same focal length as the PWFS field lens. The intersection of the micro-lenses acts as the vertex of the pyramid. The main design parameters are then the focal length and the pitch of the micro-lenses which need to be chosen in order to prevent the overlap of the four sub-pupil images. We suggest placing such a 2 x 2 micro-lens array at the center of a coronagraph occulting mask. The micro-lenses are also reflective to relay the four sub-pupil images to an imaging sensor. A band-pass filter is placed in front of the imaging sensor to work at the same wavelength as the coronagraph scientific camera. The micro-lens mask is also circular cut or edge profiled to also acts as the coronagraph occulting mask. This novel PWFS approach could be an effective solution to counter the chromatic issues of other wave-front sensing schemes since the optical design is entirely reflective. The fabrication of micro-lenses is a well-established technology and could be an easy method to implement. It could also eliminate the need of additional optics in front of the LOWFS imaging detector, simplifying the design and helping to reduce or eliminate non-common path aberrations. We have developed a simulation package that allows to identify the basic physical requirements of a LOWFS based on a micro-lens mask and compute its performance in terms of linearity and sensitivity. Discussions with micro-lenses suppliers have permit to isolate the principal key design parameters and challenges.

9909-252, Session PWed2

Dark tip-tilt sensing

Carmelo Arcidiacono, INAF - Osservatorio Astrofisico di Arcetri (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Roberto Ragazzoni, Valentina Viotto, Maria Bergomi, Jacopo Farinato, Demetrio Magrin, Marco Dima, Marco Gullieuszik, Luca Marafatto, INAF - Osservatorio Astronomico di Padova (Italy)

Tip-tilt sensing of a diffraction limited natural guide star subjected in closed loop to limited movements could represent the last obstacle of Laser Guide Star based Adaptive Optics system on large and extremely large telescope, in practice setting up the ultimate performances of such systems. Peeling up its performances and reaching the as faint as possible magnitude limit become crucial into defining the performances in terms of achievable Strehl ratio and in sky coverage.

While it is interesting that such a basic way of wave-front sensing finally would turn out to be of such paramount relevance, we revisit the already pointed out fact that most of the light involved in the tip-tilt measurement in a quad-cell approach is actually producing noise and not contributing to the accuracy or sensitivity of the measurement. Specifically, under the class of "dark wave-front sensing", tip-tilt measurements (or, better, "dark tip-tilt sensing") aim to utilize just the smallest possible amount of photons contributing to the signal, while the vast majority being used for acquisition or to handle burst of jitter otherwise resulting into a loss of loop closure. The practical implementation of this approach does not involve any subtle diffraction limit effect, in contrast with similar realization for high order wave-front sensing. We can envisage a CCD with multiple dark spots of different size and placed at the crossroads of different groups of four adjacent pixels, with the sensor locking onto different ones to achieve the ultimate performance, depending upon the residual jitter.

We set up a number of realistic simulations using different combination of light split into a full quad-cell and clocked at different timescales in order to provide rapid re-acquisition in case of loss of lock due to a burst event in the jitter time series. Comparison of performances with respect to conventional quad-cell treated with the same kind of numerical approach are outlined along with the first crude conclusions for such a kind of first order dark wave-front sensing.

9909-253, Session PWed2

Sparse aperture differential piston measurements using the pyramid wavefront sensor

Carmelo Arcidiacono, INAF - Osservatorio Astrofisico di Arcetri (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Xin-Yang Chen, Zhaojun Yan, Lixin Zheng, Chao-Yan Wang, Neng Hong Zhu, Li Zhu, Juan Cai, Zhenghong Tang, Shanghai Astronomical Observatory (China)

In this paper we report on the laboratory experiment we settled in the Shanghai Astronomical Observatory (SHAO) to investigate the pyramid wave-front sensor (WFS) ability to measure the differential piston on a sparse aperture. The ultimate goal is to verify the ability of the pyramid WFS work in close loop to perform the phasing of the primary mirrors of a sparse Fizeau imaging telescope. In the experiment we installed on the optical bench we performed various test checking the ability to flat the wave-front using a deformable mirror and to measure the signal of the differential piston on a two pupils setup. These steps represent the background from which we start to perform full close loop operation on multiple apertures. These steps were also useful to characterize the achromatic double pyramids (double prisms) manufactured in the SHAO optical workshop.

9909-255, Session PWed2

Laser guide star spot shrinkage for affordable wavefront sensors

Emmanuel Hugot, Wilfried Jahn, Lab. d'Astrophysique de Marseille (France); Laurent Pueyo, Space Telescope Science Institute (United States); Thierry Fusco, Lab. d'Astrophysique de Marseille (France) and ONERA (France); Benoît Neichel, Carlos M. Correia, Marc Ferrari, Kacem El Hadi, Kjetil Dohlen, Sandrine Pascal, Pascal Vola, Jean-Luc Gach, Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, Lab. d'Astrophysique de Marseille (France) and ONERA (France)

Laser Guide Star (LGS) WaveFront Sensing faces a technological limitation in Shack Hartman concepts, due to the so-called spot elongation that leads to the need for very large detectors in order to accommodate the spot sampling on each SH sub-aperture.

Moreover, some trade-offs to minimize the number of pixels with either undersampling or truncation of the elongated SH-spots will induce non-linearity and bias effects which, through the propagation through the tomographic reconstruction process, will dramatically affect the final WFAO performance.

Innovative optical approaches can be proposed to significantly reduce the spot elongation before the physical detection by the CCD without any significant loss in flux nor performance. These approaches, based on free form optics and complex amplitude remapping techniques should allow obtaining a WFS design with 16 to 25 less pixels than the current ones and

thus making possible the use of already existing devices. It will also avoid the use of complex centroiding measurements making the whole WFS process simpler, faster and more robust.

This talk will show the recent advances on this activity undertaken at LAM-ONERA and STScI on 1/ optical design using Zemax and , 2/ opto-mechanical designs to accommodate the entrance beams and relay the flux to a 800x800pixels detector and 3/ estimation of performance, linearity and sensitivity of the compressed system in presence of aberrations.

9909-256, Session PWed2

Solving the MCAO partial illumination issue and laboratory results

Kalyan Kumar Radhakrishnan Santhakumari, Thomas Bertram, Thomas M. Herbst, Max-Planck-Institut für Astronomie (Germany); Carmelo Arcidiacono, INAF - Osservatorio Astronomico di Bologna (Italy) and INAF - Osservatorio Astrofisico di Arcetri (Italy); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Jürgen Berwein, Frank Kittmann, Max-Planck-Institut für Astronomie (Germany)

Telescopes or instruments equipped with Multi-Conjugated Adaptive Optics (MCAO) provide uniform turbulence correction over a wide Field of View (FoV), thereby overcoming the problem of isoplanatism and enabling previously impractical science. LINC-NIRVANA (LN), the German-Italian near-infrared high-resolution imager for the Large Binocular Telescope (LBT), has an advanced and unique MCAO module, which employs the Optical Co-addition of Layer-Oriented Multiple-FoV Natural Guide Star approach to MCAO using pyramid wavefront sensors. The layer-oriented approach conjugates the Deformable Mirrors (DM) and their respective Wavefront Sensors (WFS) to the corresponding atmospheric layers. LN corrects for the aberrations in two different layers. The ground layer, conjugated to the telescope pupil ~100m above LBT, is corrected by the Ground-layer Wavefront Sensors (GWS) driving the LBT adaptive secondary mirrors, and the High-layer Wavefront Sensors (HWS) drive a pair of Xinetics DMs on the LN bench to correct turbulence in a higher layer ~7.1km above the telescope.

In the WFS optically conjugated to the ground layer, the pupil footprints of the stars overlap completely and every star footprint illuminates the entire pupil-plane (corresponding to the FoV projection). However, for a higher layer conjugation, the footprints do not overlap completely and each star illuminates a different region of the FoV projection (also called as meta-pupil). Lack of stars, therefore, results in some regions not being illuminated, meaning no information regarding the turbulence in these areas. The optimum way of correcting the high layer, given this limited information, is the crux of the “partial illumination issue”. In this paper, we propose a solution for partial illumination and discuss laboratory results from the aligned LN bench in the lab at MPIA. Currently, LN is being re-integrated and re-aligned at LBT. We will test our algorithm in the final configuration at LBT in June 2016 with simulated stars during, and on sky in the second half of 2016.

9909-258, Session PWed2

Analytical expression of a long exposure coronagraphic point spread function and application to the estimation of quasi-static aberrations in the presence of residual turbulence with COFFEE

Olivier Herscovici-Schiller, Laurent M. Mugnier, ONERA (France); Jean-François Sauvage, ONERA (France) and Lab. d’Astrophysique de Marseille (France); Faustine Cantalloube, ONERA (France); Jean-Michel Le Duigou, Ctr. National d’Études Spatiales (France)

The final performance of current and future instruments dedicated to exoplanet detection and characterization (such as SPHERE on the VLT, GPI on Gemini South or future instruments on the ELTs) is limited by intensity residuals in the scientific image plane, which originate in uncorrected optical aberrations. After correction of the atmospheric turbulence, the main contribution to these residuals comes from the quasi-static aberrations introduced upstream of the coronagraph which create long-lived speckles in the detector plane that can easily be mistaken for planets. In order to reach very high contrast such as the ones required to image earth-like planets, these aberrations need to be compensated for. We have recently proposed a dedicated focal-plane wave-font sensor called COFFEE (for COronagraphic Focal-plane wave-Front Estimation for Exoplanet detection), which consists in an extension of conventional phase diversity to a coronagraphic system: aberrations both upstream and downstream of the coronagraph are estimated using two coronagraphic focal-plane images, recorded from the scientific camera itself, without any differential aberration. Such a system has been successfully validated on the SPHERE instrument, where the phase reconstruction by COFFEE has been used to compensate for the phase aberrations upstream of the coronagraph, leading to a contrast optimization in the whole focal plane area controlled by the adaptive optics loop. The extremely high contrasts of the currently considered future missions dedicated to the direct imaging of terrestrial planets create the need to compensate for aberrations during the scientific observation itself. To this aim, the wave-front must be estimated on-sky, during the exposure. In order to address this issue, we propose in a first part an analytical expression giving the long-exposure optical transfer function of a coronagraphic system, while taking into account residual turbulence described by its phase structure function. We propose a first implementation of this formula under a form optimizing the computing time, mainly using fast Fourier transforms. The method is validated by comparison with a sum of short-exposure coronagraphic images. The second part consists in integrating this long-exposure analytical expression of the coronagraphic PSF into the COFFEE method in order to be able to estimate quasi-static aberrations on-sky in the presence of residual turbulence.

9909-259, Session PWed2

Efficient image shift measurement algorithms for extended scene Shack-Hartmann sensors

Narsireddy Anugu, Paulo J. V. Garcia, Univ. do Porto (Portugal)

Shack-Hartmann sensor extended scene slopes are usually evaluated with correlation algorithms. The evaluation involves two sub-computations: a) correlation estimation between a target and a reference. The peak of the correlation gives the image shift or slope in integer pixel precision; b) the sub-pixel precision image shifts are computed by applying a peak-finding algorithm to the correlation peak.

The estimated image shifts are usually affected by systematic errors due to pixel-locking or peak-locking effects. The nature of the systematic error is that the measured image shifts are concentrated at the closest integral pixel value. These are caused by under-sampling of the images. The magnitude of the systematic errors depends on the type of extended scene and the combination of correlation algorithm and peak-finding algorithm used. To reduce the systematic errors, several correlation and peak-finding algorithms are investigated in the field of feature tracking and strain measurement (Pan et al., 2009, Meas. Sci. Technol.). However, the real-time Shack-Hartmann wavefront sensing is significantly different from

their work. The Shack-Hartmann wavefront sensing is involved with: a) different types of images; b) images of small fields of view (for example, 16 x 16 pixels); c) real-time measurements.

In this study we approached the problem in three ways. Firstly, the performance of different correlation algorithms (cross-correlation; sum of squared differences; sum of absolute differences) is investigated for three classes of sub-aperture images (point source, elongated laser guide star, extended scenes). It is found that cross-correlation is most robust to the point source and elongated laser guide star. The sum of squared differences algorithm performances better (less failure rates) for extended scenes although it involves large systematic errors measurement.

Secondly, the performance study is extended to different peak-finding algorithms (parabola fit; threshold center of gravity; Gaussian fit; quadratic polynomial fit; pyramid fit) using the three classes of sub-aperture images. The study reveals that pyramid fit is preferable for extended scenes, while quadratic polynomial fit performs better for the elongated laser guide star. The threshold center of gravity performs better in a low SNR scenario cases, although the systematic errors in the measurements are large. It is found that no peak finding model is good enough in reducing both the systematic and the RMS centroid error.

Thirdly, a technique used in the fluid mechanics (Sjödahl 1994, App. Opt.) is applied here to overcome the above limitations. In this technique, the image sampling prior to the actual correlation matching is increased. The technique is realized in the image domain and is implemented in two steps to improve its computational efficiency: a) as a first step, the image shift is estimated by executing the cross-correlation algorithm at the original image sampling; b) next the cross-correlation is performed at a sub-pixel level spatial sampling by confining the correlation search to a small field of view (4 ? 4 pixels) centered at the position obtained in the first step.

Studies reveal that the image sampling improvement technique outperforms other first two approaches. It improves the image-shift measurement accuracy (wavefront sensing) by a factor of 5 in terms of both the systematic and the RMS errors, at the expense of twice the computational cost.

9909-260, Session PWed2

Experimental result from tip-tilt measurement with a laser guide star at Yunnan Observatories

Kai Huang, Leshan Normal Univ. (China) and Yunnan Observatories (China); Yaoheng Xiong, Rongwang Li, Dongsheng Zhai, Yu Zhou, Yuqiang Li, Yunnan Observatories (China)

We report about an experiment aimed at verifying the statistical technique, which has been proposed first by Mikhail S. Belen'kii to solve the tilt indetermination problem from the laser guide star(LGS) adaptive optics system. The tilt components of wave fronts were measured synchronously from a Rayleigh guide star by use of a 0.25-m telescope as an auxiliary telescope and from a star by use of a telescope with a 1.2-m aperture at Yunnan Observatories. The auxiliary telescope was located 45m from the 1.2-m telescope. The jitter of the star is corrected by the tilt signal from auxiliary telescope by post processing. A transform function be used to keep corresponding relation between tilt measured from the LGS and the star. The average value of the measured cross-correlation coefficient between the tilt for the star and the LGS is 0.74 through one-night experiment. Those objective stars selected from different areas of sky. The result shows that the instability of the auxiliary telescope's tracking system is an important error source of the tilt measurement. A new idea for tip-tilt measurement will be also presented and discussed in the end of this paper.

9909-261, Session PWed2

Optical characterization of a glass pyramid for wavefront sensing: setup, procedures, and test results

Marco Bonaglia, Runa Briguglio, Guido Agapito, Enrico Pinna, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The use of a pyramid WFS for astronomical adaptive optics has been demonstrated on sky by the FLAO system at LBT. In the last years the astronomical community shown an increasing interest in the use of this type of WFS, expecially for high contrast applications. The key element of the WFS is a double-glass pyramid that allows to sample the wavefront derivative on a detector. The specifications for the manufacturing of such optical elements are challenging, expecially in the framework of the next generation of Extremely large telescopes.

This paper outlines on the impact of pyramid manufacturing errors on the wavefront measurement quality and it prensents a procedure to measure them in laboratory. It also describes a test setup that has been assebled in the Arcetri Observatory laboratory to characterize the GMT NGS WFS glass pyramid.

9909-262, Session PWed2

Correlation wave-front sensing of extended objects

Matthew J. Townson, Gordon D. Love, Durham Univ. (United Kingdom); Aglaé Kellerer, Univ. of Cambridge (United Kingdom); Christopher D. Saunter, Durham Univ. (United Kingdom)

Most methods for wave-front sensing extended objects, whether they are elongated laser guide star images or solar granulation, require reference images. We present a method for creating reliable, super-sized reference images, using only wave-front sensor images. This can help mitigate some problems with truncation in laser guide star wave-front sensing, and part of the "expanding pupil problem" (where the extended field causes reduction in sensitivity to high altitude turbulence) in solar adaptive optics.

Generating a reference image requires the use of individual sub-aperture images, then aligning them in some way. This has the effect of averaging out noise found in the individual wave-front sensor images. The individual images are shifted with respect to each-other, so when a reference image is created there is information for a larger field of view than any of the individual sub-apertures. This information can be kept to make a super-sized reference image. This gives less truncation in laser guide star wave-front sensor images, and allows for smaller regions to be used in solar wave-front sensors, reducing the "expanding pupil" problem.

With both wave-front sensor images, and a reference image, it is possible to accurately estimate the optimal centroiding parameters for a centre of mass on the correlation images. Like the generation of the reference images this requires no external input, as the parameters can be estimated from noise statistics on the correlation images.

We present simulated results, for both laser guide star and solar wave-front sensing, where both centroiding parameters and reference images are calculated automatically, from a small number of wave-front sensor images. As there is no input, other than the wave-front sensor images, this process can be entirely automated, and done outside the adaptive optics system. This would allow for an adaptive optics system to run an artificially super-sized reference image with optimized centroiding parameters on a correlating wave-front sensor automatically, with no external inputs.

9909-264, Session PWed2

Development of an optical differential wavefront sensor based on binary pixelated transmission filters

Jie Qiao, Rochester Institute of Technology (United States) and Aktiwave LLC (United States); Zachary J. Mulhollan, Rochester Institute of Technology (United States); Christophe Dorrer, Aktiwave LLC (United States)

High-resolution, high-dynamic-range, and achromatic wavefront sensing is highly desired for astronomical imaging and metrology applications. Particular domains of interest include wavefront sensing of broadband sources, fast low-order sensors for real-time turbulence compensation, and characterization of highly aspherical optics and freeform optics used in imaging systems.

An optical differentiation wavefront sensor (ODWS) relies on an optical system that images the pupil to a camera. A filter with a linear amplitude-transmission gradient is located in a far field of the pupil. The fluence measured in the detection plane is linked to the input wavefront slope in the direction of the focal-plane transmission gradient. The ODWS uses the data measured in the detection plane for two orthogonal orientations of the focal-plane filter to determine wavefront-slope data along the two corresponding directions in the pupil plane. The wavefront in that plane can be reconstructed from the data via reconstruction algorithms used for other wavefront-sensing techniques measuring wavefront slopes data, for example Shack-Hartmann wavefront sensors.

Although potentially advantageous, the ODWS is not commonly used and is not commercially available, which can be attributed to the difficulty of manufacturing optical components with well-controlled spatially varying transmission. We investigate the performance of an ODWS relying on binary pixelated transmission filters. Such filters can be fabricated with high accuracy using conventional metal-on-glass lithography techniques and have been used for laser beam shaping and coronagraphy. A spatially dithered distribution of transparent and opaque pixels can synthesize a continuously varying transmission filter, a process analogous to gray-level rendition with black-and-white printing and display systems.

When the pixels of the binary filter are small enough, the noise due to pixelation and binarization is rejected at high frequencies that do not impact the performance. We numerically investigate how the resulting noise in the detection plane impacts the performance of an ODWS based on binary pixelated filters for different wavefront profiles, pixel sizes, and diagnostic parameters. This performance is compared to the performance of an ODWS implemented with an ideal continuous filter. An ODWS implemented with a binary pixelated filter having 10-micron pixels is experimentally demonstrated. The diagnostic is able to reconstruct various wavefront profiles and yields self-consistent results that are in good agreement with a commercial Shack-Hartmann sensor.

The following conceptual and practical advantages assert the relevance of the ODWS to the current and future astronomical needs: (1) The potential high-resolution and large dynamic range is relevant to the characterization of large optics and large phase gradients, which are challenging for interferometers and Shack-Hartmann sensors. (2) The implementation without refractive components reduces the chromaticity of this sensor, an advantage for wavefront sensing of polychromatic sources. (3) Acquisition in real-time and without moving parts eliminates the requirement for continuous dithering of the pyramid-apex position or use of a deformable mirror for phase diversity. (4) Commercially available binary pixelated filters, with metal-on-glass lithography techniques allow custom substrates, metal layers, and coatings for addressing different needs.

9909-265, Session PWed2

ZELDA: a Zernike sensor for near-coronagraph quasi-static measurements: concept studies and results with VLT/SPHERE

Mamadou N'Diaye, Space Telescope Science Institute (United States); Arthur Vigan, Kjetil Dohlen, Lab. d'Astrophysique de Marseille (France); Jean-François Sauvage, ONERA (France); Amandine Caillat, Anne Costille, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Rémi Soummer, Space Telescope Science Institute (United States)

The high-contrast imaging instruments VLT/SPHERE and GPI have been routinely observing gas giant planets, brown dwarfs, and debris disks around nearby stars since 2013-2014. In these facilities, low-wind effects or differential aberrations between the extreme Adaptive Optics sensing path and the science path represent critical limitations for the observation of exoplanets orbiting their host star with a contrast ratio larger than 1e6 at small separations. To circumvent this problem, we proposed ZELDA, a Zernike wavefront sensor to measure these quasi-static aberrations at a nanometric level. A prototype was installed on VLT/SPHERE during its integration in Chile. We recently performed measurements on an internal source with ZELDA in the presence of Zernike or Fourier modes introduced with the deformable mirror of the instrument. In this communication, we present the results of our experiment and report on the contrast gain obtained with a first ZELDA-based wavefront correction. We finally discuss the suitability of such a solution for a possible upgrade of VLT/SPHERE and for its use with future E-ELT instruments or space missions with high-contrast capabilities (e.g. WFIRST-AFTA, HDST).

9909-266, Session PWed2

Characterising latency for AO optical sensors: an implementation

Thomas F. Dixon, The Univ. of New South Wales (Australia); Francis Bennet, Ian Price, Francois Rigaut, The Australian National Univ. (Australia)

Adaptive Optics are a series of optical techniques utilized to mitigate atmospheric distortion of telescope measurements by performing high-speed environmental measurements and applying pre or post correction to certain optical systems. As can be easily surmised, the latency of cameras in an AO system; the time between end-of-exposure and the corresponding data becoming available, is a critical parameter to be considered. However, this value is not one commonly published by camera manufacturers.

This paper describes the methodology and preliminary results of a technique used to characterise the latency of optical devices. The purposes of this characterisation are twofold; to supplement manufacturer data for COTS cameras , allowing for a more complete cost-benefit analysis, and to improve the characterisation of the AO system as a whole.

In this methodology, pulses generated by an optical chopper are received by the camera. The duration and frequency of these pulses are controlled by manufacture of custom chopper wheels; the frequency (usually about one tenth of the camera sample rate) is altered to ensure that each pulse is distinct, and duration kept small (relative to exposure time) to allow the pulse to be timed to the end of exposure. Exposed frames are then retrieved through software and evaluated for delay, using a reference

signal from the pulse generator that serves as a time stamp.

In order to limit the influence of equipment on the latency measurement, low level software and simple analogue electronics are used wherever possible. Pulses and frames are synchronized using a serial interface implemented in C within a Linux environment; during the alignment phase, a control loop adjusts the timing of the pulse towards the end of a single frame by steadily increasing the phase of the system until a single pulse 'bleeds' into two exposures, and then reversing the most recent change. Reference signals are generated by splitting the pulse and directing one split through a high-speed photodiode into a battery powered serial converter, effectively an Analogue-Digital Converter with two states. This converter uses transistors and bias currents in a typical push-pull configuration to create a digital switch tuned to the voltage output of the photodiode.

A simpler methodology is also proposed and discussed, wherin an LED is driven from a serial port and pulsed. The timestamp of the pulse command and frame retrieval are compared to allow the computation of latency. Due to the non-linear rise and fall times of the LEDs (characterised as part of this process), optimization of pulse length and intensity is performed to develop the most optimal signal-to-noise ratio.

9909-267, Session PWed2

Low photon-count tip-tilt sensor

Rudolf Saathof, Georg Schitter, Technische Univ. Wien (Austria)

Due to the low photon-count of dark areas of the universe, signal strength of tip-tilt sensors is low, limiting sky-coverage of reliable measurements. Tip-tilt is the most prominent aberration in astronomical observations, causing motion blur due to movement of the observed object on the detector for long shutter times. These take 80% of the aberrations for 2.2 m diameter telescopes, and more if the telescope diameter decreases to Frieds parameter. Although tip-tilt can be corrected by a tip-tilt mirror using a natural guide-star or an on-CCD tip-tilt image compensator, sky coverage is limited due to the low photon count of dark areas of the universe. For aberrations other than tilt, adaptive optics (AO) systems use artificial guide stars to achieve proficient wavefront sensor signal. These systems cannot determine absolute tilt, due to wandering of the artificial guide star.

Measuring tip-tilt is usually done using a four quadrant detector (4QD), or image detectors. 4QDs have are fast and have good resolution, but are limited in linear range, have beam shape dependency, need regular calibration, and can only measure one target at a time. Therefore, many tip-tilt detector implementations divide image detectors in 4 sections to form 4QDs, offering high sensitivity, large linear range, and tracking multiple targets at once. For fast readout, detectors make use of high speed cameras combined with fast processing hardware, such as field programmable gate arrays (FPGAs). To improve quantum efficiency, single photon detectors and single photon cameras are applied, using the photo-avalanche effect.

As the signal strength of detectors is fundamentally limited by their photon-count, this paper present the conceptual design of the low photon-count tip-tilt (LPC-TT) sensor to improve the photon count of tip-tilt detector segments by its optical design. This improvement is realized by spatially sampling the image plane, overlaying these samples and summing these up to an integral image, as done in illumination systems to achieve uniform illumination, also known as field compression. Lab experiments show this sampling and integration aspect and also the ability to measure tip-tilt.

As such, the probability that two individual sources coincide on a detector segment increases. The increased probability of more photons on a segment potentially could improve the signal to noise ratio (SNR). Numerical simulations show an improved detector SNR of about 10dB compared to conventional tip-tilt sensors. This enables the LPC-TT to measure tip-tilt of darker scenes to increase sky-coverage, or decrease shutter time to increase the sampling rate to achieve higher bandwidth of tip-tilt correction.

9909-268, Session PWed2

Fast gradient-based algorithm on extended landscapes for wavefront reconstruction of Earth observation satellite

Carole Thiebaut, Laurent Perraud, Jean-Marc Delvit, Christophe Latry, Ctr. National d'Études Spatiales (France)

For future Earth observation missions, CNES plans to use systems with optical aberrations, these aberrations being measured and compensated with an active loop. In this framework, a Shack-Hartmann wave-front sensor could be used on extended scenes (landscapes). A wave-front computation algorithm should then be implemented on-board the satellite to provide to the control loop wave-front error measure. In the worst case scenario, this measure should be computed before each image acquisition. A robust and fast shift estimation algorithm between Shack-Hartmann images is then needed to fulfill this last requirement. A fast gradient-based algorithm using optical flows with a Lucas-Kanade method has been studied and implemented on an electronic device developed by CNES. This electronic device uses qualified radiations-hardened components designed for space applications. The algorithm has been simplified compared to a reference software (floating-point) which uses iterative optical flow estimation to reach the final shift measurement with image resampling between two iterations. The implemented version of the algorithm uses only two iterations and gives results comparable to the reference software ones in terms of wave-front error assessment. Furthermore, pre-processing steps such as radiometric harmonization and image aliasing reducing have been implemented. Radiometric harmonization is mandatory when computing optical flows between partially occulted and non-occulted lenslets. Image aliasing has to be reduced to correctly estimate shifts between two images. Finally not only shifts are calculated between a reference image of the Shack-Hartmann and all the others but also the wave-front estimation using Zernike polynomials is performed on the board. This board is composed of an FPGA (ATF280) and a GR712 composed of two LEON3 processors running at 80MHz. The embedded RAM is 256Mbytes. Both pre-processing and post-processing (WFE estimation from shifts between images) steps are executed in the software part of the board (LEON3), the optical flows between Shack-Hartmann images being realized in the hardware part. Optical flows algorithm is well-suited for a hardware implementation because it uses image gradients and image differences computation. Pre-processing and shift estimation processing times are satisfying for on-board applications. For the Shack-Hartmann sensor considered by CNES, these processing times are around 250ms. Performances have been compared to the reference software on an exhaustive benchmark with different input wave-front errors, different landscapes and several radiometric conditions. Some landscapes are disadvantageous for shift estimation because of low signal to noise ratio or because of a main direction in the image (road, coasts...). Selection of favorable landscapes opposed to bad ones can be performed with selection criteria which are computed during the optical flow (Cramer-Rao Lower Bound and eigenvalues of the Fisher Information Matrix). These criteria have also been implemented recently on the electronic board and lead to higher number of landscapes processed in the same time as without selection criteria. Indeed, the board interrupts its processing when the criteria are under a threshold determined over the exhaustive benchmark and goes to the next landscape. In further studies, CNES could use this board to implement other algorithms such as phase diversity on extended landscapes.

The pyramid wavefront sensor used in the closed-loop adaptive optics system

Shengqian Wang, Wenjia Zheng, Kai Wei, Changhui Rao, Institute of Optics and Electronics (China)

Pyramid wavefront sensor is a promising sensor technology based on the beam splitting in the focal plane. Due to its advantages of adjustable gain and variable spatial sampling, the pyramid wavefront sensor has been successfully applied in many large telescopes. In recent years, we have carried out the related research of this sensor. Firstly we studied the adaptive optical closed-loop system based on the liquid crystal spatial light modulator and the pyramid wavefront sensor, and then the system used the deformable mirror is also studied. Subsequently, the experiment on the 1.8-m telescope at Yunnan observatory has been successfully carried out and the high resolution images of the natural stellar star have been obtained. Currently the adaptive optical system based on the pyramid wavefront sensor with variable subaperture sampling is studied and different mode-restoration algorithm is analyzed in our lab. The latest observation experiments results are present in this paper.

9909-47, Session 13

Astronomical AO in Key Laboratory of Adaptive Optics, Chinese Academy of Sciences *(Invited Paper)*

Changhui Rao, Kai Wei, Lei Zhu, Institute of Optics and Electronics (China)

The AO progresses for astronomy in the Key Laboratory of Adaptive Optics, Chinese Academy of Sciences are reported in this presentation. For night-time astronomical observations, the recent AO technological developments, such as Laser Guide Star, Pyramid Sensor and Deformable Secondary Mirror, are introduced. The solar AO researches are also presented for day-time astronomical observations. Furthermore, we will show the on-sky high resolution observational results in the 1.8m telescope at Gaomeigu site, Yunnan Observatory and the 1-m New Vacuum Solar Telescope (NVST) at Fuxian Lake Solar Observatory respectively.

9909-48, Session 13

Robo-AO Kitt Peak: status of the system and optimizing the sensitivity of a sub-electron readnoise IR camera to detect low-mass companions

Maissa Salama, Univ. of Hawai'i at Manoa (United States); Christoph Baranec, Univ. of Hawai'i at Hilo (United States); Rebecca M. Jensen-Clem, Reed L. Riddle, Dmitry Duev, Shrinivas R. Kulkarni, California Institute of Technology (United States); Nicholas M. Law, The Univ. of North Carolina at Chapel Hill (United States)

Robo-AO KP is an autonomous laser guide star, adaptive optics (AO) instrument now deployed on the 2.1-m telescope at Kitt Peak, Arizona. It will be the only instrument on the telescope at Kitt Peak for the next three years and a portion of time will be made available to the wider astronomy community through NOAO. The system is based on a reconfiguration of the Robo-AO prototype that operated on the 1.5-m telescope at Palomar, California. Robo-AO has the unique ability to observe up to 250 targets in one night at the visible diffraction limit, ~0.1".

The addition of an infrared camera to Robo-AO KP will allow us to widen the scope of possible targets – specifically to much redder and low-mass objects, and to conduct the largest ever AO surveys in the infrared. The camera will double as an IR science detector and as a tip-tilt sensor that takes advantage of significant image sharpening in the infrared. The IR camera uses brand new infrared avalanche photodiode array technology (SAPHIRA detector), which has so far only been used for fringe tracking, demonstration tests, and with the prototype Robo-AO system on a limited basis in 2014. This will be the first long-term deployment of such a camera on an adaptive optics system for science applications.

We present the current status and performance of the system and describe the optimizations and calibrations performed since its deployment to Kitt Peak in November 2015, which we compare to its performance at Palomar. Such optimizations and calibrations include: creating and testing quad-cell response look-up-tables (for calibrations and on-sky observations), comparing a UV LED with narrowband filter to a 355nm laser with a fiber mode-scrambler used for minimizing non-common path optical errors from the wavefront sensor to the science camera, determining the optimal height in the atmosphere where the laser wavefront focus is located (laser range gate) and depth (measurement error), determining the optimal gain settings for each controlled basis function of the adaptive optics control loop to minimize residual wavefront sensor errors, and calibrating non-common path errors during on-sky operations by determining the required slope offsets with an auxiliary low-bandwidth wavefront sensor.

We will also present our near-future plans for Robo-AO at Kitt Peak, including optimizations such as deriving and testing new reconstruction matrices for the deformable mirror response to the wavefront sensor. The optimizations and commissioning of the camera happen in parallel with science observing programs.

9909-49, Session 13

The ERIS adaptive optics system

Armando Riccardi, Simone Esposito, Guido Agapito, Jacopo Antichi, Valdemaro Biliotti, Célia Blain, Runa Briguglio, Lorenzo Busoni, Luca Carbonaro, Gianluca Di Rico, Christophe Giordano, Enrico Pinna, Alfio T. Puglisi, Paolo Spanò, Marco Xompero, INAF - Osservatorio Astrofisico di Arcetri (Italy); Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Markus E. Kasper, Marcos Suárez Valles, Christian Soenke, Mark Downing, Javier Reyes-Moreno, Sebastian E. Egner, European Southern Observatory (Germany)

The Enhanced Resolution Imager and Spectrograph (ERIS) is the new Adaptive Optics (AO) instrument for the VLT aiming to replace NACO and SINFONI. Its development is led by a Consortium of Max-Planck Institut fuer Extraterrestrische Physik, UK Astronomy Technology Centre, ETH Zurich, European Southern Observatory (ESO) and Istituto Nazionale di Astrofisica (INAF). ERIS will host a new high-resolution camera (NIX) ranging from 1 to 5 microns and SPIFFIER, a refurbishment of the Integral Field Unit spectrograph currently installed in SINFONI, covering J, H and K bands. ERIS will be installed at the Cassegrain focus of the VLT UT4, which is also hosting the Adaptive Optics Facility (AOF). The ERIS AO system is developed by INAF, with ESO's collaboration, and provides a Natural Guide Star (NGS) mode to deliver high contrast correction and a Laser Guide Star (LGS) mode to extend high Strehl performance to large sky coverage, enabling observations from exoplanets to high redshift galaxies.

The science and AO beams are split by an IR/VIS dichroic. The SPIFFIER and NIX instruments are in the transmitted beam with a retractable selector mirror for feeding NIX. The ERIS AO module is fed by the reflected beam and provides single conjugate correction using two different wavefront sensors (WFS). The high order LGS WFS is a 40x40 sub-aperture Shack-Hartmann (SH) that is coupled with the standard AOF WFS camera integrating an electro-magnified CCD220 detector. The visible

(<1um) NGS WFS, also coupled with CCD220 camera, has a baseline SH design with a switchable configuration between 40x40 sub-apertures, for stand-alone NGS AO mode, and 2x2 sub-apertures, providing the tip-tilt and focus sensing to support the LGS mode observations. A possible upgrade of the NGS WFS to a Pyramid WFS is also presented, pushing the performance to higher levels of contrast and Strehl ratio. ERIS AO uses the 1170-actuator Deformable Secondary Mirror (DSM) as wavefront corrector and one of the Sodium Laser Launchers of the 4 Laser Guide Star Facility (4LGSF) of AOF. The ERIS AO module real-time computer is based on the ESO's SPARTA platform customized for the specific needs of ERIS. The use of a deformable mirror that is external to the AO module allows to design an optical relay using low-power optics to keep stable non-common-path aberrations and with reduced optical sensitivity to flexures. The WFS units are implemented as ~500x500mm optical boards supported by stages to track the focus and, in the case of the NGS WFS, to patrol the acquisition field (1 arcminute radius).

In this paper we introduce the concept of the ERIS AO module by describing its opto-mechanical design, providing an overview of the overall control strategy and, finally, presenting the estimated correction performance.

9909-50, Session 13

Status of the GTC adaptive optics program

Marcos Reyes Garcia-Talavera, Iciar Montilla Garcia, Fabio Tenegi, Luis Fernando Rodríguez-Ramos, José Carlos López-Ruiz, Carlos Martin-Diaz, Roberto L. López, Miguel Núñez Cagical, Pablo L. López, Instituto de Astrofísica de Canarias (Spain); Carmen D. Bello, Lluis Cavaller, Germán Prieto Labra, Francisco Javier Castro Lopez-Tarruella, GRANTECAN S.A. (Spain)

An Adaptive Optics (AO) system was considered necessary since the beginning of the development of the Gran Telescopio Canarias (GTC), in order to exploit the full diffraction-limited potential of the telescope. The AO system designed in the last years is based on a single deformable mirror conjugated to the telescope pupil, and a Shack-Hartmann wavefront sensor with 20 x 20 subapertures, based on an OCAM2 camera. The GTCAO system will provide a corrected beam with a SR of 0.65 in K-band with bright natural guide stars.

Most of the subsystems have been manufactured and delivered. The present status of the GTCAO system, currently in its laboratory integration phase, is summarized in this paper. The upgrade for the operation with a Laser Guide Star (LGS) system has been approved, and the conceptual design of the Laser Guide Star Facility is also presented, together with its first performance analysis.

9909-51, Session 13

First light of the deformable secondary mirror-based adaptive optics system on 1.8m telescope

Youming Guo, Ang Zhang, Xinlong Fan, Changhui Rao, Ling Wei, Hao Xian, Kai Wei, Xiaojun Zhang, Chunlin Guan, Min Li, Luchun Zhou, Kai Jin, Junbo Zhang, Longfeng Zhou, Xuejun Zhang, Yudong Zhang, Institute of Optics and Electronics (China)

An adaptive optics system (AOS), which consists of a 73-element piezoelectric deformable secondary mirror (DSM), a 9x9 Shack-Hartmann wavefront sensor (SHWFS) and a real time controller has been integrated on the 1.8m telescope at the Gaomeigu site of Yunnan Astronomical Observatory, Chinese Academy of Sciences. The vertex curvature and eccentricity of the DSM's reflecting surface are compatible with the Nasmyth focus of the 1.8m telescope. To release the requirements on the DSM and SHWFS, a tracking subsystem is introduced. The tracking subsystem consists of a tracking sensor, a processor and a fast steering mirror. Compared to the traditional AOS on the Coude focus, the DSM based AOS adopts much less reflections and consequently restrains the thermal noise and increases the energy transmitting to the system. Before the first on-sky test, this system has been demonstrated in the laboratory by compensating the simulated atmospheric turbulence generated by a rotating phase screen. The test of the convex hyperboloid surface of the DSM is a problem during the laboratory demonstration. A testbed origin from the Simpson-Oland-Meckel method is proposed and a Hindle element with a concave surface is fabricated. The system calibration procedures including the optical registration and the interaction matrix acquisition are very important for the DSM based AOS to reach the performance specifications of the design. Thus the pupil shift, rotation as well as the magnification are adjusted by measuring the SHWFS responses for the specific actuator patterns applied on the DSM. In order to reject the atmospheric turbulence during the on-sky measurement of the DSM based AOS interaction matrix, a new multichannel-modulation calibration method is proposed and verified by closed-loop experiments. The laboratory characterization and performances of the system are reported. After integration on the 1.8m telescope, the on-sky calibration of the DSM based AOS is validated. The closed-loop compensation of the atmospheric turbulence with the DSM based AOS is achieved afterwards, and the first light results from the on-sky experiments are reported.

9909-52, Session 14

Review of adaptive optics in the visible *(Invited Paper)*

Laird M. Close, The Univ. of Arizona (United States)

I will review astronomical results in the visible (<1micron) with adaptive optics. Other than a brief period in the early 1990s, there has been little astronomical science done in the visible with Adaptive Optics until the last 3 years. Visible AO has been key to thousands of observed targets with robotic AO with the Robo-AO system now installed at the Kitt Peak 2m telescope. The largest telescope with visible AO is the VLT's Sphere/Zimpol, which has made excellent polarized light maps of circumstellar disks. The most productive large telescope visible AO system at the bluest wavelengths (~0.6microns) to date is the 6.5m Magellan telescope AO system (MagAO). MagAO is an advanced Adaptive Secondary AO system at the Magellan 6.5m in Chile. This secondary has 585 actuators with < 1 msec response times (0.7 ms typically). We use a pyramid wavefront sensor. The relatively small actuator pitch (~23 cm/subap) allows moderate Strehls to be obtained in the visible (0.63-1.05 microns). MagAO uses a CCD AO science camera called "VisAO". On-sky long exposures (60s) achieve 20-30 mas resolutions, 30% Strehls at 0.62 microns (r') with the VisAO camera in 0.5" seeing with bright R < 9 mag stars, whereas with fainter R~12 mag MagAO still enables ~40mas images at H-alpha. These relatively high visible wavelength Strehls are made possible by our powerful combination of a next generation ASM and a Pyramid WFS with 378 controlled modes and 1000 Hz loop frequency. We'll review the key steps to having good performance in the visible and review the exciting new AO visible science opportunities and refereed publications in both broad-band (r,i,z,Y) and at H-alpha for accreting exoplanets (for the first time), protoplanetary disks, young stars, and emission line jets. These examples highlight the growing power of visible AO to probe circumstellar regions/spatial resolutions that would otherwise require much larger diameter (D>15m) telescopes with classical infrared (1.6 micron) AO cameras.

9909-53, Session 14

Astrometry with adaptive optics *(Invited Paper)*

Jessica R. Lu, Institute for Astronomy (United States) and Univ. of Hawai'i (United States)

The high spatial resolution delivered by adaptive optics provides large gains in relative astrometry and proper motions. Currently, AO astrometry can reach precisions of 0.15 milli-arcseconds (mas) in crowded fields and <1 mas in sparse fields. I will review science results that have most benefitted from precision AO astrometry in areas. Some examples include the discovery of the supermassive black hole at the Galactic Center, constraining orbits of exoplanets, measurement of the structure, dynamics, and initial mass function in massive young star clusters throughout the Milky Way, testing stellar evolution models with multiple star systems, and a search for free-floating stellar mass black holes. I will also present a number a future science cases where precision AO astrometry, both in crowded and sparse fields, is essential.

Additionally, I will discuss some of the technical lessons learned and how existing and future AO systems can be improved to deliver precision astrometry. For instance, one main limitation in single-conjugate AO systems is knowledge of the point spread function (PSF) both on and off-axis. Furthermore, AO system stability is essential and flexure or thermal variations can limit their capacity to reach below 1 mas. I will review the careful calibration programs and on-sky tests that are needed to validate if an existing AO system can deliver precise astrometry. In crowded fields, careful image transformation algorithms are needed to maximize astrometric precision. Finally, I will discuss astrometric capabilities on future AO systems, including on the E-ELTs, and how astrometric requirements are driving some design choices.

9909-54, Session 14

High-precision astrometry towards ELTs

Davide Massari, Giuliana Fiorentino, INAF - Osservatorio Astronomico di Bologna (Italy); Eline Tolstoy, Kapteyn Astronomical Institute (Netherlands); Remko Stuik, Leiden Observatory (Netherlands); Gijs Verdoes-Kleijn, Kapteyn Astronomical Institute (Netherlands); Richard Davies, Max-Planck-Institut für extraterrestrische Physik (Germany); Konrad Kuijken, Leiden Observatory (Netherlands); Yann Clénet, Damien Gratadour, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France) and Ctr. National de la Recherche Scientifique (France) and Observatoire de Paris (France); Alan W. McConnachie, David R. Andersen, Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada); Jörg-Uwe Pott, Gabriele Rodeghiero, Max-Planck-Institut für Astronomie (Germany); Mark Norris, Univ. of Central Lancashire (United Kingdom); Ramón Navarro, ASTRON (Netherlands); Paolo Turri, NRC - Herzberg Astronomy & Astrophysics (Canada)

Accurate astrometry will be one of the major benefits of a diffraction limited Extremely Large Telescope (ELT). The goal of the Multi-AO Imaging Camera for Deep Observations (MICADO), one of the first light instruments for the European-ELT is a relative astrometric accuracy of 50 microarcsec. In order to reach such an ambitious goal, a dual approach is necessary. Firstly to simulate stellar fields with the predicted instrumental PSF and analyse the resulting realistic images to test the predicted performance, and to help optimise the instrumental design. Secondly, present-day astrometric studies with existing Multi-Conjugate Adaptive Optics (MCAO) facilities are crucial to test the main sources of inaccuracy not purely related to the instrumental design or telescope. In this paper we present both these approaches. In particular, we investigate how to best reach the astrometric requirement for MICADO by quantifying the errors associated to the major components in the light path. This investigation is carried out making simulations with the Single Conjugate module PSF in the central region of a crowded globular cluster, with an assumed field of view of $approx 10 times 10$ arcsec.

We will also present the results of an astrometric study performed with Gemini Multi-Conjugate Adaptive Optics System (GeMS) observations of the Galactic globular cluster NGC6681. This cluster is the most centrally concentrated in the Galaxy, and thus represents a major observational challenge in terms of stellar crowding. We have previously determined proper motions from comparing two Hubble Space Telescope epochs (Massari et al. 2013). Thus this cluster is the ideal candidate to test the effects that may be introduced by MCAO corrections on proper motion measurements and related uncertainties. In particular, we looked for systematics introduced by the GeMS geometric distortions by: observing through both J and Ks filters; investigating the effect of the shape of the Natural Guide Star constellation configuration and finally the effects of the reduction software used. Our investigation is the first to address the accuracy of proper motion measurements over a temporal baseline of several years with any MCAO instrument in direct comparison with HST, and will therefore be the starting point for understanding MCAO astrometry capabilities and any future improvements in the calibration requirements and data reduction strategy for ELT observations.

9909-55, Session 15

Solar adaptive optics: specificities, lessons learned, and open alternatives

Iciar Montilla Garcia, Manuel Collados Vera, Instituto de Astrofísica de Canarias (Spain); Luzma Montoya, Observatoire de Lyon (Spain) and Instituto de Astrofísica de Canarias (Spain); Michel Tallon, Maud P. Langlois, Observatoire de Lyon (France)

First on sky adaptive optics experiments were performed on the Dunn Solar Telescope on 1979, with a shearing interferometer and limited success. Those early solar AO efforts forced to custom-develop many components, such as DMs and WFSs, which were not available at that time. Later on, the development of the correlation Shack-Hartmann marked a breakthrough in solar AO. Since then, successful Single Conjugate AO instruments have been developed for many solar telescopes, i.e. the National Solar Observatory, the Vacuum Tower Telescope and the Swedish Solar Telescope. Success with the Multi Conjugate AO systems for GREGOR and the Big Bear Solar Telescope have proved to be more difficult to attain. Such systems have a complexity not only related to the degrees of freedom, but also related to the specificities of the Sun, used as reference, and the sensing method. The wavefront sensing is performed using correlations on images with a field of view of ~10", averaging wavefront information from different sky directions, affecting the sensing and sampling of high altitude turbulence. Also due to the typical elevation at which solar observations are performed we have to include generalised fitting error and anisoplanatism, as described by Ragazzoni and Rigaut, as non-negligible error sources in the MCAO error budget. For the development of the next generation MCAO systems for the Daniel K. Inouye Solar Telescope and the European Solar Telescope we still need to study and understand these issues, to predict realistically the quality of the achievable reconstruction. To improve their designs other open issues have to be assessed, i.e. possible alternative sensing methods to avoid the intrinsic anisoplanatism of the wide field correlation Shack-Hartmann, new parameters to define the performance of an AO solar system, alternatives to the Strehl and the PSF used in night time AO but not really suitable to the solar systems, and new control strategies more complex than the ones used in nowadays solar MCAO systems. In this paper we summarize the lessons learned with past and current solar AO systems and focus on the

discussion on the new alternatives to solve present open issues limiting their performance.

9909-56, Session 15

Adaptive optics for MOSAIC: design and performance of the wide(st)-field AO system for the E-ELT

Timothy J. Morris, Alastair G. Basden, Durham Univ. (United Kingdom); Jean-Tristan M. Buey, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Fanny Chemla, Observatoire de Paris à Meudon (France); Jean-Marc Conan, ONERA (France); Ewan Fitzsimons, UK Astronomy Technology Ctr. (United Kingdom); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Éric Gendron, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); François Hammer, Pascal Jagourel, Observatoire de Paris à Meudon (France); Carine Morel, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Richard M. Myers, Durham Univ. (United Kingdom); Benoit Neichel, Lab. d'Astrophysique de Marseille (France); Cyril Petit, ONERA (France); Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France)

MOSAIC is the proposed multiple-object spectrograph for the E-ELT that will utilise the widest possible field of view provided by the telescope. In terms of adaptive optics, there are two distinct operating modes required to meet the top-level science requirements. The MOSAIC High Multiplex Mode (HMM) requires either seeing-limited or GLAO correction within a 0.6" (NIR) and 0.9" (VIS) subfields over the widest possible field for a few hundred objects. To achieve seeing limited operation whilst maintaining the maximum unvignetted field of view for scientific observation will require recreating some of the functionality present in the Pre-Focal Station relating to control of the E-ELT active optics.

MOSAIC High Definition Mode Control (HDM) requires a 25% encircled energy within 150mas in the H-band element for approximately 10 targets distributed across the full E-ELT field, implying the use of MOAO. Initial studies have shown that to meet the encircled energy requirements whilst maintaining high-sky coverage will require the combination of wavefront signals from both high-order NGS and LGS to provide a tomographic estimate for the correction to be applied to the open-loop MOAO DMs.

In this paper we present the current MOSAIC AO design and provide the first performance estimates for the baseline instrument design. We then report on the various trade-offs that will be investigated throughout the course of the Phase A study, such as the requirement to mix NGS and LGS signals tomographically. Finally, we discuss how these will impact the AO architecture, the MOSAIC design and ultimately the scientific performance of this wide-field workhorse instrument at the E-ELT.

9909-57, Session 15

Testing the pyramid truth wavefront sensor for NFIRAOS in the lab

Etsuko Mieda, Univ. of Toronto (Canada); Matthias Rosensteiner, Jean-Pierre Véran, Olivier Lardiere, Glen Herriot, NRC - Herzberg Astronomy & Astrophysics (Canada)

NFIRAOS (Narrow Field InfraRed Adaptive Optics System) is a first light adaptive optics (AO) system for Thirty Meter Telescope (TMT). It is a multi-conjugate AO system equipped with six laser guide stars (LGSs), two deformable mirrors (DMs), and a natural guide star (NGS) pyramid wavefront sensor (PWFS). The advantage of the PWFS over the conventional Shack-Hartmann Wavefront Sensor (SHWFS) is its greater sensitivity and dynamic range tuned by modulation amplitude. In NFIRAOS, the PWFS will be used as a high-order wavefront sensor when LGSs are off, and as a truth wavefront sensor (TWFS) when LGSs are on. The TWFS provides improvements over conventional AO systems by monitoring the slowly varying sodium layer profile and measuring radial wavefront errors due to these profile variations. The performance of our TWFS is therefore critical to NFIRAOS, which we test using our Herzberg NFIRAOS Optical Simulator (HeNOS) bench.

The HeNOS bench at NRC Herzberg is a scaled-down version of NFIRAOS with four LGSs, a grid of NGSs, two DMs, three turbulence screens, a SHWFS, and a science camera to simulate NFIRAOS performance in the laboratory bench. Due to the number of actuators (n=9) on the ground layer DM (DM0), the bench is equivalent to an 8-m telescope rather than a 30-m. However, we scaled the bench so that our science field of view matches with the same number of anisoplanatic angles as in NFIRAOS.

In this paper, we describe the design and the lab testing results of the newly added TWFS on HeNOS bench. Due to the space and capability of HeNOS bench in the lab, the HeNOS-TWFS is used to measure tip/tilt/defocus in addition to the simulated sodium layer profile. Our TWFS path consists of a star selection mirror (SM), a pinhole, a modulation mirror (MM), a focusing lens, a microlens array in the focal plane as a pyramid, a relay lens, and a CCD detector. Both the SM and MM are conjugated to the pupil located at DM0. The grid of NGSs is separated by 0.4", where 21 NGSs are on one axis, and the SM is able to position one NGS at the center of the pinhole at a time. The MM has the resolution and range to modulate the amplitude from r = 3?/D to 40?/D. We apply defocus to DM0 and make LGS spots on SHWFS elongated while modulating the LGS spots' intensity to simulate the time varying sodium layer profile.

9909-270, Session PThu1

Daytime turbulence profiling for EST and its impact in the solar MCAO system design

José Marco de la Rosa, Luzma Montoya, Manuel Collados Vera, Iciar Montilla Garcia, Nauzet Vega Reyes, Instituto de Astrofísica de Canarias (Spain)

An intensive site-testing campaign has been carried out by the IAC during the last years in order to characterize the daytime turbulence for the two candidate sites for the construction of the European Solar Telescope: the Observatorio del Teide (OT) in Tenerife and the Observatorio del Roque de los Muchachos (ORM) in La Palma. The main collected data consist in low height (reliable up to 2Km approximately) daytime turbulence profiles. The instrument used for acquiring the data needed to calculate those profiles is the Long Baseline Shadow Band Ranging (SHABAR). One of the objectives of this turbulence characterization campaign is the selection of the most appropriate site for building the telescope, with simultaneous observation in both observatories. Tests for ensuring the comparability of the profiles generated by the two simultaneously-working SHABARs have been performed. Tests for checking the correctness of the generated profiles where also performed by observing with both instruments in the same site at the same and different heights.

SHABAR data was calibrated with the aid of data coming from a different instrument (a Wide Field Wavefront Sensor WFWS) installed at the Swedish Solar Tower (SST), in La Palma, where one of IAC SHABARs is located. The WFWS estimates the Fried's parameter at the telescope entrance, which is useful for calibration. Data from a shorter SHABAR operated at the SST, calculating turbulence profiles for smaller heights (up to 300m approx.), was also available and used for calibration and validation of our data.

Once our data was totally calibrated and cleaned, different statistics and average profiles were calculated. Average profiles for different seasons and hours of the day, using solar noon as a reference, were calculated. All these low height profiles needed to be aggregated with the higher height profiles available from the nighttime turbulence. We work with the assumption that the ground turbulent layer is more affected by sunlight, due to convection caused by ground heating, while higher altitude layers are more stable and its behavior could be considered to be similar during night and day.

The resulting turbulence profiles covering the full important height range serve as input for software simulations for the MCAO telescope design. The objective of these simulations is finding the best number of deformable mirrors to include in the MCAO system and their positions.

This paper presents the architecture and working principle of the Long Baseline SHABAR instrument, explains the different tests that were held for validation and for calibration with SST data, explains how the low height turbulence data was cleaned, how the profiles were aggregated in order to obtain average profiles, how those profiles are fused with higher altitude turbulence profiles coming from the night turbulence data, explains the software simulations performed and how the profiles are essential inputs for calculating the most appropriate number and position of mirrors, taking into account a set of relevant variables.

9909-273, Session PThu1

Ultimate limitations of tomographic reconstruction for WFAO systems on E-ELT

Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Benoit Neichel, Lab. d'Astrophysique de Marseille (France); Jean-Francois Sauvage, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Carlos M. Correia, Lab. d'Astrophysique de Marseille (France); Noah Schwartz, UK Astronomy Technology Ctr. (United Kingdom)

WFAO systems are now the baseline of any E-ELT's AO system. LTAO, MCAO and MOAO (in order of complexity) approaches are essential to achieve the ultimate scientific return of first light and first generation of ELT's instrumentation. All these AO systems require a precise tomographic reconstruction of the turbulent volume. They are all going to use multiple Laser and natural guide stars wave-front sensing strategies to retrieve the 3D information of the atmospheric turbulence. In that frame, guide stars (Laser and Natural) asterisms and Cn2 profiles (coming up at two levels: the input "true" profile, and the prior profile used as a regularization in the tomographic reconstruction) are the fundamental ingredients of the reconstruction processes. We show that isoplanatic angle is not sufficient to characterize profiles in WFAO. The impacts of the structure and the complexity of the Cn2 profile on the residual error after tomographic reconstruction are analyzed and discussed. We highlight the importance of a well sampled Cn2 input profile and prior profile to be considered in the tomographic reconstructor and we draw some simple and yet essential engineering rules between the size of the technical FoV (3D area on which the turbulence has to be reconstructed), the number of measurements and the Cn? structures. Implications on the design and the performance of WFAO systems (LTAO, MCAO and MOAO) for the E-ELT are derived.

9909-277, Session PThu1

Comparison between simulations and lab results on the ASSIST test-bench for the AOF

Miska Le Louarn, Pierre-Yves Madec, Johann Kolb, Jérome Paufique, Paolo La Penna, Robin Arsenault, Sylvain Oberti, European Southern Observatory (Germany)

In this poster, we will present the latest comparison results between lab test carried out on the ASSIST test bench (for the ESO Adaptive Optics Facility, AOF) and Octopus end-to-end simulations. We simulated, as closely to the lab conditions as possible, the different AOF modes (Maintenance and commissioning mode (SCAO), GRAAL (GLAO in the near IR), Galacsi Wide Field mode (GLAO in the visible) and Galacsi narrow field mode (LTAO in the visible)). We then compared the simulation results to the ones obtained on the lab bench. Several aspects were investigated, like number of corrected modes, turbulence wind screens, LGS photon flux etc. The agreement between simulations and lab is remarkably good for all investigated parameters, giving great confidence in both simulation tool and performance of the AO system in the lab.

9909-280, Session PThu1

MICADO SCAO numerical simulations

Fabrice Vidal, Yann Clénet, Florian Ferreira, Nicolas Doucet, Damien Gratadour, Arnaud Sevin, Alexis Carlotti, Christophe Verinaud, Éric Gendron, Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France)

MICADO is the E-ELT first light imager, working at the diffraction limit in the near infrared. Optimized to work with the MAORY Multi-Conjugate Adaptive Optics (MCAO) module, MICADO will also come with a single conjugate adaptive optics (SCAO) capability motivated by scientific programs for which SCAO will deliver the best AO performance (e.g. exoplanets, solar system science, bright AGNs, etc).

This SCAO capability will be developed within MICADO through a dedicated SCAO module with its natural guide star (NGS) wavefront sensor (WFS), allowing MICADO to work in SCAO stand alone mode without MAORY, and inside MAORY with the same dedicated NGS WFS. Currently Shack-Hartmann (SH) or pyramid WFS are both envisioned for the wavefront measurement of the SCAO mode. In addition to WFS design considerations, numerical simulations are therefore needed to trade-off between these two WFS.

COMPASS (COMputing Platform for Adaptive optics SyStems) is a GPU-based adaptive optics end-to-end simulation platform allowing us to perform numerical simulations in various modes (SCAO, LTAO, MOAO, MCAO...). COMPASS was originally bound to Yorick for its user interface and a major upgrade has been recently done to now bind to Python allowing a better long term support to the community.

We first present the specific developments performed to achieve a fast and accurate E-ELT scale simulation (E-ELT pupil, spiders, M4 geometry and influence functions, segment cophasing error, pupil rotation...). We then present the latest simulations results performed in the framework of the MICADO SCAO study. Thanks to the speed of computation of COMPASS we are able to span quickly a very large parameters of space at the E-ELT scale. We present the results of the first study between WFS choice (SH or pyramid), WFS parameters (noise, number of subapertures, pixel scales...), turbulence parameters (including Cn2 profiles, r0 and L0 variations), and AO controls (frequency, loop gains...). Finally we try to build a first error budget comparison on some specific cases and conclude on the expected performance. These results will pave the way of work for the future developments for the SCAO of MICADO.

9909-282, Session PThu1

Status update and long term development plan for the COMPASS simulation platform

Damien Gratadour, Florian Ferreira, Nicolas Doucet, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Christophe Vérinaud, Alexis Carlotti, Institut de Planétologie et d'Astrophysique de Grenoble (France); Pierre Kestener, Maison de la Simulation (France); Mathieu Puech, Observatoire de Paris (France); Morgan Gray, Lab. d'Astrophysique de Marseille (France); Arnaud Sevin, Denis Perret, Maxime Lainé, Julien Brulé, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France)

Monte Carlo simulations called end-to-end are widely used in the community of instrumentation to predict system performance, to test new concepts and validate their behavior or to conduct trade-off studies for technological design. These multi-physics intensive simulations involve complex algorithms based on the use of a variety of mathematical libraries (random number generators, Fourier transform, and BLAS LAPACK routines). It exists, for these libraries, optimized versions generally distributed by hardware manufacturers that can be called individually with a standard, more or less portable, set of instruction. An innovative approach, appeared for less than ten years in the field of high performance computing, is to use hardware accelerators such as reprogrammable graphics processors (GPU) to overcome the limitations of the x86 architecture and maximize both the computing power / cost ratio and the computing power / required energy ratio. We proposed the implementation of a numerical development platform for AO, COMPASS, including: a full scale end-to-end simulation tool for AO with different dimensioning, a real time core that can be integrated directly on a real system and a prototype for low latency acquisition system. The development of this platform is based on a full integration of the software with the hardware and relies on the optimized migration of a simulation to a heterogeneous architecture using the GPU as accelerators. Research areas are diverse: AO modeling, real-time control in open or closed loop, acquiring images at low latency and science with AO in the context of the E-ELT instrumentation. It is a multidisciplinary collaboration combining the skills of specialists in astrophysics, instrumentation for large telescopes and high-performance computing. The project, which started in March 2013, brought together the effort of teams from six partner laboratories in France. The platform is fully functional today and can be used to simulate single conjugate AO with natural guide stars, as well as a multi-Laser tomographic AO on telescopes of different scales and with proven efficiency. Beyond the scientific exploitation of the platform that has already begun, the project is now directed towards the development of a distributed mode in order to run simulations on computer clusters equipped with GPU and thus target the largest scales AO systems while minimizing the simulation time. Significant work must be conducted on optimizing the code to make it adaptable to distributed architectures and minimize its memory footprint while maximizing performance. A user interface in Python has been developed to enable faster adoption by the community. The goal is to make this simulation platform a standard tool for the development of telescopes with extreme diameters. We will present the current status of the platform, the achieved performance on a variety of AO dimensioning and the long term maintenance plan.

9909-287, Session PThu1

Wavefront reconstruction with pupil fragmentation: study of a simple case

Sylvain Bonnefond, Miska Le Louarn, European Southern Observatory (Germany); Michel Tallon, Ctr. de Recherche Astrophysique de Lyon (France); Pierre-Yves Madec, European Southern Observatory (Germany)

The use of smaller subapertures on some recent adaptive optics systems and the presence of a thick spider in the telescope seem to yield difficulties in wavefront reconstruction. This is known as spider effect or pupil fragmentation. On these configurations, the width of the telescope spider is no more negligible compared to the size of the subapertures, and may hide full rows of subapertures. As results, the spider divides the pupil in disconnected domains, with missing or damaged measurements between them. An unseen mode made of differential pistons between the disconnected domains is then created. This effect has been clearly shown on E-ELT simulations and could be a source of the so-called SHERE low-wind effect. The difficulty is to derive the best wavefront reconstructor with such a pupil fragmentation.

In order to analyze this phenomenon, we have studied wavefront reconstruction on a simple small AO system with and without spider. The performances of various wavefront reconstructors are compared for different signal to noise ratios, using priors (minimum variance) or not (least-square) and with different assumptions for the missing wavefront measurements. The missing measurements have been either replaced by zeroes, or derived from an extension technique, or simply weighted to zero. Priors have been introduced using the FrIM (Fractal Iterative Method) algorithm. Our study allows a better understanding of the best approaches to mitigate pupil fragmentation and the limits of these mitigations.

9909-290, Session PThu1

End-to-end simulations of the E-ELT/ METIS coronagraphs

Brunella Carlomagno, Olivier Absil, Univ. de Liège (Belgium); Matthew A. Kenworthy, Leiden Observatory (Netherlands); Garreth J. Ruane, Rochester Institute of Technology (United States); Gilles P. P. L. Otten, Leiden Observatory (Netherlands); Markus Feldt, Stefan Hippler, Max-Planck-Institut für Astronomie (Germany); Elsa Huby, Univ. de Liège (Belgium); Dimitri Mawet, California Institute of Technology (United States); Christian Delacroix, Cornell Univ. (United States); Jean Surdej, Serge Habraken, Univ. de Liège (Belgium); Pontus Forsberg, Mikael Karlsson, Ernesto Vargas Catalan, Uppsala Univ. (Sweden)

The direct detection of low-mass planets in the habitable zone of nearby stars is one of the most important science cases for future ELT instruments. One of the first-light E-ELT instruments is the mid-infrared imager and spectrograph METIS, which features vortex phase masks and apodizing phase plates (APP) in its baseline design. The AGPM (Annular Groove Phase Mask) is a charge-2 vector vortex coronagraph, obtained with rotationally symmetric subwavelength gratings etched into diamond substrates. Since its first light in the VLT/NACO instrument in late 2012, its results have been remarkable, with a series of new instruments in its portfolio (LBT/LMIRCam, Keck/NIRC2, VLT/VISIR). Its impressive characteristics (small inner working angle, high throughput, clear off-axis 360° discovery space, achromaticity, simplicity) make it an attractive solution for future E-ELT instruments, and METIS in particular. However, these characteristics will be strongly challenged by the non-circular, centrally obstructed E-ELT pupil and by the residual aberrations that degrade the wavefront in presence of atmospheric turbulence. In this work, we present end-to-end performance simulations, using Fourier optical propagation, of various METIS coronagraphic modes, including focal-plane vortex phase masks and pupil-plane apodizing phase plates. In a first step, we study the effect of the E-ELT pupil architecture (central obstruction and spiders) on the coronagraphic performance. We then describe the sensitivity to tip-tilt errors (pointing jitter). Finally, the atmosphere and the AO contributions are taken into account in a realistic way to predict

the METIS on-sky coronagraphic performance. The relative performance of various concepts will be compared, and the most promising solutions will be identified.

9909-293, Session PThu1

A procedure for fast calibrating a voice-coil actuated adaptive mirror based on FE model

Ciro Del Vecchio, Runa Briguglio, Marco Xompero, Armando Riccardi, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The Finite Elements Analysis method provides an accurate modeling of a thin glass shell deformable mirror actuated via voice coil actuators and sensed via capacitive sensors. In particular, the actuator influence functions, needed to build-up the system control matrix, can be numerically computed within a 2% difference with respect to the optical measurements, after an initial tuning of the model. The most relevant advantages of the FE technique, compared to the optical calibration with an interferometer, are reduced costs, low risks and a shorter telescope down-time. Moreover, it enhances the SNR of the high order modes affected by the measurement noise.

In this paper we present a conceptual study for the synthetic calibration of an adaptive mirror driven by voice coil actuators. The goal is to generate the simulated influence functions and the control matrix, in order to close the AO loop. The reference case is the on-telescope recalibration of a DM after refurbishment and/or modules replacement. This concept of numerical calibration, in particular, is well suited for the E-ELT M4 system, a 2.5 m adaptive mirror, segmented into 6 identical petals, where the control electronics is assembled in elements called bricks: its high degree of modularity makes the proposed calibration very effective.

9909-298, Session PThu1

Simulations of E-ELT telescope effects on AO system performance

Miska Le Louarn, Pierre-Yves Madec, Enrico Marchetti, Henri M. Bonnet, Michael Esselborn, Jérome Paufique, Sylvain Oberti, European Southern Observatory (Germany)

In this poster, we will study the impact of various telescope effects (like effect of wind on main structure, phasing errors etc) on the performance of AO systems (telescope-oriented AO and instrumentation). For example, we will show what kind of AO system (number of sub-apertures, frame-rate) is necessary to compensate for these effects, to get a fully seeing limited performance from the telescope.

9909-301, Session PThu1

Pseudo-analytic simulation of woofer-tweeter MOAO system: application to MOSAIC

Carine Morel, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France) and Univ. Pierre et Marie Curie (France) and Univ. Paris 7-Denis Diderot (France); Eric Gendron, Damien Gratadour, Arnaud Sevin, Gérard Rousset, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France) and Univ. Paris 7-Denis Diderot (France) and Univ. Pierre et Marie Curie (France)

The future MOS (multi-object spectrograph) of the European ELT, MOSAIC, is designed to study the morphology and dynamics of a large number of small (≈1'') high redshift galaxies in parallel. This study will require the adaptive optics (AO) system to reach a sufficient level of ensquared energy of the PSF across a wide field of view (around 10 arcmin) which could be achieved by using multi-object OA (MOAO) technique. The numerous independent optical science channels of MOSAIC will be corrected using a ground layer (GL) compensation performed by the built-in deformable mirror of the telescope (called M4), complemented by a secondary tweeter DM in each science channel.

In order to estimate the performance of such a system, we use a pseudo-analytical approach developed in a previous article, based on the computation of the covariance matrix of the tomographic error (including aliasing error), followed by a PSF reconstruction algorithm. The covariance matrix of the tomographic error is derived from the knowledge of the minimum mean square error (MMSE) reconstructor and covariance matrices of measurements.

One of the strength point of the approach is to be applicable to ELT-scale simulations due to a highly parallel algorithm.

However, this method was previously limited to the case of a single MOAO DM.

One of the challenging parts of the adaptation of the previous approach for a 2-DM case is to define correctly the tomographic error which is spread between the 2 DMs. They will have in particular a different number of actuators which induce different fitting errors, and different influence function that do not necessarily match together.

We develop in this article how we have computed the tomographic error, using two different methods. The first method is approximate and fast, but models both DMs by using the influence functions and fitting error of the highest-order DM only. The second method is more thorough: it simulates the tomographic error on both DMs distinctively but needs much lager matrices resulting on a less time-efficient computation. We discuss and compare those methods and show how we have adapted our PSF reconstruction algorithms to cope with the 2 DMs case.

We will also comment some results obtained with this approach on a MOSAIC case. In particular, we will discuss the performance versus the number of actuators of the secondary DMs.

9909-304, Session PThu1

Accurate laser guide star wavefront sensor simulation for the E-ELT first light adaptive optics module

Laura Schreiber, Carmelo Arcidiacono, INAF - Osservatorio Astronomico di Bologna (Italy); Mauro Patti, Univ. degli Studi di Bologna (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Giovanni Bregoli, Paolo Ciliegi, Emiliano Diolaiti, INAF - Osservatorio Astronomico di Bologna (Italy); Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Philippe Feautrier, Univ. Joseph Fourier (France) and Institut de Planétologie et d'Astrophysique de Grenoble (France); Matteo Lombini, INAF - Osservatorio Astronomico di Bologna (Italy)

MAORY will be the multi-conjugate adaptive optics module for the E-ELT first light.

In order to ensure high quality correction across a Field of View of ~ 2 arcmin and high sky coverage, the baseline is to operate wavefront sensing using six Sodium Laser Guide Stars (LGS).

Three Natural Guide Stars (NGS) are also reguired to solve intrinsic

limitations of artificial beacons (tip-tilt indetermination and anisoplanatism) and to mitigate the impact of the sodium layer structure and variability.

The real impact of sodium layer behaviour on a 40 meter class adaptive telescope has never been measured, but recent studies based on simulations suggest that it might be not negligligible. In particular, some critical components of the AO system require to be designed and dimensioned in order to reduce the spurious effects arising from the Sodium Layer density distribution and variation.

It is then clear that becomes crucial to have a simulation code able to reproduce in a very accurate way the real sodium layer characteristics.

The MAORY end-to-end simulation code has been designed to accurately model the LGS image in the Shack-Hartmann wavefront sensor subapertures and to allow sodium profile temporal evolution.

The code allows also the simulation of transverse structures, possibly leading to differential effects among the Laser Guide Stars.

The fidelity with which the simulation code translates the sodium profiles in LGS images at the Wafront Sensor focal plane has been verified using a laboratory prototype.

9909-305, Session PThu1

Preparation of AO-related observations and post-processing recipes for E-ELT HARMONI

Noah Schwartz, UK Astronomy Technology Ctr. (United Kingdom); Jean-François Sauvage, ONERA (France); Benoît Neichel, Carlos M. Correia, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, ONERA (France); Arlette Pécontal-Rousset, Aurélien Jarno, Laure Piqueras, Ctr. de Recherche Astrophysique de Lyon (France)

HARMONI is a visible and near-infrared integral field spectrograph, providing the E-ELT's core spectroscopic capability. It will exploit the E-ELT's scientific niche in its early years, starting at first light. To fully exploit the spatial resolution and collecting power gain of the E-ELT, HARMONI will rely on the telescope's adaptive M4 and M5 mirrors. Two different adaptive optics (AO) systems will be used enabling both high-performance combined with low sky coverage using bright natural guide stars (SCAO) and medium performance combined with excellent sky coverage using 6 laser guide stars and faint natural guide stars for low-order correction (LTAO).

In this paper, we present numerical simulation results for the SCAO and LTAO modules of HARMONI in order to prepare observation strategies and post-processing recipes. First, an end-to-end model delivering highly accurate performance estimation is used, taking into account different aspects of the AO loop such as specific technology constrains (e.g. DM geometry, actuator stroke…), telescope configuration and limitations (e.g. spiders, LGS spot elongation…) and detailed aspects of AO control laws (e.g. calibration strategy, telescope transient regime…). We present a trade-off study and performance analysis for the choice of NGS WFSs, namely between Pyramid and Shack-Hartmann. LTAO performance is also addressed.

Complementary to the end-to-end modelling, a second model enables an efficient search of key AO parameters without relying on heavy computations. This enables us to quickly cover a large space of parameters and have a global view of performance. Realistic PSFs are rapidly generated and directly integrated in HSIM a full end-to-end HARMONI simulation tool. This will be used by the community to estimate the final performance of the instrument for specific science cases.

9909-307, Session PThu1

Deriving comprehensive error breakdown for wide field AO systems using end-to-end simulations

Florian Ferreira, Observatoire de Paris (France) and Univ. Paris 7-Denis Diderot (France); Eric Gendron, Observatoire de Paris (France); Gérard Rousset, Damien Gratadour, Observatoire de Paris (France) and Univ. Paris 7-Denis Diderot (France)

Future European Extremely Large Telescope (E-ELT) adaptive optics (AO) systems, such as Multi Object Adaptive Systems (MOAO), will aim at wide field correction and large sky coverage thanks to the use of laser guide stars (LGS). However, AO correction is only partial and images obtained with such systems can be improved by using post processing techniques for image inversion relying on a field dependent point spread function (PSF). This requires an accurate knowledge of the PSF and its variations over the science field. The PSF estimation involves characterization of the different sources of error in the AO system from the wave front sensor data. Estimating and disentangling the various error contributors is an issue due to propagation and filtering process in the AO loop, and numerical simulations are a good way to address it. However, each simulation step at the E-ELT scale is very demanding in terms of computing power and data flow, and the simulation of a long exposure PSF requires several thousands of them. Moreover, the error breakdown estimation usually requires to perform several simulations to identify the different contributors. Hence, we use COMPASS (COMputing Platform for Adaptive opticS Systems), an end-to-end simulation tool especially developed to reach acceptable simulation time for ELT scales using GPU acceleration. We have developed in COMPASS an estimation tool that provides a comprehensive error breakdown on output of a single simulation. This is done by using known internal quantities computed by the simulation to estimate on the fly the impact of those errors on the E-ELT AO system performance without interrupting the main AO loop. This error budget returns, for example, the contribution of tomography (reconstruction) error, aliasing, fitting, noise on the wavefront sensor, or temporal error due to the loop delay. After a description of the error breakdown to be computed, we outline the estimation methods and its implementation in COMPASS and we discuss the results obtained on E-ELT scale cases.

9909-309, Session PThu1

8s: a simulator for the optical calibration of the E-ELT M4

Runa Briguglio, INAF - Osservatorio Astrofisico di Arcetri (Italy); Giorgio Pariani, INAF - Osservatorio Astronomico di Brera (Italy); Marco Xompero, Paolo Spanò, INAF - Osservatorio Astrofisico di Arcetri (Italy); Matteo Tintori, Paolo Lazzarini, A.D.S. International S.r.l. (Italy); Armando Riccardi, INAF - Osservatorio Astrofisico di Arcetri (Italy)

8s (Optical Test TOwer Simulator) is a simulation tool for the optical calibration of the E-ELT deformable mirror M4 on its test facility. It has been developed to identify possible criticalities in the procedure, evaluate the solutions and estimate the sensitivity to environmental noise.

The simulation system is composed by three parts: the finite elements model of the test facility, including its thermo-mechanical behaviour and the positioning devices; the analytic influence functions of the actuators, 886 for each of the 6 shells (petals); the propagation, via a ray-tracing program, of the laser beam from the interferometer through the optical surfaces, each placed at the position defined by the user.

The tool delivers simulated phasemaps of M4, associated with the current

system status: actuator commands, optics alignment and position, beam vignetting, bench temperature and vibrations. It is possible to simulate a single step of the optical test of M4 by changing the system parameters according to a calibration procedure and collect the associated phasemap for performance evaluation.

In this paper we will describe the simulation package and outline the proposed calibration procedure of M4.

9909-310, Session PThu1

The numerical simulation tool for the MAORY multiconjugate adaptive optics system

Carmelo Arcidiacono, INAF - Osservatorio Astrofisico di Arcetri (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Laura Schreiber, Giovanni Bregoli, Emiliano Diolaiti, Italo Foppiani, INAF - Osservatorio Astronomico di Bologna (Italy); Guido Agapito, Alfio T. Puglisi, Marco Xompero, INAF - Osservatorio Astrofisico di Arcetri (Italy); Giuseppe Cosentino, Univ. degli Studi di Bologna (Italy); Reginald C. Butler, INAF - Istituto di Astrofisica e Planetologia Spaziali (Italy); Paolo Ciliegi, Fausto Cortecchia, INAF - Osservatorio Astronomico di Bologna (Italy); Mauro Patti, Univ. degli Studi di Bologna (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy); Philippe Feautrier, Institut de Planétologie et d'Astrophysique de Grenoble (France)

We developed a numerical simulation tool for the end to end simulations of the Multiconjugate Adaptive Optics RelaY (MAORY) for the ESO European-Extremely Large Telescope.

MAORY will implement Multiconjugate Adaptive Optics (MCAO) correction through three high order deformable mirrors driven by the reference signals of six Laser Guide Stars (LGSs) feeding as many Shack-Hartmann wavefront sensors. A three Natural Guide Stars (NGSs) system will provide the low order correction. The simulation tool is based on the IDL language performs a Monte-Carlo modeling of the MAORY system performance through an extensively usage of the available GPUs. Here we recall the code architecture and describe the modeled instrument components and the control strategies we implemented. The NGS system limiting magnitude and its interaction with the LGS adaptive loop is fundamental to consolidate the design of the MAORY. Here we present as an example exercise the application of the code to obtain sky coverage information.

9909-311, Session PThu1

Simulation of solar adaptive optics systems

José Marino, Dirk Schmidt, Rebecca E. Carlisle, National Solar Observatory (United States)

Solar adaptive optics (AO) simulations are a valuable tool to guide the design and optimization process of current and future solar AO and multi-conjugate AO (MCAO) systems. Solar AO and MCAO systems rely on extended object cross-correlating Shack-Hartmann wavefront sensors (SHWFS) to measure the wavefront. Accurate solar AO simulations require computationally intensive operations, which have until now presented a prohibitive computational cost.

We present an update on the status of a solar AO and MCAO simulation tool being developed at the National Solar Observatory. The tool provides accurate full simulation of solar AO and MCAO systems. In particular, it accurately simulates the imaging processes that produce the non-zero field-of-view sub-aperture images of the cross-correlating SHWFS. Such simulations are very computationally intensive and strongly benefit from fast and heavily parallelized code. Our simulation tool is a multi-threaded application written in the C++ language that takes advantage of current large multi-core CPU computer systems and fast ethernet connections. It interfaces with KAOS, a state of the art solar AO control software developed by the Kiepenheuer-Institut fuer Sonnenphysik (KIS), that provides reliable AO control.

We will report on the latest results produced by the solar AO simulation tool. In particular, applied to an optimization study of the reconstruction strategies used by the high order solar AO system, currently under development for the 4 m class DKIST solar telescope; and to a performance optimization study of the prototype solar MCAO system at the Big Bear Solar Observatory.

9909-313, Session PThu1

Effects of the outer scale on the adaptive optics simulations

Carmelo Arcidiacono, INAF - Osservatorio Astrofisico di Arcetri (Italy) and INAF - Osservatorio Astronomico di Bologna (Italy); Elena Masciadri, Guido Agapito, INAF - Osservatorio Astrofisico di Arcetri (Italy)

In the context of the characterization of the performances of adaptive optics instruments the intensive use of numerical simulation tools is a common praxis. The outer scale (L0) is in general assumed constant in space and time in the sense that all phase screens assume the same value of L0 that does not change with time. Typical numerical end to end simulations last a few hours but represent a shorter time of the instrument system evolution. This means that if we assume on the contrary that L0 changes in space and time different values of L0 might have in this temporal range a different impact on the simulations outputs. These potential effects are in reality disregarded and not taken into account at present time. Moreover a disregard of the outer scale effects brings to take less care of the modeling of this parameter. Besides, in most of the cases, vertical distribution of the outer scale is not taken into account in the common practice of the adaptive optics simulations because all phase-screens assume in general a similar outer scale. In single conjugate adaptive optics (SCAO) the more important effects of a different vertical distribution of the L0 should be expected on the performance off-axis. However the outer scale vertical distribution becomes more and more important when the field of view becomes larger and larger. In wide field of view adaptive optics (WFAO) the proper modeling of the effect of the distribution may induce the system analysis and adaptive optics engineers to tune differently the adaptive optics control system parameter in order to best match the environment conditions. A set of test cases will be considered in order to identify critical conditions and figures of merit for the simulations of different AO systems.

9909-314, Session PThu1

PASSATA: object oriented numerical simulation software for adaptive optics

Guido Agapito, Alfio T. Puglisi, Simone Esposito, INAF - Osservatorio Astrofisico di Arcetri (Italy)

We present the last version of the PyrAmid Simulator Software for Adaptive opTics Arcetri (PASSATA), an IDL and CUDA based object oriented software developed in the Adaptive Optics group of the Arcetri observatory for Monte-Carlo end-to-end adaptive optics simulations. The original aim of this software was to evaluate the performance of a single

conjugate adaptive optics system for ground based telescope with a pyramid wavefront sensor. After some years of development, the current version of PASSATA is able to simulate several adaptive optics systems: single conjugate, multi conjugate and ground layer, with Shack Hartmann and pyramid wavefront sensors. It can simulate from 8m to 40m class telescopes, with diffraction limited and resolved sources at finite or infinite distance from the pupil. The main advantages of this software are the versatility given by the object oriented approach and the speed given by the CUDA implementation of the most computational demanding routines. We describe the software with its last developments and present some examples of application.

9909-315, Session PThu1

Soapy: an adaptive optics simulation written purely in Python for rapid concept development

Andrew P. Reeves, Durham Univ. (United Kingdom)

Simulation is essential to specify, design and characterise existing and future Adaptive Optics (AO) systems. To this end, many codes exist which aim to run as quickly as possible over large parameter spaces, requiring extreme optimisation and parallelisation to do so. Whilst making these simulations fast, these techniques can also make it difficult to implement new features, such as Wave Front Sensor (WFS) concepts or new reconstructors. It can also make them difficult for those new to the field of AO to understand.

To address these requirements, we present the "Simulation Optique Adaptative in Python" (Soapy) package. Soapy is written purely in "Python", a high level, interpreted language to facilitate rapid development of new AO concepts. The code is modularised so different components, such as WFSs or deformable mirrors, can be used stand-alone. Modules can be easily extended, as core interfaces and functionalities are provided by "base" classes, allowing a developer to add new and interesting capabilities without writing much extra code. There is also a strong focus on clear documentation throughout the package to allow the user to be able to quickly understand the simulation and its internals.

Accurate simulation of Laser Guide Stars (LGS) is a focus for Soapy. Sodium LGS elongation is simulated by propagating the LGS beam down from a discrete number of altitudes within the sodium layer, which provides realistic simulation of differential focus and angular anisoplanatism between light from the top and bottom of the sodium LGS plume. LGS uplink effects are also simulated, which can use either a geometric ray tracing, or physical optical approach. Physical light propagation for downlink WFS light from either NGS or LGS is also supported, allowing studies into the effects of scintillation.

Soapy is currently in use within the Centre for Advanced Instrumentation (CfAI) at Durham University, for investigating novel laser guide star schemes. It is open source, and has proven popular amongst PhD. students and staff within the CfAI as a learning tool and for early AO concept development.

9909-316, Session PThu1

Adaptive optics (AO) system modeling performance investigation of the 4m DAG telescope

Onur Keskin, Isik Üniv. (Turkey); Laurent Jolissaint, HEIG-VD (Switzerland); Sinan K. Yerli, Middle East Technical Univ. (Turkey); Cahit Yesilyaprak, Atatürk Üniv. (Turkey)

This paper consists of the investigation of the expected performance of DAG telescope's GLAO system. While the GLAO approach uses a few bright stars to measure the wavefront perturbations in different directions and to implement corrections over a large field of view, it's a versatile system. If angle of guide stars are decreased to zero, the system becomes a classical adaptive optics system. In order to validate the optical performance of the system a MATLAB model comprised of the models of the optical elements of the system is built. The optical elements used in this model consist of a deformable mirror, a tip/tilt mirror, a control algorithm and a Shack-Hartmann wavefront sensor. Based on the site telemetric data, the result of the expected performance of DAG telescope with and without AO compensation will be presented.

9909-317, Session PThu1

Simulation study on Shack-Hartmann wavefront sensor spots centroid detection optimized algorithm

Quan Sun, Yi Yang, Yu Ning, Wuming Wu, Fengjie Xi, National Univ. of Defense Technology (China)

The threshold selection method for the spot image of Shack-Hartmann Wavefront Sensor (SH WFS)has a large influence on the centroid detection accuracy. This paper built an adaptive optics system simulation model based on wave optics theory. The influence of stray light and noise in complicated optics system on the features of spot image of a SH WFS was simulated, and the effect of the threshold of spot image on the centroid detection accuracy and wavefront reconstruction was studied, and then an adaptive optimized threshold selection method was presented. The threshold was intended to be the percentage of maximum spot energy by analyzing the effect of stray light and noise on the farfield image. The thresholds of each lenslet spot were adaptive selected by the same percentage. The results show that the method can effectively and automatically select the threshold of each frame image. The SH WFS with the threshold selection method is used in the adaptive optics system to carry out a closed-loop correction experiment. After correction, the RMS of wavefront rest distortion was improve by 60% above than simple threshold select method. Compared with ordinary methods, this method was proved more effective in extend object situation. These results showed the method can meet the practical requirements of SH WFSs.

9909-318, Session PThu1

Analysis of the performances of 45 degrees tilted deformable mirrors for the EST MCAO

Marco Stangalini, Fernando Pedichini, INAF - Osservatorio Astronomico di Roma (Italy); Dario Del Moro, Francesco Berrilli, Univ. degli Studi di Roma "Tor Vergata" (Italy)

The European Solar Telescope (EST) will be best suited for very high accuracy polarization measurements. Indeed, its optical design is such that the telescope as a whole does not modify the polarization state of the incoming light. For this reason, a mutually compensating configuration with 45° degrees tilted deformable mirrors (DMs) is proposed for its multi-conjugated adaptive optics (MCAO) system. In this work we present preliminary results about the analysis of this non-standard configuration, and the impact of DMs with large incidence angles on the overall performances of the MCAO system.

9909-319, Session PThu1

The software package CAOS 6.0: enhanced numerical modeling of astronomical adaptive optics systems

Marcel Carbillet, Lab. J.L. Lagrange (France)

The Software Package CAOS (acronym for Code for Adaptive Optics Systems) is a modular scientific package performing numerical modeling of astronomical adaptive optics (AO) systems. It is IDL-based and developed within the homonymous CAOS "problem-solving environment". In this paper we present the last version of the Software Package CAOS, which contains a number of enhancements and new modules, e.g. for ground-layer and multi-conjugate AO. Examples of application will also be given, in particular for what concerns the newly projected AO system CIAO@C2PU.

9909-271, Session PThu2

PSF calibration using the low-order wave front sensor telemetry

Garima Singh, James K. Wallace, Eugene Serabyn, Jet Propulsion Lab. (United States); Olivier Guyon, Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States)

High performance small inner working angle (IWA) coronagraphs equipped with ground-based extreme adaptive optics systems are capable of imaging exoplanets in their habitable zone. However, their performance is constrained by how well the wavefront aberrations can be controlled and calibrated. The uncorrected residual wavefront aberrations scatter the starlight, which produces intensity fluctuations and as a result creates dynamic speckle noise in the focal plane. Techniques like angular differential imaging can calibrate out the static and quasi-static features of the PSF but becomes less effective at angular separation smaller than 0.5". In order to improve the post processing of the science images at small IWA, the low-order telemetry of the residuals left uncorrected by the control loop can be used to calibrate the amount of starlight leakage at small angular separations.

To address low-order aberrations in small IWA phase mask coronagraphs, a Lyot-based low-order wavefront sensor (LLOWFS) has been developed. This sensor reliably measures up to 35 low-order Zernike modes using the starlight reflected by the Lyot stop and is operational on the SCExAO instrument at the Subaru Telescope. Using LLOWFS images, the PSF can be calibrated by recording synchronized low-order measurements and science camera frames that are used to build a library of response of the residuals on the starlight leakage. During the observation of the science target, LLOWFS residuals can be fitted with the best match in the library. The corresponding science equivalents can then be subtracted from the science image to reconstruct the PSF. This technique can significantly improve the sensitivity of a coronagraph. In this body of work, we will present the preliminary results of PSF reconstruction using the LLOWFS measurements for a H-band vector vortex coronagraph.

9909-274, Session PThu2

Point spread function reconstruction for multi-conjugate adaptive optics

Roland Wagner, Ronny Ramlau, Johann Radon Institute for Computational and Applied Mathematics (Austria); Daniela Saxenhuber, Johannes Kepler Univ. Linz (Austria)

In the upcoming generation of Extremely Large Telescopes (ELT), with mirror diameters of up to 40 m, the impact of the turbulent atmosphere is corrected by wide field Adaptive Optics (AO) system, such as Multi-Conjugate Adaptive Optics (MCAO) within the Multi-AO Imaging Camera for Deep Observations (MICADO) of the European ELT.

Even with AO correction, the quality of astronomical images still is degraded due to the time delay stemming from the wavefront sensor (WFS) integration time and adjustment of the deformable mirror(s) (DM). This results in a blur which can be described by the point spread function (PSF). The PSF of an astronomical image varies with the position in the observed field, which is a crucial aspect in MCAO on ELTs. With the knowledge of the PSF, the quality of the AO correction can be measured and furthermore the image quality can be improved using deconvolution algorithms.

We analyze and present a combined approach for PSF reconstruction throughout atmospheric tomography which is based on the algorithm by J.-P. Veran developed for Single Conjugate AO systems. Our PSF reconstruction algorithm combines existing, verified techniques in a novel way to deliver accurate field dependent PSFs in very short time. With the use of atmospheric layers reconstructed from WFS data, it is possible to determine pseudo wavefronts in different observation directions, which can be used not only to derive the DM shape(s) for the best possible correction, but also in Veran's algorithm to overcome the problem of field dependence of the PSF.

Our simulation results are obtained for the ELT setting in OCTOPUS, the ESO end-to-end simulation tool. For a variety of atmosphere and system parameters, they suggest a good qualitative performance along with reasonable computational effort.

9909-278, Session PThu2

Compensated diffraction-limited imaging with adaptive optics at the GREGOR Solar Telescope

Oskar F. von der Lühe, Lars Bielak, Sebastian Hoch, Thomas Berkefeld, Kiepenheuer-Institut für Sonnenphysik (Germany)

The combination of adaptive optics with post processing of sequences of short exposures is a very successful technique to produce diffraction limited images of the solar photosphere throughout the visible spectral domain. Viable approaches are multi frame blind deconvolution and speckle imaging, and both approaches have been used with great success in the past 15 years. While blind deconvolution solves for both the undisturbed image and the optical transfer function for every frame in the sequence, speckle imaging makes assumptions about the statistics of the partially compensated wavefront and the resulting transfer functions which apply to the speckle signal. These depend on the shape of the entrance aperture and on the characteristics and performance of the adaptive optics system, and therefore need to be established separately for every telescope.

We have calculated the speckle transfer function (STF) for the GREGOR solar telescope as a function of seeing and control performance of GREGORs adaptive optics system GAOS. The calculations are based on simulations of optical propagation through an extended, turbulent atmosphere and field dependent, partial compensation by a conventional adaptive optics system. The compensation characteristics are based on actual measurements of the performance of GAOS. We present the results of the simulations and compare image reconstruction using the simulated transfer functions with reconstructions based on the previously used analytic STF models.

9909-281, Session PThu2

Spatially variant PSF modeling and image deblurring

Éric M. Thiébaut, Ctr. de Recherche Astrophysique de Lyon (France); Loïc Dénis, Lab. Hubert Curien (France); Férréol Soulez, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Rahul K. Mourya, Lab. Hubert Curien (France)

Regularized image deconvolution is a powerful tool to achieve the ultimate spatial and spectral resolution from astronomical data. However, in their quest for observing larger and larger fields of view and collecting spectral and spatial information at the same time, the astronomical instruments are becoming more and more complex and their point spread function (PSF) is no longer stationary. In words, a simple convolution cannot properly approximate the instrumental blur and, as a consequence, a deconvolution cannot remove this blur. Thus, in an increasing number of cases, the deblurring of astronomical images poses a triple problem. First, a good approximation of a shift-variant blur is needed. Second, image restoration methods must be adapted to use such a model. Third, practical means to calibrate a shift variant blur must be found. In this contribution, we quickly review existing blur models with a particular emphasis on the models which are the most suitable for astronomy and for being used in restoration methods. For instance, with a non-stationary blur the deblurring methods must be iterative and having a fast model is important. We will show that improved results can be obtained in a variety of astronomical contexts when the proper shift variant blur model and image restoration method are used. In particular, correctly taking into account a shift-variant blur is of major importance to correctly estimate physical parameters such as the photometry, the shape and the position of the observed objects. Finally, we will present preliminary results concerning the estimation of the shift-variant blur in practice.

9909-283, Session PThu2

PSF Reconstruction for the Keck integral-field spectrograph OSIRIS

Tuan Do, Gunther Witzel, Breann N. Sitarski, Michael P. Fitzgerald, Andrea M. Ghez, Univ. of California, Los Angeles (United States); Jessica R. Lu, Institute for Astronomy (United States); James E. Lyke, Randall D. Campbell, W. M. Keck Observatory (United States)

We discuss a method for predicting laser guide-star adaptive optics (LGS AO) point spread functions (PSFs) on an integral-field spectrograph (IFU) based on off-axis parallel imaging and measurements of atmospheric turbulence. Because the field of view of IFUs are very small, it is often not possible to sample the PSF over a large radial range. For extended sources, it is even more difficult to obtain reliable estimates of the PSF. The OSIRIS instrument on the Keck I telescope consists of both an imager and an IFU that can be used simultaneously for PSF measurements. However, the center of the imager is separated by about 20" from the center of the IFU, so it is necessary to correct for anisoplanatism and differences in instrumental aberrations between the imager and IFU. This method begins with measurements of point sources with the imager to obtain an off-axis empirical PSF. Then, we use the knowledge of the atmospheric turbulence profile obtained with MASS/DIMM measurements, and measurements of the instrumental aberrations to deconvolve the empirical PSF to obtain an estimate on the spectrograph. We also model the wavelength dependence of the PSF as well as the effect of different integration times between the observations on the imager and the spectrograph. This technique is based on tools developed for AO PSF reconstruction with the NIRC2 imager on Keck. We will present preliminary results on observations of the Galactic center, where the crowding from stars make PSF determination especially difficult on the IFU. We will discuss metrics for the comparison such as the level residuals and the effect on the final signal-to-noise ratio of the extracted spectra. We will release these tools to the community at the end of the project.

9909-286, Session PThu2

Speckle statistics in adaptive optics images at visible wavelengths

Marco Stangalini, Filippo Ambrosino, Mauro Centrone, INAF - Osservatorio Astronomico di Roma (Italy); Dario Del Moro, Univ. degli Studi di Roma "Tor Vergata" (Italy); Fernando Pedichini, INAF - Osservatorio Astronomico di Roma (Italy)

Residual speckles in adaptive optics (AO) images represent a well known limitation to the achieve of the minimum contrast needed for faint stellar companions detection. Speckles in AO imagery can be either the result of residual atmospheric aberrations not corrected by the AO, or slowly evolving aberrations induced by the optical system. In this work we take advantage of new data with very high frame rate (1 KHz) acquired from the SHARK forerunner experiment at the Large Binocular Telescope (LBT), to provide a characterization of the AO residual speckles. By means of an automatic identification of speckles, we outline the main statistical properties of AO residuals at visible wavelength, and study the memory of the process, and the clearance time of the atmospheric aberrations, by using the information theory. These information are important either for increasing the realism of numerical simulations aimed at assessing the instrumental performances, or for the application of post-processing techniques on AO imagery.

9909-289, Session PThu2

A comparison between different coronagraphic data reduction techniques

Elena Carolo, INAF - Osservatorio Astronomico di Padova (Italy); Daniele Vassallo, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli studi di Padova (Italy); Jacopo Farinato, Maria Bergomi, INAF - Osservatorio Astronomico di Padova (Italy); Mariangela Bonavita, The Royal Observatory, Edinburgh (United Kingdom); Alexis Carlotti, Institut de Planétologie et d'Astrophysique de Grenoble (France); Davide Greggio, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli studi di Padova (Italy); Demetrio Magrin, Dino Mesa, INAF - Osservatorio Astronomico di Padova (Italy); Enrico Pinna, Alfio T. Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Marco Stangalini, INAF - Osservatorio Astronomico di Roma (Italy); Christophe Vérinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France); Valentina Viotto, INAF - Osservatorio Astronomico di Padova (Italy)

A solid post processing technique is mandatory for analysing the coronagraphic high contrast imaging data. Angular Differential Imaging (ADI) and Principal Component Analysis (PCA) are the most used approaches to suppress the quasi-static structure presents in the Point Spread Function (PSF) for revealing planets at different separation from the host star.

We present the comparison between ADI and PCA applied to SHARK-NIR, a coronagraphic camera which will be implemented at LBT. The

comparison has been carried out by using as starting point the simulated wavefront residuals of the Large Binocular Telescope Adaptive Optics (LBT AO) system, in different observing conditions.

Accurate tests for tuning the post processing parameters to obtain the best performance from each technique were performed with various seeing conditions (0.4" – 1.2") for star magnitude ranging from 8 to 12, with particular care in finding the best compromise between quasi static speckle cancellation and planets detection. The quasi static speckle contribution introduced in the simulations has been tuned based on real data observations performed on sky.

For the simple ADI version a reference PSF is obtained by taking the median of all images in the sequence (we also analysed the possibility to perform a second reference PSF subtraction using the median of few images as close in time as possible) and then subtracted to each image to remove the quasi-static structure. To mimic the real procedure, after the inclusion of fake planets in the simulated data-cubes, all the image differences are de-rotated to align the FoV and finally a final median is performed. A minimum FoV rotation of 30-50 degrees is considered, in order to make sure that even at small angular separations the signal from the possible companion after the subtraction would be largely preserved.

We evaluated also the implementation of the PCA techniques, that is based on a mathematical representation of each frame in the data-cube as a linear combination of its principal orthogonal components by selecting the structures present in most of the images. Its application has been reported to be very effective particularly by manipulation of the number of PCs to maximize the signal from the planet near its host star.

The detection limits are calculated using the ratio of simulated planets peak intensities over the noise in the residual image as a function of the angular separation, to take into account the cancellation value due to the used post processing technique.

9909-291, Session PThu2

Metrics and quality control with adaptive optics instruments at the VLT

Julien H. V. Girard, Julien Milli, European Southern Observatory (Chile); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Thierry Fusco, Jean-François Sauvage, ONERA (France); Markus E. Kasper, European Southern Observatory (Germany); Gérard Zins, European Southern Observatory (Chile); Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Jean-Luc Beuzit, Institut de Planétologie et d'Astrophysique de Grenoble (France); Zahed Wahhaj, European Southern Observatory (Chile); Johann Kolb, European Southern Observatory (Germany)

There are many Adaptive Optics (AO) fed instruments on Paranal and more to come. To monitor their performances and assess the quality of the scientific data, we have developed a scheme and a set of tools and metrics adapted to each flavour of AO and each data product. Our decisions to repeat observations or not depends heavily on this immediate quality control "zero" (QC0). Atmospheric parameters monitoring can also help predict performances . At the end of the data production chain chain, the user must be able to get data matching his/her needs translated into a set of requirements based on simulations done with an exposure time calculator (ETC). Predictions and real performances must match and the assessment must be intelligible to the community. We will emphasis on the difficulties encountered to perform quality control with SPHERE and the need for different metrics at various levels of wavefront: i.e Strehl ratio and FWHM for SCAO/LTAO/MCAO, contrast for an xAO, EE for GLAO, etc.

9909-296, Session PThu2

PSF reconstruction for the MUSE-GALACSI GLAO mode in Python

Manuel Silva, Instituto Superior Técnico (Portugal) and Univ. do Porto (Portugal); Thierry Fusco, Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Joana Ascenso, Instituto Superior Técnico (Portugal) and Univ. do Porto (Portugal); Paulo J. V. Garcia, Univ. do Porto (Portugal) and Instituto Superior Técnico (Portugal)

The use of AO systems is growing at an increasing rate and ESO is already preparing the next generation of AO instruments for both the VLT and the E-ELT.

Even though the corrected images obtained with these instruments are closer to the ultimate diffraction limit, the correction is not perfect, particularly in the case of a large Field of View. Thus, it is often necessary to use a posteriori image processing techniques in order to improve estimation of astrophysical data.

These techniques require accurate knowledge of the system's PSF in an arbitrary position in the Field of View. We present a PSF reconstruction software which estimates the PSF in the particular case of the MUSE/GALACSI instrument. It includes the Field of View location and wavelength dependencies.

9909-297, Session PThu2

The software package AIRY 7.0: new efficient deconvolution methods for post-adaptive optics data

Andrea La Camera, Univ. degli Studi di Genova (Italy); Marcel Carbillet, Univ. de Nice Sophia Antipolis (France); Marco Prato, Univ. degli Studi di Modena e Reggio Emilia (Italy); Patrizia Boccacci, Mario Bertero, Univ. degli Studi di Genova (Italy)

The Astronomical Image Restoration in interferometrY (AIRY) software package is a complete tool for the simulation and the deconvolution of astronomical images. The typical data can be a set of Fizeau interferometric multiple images as well as a more general case of post-adaptive-optics single image or even a mono-dimensional signal. Written in IDL and freely downloadable from both http://www.airyproject.eu and http://lagrange.oca.eu/caos websites, AIRY is a package of the CAOS Problem Solving Environment. It is made of different modules, each one performing a specific task, e.g. simulation, deconvolution, I/O, and visualization of the data.

In this paper we first present the last major release of AIRY with a short description of the whole set of modules. Then, we introduce a new optimized method for the deconvolution problem, based on the scaled-gradient projection (SGP) algorithm which has been recently extended with a set of regularization functions. The existing algorithms within the deconvolution module (DEC) are flanked by the new method proposed here. Moreover, we provide a brief description of the renewed DEC's graphical user interface.

Next, we introduce a new multi-component deconvolution (MCD) module, which contains a method developed in the last years by our group for deconvolving high dynamic range images. Indeed, in particular cases, the unknown object is made of one or more bright point-like sources superimposed on a fainter diffuse component. Our multi-component algorithm is able to separately reconstruct the two components. MCD uses the SGP-based new algorithms just introduced in DEC.

In the last part of the paper we describe our multi-step method, developed in 2015 by our group. This method is very useful, again, in the case of

high dynamic range images and it is an extension of the multi-component method. We give some example projects (provided together with the Software Package AIRY) in order to show each step and the main results achievable with this approach.

By using AIRY v.7.0, users have a powerful tool for simulating the observations and for reconstructing their real data.

9909-302, Session PThu2

Post-processing of multispectral images for exoplanets detection and characterization: the MEDUSAE algorithm

Faustine Cantalloube, Institut de Planétologie et d'Astrophysique de Grenoble (France) and ONERA (France); Marie Ygouf, Space Telescope Science Institute (United States); Laurent M. Mugnier, ONERA (France); David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France)

The new generation of high contrast instruments for ground-based telescopes that are dedicated to exoplanet imaging are all equipped with an Integral Field Unit (IFU), such as SPHERE/IFS, GPI and SCExAO/CHARIS in order to obtain spectra of the observed objects. Despite the advanced technologies constituting these instruments, they are still limited by the presence of quasi-statics speckles in the image field that are due to remaining instrumental aberrations. Advanced image processing tools can be used to separate these speckles from the scientific signals, taking advantage of the different spectral behavior of these two components.

MEDUSAE (Multispectral Exoplanet Detection Using Simultaneous Aberration Estimation) is an image processing method that specifically uses the spectral diversity of multispectral images to detect and characterize exoplanets. This method is based on an inverse problem solving algorithm, which jointly estimates the instrumental aberrations and the astrophysical scene. The multispectral redundancy is used to estimate the optical path differences and the positions of the companions, which are the same whatever the wavelength. The estimation is alternate between the speckle field (estimated thanks to a phase retrieval) and the object map (estimated via a non-myopic deconvolution).

This algorithm has been successfully validated on simulated data built with the same model than the one used to solve the inverse problem. We present results from the application of this algorithm on real data from the VLT/SPHERE-IFS instrument. In particular, we comment the discrepancy between the model and the real data, mostly about the coronagraph behavior compared to its model which is ideal (all the on-axis starlight is rejected). We also discuss which prior knowledge can be included in the algorithm, either from instrument calibrations or analytical estimations, to assess the static wavefront error and the turbulent wavefront residuals. We then present its overall performance on real data by analyzing on-sky images in which we injected fake companions to assess the detection and spectral extraction capabilities of MEDUSAE. Finally we present how it compares to other algorithms exploiting the temporal variation of the images that are widely used by the exoplanet direct imaging community because they are the most efficient in subtracting the starlight residuals. Also, the chosen approach brings useful insights regarding the co-design of the future ELT's instruments, together with their calibration procedures and the methods chosen to process the produced images.

9909-303, Session PThu2

ABISM: an interactive image quality and Strehl ratio measurement tool for adaptive optics instruments

Julien H. V. Girard, Martin Tourneboeuf, European Southern Observatory (Chile)

ABISM (Automatic Background Interactive Strehl Meter) is an interactive tool to evaluate the image quality of astronomical images. It works on seeing-limited point spread functions (PSF) but was developed in particular for diffraction-limited PSF produced by adaptive optics (AO) systems. In the VLT service mode (SM) operations framework, ABISM is designed to help astronomers or telescope operators to quickly measure the Strehl ratio (SR) during or right after an observing block (OB) to evaluate whether it meets the requirements/predictions or whether is has to be repeated and will remain in the SM queue. It's a Python-based tool with a graphical user interface (GUI) that can be used with little AO knowledge. The night astronomer (NA) or Telescope and Instrument Operator (TIO) can launch ABISM in one click and the program is able to read keywords from the FITS header to avoid mistakes. A significant effort was also put to make ABISM as robust (and forgiven) with a high rate of repeatability. As a matter of fact, ABISM is able to automatically correct for bad pixels, eliminate stellar neighbours and estimate/fit properly the background, etc. We present an update and a partial release of this handy quality control tool.

9909-306, Session PThu2

Detection of faint companions in multi-spectral data using a maximum likelihood approach

Kenneth Hanley, Nicholas Devaney, National Univ. of Ireland, Galway (Ireland); Éric M. Thiébaut, Ctr. de Recherche Astrophysique de Lyon (France)

Direct, ground-based exoplanet detection is an extremely challenging task requiring extreme adaptive optics (AO) systems and very high contrast. Dedicated planet hunters, such as SPHERE and GPI have been designed with these requirements in mind. Despite this, direct detection is still limited due to the presence of residual speckles.

Smith et al. (2009) describe a maximum likelihood estimation technique for the detection of exoplanets in speckle data in which the planet appears to rotate about a host star when observing with an alt-az telescope.

We propose the adaptation of this technique to operate on multi-spectral data, such as produced by the integral field spectrographs present on both SPHERE or GPI.

As the speckle pattern approximately scales smoothly with wavelength, it is possible to resample data to a single reference wavelength in which speckles will remain fixed in the wavelength dimension while any companions that are present will exhibit radial motion in a predictable manner. We simulate data comparable to SPHERE and with this, we compare the performance of our algorithm with other multi-spectral detection techniques, such as spectral deconvolution.

We compare the techniques using a ROC (Receiver Operating Characteristic) analysis.

Results have shown that the performance of our maximum likelihood algorithm is found to be superior at separations smaller than 0.5 arcseconds from the host star and comparable beyond that.

9909-308, Session PThu2

Point spread function reconstruction on the HeNOS bench

Luc Gilles, Thirty Meter Telescope (United States); Matthias Rosensteiner, NRC - Herzberg Astronomy & Astrophysics (Canada)

This paper reports on point spread function reconstruction (PSFR) work on the Herzberg NFIRAOS Adaptive Optics Simulator (HeNOS) bench at NRC-HIA. An initial set of experiments was carried out in March 2016 with the bench running in laser guide star (LGS) single-conjugate adaptive optics (SCAO) mode or laser tomography adaptive optics (LTAO) mode. We discuss data acquisition and data reduction. An analysis of angular and focal anisoplanatism is also carried out.

LGS multi-conjugate adaptive optics (MCAO) experiments are planned for the second half of 2016 and will be reported elsewhere.

9909-272, Session PThu3

E-ELT M4 adaptive unit final design and construction: a progress report

Roberto Biasi, Mario Andrighettoni, Gerald Angerer, Dietrich Pescoller, Mauro Manetti, Christian Patauner, Microgate S.r.l. (Italy); Daniele Gallieni, Matteo Tintori, Marco Mantegazza, Pierluigi Fumi, Lazzarini Paolo, A.D.S. International S.r.l. (Italy); Armando Riccardi, Runa Briguglio, Marco Xompero, INAF - Osservatorio Astrofisico di Arcetri (Italy); Giorgio Pariani, INAF - Osservatorio Astronomico di Brera (Italy); Elise Vernet, Lorenzo Pettazzi, Paul Lilley, Marc Cayrel, European Southern Observatory (Germany)

The E-ELT M4 adaptive unit is a fundamental part of the E-ELT: it provides the facility level adaptive optics correction that compensates the wavefront distortion induced by atmospheric turbulence and partially corrects the structural deformations caused by wind. The unit is based on the contactless, voice-coil technology already successfully deployed on several large adaptive mirrors, like the LBT, Magellan and VLT adaptive secondary mirrors. It features a 2.4m diameter flat mirror, controlled by 5316 actuators and divided in six segments. The reference structure is monolithic and the cophasing between the segments is guaranteed by the contactless embedded metrology. The mirror correction commands are usually transferred as modal amplitudes, that are checked by the M4 controller through a smart real-time algorithm that is capable to handle saturation effects. A large hexapod provides the fine positioning of the unit, while a rotational mechanism allows switching between the two Nasmyth foci.

The unit has entered the final design and construction phase in July 2015, after an advanced preliminary design. The final design review is planned for fall 2017; thereafter, the unit will enter the construction and test phase. Acceptance in Europe after full optical calibration is planned for 2022, while the delivery to Cerro Armazones will occur in 2023.

Even if the fundamental concept has remained unchanged with respect to the other contactless large deformable mirrors, the specific requirements of the E-ELT unit posed new design challenges that required very peculiar solutions. Therefore, a significant part of the design phase has been focused on the validation of the new aspects, based on both analysis, numerical simulations and experimental tests. Several experimental tests have been executed on the Demonstration Prototype, which is the 222 actuators prototype developed in the frame of the advanced preliminary design.

We present the main project phases, the current design status, and the most relevant results achieved by the validation tests.

9909-275, Session PThu3

Developments of piezo deformable mirrors

Hubert Pages, Tania Antonini, Tarik Aribi, Marie Aubry, Arnaud Bastard, Emmanuel Beaufort, Raphael Cousty, Gabrielle Dutey, Catherine Grèzes-Besset, Denis Groëninck, Hélène T. Krol, Nicolas Marchet, Aurélien Moreau, Pierre Morin, Richard Palomo, Jean-Christophe Sinquin, CILAS (France)

We present recent developments on deformable mirrors (DMs) for astronomy with ground-based telescopes. Pioneer in the field of adaptive optics, CILAS has developed and manufactured for many years piezoelectric deformable mirrors. CILAS current technology is based on two types of deformable mirrors: Stack Array Mirrors (SAM) and Monomorph mirrors (MONO).

SAM technology offers high order correction, with up to several thousands of actuators, controllable at high frequency, up to several kHz. We present developments performed in collaboration with European Southern Observatory (ESO) and Thirty Meter Telescope (TMT). A new generation of piezo actuators has been developed. Their reliability has been improved thanks to an optimization of the fabrication processes while keeping the required correction performances. Experimental results of accelerated ageing tests and mechanical fatigue are presented. This new generation of actuators is suitable for a large range of DMs, including future needs for Extremely Large Telescopes (ELTs).

Modelling analysis and operational feedback of previous DMs allowed the improvement of the design and the fabrication of CILAS piezo-stack DMs. We present the design and the modelling of next DMs for adaptive optics systems on next ELTs: multi-conjugate DMs for NFIRAOS instrument on the TMT and DMs for Multi-conjugate Adaptive Optics RelaY (MAORY) on the European Extremely Large Telescope (E-ELT).

Performances of SAM have a low dependence to environment and temperature. A DM prototype with high stroke has been designed and is under manufacturing to validate the behaviour of SAM at low temperature (-30C) for TMT.

CILAS monomorph technology benefits from the great history of bimorph mirrors which have been commonly used to correct atmospheric turbulences on astronomical telescopes since 1996. Compared to the bimorph technology, the monomorph presents an optimized architecture which secures its manufacturing and increases its reliability. The monomorph mirrors benefits from a return of experience of 10 years with an unfailing reliability on ground from astronomical telescopes (adaptive optics) to high power laser chains (active optics).

Important developments are on-going for space-borne instrumentation. The associated analyses and tests confirm the reliability and the sturdiness of the MONO technology. Compared to the former bimorph mirrors, MONO technology presents higher intrinsic performances (optical quality, stroke) which can be exploited in closed loop but also in open loop. In-situ return of experience on high power laser chains demonstrates the extreme stability of the monomorph operating in open loop during the laser shots. In addition, a novel approach was developed to cancel the natural drift of the piezoelectric ceramics in open loop operation (so called “creep” effect). For ground-based telescopes requiring real-time correction of atmospheric turbulences, a specific mechanical interface was developed to cancel the first Eigen frequencies of the mirror and thus to increase its bandwidth. This technological breakthrough allows astronomical telescopes to take advantage of the developments of monomorph mirrors for laser applications including their large pupils of 250 mm diameter and more.

9909-276, Session PThu3

GMTIFS: deformable mirror environmental testing for the on-instrument wavefront sensor

Michael Copeland, Francis Bennet, Gabriel J. Bloxham, Robert Boz, David Bundy, Brady Espeland, Ian Price, Francois Rigaut, Robert Sharp, The Australian National Univ. (Australia)

To achieve the high adaptive optics sky coverage necessary to allow the GMT Integral-Field Spectrograph (GMTIFS) to access key scientific targets, the on-instrument adaptive-optics wavefront-sensing system utilises a deformable mirror (DM) to provide an off-axis correction to the natural guide star. To avoid flexure concerns, this DM is located inside the instrument cryostat. Commercial off the shelf DMs are not able to operate in the cryogenic and vacuum environment of GMTIFS, therefore the DM must be housed in a windowed chamber within the instrument which is pressurised and warmed relative to the cryogenic environment. To reduce thermal emissions and additional heat load on the thermal control systems the temperature difference of the DM chamber and instrument is minimised. Thus a test is required to determine the lowest operating temperature at which the DM will meet the instrument performance requirements without significantly reducing reliability.

We will report on the optical system built to measure the performance of three DMs. Two continuous surface DMs are tested with the ALPAO DM69 and Boston Micromachines 492-DM. The third DM tested is an Iris AO PTT111 which is made of 37 individual piston, tip and tilt segments. These DMs provide an accurate representation for construction and performance of larger DMs which are considered for use in the GMTIFS OIWFS. The DMs are subject to a suite of static and dynamic tests where the surface of the DM is measured by a Shack Hartmann wavefront sensor (WFS). The WFS oversamples the DMs by approximately 4 subapertures per actuator to allow for measurement of the interactuator stroke. The WFS features a large dynamic range so resolution of between 1% of actuator stroke to full interactuator stroke is achieved, which gives a sensitivity of between <20nm and 5μm mirror surface deformations. High temporal sampling is also achieved for single actuator response measurements with sampling rates of at least 8kHz possible through region of interest selection.

Initial DM testing is conducted at room temperature to obtain a baseline for DM performance. The tests performed on the DMs measure the steady state mirror surface and actuator response while moving to a defined position. Cold testing will subject the DMs to identical tests with incrementally reducing temperatures. Tests are conducted down to a temperature of -60 degrees Celsius, however testing may cease at warmer temperatures if there is a risk of damage to the DMs. Comparison with the room temperature baseline tests provide an indication of the effects of cold temperatures to DM performance and any thermal effects to the structure such as surface ripple. The tests will determine the minimum temperature the DMs will operate within the instrument without significant performance degradation or increased risk of failure.

9909-284, Session PThu3

Long-term stability and temperature variability of Iris AO segmented MEMS deformable mirrors

Michael A. Helmbrecht, Carl J. Kempf, Franck Marchis, Iris AO, Inc. (United States) and SETI Institute (United States)

Iris AO has been developing microelectromechanical systems (MEMS) based deformable mirrors (DM) for a number of years. We currently manufacture two type of deformable mirrors, the PTT111 made of 37 hexagonal segments (111 actuators) and the PTT489 made of 163 hexagonal segments (489 actuators). Our mirrors are factory calibrated and can be positioned in piston and tip-tilt. This paper presents a study of the stability of several PTT111s deformable mirrors over about 2 years, focusing essentially on the stability of the open-loop positioning and the variability with temperature changes.

9909-288, Session PThu3

Development of a silicon carbide deformable mirror with 37 actuators for adaptive optics

Kyohoon Ahn, Univ. of Science & Technology (Korea, Republic of) and Korea Research Institute of Standards and Science (Korea, Republic of)

Adaptive optics (AO) were developed for military and astronomy applications, e.g., in telescopes to correct wavefronts distorted by the earth atmosphere and to obtain an undistorted image of stars and galaxies. Nowadays, AO systems have become more available and are used in various other fields including ophthalmology, microscopy, and underwater imaging. DMs used in high-power lasers (HPL), however, suffer from thermal distortion problems, where the energy absorbed by the DM due to the imperfect reflective coating distorts the faceplate and degrades the system performance. Therefore, DM for HPL systems must have an active or passive cooling system to dissipate the heat, and the proper selection of the faceplate material is also crucial.

In this paper, we deal with a silicon carbide (SiC) deformable mirror (DM) with 37 actuators for adaptive optics (AO). Compared with conventional optical glass materials, SiC has superior optomechanical properties, including extremely high specific stiffness and thermal conductivity and little distortion by thermal energy or pressure. Based on the study by Ealey et al (1992), we selected SiC as the faceplate material for the DM in HPL applications, as SiC has a high thermal diffusivity that effectively minimizes the mirror distortions due to thermal gradients. As a predecessor of the monolithic DM having active cooling channels inside, we developed a pilot DM made of silicon carbide (SiC) for HPL applications to verify the fabrication capability and actuation performances. The DM has a continuous SiC faceplate, the diameter and the thickness of which are 100 mm and 2 mm, respectively, and 37 stack-type piezoelectric actuators arranged in a rectangular grid. The faceplate is thick enough to embed monolithic cooling channels inside the faceplate in the next version. The faceplate without cooling channels presented in this paper has a high bending stiffness compared with glass DM's, and the proposed actuator configuration has a flexure support to reduce the shear stress at the adhesive while preserving optical performances. To examine the characteristics of the SiC DM, we simulated the influence functions (IFs) by using a finite element analysis (FEA) and then compared them with the IFs measured by using an optical interferometer. The IF describes the shape to which the mirror will deform when a voltage is applied to a single actuator. Using these IFs, we could estimate the command to make the final shape of the DM. Also, in order to verify bandwidth of the DM, we measured the response time of actuator and frequency response of the DM. The optical performance of the DM was verified by generating Zernike polynomials modes based on the IFs measured with the interferometer and by compensating arbitrarily distorted wavefront.

9909-292, Session PThu3

Research on the optimization of a bimorph piezoelectric deformable mirror-based on zeroth-order method

Hairen Wang, Purple Mountain Observatory (China)

The deformable mirror adjusts the mirror surface shape to compensate the wavefront error in the adaptive optics system. Recently, the adaptive optics has been widely used in many applications, such as astronomical telescopes, high power laser systems, etc. These applications require large diameter deformable mirrors with large stroke, high speed and low cost. Thus, the bimorph piezoelectric deformable mirror, which is a good match for the applications, has attracted more and more attentions. In this paper, we use zeroth-order optimization method to optimize the physical parameters of a bimorph piezoelectric deformable mirror that consists of a metal reflective layer deposited on the top of a slim piezoelectric ceramic surface layer. The electrodes are deposited on the bottom of the piezoelectric ceramic layer. The physical parameters to be optimized include the optimal thickness ratio between the piezoelectric layer and reflective layer, inter-electrode distance, and so on. A few reasonable designs are obtained by a comparative study presented for three geometries of electrodes, which are circular, square and pentagon, respectively.

9909-294, Session PThu3

Bimorph Mirrors for Adaptive Optics in Space Telescopes

David Alaluf, André Preumont, Horodinca Mihaita, Univ. Libre de Bruxelles (Belgium); Ioan Burda, Univ. Babes-Bolyai (Romania); Grégory Martic, BCRC Inisma (Belgium); Renaud P. Bastaits, Univ. Libre de Bruxelles (Belgium)

This paper considers the design of deformable mirrors to be used as wavefront correctors for space telescopes. These are intended to compensate for manufacturing errors, gravity release and thermal distortion affecting large lightweight, low-cost Aluminium primary mirrors. The mirror consists of a unimorph design actuated with an array of piezoelectric (PZT) actuators operating in the d31 mode.

The first part of the paper reviews the merit of various possible configurations proposed in the literature with respect to their thermal stability, natural frequency and control authority (deformation amplitude). Some new configurations are suggested.

The second part describes a demonstrator developed on behalf of ESA. It consists of a single-crystal Silicon wafer (D=75 mm t=500µm) actuated with a PZT actuator with 25 independent electrodes. It is mounted on an isostatic support that allows the control of the rigid-body motion (Figure 1). The PZT actuating layer is glued under electrical voltage, in order to allow to be operated with a constant bias (single sided operation, V>0). The keystone electrode pattern is done by laser ablation and is modified to include the feeding tracks, in such a way that the electrical connections are outside the pupil. This mirror has demonstrated the capability to control the first 15 Zernike modes with a RMS error < lambda nm in a pupil of 30 mm (< lambda/20 for lambda=633nm). The first natural frequency is 245 Hz. Environmental tests are under way.

9909-299, Session PThu3

Development of a compact space-capable deformable mirror controller

Eduardo A. Bendek, Dana H. Lynch, Ruslan Belikov, NASA Ames Research Ctr. (United States); Pedro Godoy, Teilch LLC (United States)

Direct imaging exoplanet missions require a Starlight Suppression System (SSS) to observe exoplanets around nearby stars. An SSS that uses an internal coronagraph requires controlling the wavefront error level down to nanometer or even angstrom level to avoid starlight contamination or speckles.

With standard high-quality optics and a modern coronagraph such as the Phase Induced Amplitude Apodization (PIAA) contrasts are limited to 1x10-5 due to optics aberrations and alignment errors. To overcome this challenge current direct imaging exoplanet testbed demonstrators utilize a Deformable Mirror (DM) to correct manufacturing and alignment wave front errors. Deformable mirrors have allowed different facilities to reach record contrast levels of 1x10-8 in air at the NASA Ames laboratory and 1x10-9 in vacuum at JPL.

Modern coronagraph utilizes at least 1,000 actuators with strokes of ~2?m which for many DM designs results in 200V potentials to be applied and a resolution of at least 14bits over the voltage dynamic range. These requirements result in bulky, heavy and high power consumption DM controllers that are not suitable for space missions, especially small ones.

We present the development and test results of a compact space-capable DM controller that is able to control a BMC Kilo-DM with 14bit resolution over 250V dynamic range. The controller will fit in a 0.5U volume, weights 0.5kg, and consumes less than 10W. Such a controller will enable small space telescope missions utilizing coronagraphs and will retire important risks for larger missions.

9909-321, Session PThu3

Fault-tolerant drive electronics for a Xinetics deformable mirror at GeMS DM0

Michael J. Barberio, Cambridge Innovations (United States)

Gemini South is replacing one of the (3) CILAS DMs with a 349-actuator Xinetics DM in its GeMS MCAO system. Xinetics mirrors operate over a 40-100V dynamic range and require that inter-actuator stroke differences are limited to half-scale; each actuator must be within 30V of its neighbor to prevent mechanical stress and possible face sheet separation. A robust way to implement this protection is to use high power transient voltage suppressors (TVSs) as a 2D-mesh between the amplifiers and mirror, but this has system implications. A sustained clamp condition dissipates significant power in the devices, and if an actuator fails as a short (which occurred once with the DM in a thermal chamber), the system is subject to a cascade failure event as multiple outputs drive the shorted actuator through the TVS network. This latter risk is readily resolved by using series fuses to the DM. In this third-generation driver, current sensing and logic inhibit amplifier outputs after a sustained TVS clamp condition or shorted output, and LED indicators show the location. Redundant thermal sensing is used on modular TVS row and column boards. A second 2D-mesh of high impedance resistors after the fuses will hold an unpowered channel to the average voltage of its neighbors, with a negligible influence function. A Failure Modes and Effects Analysis shows significant fault tolerance.

9909-58, Session 16

Review of the outer scale of the atmospheric turbulence *(Invited Paper)*

Aziz Ziad, Lab. J.L. Lagrange (France)

Outer scale is a relevant parameter for the experimental performance evaluation of large telescopes. The actual size of the outer scale has long been controversial, with measured values ranging from less than 10 m to more than 2 km. What is not controversial is the conclusion that when the diameter of the telescope approaches or exceeds the size of the outer scale, the optical consequences of atmospheric turbulence are changed dramatically from their traditional Kolmogorov behavior. In particular, power in the lowest Zernike aberration modes, e.g., tip and tilt and the overall stroke required for an Adaptive Optics (AO) system can be much reduced. A finite outer scale has implications for interferometry as well. With the current interest in the design of extremely large ground-based optical and infrared telescopes, reliable estimates of the outer scale profile

have assumed considerable importance.

Different techniques have been used for the outer scale L0 estimation. In situ measurements with radio-balloons have given very small local L0. The outer scale has also been estimated directly at the ground from the wave-front analysis from High Angular Resolution (HAR) techniques using interferometric or Shack-Hartmann or more generally AO systems data. Dedicated instruments have been also developed for the outer scale monitoring such as the Generalized Seeing Monitor (GSM) and the Monitor of Outer Scale Profile (MOSP). The measured values of outer scale from HAR techniques, GSM and MOSP are somewhat coherent and are larger than the in-situ results. The main explanation of this difference comes from the definition of the outer scale itself.

This paper aims to give a review of different techniques and instruments for the measurement of the outer scale. Comparisons of outer scale measurements will be discussed in light of the different definitions of this parameter and the associated observable quantities.

9909-59, Session 16

Local turbulence and its influence on adaptive optics performance at the GREGOR solar telescope

Detlev Sprung, Erik Sucher, Karin U. Stein, Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany); Oskar F. von der Lühe, Thomas Berkefeld, Kiepenheuer-Institut für Sonnenphysik (Germany)

The images of ground-based astronomical telescopes operating in visible or infra-red wavelengths are affected by turbulence in the Earth's atmosphere which, at a good astronomical site, is concentrated to layers close to the ground in daytime conditions. The resulting image degradation affects the performance of adaptive optical systems and causes residual aberrations in the science focus which reduce the spatial resolution of solar observations. Additional sources of turbulence are heating of the infrastructure close to the telescope and obstructions to a free air flow which otherwise would improve local seeing. These effects are usually a big concern for telescope operations, but difficult to detect and to monitor. So far, there is little knowledge about local influence of the infrastructure on the image quality of a solar telescope.

The strength of optical turbulence is determined by the structure function parameter of the refractive index Cn2. We investigate the temporal behavior of the free flow turbulence at the telescope dome level through continuous measurements of Cn2 using a laser scintillometer between the towers of the Vacuum Tower Telescope and of GREGOR at the Teide observatory at Tenerife in the Canary Islands since September 2012. In addition, local measurements of Cn2 are being taken in the vicinity of the GREGOR telescope using three ultrasonic anemometers since May 2015. Two anemometers are located at the north and south ends of the telescope platform, a third one can be placed close to the telescope. The comparison of the results of the four instruments is presented and discussed. It appears that the mountain ridge effects on turbulence are more relevant than any local causes of seeing close to the telescope. We compare the results of the turbulence effects with image quality indicators collected by the adaptive optics system GAOS at the GREGOR telescope

9909-60, Session 16

Modeling and prediction of non-stationary optical turbulence behavior

Niek Doelman, TNO (Netherlands) and Leiden Observatory (Netherlands); James Osborn, Durham Univ. (United Kingdom) and Ctr. for Advanced Instrumentation (United Kingdom)

Optical turbulence parameters, such as seeing angle, outer scale, isoplanatic angle and coherence time show temporal variability. Modelling and prediction of the temporal behaviour of the parameters is essential for the following reasons:

(1) the efficient scheduling of scientific programs and use of astronomical instruments,

(2) the tuning of AO systems and instruments towards the actual atmospheric condition,

(3) the simulation of astronomical instrument's performance under time-varying turbulence.

Furthermore, turbulence modelling and prediction can be used to:

(4) improve the adaptive tracking performance of Linear Quadratic Gaussian (LQG)-type controllers, as LQG controllers need to be tuned towards the specific turbulence conditions.

We have analysed integrated turbulence data from the Stereo-SCIDAR instrument (Durham University), installed at the 2.54m INT telescope, La Palma (2014 and 2015). Before model fitting, the pre-processing of data is crucial, in particular regarding: the non-uniform sampling intervals, missing samples and the non-negative values. It has turned out that a fractionally integrated stochastic model gives an accurate description of the temporal behaviour of the integrated seeing angle over 18 nights of Stereo-SCIDAR observations.

Based on the characteristics of this stochastic model we can conclude that the time series of the seeing angle is non-stationary. This implies that the variance of the forecast error will a) increase with the prediction horizon and b) will diverge for long predictions horizons. Similar modelling and forecast results have been obtained for the isoplanatic angle and the coherence time from the Stereo-SCIDAR measurements at INT.

Moreover, using data from 9 observing nights of the Generalized Seeing Monitor (GSM) at Paranal (2007), we have found that the temporal evolution of the turbulence outer scale can be captured by a similar stochastic model. Outer scale modelling and forecasting is of particular interest to Extremely Large Telescopes.

The paper discusses the time series pre-processing, the modelling procedure and the impact on turbulence parameter forecasting.

9909-61, Session 16

E-ELT turbulence profiling with stereo-SCIDAR at Paranal

James Osborn, Richard W. Wilson, Timothy Butterley, Timothy J. Morris, Cornelis M. Dubbeldam, Durham Univ. (United Kingdom); Frédéric J. Dérie, Marc S. Sarazin, European Southern Observatory (Germany)

Vertical profiles of the atmospheric optical turbulence strength and velocity is of critical importance for simulating, designing, and operating the next generation of instruments for the European Extremely Large Telescope. Many of these instruments are already well into the design phase, meaning these profiles are required immediately to ensure they are optimised for the unique conditions likely to be observed.

Stereo-SCIDAR is a generalised SCIDAR instrument which is used to characterise the profile of the atmospheric optical turbulence strength and wind velocity using triangulation between two stars. The data are analysed and made available to observatory systems in real-time. Stereo-SCIDAR has demonstrated the capability to resolve turbulent layers with the required vertical resolution to support wide-field ELT instrument designs. These high resolution atmospheric parameters are critical for design studies and statistical evaluation of on-sky performance under real conditions.

Here we report on the new Stereo-SCIDAR instrument installed on one of the Auxillary Telescope ports of the Very Large Telescope array at Cerro Paranal. Paranal is located approximately 20 km from Cerro Armazones, the site of the E-ELT. Although the surface layer of the turbulence will

be different for the two sites due to local geography, the high-altitude resolution profiles of the free atmosphere from this instrument will be the most accurate available for the E-ELT site.

In addition, these independent profiles can also be used to further characterise the site of the VLT. This can enable instrument performance calibration, optimisation and data analysis of, for example, the ESO Adaptive Optics facility and the Next Generation Transit Survey. It will also be used to validate atmospheric models for turbulence forecasting.

We show early results from the commissioning of the instrument and address future implications of the results.

9909-62, Session 17

The AIROPA software package: milestones for testing general relativity in the strong gravity regime with adaptive optics

Gunther Witzel, Univ. of California, Los Angeles (United States); Jessica R. Lu, Univ. of Hawai'i (United States); Andrea M. Ghez, Michael P. Fitzgerald, Breann N. Sitarski, Univ. of California, Los Angeles (United States); Randall D. Campbell, W. M. Keck Observatory (United States); Maxwell Service, Univ. of Hawai'i (United States); Tuan Do, Matthew C. Britton, Univ. of California, Los Angeles (United States); Keith Y. Matthews, California Institute of Technology (United States); Mark R. Morris, Eric E. Becklin, Univ. of California, Los Angeles (United States); Peter L. Wizinowich, W. M. Keck Observatory (United States); Gregory W. Doppmann, Univ. of Hawai'i (United States); James E. Lyke, Marc Kassis, Luca Rizzi, W. M. Keck Observatory (United States); Sam Ragland, Univ. of Hawai'i (United States); Scott J. Lilley, Univ. of California, Los Angeles (United States); Rachel Rampy, W. M. Keck Observatory (United States)

Adaptive optics (AO) near-infrared observation with NIRC2 @ Keck II has enabled us to monitor stellar orbits in the innermost arcsecond of the Galactic Center (GC), and led to the detection of the supermassive black hole and many unexpected findings about its environment. With almost two decades of data, continuing this experiment will allow us to test General Relativity in the strong-gravity regime starting in 2018. Our data analysis tool of choice is the IDL point spread function (PSF) fitting package, StarFinder, for extracting precise astrometry and photometry (Diolaiti et al. 2000). However, StarFinder does not fully account for the spatial variability of the PSF due to atmospheric anisoplanatism and instrumental aberrations as seen in NIRC2 images. Recently, it became evident that spatial variability of the PSF is one of the major sources of our remaining systematic uncertainty in AO astrometry and photometry.

The Galactic Center Group @ UCLA is in the final year of a project in which we have developed algorithms to predict how the PSF varies and incorporated them into a new software package: AIROPA (Anisoplanatic and Instrumental Reconstruction of Off-axis PSFs for AO). This software package makes use of independently measured atmospheric turbulence profiles and predicts the differential OTFs between different field positions. Based on ARROYO (M. Britton 2006), a set of C++ class libraries that aim to support simulations of electromagnetic wave propagation through turbulence and through optical systems, AIROPA includes C++ tools for predicting both natural guide star and laser guide star PSFs, as well as application program interfaces (APIs) for IDL. Furthermore, it provides an extensive set of IDL modules for Fourier-based PSF manipulation and for PSF modeling from any externally generated aberration maps. These IDL routines and APIs are integrated with a modified version of StarFinder.

In order to characterize the instrumental aberrations of NIRC2 we derived phase maps as a function of detector position from phase diversity measurements. These measurements show a differential wavefront error up to 220 nm across the detector. A detailed model of the instrumental PSF variability and its stability over time was developed. In order to make use of the new software in the context of astrometric measurements, a new distortion map for NIRC2 was derived from recent observations.

AIROPA configuration files provide easy adaptation to NIR instruments other than NIRC2. In this talk we present the summary of our project and the key developments that we intend to disseminate. We demonstrate that AIROPA predicts the observed differences in Strehl-ratio of up to ~5% under typical GC conditions in K-band (~10% in H-band) reliably, reduces PSF residuals by at least a factor of three in comparison to single-PSF analysis, and delivers more precise astrometry and photometry for stellar orbits at the Galactic Center and other NIRC2 projects. It is a milestone on the way to the measurements of general relativistic effects on stellar orbits.

9909-63, Session 17

Point spread function determination for Keck adaptive optics

Sam Ragland, W. M. Keck Observatory (United States); Laurent Jolissaint, Haute Ecole Spécialisée de Suisse Occidentale (Switzerland); Peter L. Wizinowich, W. M. Keck Observatory (United States)

W. M. Keck Observatory (WMKO) was the first to implement both natural guide star (NGS) and laser guide star (LGS) AO systems on a large telescope in order to achieve angular resolutions in the near-infrared that match the capabilities of the Hubble Space Telescope in the visible. Over 600 refereed science papers have been produced using the Keck AO systems. In addition to providing the first NGS and LGS AO facilities on a large telescope, WMKO has endeavored to continually improve the capabilities of these systems.

One of the primary scientific limitations of AO has been the incomplete knowledge of the point spread function (PSF), which has made it difficult to use AO for accurate photometry and astrometry in both crowded and sparse fields, for extracting intrinsic morphologies and spatially resolved kinematics, and for detecting faint sources in the presence of brighter sources. To address this we initiated a program to determine and demonstrate PSF determination for science observations obtained with Keck AO. The goal is to provide a PSF estimate for every point in the science field. The resulting capability of producing a high-fidelity PSF estimate will provide dramatic science gains and stands as one of the next major challenges for achieving further breakthroughs in high angular resolution science. This paper aims to give a broad view of the progress achieved in implementing this capability for Keck AO science observations.

The concept and the implementation are briefly described. Our approach involves (1) computing the guide star PSF from wave front sensor (WFS) measurements using the technique introduced by Jean-Pierre Véran et al. (1997), (2) determining low order aberrations that are apparently unseen by the wavefront sensor using on-sky phase diversity, and (3) computing the science PSF by applying anisoplanatic corrections to the guide star PSF using a modified version of the Arroyo software package written by Matthew Britton (2015).

The design and development of operational tools for automated PSF reconstruction is presented along with the latest on-sky results using the NIRC2 science instrument. The operational tool kit includes a database and data management tools to handle large volume of AO telemetry data and facilitate multitasking across multiple computers on the network.

On-sky performance of the technique is discussed by comparing the Strehl ratio and the full with half maximum (FWHM) of the reconstructed PSFs to that of the NIRC2 PSFs. Initial results from shared-risk science verification are also presented.

Results from a trade-off study comparing two sets of software tools for

atmospheric seeing estimation and non-common path static aberrations (one developed at the WMKO and the other at University of Applied Sciences Western Switzerland) are presented. The statistics on seeing conditions and telescope/AO performance over a two year period are also presented along with their impact on contributions from the individual PSF reconstruction error terms. The statistical results are discussed in the context of AO science with the current and future optical telescopes and instruments. The PSF algorithm development for this program is presented in a separate paper.

9909-64, Session 17

MOAO PSF reonstruction validated using on-sky CANARY data

Olivier Martin, Carlos M. Correia, Lab. d'Astrophysique de Marseille (France); Éric Gendron, Observatoire de Paris (France); Timothy J. Morris, Durham Univ. (United Kingdom); Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Yoshito H. Ono, Tohoku Univ. (Japan); Alastair G. Basden, Durham Univ. (United Kingdom); Fabrice Vidal, Observatoire de Paris (France); Thierry Fusco, Lab. d'Astrophysique de Marseille (France) and ONERA (France); Gérard Rousset, Observatoire de Paris (France); Richard M. Myers, Durham Univ. (United Kingdom)

We discuss a Real Time Computer (RTC)-based point spread function reconstruction (PSFR) algorithm for Laser Guide Stars (LGS)-assisted tomographic AO systems. Our approach consists in retrieving relevant system and turbulence parameters, as the seeing, layer strengths, outer scale and wind speed profiles. We then derive covariance matrices and pupil-averaged phase structure functions to get stationary Optical Transfer Functions (OTF) and thereupon PSFs.

The algorithm is a generalization of the error breakdown proposed for the MOAO pathfinder Canary developed by LESIA and Durham University: the residual OTF is split into a product of several OTFs, each representative of an error term. We describe how each of these OTFs is determined and their variation as a function of the inputs provided by the RTC.

Based on the post-processing of a large amount of on-sky data we show statistics of the PSFR and demonstrate our ability to reliably reconstruct the PSF.

The prospects of scaling this approach to ELTs, in particular in the context of the Harmoni project are also considered.

9909-65, Session 17

Exploiting physical constraints for multi-spectral exoplanet detection

Éric M. Thiébaut, Ctr. de Recherche Astrophysique de Lyon (France); Nicholas Devaney, National Univ. of Ireland, Galway (Ireland); Maud P. Langlois, Ctr. de Recherche Astrophysique de Lyon (France); Kenneth Hanley, National Univ. of Ireland, Galway (Ireland)

The residual speckles due to the host star set the most serious limitation in the detection of exo-planets in high contrast coronographic images provided by instruments such as SPHERE or GPI. Instead of working on image differences, we propose to tackle the exo-planet detection as an inverse problem where the residual speckles and the exo-planet parameters (position and spectrum) are jointly estimated from a set of multi-spectral images and, possibly, multiple exposures. In order to reduce the number of degrees of freedom, we impose specific constraints on the spatio-spectral distribution of stellar speckles. These constraints are deduced from the multi-spectral Taylor series expansion of the diffraction pattern for an on-axis source which implies that the speckles are a combination of spatial modes with deterministic chromatic magnification and weighting. We show how a practical way to solve the difficult problem of joint estimation of all the parameters given the data. For instance, the non-trivial problem of the estimation of the spatial modes and the spectral weights is solved by a low-rank approximation method. Thanks to the physically motivated constraints on the stellar leakage, optimal speckle suppression is achieved without the need to introduce additional heuristic parameters. As a by-product, our approach yields the maximum likelihood estimator of the planet spectral energy distribution (SED) and its covariance. The proposed method is versatile and can take into account any kind of multi-variate data. We present results based on both simulated and real data from the integral field spectrograph of SPHERE.

9909-66, Session 17

Measurement and correction of distortion for optimal image stacking in wide-field multi-conjugate adaptive optics: application to GeMS data

Anais Bernard, Benoît Neichel, Lab. d'Astrophysique de Marseille (France); Laurent M. Mugnier, ONERA (France); Manash R. Samal, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, ONERA (France) and Lab. d'Astrophysique de Marseille (France); Morten Andersen, Gemini Observatory (Chile); Annie Zavagno, Lab. d'Astrophysique de Marseille (France); Christopher J. Evans, UK Astronomy Technology Ctr. (United Kingdom); Henri Plana, UESC (Brazil)

The advent of a new generation of Wide Field Adaptive Optics (WFAO) systems marks the beginning of a new era in high spatial resolution imaging. By using multiple Laser Guide Stars (LGS), WFAO significantly increases the field of view of the AO-corrected images, and the fraction of the sky that can benefit from such correction. The newly commissioned Gemini South Multi-Conjugate Adaptive Optics System (GeMS) combined with the infrared camera GSAOI is delivering almost diffraction- limited images over a field of ? 2 arc-minutes across. However, despite the excellent performance of the GeMS/GSAOI system, the correction provided is not perfectly uniform and may generate variable Point Spread Function (PSF) over the field. The ability to deal with those PSF variation is critical for high-precision astrometry and photometry studies. In a first part of this paper we expose the existing photometric tools, their performance and limitations. We also present upgrades implemented using the current photometric tool STARFINDER to adapt it to variable PSF over the field of view. This analysis is done using simulated as well as on sky data obtained with the GeMS/GSAOI system : a recent observations of a very active and young star-forming region N-159W located in the Large Magellanic Cloud. We obtained deep J,H, and Ks images in order to study the properties of the cluster stellar members and bring new elements to our understanding of the massive star formation process. In a second part of this paper, we pay attention to a phenomena that critically amplify the PFS variation over the field and can strongly degrade the resolution and reduce the sensitivity when combining multiple frames : the optical distortion introduced by the optical components present in the telescope and the instruments. In particular, GSAOI is severely affected by static and quasi-static distortion that may vary from one frame to another. We investigate here, an optimal way to correct for the distortion following an inverse problem approach based on the work presented in Gratadour et al. (Astron. Astrophys., 443 :357–365, November 2005.) on image re-centering, but generalized to all distortion modes. In this paper we present the formalism as well as simulation results. We also show first application on real data and we confront our method with existing tools.

9909-67, Session 18

The GMT active and adaptive optics control strategies

Rodolphe Conan, Antonin H. Bouchez, Fernando Quirós-Pacheco, GMTO Corp. (United States); Brian McLeod, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The Giant Magellan Telescope (GMT) has a Gregorian 25.4-meter diameter primary mirror composed of seven 8.4-meter diameter segments.

The secondary mirror consists of seven 1.1-meter diameter segments.

In the active and adaptive operation modes of the GMT, around a dozen wavefront sensors are selectively used to monitor the optical aberrations across the focal plane.

A dedicated wavefront control system drives slow and fast corrections at the M1 and M2 mirrors to deliver image quality optimized for the field of view of the scientific instrument in use.

This paper describes the control strategies for the active and adaptive optics modes of the GMT.

Different wavefront estimation algorithm are compared and the performance of the GMT, in the different observing modes, is evaluated using the Dynamic Optical Simulation package.

9909-68, Session 18

AOF laser tomography mode: reconstruction strategy and first test results

Sylvain Oberti, Johann Kolb, Miska Le Louarn, Pierre-Yves Madec, Paolo La Penna, Robert H. Donaldson, Christian Soenke, Marcos Suárez Valles, Robin Arsenault, European Southern Observatory (Germany)

GALACSI is the Adaptive Optics (AO) system serving the instrument MUSE in the framework of the Adaptive Optics Facility (AOF) project. GALACSI offers two AO correction modes:

- The Wide Field Mode (WFM) is a Ground Layer AO (GLAO) mode delivering a homogeneous PSF across a FoV of 1' diameter. The results obtained during the WFM system tests are described in another paper at this conference (J. Kolb et al.)

- The Narrow Field Mode (NFM) is a Laser Tomography AO (LTAO) mode delivering high resolution in the visible across a small FoV of 7.5" diameter around the optical axis.

GALASCI NFM relies mostly on the same main subsystems as the WFM, i.e. a Deformable Secondary Mirror (DSM) with 1156 voice coil actuators in the pupil, controlled by 4 Laser Guide Star (LGS) Shack-Hartmann (SH) Wave Front Sensors (WFS) composed of 40x40 subapertures of 6x6 pixels, via the Real Time Computer (RTC) SPARTA. The main difference with respect to the WFM comes from the fact that instead of a simple visible Tip/Tilt sensor, GALACSI NFM makes use of a Low Order (LO) Natural Guide Star (NGS) loop correcting Tip/Tilt and Defocus thanks to an InfraRed (IR) 2x2 SH-WFS. An adaptive vibration tracking algorithm is applied along these three modes to cancel vibrations whose frequency is higher than the AO correction bandwidth.

From a reconstruction standpoint, GALACSI NFM intends to optimize the correction on axis by estimating the turbulence in volume via a tomographic process, then projecting the turbulence profile onto one single DM located in the pupil, close to the ground.

In this paper, the laser tomographic reconstruction process will be described. Several methods (virtual DM, projection method) will be studied, under the constraint of a single matrix vector multiplication. The LTAO interaction matrix model design will be analysed and the reconstruction parameter space will be explored, in particular the number of reconstructed layers and the regularization terms.

Furthermore, we will present the strategy to define the controlled modal basis and split the control between the LO loop and the HO loop.

Finally, closed loop performance obtained with a 3D turbulence generator on the ASSIST test bench will be analysed with respect to the most relevant system parameters to be tuned.

9909-69, Session 18

Fast tomographic reconstructors for ELT-sized wide field of view AO systems

Ronny Ramlau, Daniela Saxenhuber, Johannes Kepler Univ. Linz (Austria); Roland Wagner, Johann Radon Institute for Computational and Applied Mathematics (Austria)

Wide field of view Adaptive Optics (AO) systems, such as Multi-Conjugate Adaptive Optics (MCAO), Laser Tomography AO (LTAO) and Multi-Object AO (MOAO), require an accurate reconstruction of the turbulent atmosphere in order to obtain a good correction over a large field of view. For the upcoming generation of Extremely Large Telescopes (ELT), with mirror diameters of up to 40m, this involves the solution of huge systems under restrictive time constraints. Therefore, fast reconstruction algorithms for atmospheric tomography are needed.

In this talk, we analyze the problem of atmospheric tomography, review and study the performance of fast iterative methods, such as the wavelets based FEWHA (Finite-Wavelet Hybrid Algorithm), the Gradient-based method and the Kaczmarz algorithm. All of these iterative algorithms solve the tomography problem in a functional setting, i.e. without any matrix-vector-multiplication. Thus, they scale linearly with the number of unknowns, and exhibit superior speed performance.

Furthermore, we present several new approaches for improvements in the field of atmospheric tomography: In the context of MCAO, a combined approach for PSF reconstruction throughout atmospheric tomography is described along with a new algorithm for the DM fitting step.

Our PSF reconstruction algorithm combines existing, verified techniques in a novel way to deliver accurate field dependent PSFs in very short time.

Novel approaches for cost reduction via compression of the reconstruction profile before as well as during tomography itself are presented. On the one hand this consists of a compression algorithm to determine the optimal reconstruction profile from a given atmospheric model. On the other hand, a joint optimization of tomographic reconstruction and layer profile that serves as model reduction is presented.

Our simulation results are obtained on OCTOPUS, the ESO end-to-end simulation tool. For a variety of atmosphere and system parameters, they suggest a good qualitative performance along with a considerable reduction of computational effort.

9909-70, Session 18

20 kHz real-time control system for adaptive optics

Tuan Truong, Rick S. Burruss, Jennifer E. Roberts, Lewis C. Roberts Jr., Jet Propulsion Lab. (United States); Chris Shelton, Jet Propulsion Lab. (United States)

GPU-based systems have become the standard for low latency adaptive optics real-time control systems. While GPU systems are able to meet latency requirements of many instruments in operation today, they are limited in their processing capability by two factors: the lack of GPU support for application-level direct access to PCI Express and the absence

of frame grabbers with application-tuned DMA transfer size capability. We present here a multi-DSP based real-time control system for adaptive optics that leverages on the PCI Express multicast capability and DMA-tuned frame grabbers to deliver processing rates in excess of 20 kHz and a latency in single-digit microsecond range for 56x64 pixel frames.

9909-71, Session 19

NGS2: a focal plane array upgrade for the GeMS multiple tip-tilt wavefront sensor

Francois Rigaut, Francis Bennet, Ian Price, The Australian National Univ. (Australia); Vincent Garrel, Gemini Observatory (Chile); Celine d'Orgeville, Research School of Astronomy & Astrophysics (Australia); Chadwick A. Trujillo, Vanessa Montes, Gemini Observatory (Chile)

GeMS, the Gemini Multi-Conjugate Adaptive Optics System, is currently using an Avalanche Photo Diode (APD) based Natural Guide Star Wavefront Sensor (NGSWFS). APDs are well suited to the low counts generally dealt with, but unfortunately they are rather bulky and difficult to integrate into optics. The current NGSWFS is using a rather complex optical design, with pyramids in the focal plane, feeding the light to fibres, that transmit it to the APD themselves. Optical component are tiny, and very difficult to align. The current optical throughput has been measured to be around 4%, reducing drastically the sensitivity of the NGSWFS and impacting directly GeMS sky coverage (around 6% instead of the 30% initially specified). We will present NGS2, an upgrade for the GeMS NGSWFS based on a single focal plane array, from which up to three Regions of Interest (ROIs) are read. NGS2 is using a Nuvu HNu512 EMCCD detector, the first available high sensitivity science array available with multiple ROI capability, providing frame rate of up to 800Hz with three 8x8 pixel windows. We will report on the design, detector characterisation, system performance, as well as on sky results, if available. We will also discuss the advantages and challenges of this type of focal plane array design compared with more conventional design (e.g. the current APD-based multiple guide probe design), in light of sensitivity, operational and astrometric considerations.

9909-72, Session 19

Validation of tomographic laser guide star uplink tip-tilt determination with CANARY

Andrew P. Reeves, Timothy J. Morris, Richards M. Myers, Alastair G. Basden, Durham Univ. (United Kingdom); Éric Gendron, Carine Morel, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); James Osborn, Durham Univ. (United Kingdom); Gérard Rousset, Fabrice Vidal, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France)

Laser Guide Stars (LGS) have greatly increased the sky-coverage of Adaptive Optics (AO) systems, but due to the up-link turbulence experienced by LGSs, a Natural Guide Star (NGS) is still required for tip-tilt correction. This limits sky-coverage to areas where bright NGS are available. For many scientifically interesting areas of the sky, this is not the case, curtailing the impact of ground based astronomy. A method has recently been presented which promises to determine the LGS uplink tip-tilt in tomographic LGS AO systems by using the fact that each LGS Wave Front Sensor (WFS) in a tomographic AO system observes the uplink path of other LGSs. It has been shown through simulation that tip-tilt information from high altitude turbulence can be determined from LGS alone leaving only contributions from turbulence near the ground. As low altitude turbulence is common to a large field, it is then possible to use NGS further from the science target to obtain the remaining tip-tilt information. Such a technique has the potential to greatly increase the sky-coverage of Multi-Object, Laser Tomographic and Multi-Conjugate AO systems by allowing further off-axis NGS tip-tilt stars to be used for correction. For certain low spatial resolution scientific applications, it may even allow the entire sky to be observed with no tip-tilt NGS.

Here, we summarise the LGS tip-tilt retrieval method and show results from simulation that show the determination of high altitude tip-tilt. The increase in allowed off-axis tip-tilt NGS position is estimated, and thus the increase in sky coverage of tomographic AO systems. We also assess the performance of tomographic LGS AO systems with no tip-tilt NGS correction. Previously, the method required simulated covariance matrices to form a LGS tip-tilt retrieving tomographic reconstructor, which would not be practical to create for real AO systems. An analytical approach to creating those matrices, where LGS uplink turbulence is included, is described, allowing a "Learn and Apply" type approach to be followed, opening the algorithm for use with on-sky AO systems. We finally present analysis of open loop wave front sensor data from the CANARY Multi-Object AO demonstrator, which features four LGS in a tomographic configuration, with an on-axis "truth" WFS observing in the direction of a science target. This analysis validates that the technique works with on-sky AO systems.

9909-73, Session 19

Anti-aliasing optical method for Shack Hartmann WFSs

Glen Herriot, Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada)

Measurement errors due to aliasing in a Shack-Hartmann WFS are typically 40% larger in variance than the fitting error of an AO system. On bright stars, aliasing is the dominant error within the control radius of the deformable mirror. Wavefront spatial frequencies beyond the WFS' Nyquist frequency corrupt measurements below this frequency. A common misconception is to think that aliasing primarily affects the higher spatial frequency measurements. But in fact aliasing propagates to the lowest order modes, and corrupts even tip/tilt. There are many examples including the observation that the temporal power spectrum of measured tip/tilt from a WFS does not correspond to Kolmogorov theory. We propose a simple optical modification to a SH WFS (borrowed from the digital video camera industry), and present simulation results showing that the aliasing errors are dramatically reduced.

9909-74, Session 19

The QACITS pointing sensor: from theory to on-sky operation on Keck/NIRC2

Elsa Huby, Olivier Absil, Univ. de Liège (Belgium); Dimitri Mawet, California Institute of Technology (United States); Bruno Femenia-Castella, W. M. Keck Observatory (United States); Michael Bottom, California Institute of Technology (United States); Pierre Baudoz, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Henry Ngo, California Institute of Technology (United States); Eugene Serabyn, Jet Propulsion Lab. (United States)

Small inner working angle coronagraphs are essential to benefit from the full potential of large and future extremely large ground-based telescopes, especially in the context of the detection and characterization of exoplanets. Among existing solutions, the vortex coronagraph, and in particular the AGPM (Annular Groove Phase Mask, a sub-wavelength

grating creating a vortex phase of charge 2), stands amongst the most effective and promising solution. However, a small inner working angle comes necessarily with a high sensitivity to pointing errors. This is the reason why a pointing control system is imperative to stabilize the star on the vortex center against pointing drifts due to mechanical flexures, that generally occur during observation due for instance to temperature variations.

We have therefore developed a technique called QACITS (Quadrant Analysis of Coronagraphic Images for Tip-tilt Sensing), which is based on the analysis of the coronagraphic image shape to infer the amount of pointing error. We show that the flux gradient in the image is directly related to the amount of tip-tilt affecting the beam. The main advantage of this technique is that it is does not require any additional setup and it can thus be easily implemented on all current facilities equipped with a vortex phase mask.

In this presentation, we will introduce the theoretical model we have derived to predict the shape of the image in presence of low-order aberrations in a vortex coronagraph. For that purpose, we have based our computations on Zernike formalism. This basis has turned to be very convenient to derive the effect of a vortex phase on small aberrations. The results of these developments can be summarized with an aberration conversion table between the entrance and exit pupil (Lyot) of the coronagraph. For instance, a given tip-tilt mode is redistributed onto both tip-tilt modes after the coronagraph, while a defocus aberration is turned into astigmatism, and conversely, astigmatism is turned into defocus.

Finally, we will present our latest results obtained with an L-band AGPM commissioned at Keck/NIRC2 in June and October 2015, validating the theoretical model on-sky. A close-loop correction was implemented and successfully tested on-sky, in conjunction with a speckle nulling correction. The algorithm operates in three steps: flux and background calibration, alignment optimization and science acquisition sequence. It has been designed to be easily handled by any user observing in vortex mode. We show that the QACITS algorithm stabilizes the star down to 0.027 lambda/D (2mas) rms in average, and down to 0.013 lambda/D (1mas) rms in the best cases. This pointing sensor is mainly correcting for drifts that affect the beam at the rate of up to 0.04 lambda/D per mn, while the speckle nulling map was correcting for quasi-static aberrations. To conclude, we will present the contrast curve achieved with this correction.

9909-75, Session 19

The coronagraphic modal wavefront sensor: focal-plane sensing for high-contrast imaging

Michael J. Wilby, Christoph U. Keller, Leiden Observatory (Netherlands)

Non-Common Path Errors (NCPEs) are one of the dominant factors limiting the performance of current astronomical high-contrast imaging instruments. If uncorrected, the resulting quasi-static speckle noise floor limits the achievable raw contrast to typically 10-3-10-4, a value which does not improve with increasing integration time.

The coronagraphic Modal Wavefront Sensor (cMWS) is a hybrid phase optic which uses holographic PSF copies to supply focal-plane wavefront sensing information directly to the science camera, whilst also maintaining a bias-free coronagraphic PSF. The initial concept has been successfully implemented on-sky at the William Herschel Telescope (WHT), La Palma (Wilby et al., in prep.), demonstrating both real-time wavefront sensing capability and successful extraction of slowly varying wavefront errors under a dominant and rapidly changing atmospheric speckle foreground.

In this work we present an optimised cMWS capable of efficient NCPE correction using only a limited number of tailored sensing modes. We assess sensor performance under realistic observing conditions, pending on-sky closed-loop testing with the Leiden Adaptive Optics Testbed at the WHT.

Conference 9910: Observatory Operations: Strategies, Processes, and Systems VI

SPIE. ASTRONOMICAL TELESCOPES + INSTRUMENTATION

Monday - Friday 27–1 July 2016

Part of Proceedings of SPIE Vol. 9910 Observatory Operations: Strategies, Processes, and Systems VI

9910-1, Session 1

Operational metrics for the ESO Very Large Telescope: lessons learned and future steps

Francesca Primas, Stéphane Marteau, Lowell E. Tacconi-Garman, Vincenzo Mainieri, Sangeeta Mysore, Marina Rejkuba, Michael Hilker, Ferdinando Patat, Michael Sterzik, European Southern Observatory (Germany); Andreas Kaufer, Steffen Mieske, European Southern Observatory (Chile)

When ESO's Very Large Telescope started its operations in April 1999 it was the first ground-based facility to offer to the scientific community at large access to an 8-10m class telescope with both classical and queue observing. The latter was considered to be the most promising way to ensure the observing flexibility necessary to execute the most demanding scientific programmes under the required, usually very well defined, conditions.

Since then new instruments have become operational and 1st generation ones replaced, filling the 12 VLT foci and feeding the VLT Interferometer and its four Auxiliary Telescopes. Efficiently operating such a broad range of instruments installed and available every night of the year on four 8-metre telescopes offers many challenges. Although it may appear that little has changed since 1999, the underlying VLT operational model has evolved in order to accommodate different requirements from the User Community and features of new instruments.

Did it fulfil its original goal and, if so, how well? How did it evolve? What are the lessons learned after more than 15 years of operations? A careful analysis and monitoring of statistics and trends in Phase 1 and Phase 2 has been deployed under the DOME (Dashboard for Operational Metrics at ESO) project. The main goal of DOME is to provide robust metrics that can be followed with time in a user-friendly manner. Here, we summarize the main findings on the handling of service mode observations and present the most recent developments.

9910-2, Session 1

The impact of science operations on science return at the Very Large Telescope

Michael Sterzik, Uta Grothkopf, European Southern Observatory (Germany); Andreas Kaufer, European Southern Observatory (Chile); Bruno Leibundgut, European Southern Observatory (Germany); Steffen Mieske, European Southern Observatory (Chile); Ferdinando Patat, Marina Rejkuba, Martino Romaniello, Lowell E. Tacconi-Garman, European Southern Observatory (Germany)

The operational implementation of observing programmes influences the scientific return of an Observatory. More than 15 years of observations with the VLT/Paranal Observatory allow us to assess the impact of science operations and programme implementation on its scientific performance. Bibliometric parameters are used to derive programme productivities and their relation to scheduling implementation (such as service and visitor mode) and programme types.

In this contribution we present a set of performance indicators comparing specific programme implementation and execution parameters.

Results of this analysis help us to identify strengths and weaknesses of the operational model adopted. It may entail improvements for an integrated VLT and ELT operations scheme in the next decade.

9910-3, Session 1

Improving SALT productivity by applying the theory of constraints

Johannes C. Coetzee, South African Astronomical Observatory (South Africa); Petri Vaisanen, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa); Darragh E. O'Donoghue, The SALT Foundation (South Africa); Johan Kotze, Encarni Romero Colmenero, Brent Miszalski, Steven M. Crawford, Alexei Kniazev, Eric Depagne, Paul Rabe, Christian Hettlage, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa)

SALT, the Southern African Large Telescope, is a very cost effective 10 m class telescope. This statement is based on its low initial capital investment and annual operating cost. The cost per refereed science paper is currently in the order of $70,000 (based on 32 papers published in 2015).

To achieve this competitive advantage, specific design trade-offs had to be made. The biggest constraint is the fact that the telescope structure is fixed in elevation, at 37 degrees from the zenith. The movable tracker provides ± 6 degrees deviation from the fixed elevation. This constraint restricts the observation annulus from -43 degrees to -31 degrees from the zenith. Despite these constraints, the fully queue-scheduled telescope can observe more than 70% of the sky available from Sutherland.

On the other hand, the telescope has many advantages, such as being able to switch between different instruments and observing modes during the night.

The SALT Operations team (integrated astronomy and technical teams) applied the principles of the theory of constraints to review the entire "science generation" process. The Theory of Constraints, by Dr. Eliyahu M. Goldratt, is a well-known and widely applied industrial engineering technique used to improve the productivity of a manufacturing or similar processes. Our goal was to identify how more observations could be done with the telescope and its instruments in its current configuration without spending large amounts of money on modifications and upgrade projects. Constraints were identified throughout the process starting from the PIs program proposals to their Time Allocation Committees (TACs), through to published refereed papers.

A 5-point plan was developed to address constraints:

1. Better interaction with PIs and TACs to advise them of how to achieve better results by taking into account telescope and instrument advantages and limitations.

2. Better simulation and scheduling tools. Simulating the probabilities of observing Priority 0 to P4 targets during the semester. This simulation determines what and how many programs could be completed during the semester. Another tool calculates the probability of observing a specific target during the semester. A scoring algorithm helps the astronomer to make optimised observation decisions during the night despite rapidly changing weather, humidity and seeing conditions.

3. Prioritized projects aimed at yielding better data quality and

productivity. These projects are beyond the scope of this paper but typically include the new edge sensor system for the primary mirror (SAMS). This system will reduce downtime and improve image quality.

4. Dashboard and Fault Tracking System to measure contracted metrics. They include for example, science time, number of observations, downtime, faulty, etc. and numbers of refereed papers published. The fault tracker provides details and durations of sub-systems causing downtime.

5. Interacting with PIs regarding the status of their data and helping them to process the data, if required, to publish refereed papers.

This 5-point plan resulted in better synergy, focus and coordination of the SALT Operations team. The end result is that the previous record number of observations per semester was beaten by 16%.

9910-4, Session 1

A bibliometric analysis of observatory publications for the period 2009-2013

Dennis R. Crabtree, NRC - Herzberg Astronomy & Astrophysics (Canada)

The primary scientific output from an astronomical telescope is the collection of papers published in refereed journals. A telescope's productivity is measured by the number of papers published which are based upon data taken with the telescope. The scientific impact of a paper can be measured quantitatively by the number of citations that the paper receives. In this paper I will examine the productivity and impact of over 25 telescopes, optical/IR, radio and space-based, for the years between 2009 and 2013.

9910-5, Session 1

Observatory bibliographies: an important resource in operating an observatory

Sherry L. Winkelman, Arnold H. Rots, Smithsonian Astrophysical Observatory (United States)

The Chandra Data Archive (CDA) maintains an extensive observatory bibliography. By linking the published articles with the individual datasets analyzed in the paper, we have the opportunity to join the bibliographic metadata (including keywords, subjects, objects, data references from other observatories, etc.) with the metadata associated with the observational datasets. This rich body of information is ripe for far more sophisticated data mining than the two repositories (publications and data) would afford individually. Throughout the course of the mission the CDA has investigated numerous questions regarding the impact of specific types of Chandra programs such as the relative science impact of GTO, GO, and DDT programs or observing, archive, and theory programs. Most recently the Chandra bibliography was used to assess the impact of programs based on the size of the program to examine whether the dividing line between standard and large projects should be changed and whether another round of X-ray Visionary Programs should be offered. Traditionally we have grouped observations by proposal. For this investigation we aggregated observations by pointing and instrument configuration such that objects observed multiple times in the mission were considered single observing programs. This change in perspective has given us new ideas for assessing the science impact of Chandra and for presenting data to our users. In this paper we present the methodologies used in the recent study, some of its results, and most importantly some unexpected insights into assessing the science impact of an observatory.

This work is supported by NASA contract NAS8-03060.

9910-6, Session 2

Data products in the ALMA and NRAO archives

Mark D. Lacy, National Radio Astronomy Observatory (United States)

The increasing size and complexity of radio astronomical datasets has resulted in demand for fully reduced data products (image cubes) to be made available to the user community from observatory archives. This is important both to allow novice users who have little radio astronomy experience to use these new facilties and for more experienced scientists to be able to quickly assess the quality of their datasets and speed up their analyses. This new requirement presents challenges of generation, storage and server-side visualization and analysis of very large datacubes. In this paper we estimate the relative size of data products and raw data as a function of observational parameters, plans for user-initiated reprocessing of data in the ALMA and NRAO archives (in addition to a default pipeline execution) and a discussion of future tools for remote visualization and analysis.

We also discuss the general implications for the design of future astronomical archives as we move away from the concept of an archive for storage and retrieval only into one that can also function as a portal for server-side data analysis.

9910-7, Session 2

Validation of ESO Phase 3 data submissions

Nausicaa A. R. Delmotte, Magda Arnaboldi, Stephan Geier, Laura Mascetti, Alberto Micol, Joerg Retzlaff, European Southern Observatory (Germany)

The data validation phase is an essential step of the Phase 3 process at ESO that is defining and providing an infrastructure to deal with interactions between the data producers and the archive. We are using a controlled process to systematically review all Phase 3 data submissions to ensure a homogeneous and consistent science archive with well traceable and characterised data products, to the benefits of archive users.

How the Phase 3 data validation plan is defined, and how its results are subsequently managed will be described in the presentation.

[For a description of its technical implementation, please refer to the submitted contribution by L. Mascetti.]

9910-8, Session 2

Publication of science data products through the ESO archive: lessons learned and future evolution

Joerg Retzlaff, Magda Arnaboldi, Nausicaa A. R. Delmotte, Laura Mascetti, Alberto Micol, European Southern Observatory (Germany)

Phase 3 denotes the process of preparation, submission, validation and ingestion of science data products for storage in the ESO Science Archive Facility and subsequent publication to the scientific community. In this paper we will review more than four years of Phase 3 operations at ESO and we will discuss the future evolution of the Phase 3 system.

9910-9, Session 2

The TESS science data archive

Daryl A. Swade, Space Telescope Science Institute (United States); Cory Heiges, General Dynamics (United States); Jon M. Jenkins, NASA Ames Research Ctr. (United States); David W. Latham, Harvard-Smithsonian Ctr. for Astrophysics (United States); Sean D. McCauliff, NASA Ames Research Ctr. (United States); Edward H. Morgan, MIT Kavli Institute for Astrophysics and Space Research (United States); William B. Sparks, Space Telescope Science Institute (United States); Roland Vanderspek, Massachusetts Institute of Technology (United States)

The Transiting Exoplanet Survey Satellite (TESS) is a survey mission designed to discover exoplanets around the nearest and brightest stars. TESS has been selected by NASA as an Astrophysics Explorer mission with a scheduled launch in August 2017. The Mikulski Archives for Space Telescopes (MAST) at the Space Telescope Science Institute (STScI) will serve as the archive for TESS science data.

TESS will conduct large area surveys of bright stars and known M dwarfs within about 60 parsecs. TESS will observe a single 24 degree by 96 degree sector of the sky for approximately 27 days before pointing to a new sector, surveying the entire sky over the two year prime mission.

Science data are captured in two observation types: Target Data and Full Frame Images. Target Data result from a subarray of pixels read out with a two-minute cadence from approximately 25,000 stars per sector. Target stars change every sector, but targets near the ecliptic poles may be observed in multiple sectors. The entire field of view is captured in Full Frame Images taken at thirty-minute cadence. Full Frame Images provide a rich source of high time resolution data for many astronomical investigations.

Archive data products originate from multiple elements within the TESS ground segment. The Payload Operations Center provides the archive with raw data from the spacecraft, operational files, and focal plane characterization models. The Science Processing Operations Center pipeline generates FITS files for the Target Data and Full Frame Images. Light Curves and Centroids are extracted from the Target Data. Threshold Crossing Events are identified from the Light Curves in the Transiting Planet Search pipeline and Data Validation Reports are generated. MAST will stage catalog data generated by the TESS Science Office (TSO). The TESS Input Catalog contains approximately half a billion objects that are potential TESS targets or may influence the photometry of TESS targets. The TESS Objects of Interest Catalog lists planetary candidates identified as Threshold Crossing Events. In addition, the TSO will manage the TESS Follow-up Observing Program in which ground and space based telescope will be used for follow-up observations of TESS Objects of Interest. Follow-up Observing Program participants will be responsible for submission of follow-up data to MAST.

The services provided by MAST for the TESS mission are to store science data and provide an Archive User Interface for data documentation, search, and retrieval. Target Data and Full Frame Images are expected to be available in MAST within two months after conclusion of a sector's data collection. Current estimates have 38 Terabytes of TESS data available through MAST for each year of the mission.

The MAST architecture is designed to support multiple missions. MAST currently serves data from the Hubble Space Telescope, Kepler, and approximately ten other missions, as well as numerous additional high-level science data products. MAST will be the JWST data archive. The TESS mission takes advantage of this multi-mission architecture to provide a cost effective archive that allows integration of TESS data with data from other missions.

9910-10, Session 3

Providing comprehensive and consistent access to astronomical observatory archive data: the NASA archive model

Thomas McGlynn, NASA Goddard Space Flight Ctr. (United States); Giuseppina Fabbiano, Alberto Accomazzi, Smithsonian Astrophysical Observatory (United States); Alan Smale, NASA Goddard Space Flight Ctr. (United States); Richard L. White, Thomas Donaldson, Alessandra Aloisi, Space Telescope Science Institute (United States); Joseph M. Mazzerella, Rick Ebert, Olga Pevunova, David Imel, Graham B. Berriman, Harry I. Teplitz, Steve L. Groom, Vandana R. Desai, Infrared Processing and Analysis Ctr. (United States) and California Institute of Technology (United States)

Since the turn of the millennium a constant concern of astronomical archives has been providing data to the public through standardized protocols unifying data from disparate physical sources and wavebands across the electromagnetic spectrum into an astronomical virtual observatory (VO). In October 2014, NASA began support for the NASA Astronomical Virtual Observatories (NAVO) program to coordinate the efforts of NASA astronomy archives in providing data to users through implementation of protocols agreed within the International Virtual Observatory Alliance (IVOA). While NAVO directly funds efforts at the HEASARC, IRSA, MAST and NED, other NASA projects, in particular the Chandra Data Archive and the ADS are also active in the VO arena and actively coordinate their activities with NAVO as part of the NASA Astronomy Data Centers Executive Committee (ADEC) . These NASA archives and projects maintain key VO infrastructure in the US and are members of the US Virtual Observatory Alliance (USVOA). The USVOA is the national coordination body, which represents the US VO activities in the IVOA. Together with the NASA archives, it also includes the AAS community at large, providing a forum for VO discussion and activities representative of all branches of US astronomy including ground-based observatories and data centers to ensure that the US community is fully engaged in the VO process.

Over the past decade the number of protocols agreed by the IVOA has swelled to over 40 agreed upon technical standards with another 10 or so in various stages of development. Many of these standards have optional capabilities and some have gone through multiple versions during their development.

A major goal of the USVOA and in particular the NASA ADEC and NAVO collaboration has been to assess the available IVOA standards and define what the appropriate presence for the US and NASA astronomy archives in the VO should be. This includes evaluating what optional capabilities in the standards need to be supported, the specific versions of standards that should be used, and returning feedback to the IVOA, to support modifications if needed.

The NAVO collaboration has defined a basic model and are now implementing capabilities. Our standard model provides for discovery of resources through the VO registries, access to observation and object data, downloads of image and spectral data and general access to archival datasets. Specific protocol versions have been chosen, minimum capabilities defined, and all dependencies have been identified. The model will evolve as the capabilities of the virtual observatory and needs of the community change. The other NASA archives are active participants in this process and in particular the ADS is leading the NASA effort to incorporate Digital Object Identifiers (DOIs) in referencing both data and publications.

This paper discusses our model, the progress we have made in implementing it, and the challenges that we – and likely other archives – will face in providing compatible interfaces to astronomical data using the virtual observatory standards.

9910-11, Session 4

Public surveys at ESO

Magda Arnaboldi, Nausicaa A. R. Delmotte, Michael Hilker, Gaitee Hussain, European Southern Observatory (Germany); Laura Mascetti, Terma GmbH (Germany); Alberto Micol, Monika Petr-Gotzens, Marina Rejkuba, Joerg Retzlaff, European Southern Observatory (Germany); Steffen Mieske, Thomas Szeifert, European Southern Observatory (Chile); Martino Romaniello, Bruno Leibundgut, Rob J. Ivison, European Southern Observatory (Germany)

This paper presents an overview of the fourteen ESO public survey projects completed or on going at the ESO facilities (Survey telescopes, VISTA and VST, on the VLT instruments, UVES, FLAMES, VIMOS, and MUSE, and on the NTT, with SOFI and EFOSC) at the La Silla-Paranal Observatory. The paper outlines the motivations behind these large projects, the policies, tools and services in place to support and monitor the execution of these programmes at the telescopes, and their current completion status. The paper presents how these programmes continue to publish their data through the ESO Science Archive Facility, and from then on how they become accessible to the astronomical community. It concludes with an outlook on the future developments of public surveys at ESO, with the recent call for VISTA public surveys and the wide area spectrographs 4MOST and MOONS.

9910-12, Session 4

Not letting the perfect be the enemy of the good: steps toward science-ready ALMA images

Amanda Kepley, Jennifer Donovan Meyer, Crystal Brogan, Arielle Moullet, John E. Hibbard, Remy Indebetouw, Brian S. Mason, National Radio Astronomy Observatory (United States)

Historically, radio observatories have placed the onus of calibrating and imaging data on the observer, thus restricting their user base to those already initiated into the mysteries of radio data or those willing to develop these skills. To expand its user base, the Atacama Large Millimeter/submillimeter Array (ALMA) has a high-level directive to produce calibrated visibilities and images from these visibilities for PIs. Although an ALMA calibration pipeline is in place, all images continue to be produced for the PI by hand. In this talk, I will describe on-going efforts at the Northern American ALMA Science Center to produce more uniform imaging products that more closely meet the PI science goals and provide better archival value. As a first step, the NAASC imaging group produced a simple imaging template designed to help scientific staff produce uniform imaging products. This script allowed the NAASC to maximize the productivity of data analysts with relatively little guidance by the scientific staff by providing a step-by-step guide to best practices for ALMA image. Finally, I will describe the role of the manually produced images in verifying the imaging pipeline and the on-going develop of said pipeline. The development of the imaging template, while technically simple, shows how small steps toward unifying processes and sharing knowledge can lead to large gains for science data products.

9910-13, Session 4

Science data management at ESO

Martino Romaniello, European Southern Observatory (Germany)

Providing the best science data is at the core of ESO's mission to enable major science discoveries from our science community. I will briefly describe the steps that ESO undertakes to fulfill this, namely ensuring that instruments are working properly, that the science content can be extracted from the data and, finally, delivering the science data to our users, PIs and archive researchers alike.

Metrics and statistics that gauge the results and impact of these efforts will be discussed.

9910-14, Session 5

ANTARES: a time-domain broker for the LSST era

Abhijit Saha, Thomas Matheson, National Optical Astronomy Observatory (United States); Gautham Narayan, Richard Snodgrass, John Kececioglu, Carlos Scheidegger, Zhe Wang, Shuo Yang, The Univ. of Arizona (United States)

The Arizona-NOAO Temporal Analysis and Response to Events System (ANTARES) is a joint project of the National Optical Astronomy Observatory and the Department of Computer Science at the University of Arizona. The goal is to build the software infrastructure necessary to process and filter alerts produced by time-domain surveys, with the ultimate source of such alerts being the Large Synoptic Survey Telescope (LSST). The ANTARES broker adds value to alerts by annotating them with information from external sources such as previous surveys from across the electromagnetic spectrum. In addition, the temporal history of annotated alerts will provide further elucidation for analysis. Also incorporated is a "touchstone," a knowledge repository of properties and features of known or predicted kinds of variable astronomical sources. An incoming alert's features can be compared to the information in the touchstone through a series of filtering stages to ascertain whether it is 'interesting.' For the prototype, 'interesting' is defined as the rarest or most unusual alert, or alerts that need immediate follow-up observations, but the architecture supports incorporating alternate logic and goals. The system is designed to be flexible, allowing users to access the stream at multiple points throughout the process and to insert custom filters where necessary. The repository of annotated alerts, including association with known objects in the sky is an additional data product that can serve the needs of users seeking categories of time varying phenomena that are not critical for immediate follow up. In addition to its projected scientific scope, we describe the current state of development of ANTARES, examples of some working algorithms, its architecture and scalability, operational stability, and development time-line.

9910-16, Session 5

DDOTI: the deca-degree optical transient imager

Alan M. Watson, William H. Lee, Fernando Ángeles, Univ. Nacional Autónoma de México (Mexico); Michel Boer, Observatoire de Haute-Provence (France); Nathaniel R. Butler, Arizona State Univ. (United States); Jose A. de Diego, Alejandro S. Farah, Univ. Nacional Autónoma de México (Mexico); Neil A. Gehrels, NASA Goddard Space Flight Ctr. (United States); Yilen Gómez Maqueo Chew, Univ. Nacional Autónoma de México (Mexico); Alain Klotz, Institut de Recherche en Astrophysique et Planétologie (France); Alexander S. Kutyrev, NASA Goddard Space Flight Ctr. (United States); Fernando Quirós, Univ. Nacional Autónoma de México (Mexico); Maurico Reyes-

Ruiz, Observatorio Astronómico Nacional (Mexico); Carlos G. Román-Zúñiga, Univ. Nacional Autónoma de México (Mexico); Pierre Thierry, Observatoire de Roudiere (France); Eleonora Troja, NASA Goddard Space Flight Ctr. (United States)

DDOTI will be a wide-field robotic imager consisting of six 28-cm telescopes with prime focus CCDs mounted on a common equatorial mount. Each telescope will have a field of view of 12 square degrees with 2 arcsec pixels, and the set of six will provide an instantaneous field of view of about 72 square degrees. DDOTI uses commercial components almost entirely. The five-sigma limiting magnitude will be about magnitude 19 in 60 seconds. DDOTI will be installed at the Observatorio Astronómico Nacional in Sierra San Pedro Martír, Baja California, México in late 2016.

The main science goal of DDOTI is the localization of the optical transients associated with GRBs detected by the GBM instrument on the Fermi satellite. DDOTI can cover the majority of the typical initial error region of 100 square degrees in just two pointings. We expect that DDOTI will be able to quickly localize about 45 GBM GRBs per year, about 20% of the total detected by GBM. Fast localizations will permit spectroscopy from larger telescopes to determine the redshift, which is currently unknown for the vast majority of GBM GRBs. Thus, DDOTI promises to be a key part of a chain that will allow us to fully exploit the GBM instrument. DDOTI will also be used to follow-up gravity-wave transients, for studies of AGN and YSO variability, and to determine the occurrence of hot Jupiters.

The principal advantage of DDOTI compared to other similar projects such as iPTF, ZPTF, and BlackGEM is cost: a single DDOTI installation costs only about US$500,000. This makes it possible to contemplate a network of DDOTI installations around the world. Such geographic diversity would give faster access to GBM GRBs and a higher localization and follow-up rate.

In this contribution, we will discuss the DDOTI hardware and software, our tests on the sky of the single-telescope prototype, our reference science cases, the state of the six-telescope imager for the Observatorio Astronómico Nacional, and our plans for a future world-wide network.

9910-98, Session 5

CARMENES: data flow

Jose A. A. Caballero, Landessternwarte Koenigstuhl (Germany); Mauro López del Fresno, Ctr. de Astrobiología (Spain); Mathias Zechmeister, Institut für Astrophysik Göttingen (Germany); Josep Guàrdia, Institut de Ciències de l'Espai (Spain); Enrique de Juan, Enrique de Guindos, Ctr. Astronómico Hispano-Alemán (Spain); Enrique Solano, Ctr. de Astrobiología (Spain); Hans-Juergen Hagen, Hamburger Sternwarte (Germany); Rafael Morales Muñoz, Instituto de Astrofísica de Andalucía (Spain); Ansgar Reiners, Institut für Astrophysik Göttingen (Germany); Ignasi Ribas, Institut de Ciències de l'Espai (Spain); Walter Seifert, Andreas Quirrenbach, Landessternwarte Koenigstuhl (Germany); Pedro J. Amado González, Instituto de Astrofísica de Andalucía (Spain)

The long CARMENES acronym, Calar Alto high-Resolution search for M dwarfs with Exoearths with Near-infrared and optical Échelle Spectrographs, consists actually of a few words that are carefully chosen. This new instrument, built by a consortium of German and Spanish institutions, is as complex as expected for a spectrograph that covers for the first time from 0.55 to 1.70 mum in only one shot and that has enough high resolution and thermo-mechanical stability for reaching the 1 m/s accuracy. CARMENES consists of a number of subsystems: (i) a front-end in the Cassegrain focus of the 3.5 m Calar Alto telescope with a pick-up mirror, and double-prism atmospheric dispersion corrector, an acquisition and guiding system, a dichroic at 0.95 mum, and a double fibre input unit; (ii) an optical-fibre relay system (including both circular and octagonal fibres) with a fibre shaker; (iii) two spectrographs, one for the visible region bluewards of 0.95 mum, the other one for the near-infrared region redwards of it, each of them with no movable parts but with a continuous cooling-flow detector cryostat, a reliable vacuum system with pumps and liquid N2 pipes, an exposure-meter, and numerous pressure, temperature and valve sensors; (iv) a cooling unit for the near-infrared channel based on a continuous flow of gaseous N2; (v) two calibration units, one for each channel, with hollow cathode lamps and flat-field halogen lamps, shutters and filters; (vi) two Fabry-Pérot etalons for simultaneous wavelength calibration; (vii) three air-conditioned rooms for the near-infrared spectrograph, the visible spectrograph and the calibration devices; (viii) a double interlocks system for safety control of hazardous items; (ix) an instrument control with a friendly graphical user interface and an automatic scheduler; and (x) an automatic pipeline that provides the observer with extracted spectra and computed radial velocities less than one minute after the end of the exposure. A dozen main computers, not counting spares, control the whole system. Together with the acquisition-and-guiding images, visible and near-infrared spectra, exposure meters data (number of counts per second during exposure as measured in the zeroth order of the échelle grating) and pipeline output files, we store over 250 parameters per observing block in the corresponding fits headers (from local sidereal time, through V-band seeing, age of used hollow cathode lamp and current of the fibre shaker, to temperatures in 16 locations on the near-infrared optical bench). In the following morning, all data are copied to a computer in the Calar Alto observatory, from which they are retrieved, stored and made available to the consortium members or to the public through a virtual-observatory data server located in Madrid. Eventually, all the CARMENES data, raw and/or processed, arrive on the same day to the astronomers' computers in a friendly, comprehensive and automatic way.

9910-17, Session 6

Operations concept for the Square Kilometre Array

Gary R. Davis, SKA Organisation (United Kingdom); Douglas C. Bock, CSIRO Astronomy and Space Science (Australia); Antonio C. Chrysostomou, Cornelius Taljaard, SKA Organisation (United Kingdom)

The Square Kilometre Array (SKA) is an ambitious project to build the world's largest radio telescope, eventually reaching one square kilometre in collecting area. When complete it will be one of the world's engineering marvels. The first phase of the project, SKA1, will consist of two telescopes: SKA1-LOW, comprising ~131,000 dipole antennas at the Murchison Radio Observatory in Western Australia covering the range 50–350 MHz, and SKA1-MID, comprising ~200 x 15-m dishes in the Karoo desert in South Africa covering the range 0.35–13.8 GHz. SKA1 is scheduled to commence operations in 2023 and, in order to appropriately influence the design of the system, operational planning has commenced. This paper will report on the initial stages of developing the operational concept and its implementation.

The science programme for the SKA is not yet defined, but is expected to consist of both large projects requiring more than 1000 hours of observing time (Key Science Projects), and conventional, smaller, PI-driven programmes. The observatory is required to support both types of project, and also to deliver appropriate return on investment for the partner countries. The science programme is significantly integrated between the two telescopes and operations will therefore emphasise the commonalities between LOW and MID as far as practicable.

The concept for science operations has been developed with the goal of delivering maximum scientific impact within the available resources. Observations will be carried out in service mode for 24hr/day, using flexible queue scheduling, all to enhance observational efficiency. Targets

of Opportunity and transients form an important part of the SKA's science case, and the observing system will automate these observations to the maximum possible extent. The flexibility of the system will enable multiplexing of observations in various ways: e.g., configuration of the two telescopes into multiple, independent sub-arrays for simultaneous observations, or sharing of datasets between multiple science teams. In collaboration with the SKA member states, a high level of user support will be provided to ensure that the diverse, world-wide user community is able to fully exploit the observatory's capabilities.

The concept for engineering operations is based on the requirement for high availability. The system is being designed for high reliability, and maintenance in the field will be strictly limited, based on replacement of modular units.

The SKA will generate unprecedented volumes of data, leading to the requirements for high-performance computational capabilities at the back end of each telescope for the generation of data products and for innovative arrangements for further science processing and distribution to end users. The data flow concept is currently under study and will likely be based on a global network of coordinated, regional science and data centres.

Implementation of this operational concept requires the development of an organisational structure that reflects the unique nature of the SKA as a globally-distributed observatory, with telescopes in two countries and a headquarters in a third (the UK), and with data centres and technology development centres throughout the member countries.

9910-18, Session 6

A preliminary operations concept for the ngVLA

Mark M. McKinnon, Claire J. Chandler, John E. Hibbard, Jeffrey S. Kern, Peggy Perley, National Radio Astronomy Observatory (United States)

A future large area radio array optimized to perform imaging of thermal emission down to milliarcsecond scales is currently under consideration in North America. This `Next Generation Very Large Array' (ngVLA) will have ten times the effective collecting area of the JVLA, operate from 1GHz to 115GHz, have ten times longer baselines (300 km), and include a dense core on kilometer scales for high surface brightness imaging. The current VLA site in the southwest USA is being considered as a possible location for the ngVLA.

The large number of antennas and their large geographical distribution pose significant challenges to ngVLA operations and maintenance which must be addressed in the early stages of the project to minimize operations cost while maximizing the scientific productivity of the instrument. We draw on experience from operating the JVLA, VLBA, and ALMA to highlight notable operational issues and outline a preliminary operations concept for the ngVLA.

For array operations and maintenance, a number of features are planned to reduce the operational costs of the ngVLA. Current plans call for the antennas to be fixed in location. Maintenance at each antenna will be minimized by building high reliability into antenna systems and components, modularizing components to facilitate quick repairs, and providing remote resets or reboots of systems to minimize antenna maintenance visits. While maintenance operations will be concentrated at the array core, a set of small satellite maintenance teams will service the antennas on longer baselines on a continuous basis. Antenna sites should be readily accessible via existing roads to minimize observatory maintenance of the roads it must build for antenna access. Electrical power will be taken from local grids, with the goal of tapping into those with renewable energy (solar and wind) as their power generation source. In an effort to minimize antenna power consumption, a development program has been initiated to improve the efficiency of cryogenic cooling systems through the use of variable speed drives.

For science operations, the ngVLA is envisioned to be a general purpose, PI-driven, pointed telescope, much like the JVLA, as opposed to a survey instrument that delivers generic data products. The array will be fully dynamically scheduled to match weather, phase stability, and other criteria to observer requirements in order to improve observing efficiency. Dynamic scheduling will also enable time critical observations within a few hours of triggering. A flexible data reduction system will be provided; pipeline operations will be implemented for calibrating data and generating image products, but multi-access to raw data, calibrated data, and image products will also be provided to users ranging from novice to expert to ensure that data delivery to investigators is not unnecessarily delayed. Given the number of antennas and receiver bandwidths, data rates from the ngVLA will be large, suggesting that data processing will be done in remote batches, either on dedicated localized hardware or on cloud resources.

9910-21, Session 6

A new procedure to maintain and calibrate very large geographically distributed radio telescope arrays

Rosario F. Cimmino, Antonio Saitto, Consorzio Nazionale Interuniversitario per i Transporti e la Logistica (Italy); Francesco Romano, EExSKA (Italy); Alessandro Trifiletti, Sapienza Univ. di Roma (Italy)

In the recent years the design of radio-telescopes has been oriented towards very large geographically distributed array systems, such as SKA system.

For the proper operation of the system the antennas are to be kept in phase so that they behave as a single very large antenna. This result is obtained through a very accurate timing ,analogue to digital (AD) conversion of the signals received by the individual antennas, and a very sophisticated life cycle design, capable of maintaining the performance of the large array along a very large time window of years (at least 20).

In order to maintain the system efficiency, it is therefore advisable to routinely perform a check of the electromagnetic performance of each antenna and of each antenna with respect to the others. This periodic monitoring and correction system, should be obtained avoiding conventional calibration procedures, which are a very expensive and time consuming task.

The procedure proposed in this paper considers two major sources of errors:

• The former due to changes with respect to modification of the antenna (or the feed) geometry.

• The latter due to variations of the antenna location one with respect to the others.

On the Antenna Geometry verification it has to be noted that acceptance tests include a dimensional check of the optics as well as an electromagnetic test (radiation solid). The radiation solid allows to diagnostic the optics impairments if any inclusive of the ones due to the geometrical impairments. The time required to perform these tests ranges from days to weeks. This is acceptable for a single antenna whereas it is not for hundreds of antennas to be monitored routinely. The alternative method proposed in the paper to perform test on the far field radiation pattern using the Airy zone of the focal plane ("Airy disk"). The measurement allows to get the antenna behavior with a single synoptic test.

On the location of each antenna with respect to each other, i.e. with respect to a common reference system the paper proposes the combined use of GNSS satellite (using the RTK function) and radio images obtained from SAR satellite interferometry.

The proposed methodology allows the control of the mutual positions of the elements of the array in real time, simplifying the procedure of

managing the life cycle of such an infrastructure.

For the deployment time of future radio telescope arrays the Galileo Constellation in addition to GPS will be available, while SAR satellite are already available now. The combined use of these solutions supplies a powerful tool for analysis and operational monitoring implementing a very accurate “three-dimensional matrix” presenting the positioning errors of geographically distributed arrays and supporting the maintenance and calibration procedures along the years.

9910-23, Session 6

Centralized operations and maintenance planning at the Atacama Large Millimeter/submillimeter Array (ALMA)

Bernhard Lopez, Nicholas D. Whyborn, Serge Guniat, Octavio Hernandez, ALMA (Chile); Stefan Gairing, Joint ALMA Observatory (Chile)

The Atacama Large Millimeter/submillimeter Array (ALMA) is a joint project between astronomical organizations in Europe, North America, and East Asia, in collaboration with the Republic of Chile. ALMA consists of 54 twelve-meter antennas and 12 seven-meter antennas operating as an aperture synthesis array in the (sub)millimeter wavelength range.

Since the inauguration of the observatory back in March 2013 there has been a continuous effort to establish solid operations processes for effective and efficient management of technical and administrative tasks on site. Here a key aspect had been the centralized maintenance and operations planning: input is collected from science stakeholders, the computerized maintenance management system (CMMS) and from the technical teams spread around the world, then this information is analyzed and consolidated based on the established maintenance strategy, the observatory long-term plan and the short-term priorities definitions.

This paper presents the high-level process that had been laid out for the planning and scheduling of planned- and unplanned maintenance tasks, and for site operations like the telescope array reconfiguration campaigns. We focus on the centralized planning approach by presenting its genesis, its current implementation for the observatory operations including related planning products, and we explore the necessary next steps in order to fully achieve a comprehensive centralized planning approach for ALMA in steady-state operations.

9910-25, Session 6

Power monitoring and control for large scale projects: SKA: a case study

Domingos Barbosa, Instituto de Telecomunicações (Portugal) and Engage SKA (Portugal); João Paulo Barraca, Instituto de Telecomunicações (Portugal) and Univ. de Aveiro (Portugal) and Engage SKA (Portugal); Dalmiro Maia, Univ. do Porto (Portugal) and Engage SKA (Portugal); Jorge M. Vieira, Critical Software S.A. (Portugal) and Engage SKA (Portugal); José Carlos Amador, Martifer Solar (Portugal) and Engage SKA (Portugal); Paulo Soeiro, Visabeira Global (Portugal) and Engage SKA (Portugal); Swaminathan Natarajan, Tata Research Development and Design Ctr. (India); Paul Swart, SKA South Africa (South Africa)

Large sensor-based science infrastructures for radio astronomy like the SKA will be among the most intensive data-driven projects in the world, facing very high demanding computation, storage, management, and above all power demands. The geographically wide distribution of the SKA and and its associated processing requirements in the form of tailored High Performance Computing (HPC) facilities, require a Greener approach towards the Information and Communications Technologies (ICT) adopted for the data processing to enable operational compliance to strict power budgets. Addressing both the reduction of electricity costs and the generation and management of electricity at system level is paramount to avoid future inefficiencies and higher costs, while enabling fulfillments of Science Cases like Transient observations or other Virtual Observatory (VO) triggered observations whose operational modes may produce sudden peak power loads. In particular, since the (power hungry) data processing location is conditioned by the experiment, and not by the computational facilities, it results in far from optimal efficiency, higher capital expenditure (CAPEX) and higher OPEX. As an example, VO triggered events will require precise metering, operating under the constraints of Power forecast budget, while considering power buffer allocations for these unexpected, yet extremely relevant astronomical events. Management of these operational modes require power forecast at subsystem level and power buffers, eventually with reconfiguration, disconnection or graceful operational downgrade of some other telescope components. Hence, at system planning, we must consider a combination of low power computing, efficient data storage, local data services, Smart Grid power management, and potential inclusion of other non-grid sources like Renewable Energies in the form of heterogeneous system mix, and a heterogeneous power mix at provision level.

Of particular importance, Smart Grid technologies enable power management and control (M&C) at component level through a combination of distributed IT, field automation, remote sensors and its wealth of endpoints. These attributes will drive the functional integration of new distribution management capabilities into the SKA telescope’s instances though its energy management centers. Besides greater efficiency, the Smart Grid technologies benefits include detailed power forecasts, improved service reliability, more efficient power asset management, and better operational planning. Power monitoring of systems antennas and ancillary systems, Correlators, HPC facilities or related data center tiered systems must include advanced metering technologies, efficient distribution automation and Network Operation Centers (NOC).

Here we outline the major characteristics and innovation approaches to address power efficiency, lifecycle impact and long-term power sustainability for radio astronomy projects like the SKA.

9910-28, Session 6

The Australian SKA Pathfinder: operations management and user engagement

Lisa Harvey-Smith, CSIRO Astronomy and Space Science (Australia)

The Australian SKA Pathfinder is an innovative new radio telescope comprising 36 parabolic dishes fitted with ‘phased array feeds’ - radio cameras with a 30 square degree instantaneous field-of-view. For the first five years of ASKAP operation, approximately 75% of the available observing time will be dedicated to large surveys, with the remainder being available for guest science projects.

ASKAP is currently in its final stages of construction and is being commissioned by a team of astronomers and engineers. The ASKAP early science program will begin in 2016, in parallel with continued receiver integration and commissioning. The major ASKAP surveys will begin in 2018.

In this talk, the ASKAP Project Scientist will describe how the observatory has engaged the major ASKAP survey teams throughout the telescope design process, how plans have changed in light of a major re-design of the receiver systems, what preparations are being made for survey-mode observatory operations (including operator interfaces, survey optimisation tools, operations benchmarks and metrics) and describe lessons learned.

9910-125, Session 6

STELLA: 10 years of robotic observations Tenerife

Michael Weber, Thomas Granzer, Klaus G. Strassmeier, Leibniz-Institut für Astrophysik Potsdam (Germany)

STELLA is a robotic observatory on Tenerife, which is currently housing two 1.2m robotic telescopes. One telescope is fibre-feeding a high-resolution (R=55,000) echelle spectrograph (SES), while the other telescope is equipped with a visible wide-field (FOV=22'x22') imaging instrument (WiFSIP). Robotic observations started mid 2006, and the primary scientific driver is monitoring of stellar-activity related phenomena.

The STELLA control system (SCS) software package was originally tailored to the STELLA roll-off style building and high-resolution spectroscopy, but was extended over the years to support the wide-field imager, an off-axis guider for the imager, separate acquisition telescopes, classical domes, and targets-of-opportunity. The SCS allows for unattended, off-line operation of the observatory, targets can be uploaded at any time and are selected based on merit-functions in real-time (dispatch scheduling).

We report on the current status of the observatory and the current capabilities of the STELLA control system.

9910-20, Session 7

LBTO's long march to full operation: step 2

Christian Veillet, David S. Ashby, Julian C. Christou, John M. Hill, John K. Little, Douglas M. Summers, R. Mark Wagner, Large Binocular Telescope Observatory (United States); Elena Masciadri, Alessio Turchi, INAF - Osservatorio Astrofisico di Arcetri (Italy)

The march of the Large Binocular Telescope Observatory to full operation is a long journey, which is both exciting and challenging. Exciting as the long awaited suite of first generation instruments and GLAO will eventually become available for binocular operations, while regular interferometric observations will make LBT the first operational ELT. Challenging because LBTO will have to handle maintenance and upgrades of instruments or key components like its adaptive secondaries about which it has much to learn.

Step1 outlined a a six-year plan aimed at optimizing LBTO's scientific production while mitigating the consequences of the inevitable brought on by the considerable complexity of the telescope and the very diverse nature of the LBTO partnership.

Step 2 will focus on the first two years of implementation of this plan, presenting the encountered obstacles, technical, cultural, and political, and how they were overcome. It will also highlight milestones such as the completion of the commissioning of the first generation instruments now available for binocular operations and the first science publications using LBT as a 23-m telescope through interferometry.

9910-22, Session 7

Response to major earthquakes affecting Gemini twins

Michiel van der Hoeven, Rolando Rogers, Gemini Observatory (Chile); Mathew J. Rippa, Gemini Observatory (United States); Gabriel Perez, Vanessa Montes, Cristian Moreno, Gemini Observatory (Chile)

Both Gemini telescopes, in Hawaii and Chile, are located in highly seismic active areas. That means that the seismic protection is included in the structural design of the telescope, instruments and auxiliary structure. We will start this paper by introducing the specific design features to reduce permanent damage in case of major earthquakes. At this moment both telescopes have been affected by big earthquakes in 2006 and 2015 respectively. There is an opportunity to compare the original design to the effects that are caused by these earthquakes and analyze their effectiveness.

The paper describes the way the telescopes responded to these events, the damage that was caused, how we recovered from it, the modifications we have done to avoid some of this damage in future occasions, and lessons learned to face this type of events. Finally we will cover on how we pretend to upgrade the limited monitoring tools we currently have in place to measure the impact of earthquakes.

9910-24, Session 7

Technical maintenance activities at Paranal Observatory

Maxime Boccas, Eva Díaz Catalá, Michel Frantz, Javier Gonzalez, Sergio E. Gonzalez, Gerhard Hüdepohl, Ismo Kastinen, Alex Morales, Matteo Pozzobon, Christian Ramirez, Claudio Reinero, Fernando Salgado, Waldo Siclari, Christian Stephan, Javier Valenzuela, European Southern Observatory (Chile)

After more than 15 years of operation, the Paranal Observatory has accumulated a lot of experience with maintenance of systems, and has recently adopted the methodology called Maintien en Condition Operationnelle (MCO). We will describe and review the practical implementation of this strategy, the tools used, the benefits and challenges as well as practical examples and how it is overall managed. The approach is also a benchmarking exercise for operation of the E-ELT in the future.

9910-26, Session 7

Worth its SALT: four years of full science operations with the Southern African Large Telescope

Petri Vaisanen, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa); Chris Coetzee, David A. H. Buckley, Steve M. Crawford, Anja Schroeder, Janus Brink, Eric Depagne, Alexei Kniazev, Thea Koen, Paul Kotze, Fred Marang, Brent Miszalski, Encarni Romero Colmenero, Ockert Strydom, Veronica Van Wyk, Theodore B. Williams, South African Astronomical Observatory (South Africa)

SALT is a 10-m class optical telescope located in Sutherland, South Africa, owned by an international consortium and operated in fully queue-scheduled mode by the South African Astronomical Observatory.

In this paper we present an update on all observatory performance metrics since the start of full science operations in late 2011, including science time, weather and technical downtime, and time used for planned engineering activities and commissioning. We analyze key statistics describing the science output of SALT, the completion fractions of scheduled observations and programs per priority class, and analyze the more than 120 refereed papers to date since first light based on SALT data.

There has been a steady improvement in statistics under our control over the four years. In particular, the efficiency at which the time available

for science is converted to completed observations and programs has increased significantly, while the downtime due to technical or operational problems has decreased steadily. In the second semester of 2015, SALT completed 80% of the highest science priority observations in the queue. Full program completeness is lower, however, due to many programs splitting their time over high and low priorities, and we discuss the possible effects of this policy. We also discuss the many layers of software developed to maintain the efficiency in planning programs, streamlining the scheduling and tracking of their execution, and reducing the data. Some of these, along with the latest developments in instrumentation and engineering projects, are presented in detail in other SPIE paper submissions.

The refereed paper output has been increasing, with 35 papers during the 2015 calendar year. When counted from the start of science operations, we show that the trend is very similar to other 6-10 m observatories when scaled by the number of telescopes. In particular, when scaled by operations costs, where known, we show that SALT is very cost-effective compared to most other large telescope operations. We discuss the lessons learned in striving to make the most of SALT within the constraints of its design and site characteristics, including the challenging goal of guiding the user community to maximize outputs by utilizing the strengths of the telescope.

By far the most papers on SALT are based on data from the Robert Stobie Spectrograph (RSS) and, not surprisingly, the most efficient output to date is with long-slit spectroscopic observations. Modes requiring more specialist knowledge in reductions, multi-object spectroscopy and Fabry-Perot imaging spectroscopy, are more rare but are also starting to produce refereed publications. The hand-over to SALT Operations of the newest instrument, the High Resolution Spectrograph (HRS, status of which is described in another SPIE submission), happened in 2015, and the instrument has just seen its first data published. We discuss the need for a data reduction pipeline in making the science output of this type of instrument efficient.

Finally, we also present the operational structure of the SALT organization, in particular since moving to an integrated operations team in 2015.

9910-27, Session 7

A collimated beam projector for precise LSST throughput calibration

Michael Coughlin, Kairn Brannon, Christopher W. Stubbs, Harvard Univ. (United States); Timothy M. C. Abbott, Cerro Tololo Inter-American Observatory (Chile); Chuck Claver, Large Binocular Telescope Observatory (United States); Peter E. Doherty, Harvard Univ. (United States); Patrick J. Ingraham, LSST (United States); Merlin Fisher-Levine, Brookhaven National Lab. (United States); Robert H. Lupton, Princeton Univ. (United States)

The precise determination of the instrumental response function vs. wavelength is a central ingredient in contemporary photometric calibration strategies. This typically entails sending narrowband illumination through the system pupil, and comparing the detected photon rate across the focal plane to the amount of incident light as measured by a calibrated photodiode. But stray light effects and reflections/ghosting (especially on the skirts of filter passbands) in the optical train constitute a major source of systematic uncertainty when using a flat-field screen as the illumination source. A collimated beam projector (CBP) that illuminates a mask onto the focal plane of the instrument can distinguish focusing light paths from stray and scattered light, allowing for a precise determination of instrumental throughput. We describe the conceptual design of such a system, outline its merits, and present results from a prototype system used with the DECam wide field imager on the 4 meter Blanco telescope. We also present a calibration scheme that blends results from flat-field images with CBP data, to obtain the equivalent of an illumination correction, at high spectral and angular resolution. In addition to providing a precise system throughput calibration, by monitoring the evolution of the intensity of the ghosts in the optical system, the CBP can be used to track the evolution of the filter transmission properties and various anti-reflection coatings in the optical system.

The basic design concept is as follows. An optical fiber (monochromatic or any other desired spectral distribution) brings light originating from some source to an integrating sphere. The light then travels through a shutter to a filter wheel containing a set of ten filters which allows a choice of a variety of mask patterns. After the light has been modified it travels through the focuser, translation stage, collimating telescope, and out of the system. The light is then re-imaged onto the telescope focal plane. The collimator optic will reside inside of the enclosure on an alt-az type mount so that the collimated beam can be re-imaged onto any desired location on the focal plane. With the additional freedom of moving the telescope within the enclosure, the collimated beam can achieve any desired position within the telescope's input pupil. Consequently, the entire 4-d phase space of input ray positions and angles, in principle, can be scanned.

9910-29, Session 7

The JCMT as operated by the East Asian Observatory: a brief (but thrilling) history

Jessica T. Dempsey, Paul T. P. Ho, Craig A. Walther, Per Friberg, East Asian Observatory (United States)

The newly formed East Asian Observatory assumed operations of the James Clerk Maxwell Telescope in March of 2015. In just three weeks, the facility needed to run up completely mothballed observatory operations, introduce the telescope to a vast new scientist base with no familiarity with the facility, and create a non-existent science program. The handover to the EAO has since been a succession of challenging time-lines, and nearly unique problems requiring novel solutions. The results, however, have been spectacular, with subscription rates at unprecedented levels, a new series of Large Programs underway, as well as an exciting Future Instrumentation Project that together promises to keep JCMT at the forefront of wide-field submillimeter astronomy for the next decade.

9910-30, Session 7

SOAR Telescope operation in the LSST era: real-time follow-up on large scales

Jonathan Elias, SOAR Telescope (Chile); Cesar Briceño, Ctr. de Investigaciones de Astronomía (Venezuela)

The SOAR telescope will be well situated, both in terms of location and aperture, to follow up on the stream of brighter transient events generated by the Large Synoptic Survey Telescope (LSST). A critical aspect is that the operation is less likely to be responding to occasional targets of opportunity, and more likely to be responding to a continuing follow of events that must be efficiently prioritized and observed. We discuss the implications for observatory operations, including potential modifications to the telescope itself or to the instrument suite. Representative "use cases" are described to assist in putting potential operational modes into context.

9910-31, Session 7

Organizational transformation to improve operational efficiency at Gemini South

Michiel van der Hoeven, Diego Maltes, Rolando Rogers, Gemini Observatory (Chile)

In this paper we will describe how the Gemini South Engineering team has been reorganized from different functional units into a cross-disciplinary team while executing the transition plan that imposes several staff reductions. While this implies we have a more self-contained engineering team at each site to cover routine operations, we still aim to maintain some sharing of expertise on specialist activities between both sites in Chile and Hawaii.

This reorganization process has been triggered by the budget cuts as a result of the withdrawal of one of the major partners in the Gemini consortium. Whereas these reductions in budget pose severe limitations on how the observatory can operate, at the same time it has provided an opportunity to streamline all the processes.

We will compare how problems are approached under the system based organization and discuss the benefits and challenges we have come across. During any change in organization, the alignment of several factors in such organization is of critical importance in order to be successful. Budgetary processes, staff diversity, leadership style, skill sets and planning are all important factors to take into account to achieve a successful outcome. We will analyze the organizational alignment by using some proven management models and concepts.

Gemini South is placed in a very dynamic and exciting environment with many new astronomy projects coming on-line, now and over the coming years. It becomes a real challenge to maintain a competent and experienced workforce with many new opportunities coming up. By joining forces between the AURA centers (of which Gemini forms part) we have are actively working on sharing resources, that provides interesting career perspectives and leads to staff retention and as well making the overall operation of AURA telescopes more efficient.

Finally we will give some examples how at Gemini we have been searching for creative solutions to do the same with less by activating our (local) community and outsourcing some activities.

9910-32, Session 7

CARMENES-NIR channel spectrograph: how to achieve the full AIV at system level of a cryo-instrument in nine months

Santiago Becerril, Instituto de Astrofísica de Andalucía (Spain)

CARMENES is the new high-resolution high-stability spectrograph built for the 3.5m telescope at the Calar Alto Observatory (CAHA, Almería, Spain) by a consortium formed by German and Spanish institutions. This instrument is composed by two separated spectrographs: VIS channel (550-1050 nm) and NIR channel (900-1700 nm). The NIR-channel spectrograph's responsible is the Instituto de Astrofísica de Andalucía, IAA-CSIC. The channel has been manufactured, assembled, integrated and verified in the last two years. It was delivered to the observatory in fall 2015, and commissioned in December 2015. The expected performances comply with the scientific requirements and its science verification started.

The contouring conditions of this project have led the CARMENES instrument to be a schedule-driven project with a very tight planning. This plays in contradiction to the very complex, calm-requiring tasks and development phases faced during the Assembly, Integration and Verification (AIV) of the NIR-channel spectrograph. In particular, the AIV at system level has been fully designed and implemented at IAA through a very ambitious and zero-contingency plan. This NIR-channel AIV plan has been continuously reviewed and agreed along the project with the CARMENES overall, high-level plan –coordinating the needs of both channels as a whole- developed by the FRACTAL company, holding the Systems Engineering and Project Management of the instrument.

As a large cryogenic instrument, the NIR channel's AIV plan at system level includes necessarily a certain number cryo-vacuum cycles, this factor being the most important for the overall duration of this phase. Indeed, each cryo-vacuum cycle of the NIR-channel runs during 3 weeks roughly to lead the instrument from atmospheric conditions to cryo-vacuum working conditions and again to atmospheric conditions in warm. This plan has therefore been driven to minimize the amount of cryo-vacuum cycles.

Such huge effort has led the AIV at system level at IAA lab to be executed in 9 months from start to end -an astonishingly short duration for a large cryogenic, complex instrument like CARMENES NIR channel- which has been fully compliant with the final deadline of the installation of the NIR channel at CAHA 3.5m telescope. The detailed description of this planning, as well as the way how it was actually performed, is the main aim of the present paper.

9910-33, Session 7

Precipitable water vapour statistical results at Teide Observatory from a routine GPS monitor

Julio A. Castro-Almazán, Casiana Muñoz-Tuñón, Gabriel Pérez-Jordán, Antonia Varela, Begoña García-Lorenzo, Instituto de Astrofísica de Canarias (Spain)

We present statistical results of Precipitable Water Vapour (PWV) at Teide Observatory (OT) since 2009 from a new PWV GPS monitor that has been commissioned at the OT for routine operation in real time. The software for the data processing was validated with other different monitor using the same GPS antenna. On the other hand, the GPS technique itself, was validated by inter-comparison with the output of the Weather Research and Forecasting (WRF) numerical model, previously calibrated with in-situ radiosounding data.

9910-72, Session PWed

ASTRI SST-2M archive system: a prototype for the Cherenkov Telescope Array

Alessandro Carosi, INAF - Osservatorio Astronomico di Roma (Italy) and Agenzia Spaziale Italiana (Italy); Stefano Gallozzi, INAF - Osservatorio Astronomico di Roma (Italy); Fabrizio Lucarelli, Saverio Lombardi, Lucio A. Antonelli, Michele Mastropietro, INAF - Osservatorio Astronomico di Roma (Italy) and Agenzia Spaziale Italiana (Italy); Alberto Madonna, INAF - Osservatorio Astronomico di Roma (Italy)

The ASTRI SST-2M is a dual-mirror, small-sized, end-to-end Cherenkov telescope prototype developed by the Italian National Institute for Astrophysics (INAF) in the framework of the Cherenkov Telescope Array (CTA) gamma-ray observatory. Data preservation and accessibility is guaranteed by means of the ASTRI SST-2M Archive System (AAS) that is responsible for both the on-site and off-site archiving of all data produced by the different ASTRI SST-2M prototype sub-systems. Science, calibration, and Monte Carlo data together with the dedicated Instrument Response Functions (IRFs) (and corresponding metadata) will be properly stored and organized in different branches of the archive. A dedicated technical data archive (TECH archive) will store the engineering and auxiliary data and will be organized under a parallel database system. Through the use of a physical system archive and few logical user archives that reflect the different archive use-cases, the AAS has been designed to be independent from any specific data model and storage technology. A dedicated framework to access, browse and download the telescope data has been identified within the proposal handling utility that stores and arranges the information of the observational proposals. The development of the whole archive system follows the requirements of the CTA data archive and is currently carried out by the INAF-OAR & ASI-Science Data Center (ASDC) team. The prototype AAS is fully adaptable and ready for the ASTRI mini-

array that, formed of nine ASTRI SST-2M telescopes, is proposed to be installed at the CTA southern site.

9910-73, Session PWed

The usefulness and dangers of relying on grant acknowledgments in an observatory bibliography

Sherry L. Winkelman, Arnold H. Rots, Smithsonian Astrophysical Observatory (United States)

The Chandra Data Archive has been maintaining an observatory bibliography for many years by: 1) searching for broad key words, such as "x-ray", in the ADS to find all potential ADS records which may contain Chandra references; 2) accessing those articles in an automated way to perform a full-text search of the article for specific words such as "Chandra"; and 3) reviewing those articles which have passed the first two tests to assess their inclusion in the bibliography. During the assessment phase, we link Chandra data used in the article to the article's bibcode and use this linking as the starting point for measuring the scientific impact of the Chandra observatory. We also make determinations based on data links, author lists, and principal investigators (PI) to assess the impact of PI teams.

In addition to observing programs which result in new Chandra data, the Chandra X-ray Center also provides funding for archival research or theoretical work using public Chandra data. Assessing the science impact of these programs is difficult to assess from a bibliography based on data links. However, recently the Chandra Data Archive (CDA) has obtained access to funding information related to all approved Chandra proposals and we intend to use grant information acknowledged in manuscripts to assess these programs. Using grant acknowledgments is becoming a popular means of maintaining observatory bibliographies, but the accuracy of this method is difficult to assess. The CDA is in a unique position to compare program statistics based on grant acknowledgments to those based on data links. The purpose of this paper is to present in a quantitative way an assessment of how well grant and/or program acknowledgments reflect the scientific impact of Chandra observing, archive and theory programs.

This work is supported by NASA contract NAS8-03060.

9910-74, Session PWed

Gemini base facility operations environmental monitoring: key systems and tools for the remote operator

Martin Cordova, Andrew W. Serio, Javier Fuentes, Francisco Meza, Gemini Observatory (Chile); Gustavo Arriagada, Jesse Ball, Gemini Observatory (United States); Hector Swett, Gemini Observatory (Chile); Paul Collins, Neal Masuda, Gemini Observatory (United States)

In 2013 Gemini Observatory started the base facility operations (BFO) project. The project's goal is to provide the ability to operate the two Gemini telescopes from their base facilities (respectively Hilo, HI at Gemini North, and La Serena, Chile at Gemini South). BFO has been identified as a key project for Gemini's transition program as it creates an opportunity to reduce operation costs. The Gemini North telescope started remote operations from the Hilo base facility in Hawaii in November 2015, and we are starting the process at Gemini South to implement BFO by 2016.

In order to provide night-time staff with the necessary tools for remote observing, the following critical environmental factors that affect night time observations were identified: wind speed, outside temperature, outside humidity, outside dew point, precipitation, ice on the dome, precipitation, cloud cover, presence of fog and earthquake detection. This paper focuses on the environmental monitoring portion of the BFO project, which is needed to inspect these critical factors. For the Gemini North telescope we divided environmental monitoring into the following work packages: weather sensor upgrades (wind speed, temperature, humidity, precipitation, and ice), cloud-sensing systems (cloud cover), fog detection (A&V) and earthquake detection system (earthquake detection). All these work packages have been successfully implemented at Gemini North by the author and co-authors of this paper. For Gemini south telescope these four work packages have been consolidated into one larger work package for environmental monitoring.

This paper will show the methods and design used at the Gemini North and Gemini South telescopes to monitor these critical environmental conditions.

9910-75, Session PWed

Approximations of the synoptic spectra of atmospheric turbulence by sums of spectra of coherent structures

Vladimir P. Lukin, Viktor V. Nosov, Andrey V. Torgaev, Evgeny V. Nosov, V.E. Zuev Institute of Atmospheric Optics (Russian Federation)

In article it is shown that at measuring of turbulent parameters it is enough, that the interval of the registered frequencies of fluctuations overlapped the most part of a micro-meteorological interval of a spectrum of atmospheric turbulence as interval the basic energy of turbulent fluctuations of a surface layer is concentrated. At measuring of the meteorological parameters related to low-frequency daily and seasonal changes of a meteo-situation, often it is already not enough width of one this interval. In this case averaging time at the parameter recording is usually incremented from 2-3 minutes to 10 minutes (and more), at the expense of expansion of an interval of measured frequencies.

In the range of continuances from minutes till several hours the field of a mezzo-meteorological minimum is observed in a spectrum of atmospheric turbulence. Spectra again start to increasing in low-frequency field (at decrease of frequency), transiting through the intermediate 12 hour maximum, and reach a synoptic maximum (a continuance of fluctuations about 4-6 days), and then again decrease. Synoptic spectrums viewed in given article cover a wide frequency band, including the micrometeorological, mezo-meteorological and synoptic intervals. On the basis of theoretical Karman model of a three-dimensional spectrum of the temperature fluctuations the theoretical spatial one-dimensional spectrum of a single coherent structure has been found. Use of such spectrum has allowed us to show that the experimental spectrums of a really observable atmospheric turbulence (with frequencies from a micro-meteorological interval, including Kolmogorov turbulence), represent the sums of spectrums of the separate coherent structures of the different sizes (with various outer scales).

Thus, in article, on the basis of gained by us earlier a frequency spectrum of single coherent structure in a micrometeorological interval of atmospheric turbulence, calculate expression for a spectrum of single coherent structure.

The sums of spectrums of coherent structures with various outer scales successfully approximate the experimental spectrums of atmospheric turbulence in a wide frequency band (including micro-meteorological, mezzo-meteorological and synoptic intervals). The results gained in the present work confirm and expand on the field of very low frequencies made earlier in our articles a conclusion that, despite their complex internal structure, coherent structures are a elemental components (fundamental particles) of atmospheric turbulence. It is shown that known experimental synoptic spectrums of really observable atmospheric turbulence (including spectrums of small-scale turbulence, the spectrum by Van ??? Hovena, 1957; the spectrum by Monin and Kolesnikova, 1965) represent the sums of spectrums of single coherent structures with the different sizes (with

various outer scales).

The authors are grateful to the Russian Foundation for Basic Research for financial support (grant no. 15-05-05404).

9910-76, Session PWed

ALMA array operation group process overview

Emilio Barrios, Hector Alarcon, ALMA (Chile)

ALMA observatory is a very complex interferometer consisting in 66 antennas, 4 different antennas model and 2 correlators installed on Llano de Chajnantor, at 5050 m altitude in the Chilean Andes. The complexity of the system is a particular challenge to engineers, scientists and operators alike.

Science operations activities in Chile are responsibility of the Science Operations Department, which consists of three groups: the Program Management Group, the Data Management Group and the Array Operations Group (AOG).

The Array Operation Group (AOG) consist in 10 operators, one Array operator group Manager and 1 deputy Manager. The group does provide support for Science Observations and to the day-to day engineering activities, in parallel with the observations, operating safely and efficiently the Interferometric Arrays, remotely from the Operation Support Facility at 2,950 meters Altitude.

They should follow the observatory goals and objectives yearly defined, the science and engineering coverage needs, the management and coordination agreements, the ALMA Safety and emergency rules, the weather conditions and the antenna operation policies and permissions.

AOG is responsible for operate the antennas and their instrumentation, ensure the correct execution of semiautomatic processes, monitor the antenna performance, the environmental and safety conditions, adjust the relevant system parameters accordingly, perform basic diagnosis and correction of problems that may arise during the work shift, prepare systems before the observation time and maintenance activities, execute and monitor the observations progress, report problems, and develop and maintain operational procedures and tools (checklist, internal communication flow, procedures updated, troubleshooting guide lines, scripts)

Array operators works in 8x6 turnos (7 effective shifts) providing 24 hrs coverage with 4 rotative shifts (Morning, Afternoon, Evening and Night). The AOG deputy is responsible to organize and consolidate the schedule among the Array Operators with at least one month in advance.

The Array Operator lead is the AOG Manager that supports the head of Science Operations in defining policies and procedures for ALMA science operations as well as in planning and coordinating science operations activities. Also organize and evaluate tests of the OMC software tool (operators interface to the control system), Shiftlog, Problem Reporting System, Alarms System, and Logging System.

The purpose of the Poster is to show an overview of the Array Operation process, group management and tools used in the context of the Science Operation Observations.

9910-77, Session PWed

System-dependent earthquake inspection procedures at Paranal Observatory

Juan Osorio, Andres Ramirez, European Southern Observatory (Chile)

Paranal Observatory is located near Antofagasta city, northern Chile , one of the most seismic regions in the world. Telescopes and scientific instruments are permanently exposed to the risk of damage caused by earthquake events, ranging from optical misalignment to complete cease of operations. A seismic monitor is installed on the site, providing real-time data to make rapid post-earthquake assessments of expected damage and determine the areas, type and level of inspections to be carried out before continuing with the regular operations. With more than ten years of seismic data and its correlation with reported issues, we show that the inspection and recovery strategy can be defined taking into account the characteristics of the seismic event and according to system-dependent criteria.

SystMon: a data visualization tool for the analysis of telemetry data

Juan Carlos Guerra Ramon, Christian Stephan, Javier Valenzuela, Pedro Mardones, Nicolas F. Haddad, Eduardo Peña, European Southern Observatory (Chile)

The Paranal Very Large Telescopes (VLT) Observatory is a complex multifunctional observatory where many different systems are generating telemetry parameters. As systems becoming more and more complex, also the amount of telemetry data is increasing. This telemetry data is usually saved in various data repositories. In order to obtain a full system overview, it is necessary to link all that data in a meaningful and easy to interpret way. A step forward from simple telemetry data visualization has been done by developing a new tool that can combine different data sources and has a powerful graphing capability. This new tool, called SystMon, is developed in iPython an interactive-web browser environment under the philosophy of notebooks which combine the code and the final product. The application can be shared among other colleagues and having the code side by side gives the accessibility to inspect and review the process improving and adding new capabilities to the application. SystMon allows to manipulate, generate and visualize data in different types of graphs and also to create directly statistical reports. SystMon helps the user to model, visualize and interpret telemetry data in a web-based platform for monitoring the health of systems, understanding short- and long-term behaviour and to anticipate corrective interventions.

Obsolescence of electronics at the VLT

Gerhard Hüdepohl, Juan Pablo Haddad, European Southern Observatory (Chile)

The ESO Very Large Telescope Observatory (VLT) at Cerro Paranal in Chile had its first light in 1998. Most of the telescopes electronics components were chosen and designed in the mid 90s and are now around 20 years old. This leads to the problem of increasing failure rates due to aging and lack of spare parts, as many of them are no longer available on the market.

The lifetime of large telescopes is generally much beyond 25 years. Therefore the obsolescence of electronics components and modules forces the operations teams to upgrade the systems to new technology.

This is a time and money consuming process, which often is not straightforward and has various types of complications.

This poster shows the analysis, approach, timeline, complications and progress in upgrades at the Paranal Observatory.

9910-81, Session PWed

Operation of AST3 Telescope and site testing at Dome A, Antarctica

Zhaohui Shang, Tianjin Normal Univ. (China) and National

Astronomical Observatories (China); Yi Hu, Bin Ma, National Astronomical Observatories (China)

We have successfully operated the AST3 telescope remotely as well as robotically for time-domain sky survey in 2015. We have set up a real-time system to support the operation of the unattended telescope, monitoring the status of all instruments as well as the weather conditions. The weather tower also provides valuable information of the site at the highest plateau in Antarctica, demonstrating the extremely stable atmosphere above the ground and implying excellent seeing at Dome A.

The real-time monitoring system has a web-based interface displaying a picture of the site and the telescope taken with a webcam every hour. The observatory consists of the telescope, a CCD camera, an on-site Control, Operation and Data System (CODS), other small experiments, and an independent supporting system, PLATO-A, for power and communication. During the operation season, CODS ran many daemon programs and scripts in the background to collect information from different sources which is transferred back via Iridium satellites and then shown on our website in real-time. All data sampling rates can be customized remotely. We were able to show key status of the telescope, including various temperatures, voltages and currents, pointing and tracking, and focusing etc. We were also able to monitor the CCD camera temperatures and image quality in real-time. CODS collects information on its control computer, data storage system, and pipeline system as well. There is also an alarming system which, once triggered by any malfunction or pre-defined conditions, sends different SMS immediately to different people in charge. In addition, we have set up a 15-m weather tower with sensors at various heights for site testing as well as assisting the operation. It records very strong temperature inversion and stable atmosphere, especially in local winter, confirming what we have found in 2011 and indicating a very promising site for astronomical observations. Further data analysis will quantitatively evaluate the quality of the site as an astronomical observatory for large telescopes.

Operations of the laser traffic control system in Paranal

Paula Santos, Paola Amico, European Southern Observatory (Germany); Douglas M. Summers, Large Binocular Telescope Observatory (United States); Philippe R. Duhoux, Robin Arsenault, Thomas Bierwirth, Harald Kuntschner, Pierre-Yves Madec, European Southern Observatory (Germany); Michael Pruemm, European Southern Observatory (Germany) and Informate (Germany); Marina Rejkuba, European Southern Observatory (Germany)

The Laser Traffic Control System (LTCS) of the Paranal Observatory is the first component of the Adaptive Optics Facility (AOF) to enter routine operations on the 1st of October of 2015. Its genesis dates back to the 2009 AOF final design review, when the need for a laser beam avoidance tool was recognised as the best way to support operations of an observatory equipped with four powerful lasers and a large number of laser-sensitive instruments.

After an initial review, the LTCS developed for Maunakea, and operated since 2002, became the tool of choice for the Paranal Observatory, provided it could be adapted to fit its operational model, in particular, interfacing with Paranal's observing tools.

LTCS-Paranal, now deployed and embedded in the Observatory's operational environment, provides the observers with real-time information about on-going collisions, predictive information for possible collisions, and priority resolution between telescope pairs, where at least one telescope is operating a laser. It supports: 1) high configurability of telescopes and instruments, in particular the frequent changes of station of the Auxiliary Telescopes on the VLT Interferometer platform; 2) right-of-way priority rules that support the different operational scenarios at the Observatory, namely mixed visitor and service mode nights (Q-scheduling), high priority observations (Target of Opportunity, Rapid Response Mode, etc.) and commissioning runs; 3) changes of laser constellation configurations, enabling to switch, even during a night, between single centrally propagated laser to the different available 4-laser constellations, typical for the AOF instruments such as MUSE and HAWK-I; 4) future laser-equipped telescopes (including the E-ELT) and 5) interfacing with ESO's observing tools, OT (Observing Tool) and vOT (visitor Observing Tool), for service and visitor mode observations.

The observing tools have been interfaced with the LTCS, tested and deployed at the observatory in March 2015. Since then, they offer laser collision detection features to the users. For each observation, information on possible collisions is obtained through HTTP get requests to the LTCS Query Server and suitably displayed in the graphical user interface. The tools also support laser sensitivity analysis, avoiding collision reports whenever the setup used for an observation is not sensitive to the laser.

While LTCS' displays and alarms cover the real-time operational scenario, the new laser collision detection features available in OT and vOT facilitate the short-term observation planning, informing the users of any laser collisions before starting an observation in a "what-if" scenario: "if I start this observation now, will there be any laser collisions?". Altogether, LTCS-Paranal and the observing tools allow the night operators to plan and execute their observations without worrying about possible collisions between the laser beam(s) and other laser-sensitive equipment, aiming at a more efficient planning of the night and, consequently, preventing time losses and laser-contaminated observations.

NIRSpec pre-imaging

Leonardo Ubeda, Tracy Beck, Space Telescope Science Institute (United States)

Most observations with NIRSpec spectroscopy (such as all MSA observations, as well as crowded-field observations using the IFU and FS) will require high spatial resolution images of the science field previous to performing the spectroscopy. This is due to the fact that the standard NIRSpec target acquisition (TA) procedure needs to acquire reference stars with a position RMS of less than 20mas. NIRSpec TA uses 8-20 reference stars with accurate astromerty (<5mas) calculates centroids of the individual stars on the detector, transforms their pixel coordinate positions into positions on the sky, and iterates on the telescope pointing and slew until the position RMS of the reference stars is less than 20mas.

For some planned observations, very high spatial resolution HST images (either ACS/WFC or WFC3/UVIS/IR) might be already available and, in other cases, NIRCam observations will be performed.

For a planned NIRSpec observation, we describe in detail the proposed method to generate a high resolution mosaic of the NIRSpec field of view. We show the results of an example using existing HST/ACS observations and we also describe the proposed procedure using simulated NIRCam images. We also describe the creation of source catalogs. These two data products will be crucial for the success of most NIRSpec observations.

Sun avoidance strategies at the Large Millimeter Telescope

Kamal Souccar, Univ. of Massachusetts Amherst (United States); David R. Smith, MERLAB, P.C. (United States); F. Peter Schloerb, Gary Wallace, Univ. of Massachusetts Amherst (United States)

The Large Millimeter Telescope observatory is extending its night time operation to the day time. A sun avoidance strategy was therefore implemented in real-time in the control system to avoid excessive heating of the secondary mirror and the prime focus.

The LMT uses an “on-the-fly” trajectory generator that receives as input the target location of the telescope and in turn outputs a commanded position to the servo system. The sun avoidance strategy is also implemented “on-the-fly” where it intercepts the input to the trajectory generator and alters that input to avoid the sun. Two sun strategies were explored. The first strategy uses a potential field approach where the sun is represented as a “high-potential” obstacle in joint space and the target location is represented as a “low-potential” goal. The potential field is repeatedly calculated as the sun and the telescope move and the telescope follows the induced force by this field.

The second strategy is based on path planning using visibility graphs where the sun is represented as a polygonal obstacle in joint space and the telescope follows the shortest path from its actual position to the target location via the vertices of the sun’s polygon.

The visibility graph approach was chosen as the favorable strategy due to the efficiency of its algorithm and the simplicity of its computation.

Observing with FIFI-LS on SOFIA: time estimates and strategies to use a field imaging spectrometer on an airborne observatory

Christian Fischer, Aaron Bryant, Simon Beckmann, Sebastian Colditz, Fabio Fumi, Univ. Stuttgart (Germany); Norbert Geis, Max-Planck-Institut für extraterrestrische Physik (Germany); Thomas Henning, Max-Planck-Institut für Astronomie (Germany); Rainer Hönle, Christof Iserlohe, Univ. Stuttgart (Germany); Randolf Klein, NASA Ames Research Ctr. (United States); Alfred Krabbe, Univ. Stuttgart (Germany); Leslie W. Looney, Univ. of Illinois at Urbana-Champaign (United States); Albrecht Poglitsch, Max-Planck-Institut für extraterrestrische Physik (Germany); Walfried Raab, European Space Research and Technology Ctr. (Netherlands); Felix Rebell, Univ. Stuttgart (Germany); Christopher Q. Trinh, NASA Ames Research Ctr. (United States)

Observing on the Stratospheric Observatory for Infrared Astronomy (SOFIA) requires a strategy that takes the specific circumstances of an airborne platform into account. Observations of a source cannot be extended or shortened on the spot due to flight path constraints. Still no exact prediction of the time on source is available since there are always wind and weather conditions and sometimes technical issues. Observations have to be planned to maximize the observing efficiency while maintaining full flexibility for changes even during the observation.

The Field-Imaging Far-Infrared Line-Spectrometer (FIFI-LS) entered service on SOFIA in March 2014. Up to November 2015 it has completed 24 commissioning and science observing flights. The instrument features two parallel spectral channels with wavelength ranges of ~51?m to ~120?m and ~115?m to ~203?m respectively. Each channel has a field of view of 5 by 5 spatial pixels with a size of 6”/pixel in the short wavelength channel and 12”/pixel in the long wavelength channel. The spectral resolution of the instrument is in the range of R=~1000 to ~2000. With its combination of wavelength range, resolution and imaging capabilities FIFI-LS is designed specifically for the investigation of the interstellar medium in our own and other galaxies.

The complex nature of observations with FIFI-LS, e.g. the interlocking cycles of the mechanical gratings, telescope nodding and dithering, is considered in the observing strategy as well. Starting with SOFIA Cycle 3, FIFI-LS is available to general investigators. Requested observations are planned in a standardized way. One must be able to define the needed parameters simply, without being familiar with the instrument. These parameter sets will still result in efficient observations and have all the information for the inflight team to maximize the science output as boundary conditions change.

In this poster/paper we will describe the observing process with FIFI-LS from the integration time estimate and the mapping area to the actual observation performed in flight. This includes an overview of the observing scenarios that have proven to be useful for FIFI-LS. Using typical FIFI-LS observations, we show how observations are laid out. This will include:

• mapping of bright and faint sources including spatial redundancy due to the challenging calibration of far infrared measurements,

• how the required spectral coverage and redundancy affect the observing efficiency and strategy,

• how to efficiently distribute observations of the same target over multiple flights,

• how to implement observatory specific features e.g. “line of sight rewinds” into the observations while keeping the observations flexible until the commence for consortium as well as for general investigator targets,

• how the performance parameters of the SOFIA telescope lead to certain observing modes that are efficient yet still flexible.

9910-86, Session PWed

High precision tracking method for solar telescope

Jingjing Guo, Chinese Academy of Sciences (China); Yunfei Yang, Kaifan Ji, Song Feng, Kunming Univ. of Science and Technology (China); Jiaben Lin, Zhen Zeng, Bingxiang Wang, Chinese Academy of Sciences (China)

A high-precision real-time tracking method for solar telescope was introduced, this method was based on the full-disk solar image barycenter algorithm. To make sure the calculation of the barycenter was accurate and reliable, a series of strict logic limits were set, such as the gray threshold, the range limit of the barycenter displacement and its deviation from a perfect disk. So we could eliminate noise caused by bad weather, such as clouds and fog, and located the barycenter of the full-disk solar images which recorded by large array CCD in real time robustly. The barycenter displacements detection and the telescope axis control formed an automatic close loop and realized the high precision tracking. An Ethernet interface was also provided for remote control. In the observation, the precision of this new method was better than 1?/30 minutes.

ESO Phase 3 automatic data validation: groovy-based tool to assure the compliance of the reduced data with the science data product standard

Laura Mascetti, Terma GmbH (Germany) and European Southern Observatory (Germany); Vincenzo Forchi, Magda Arnaboldi, Nausicaa A. R. Delmotte, Alberto Micol, Joerg Retzlaff, Stefano Zampieri, European Southern Observatory (Germany)

The ESO Phase 3 infrastructure provides a channel to submit reduced data products for publication to the astronomical community and long-term

data preservation in the ESO Science Archive Facility. To be integrated into Phase 3, data must comply with the ESO Science Data Product Standard in terms of format and metadata. For this purpose ESO has developed a new Groovy based tool that carries out an automatic validation of the reduced products triggered when data are submitted.

Here we present the structure of the tool and the checks that are implemented. The rules involved are organized in a hierarchical way and grouped in sets in order to perform a validation customized to the different type of products, for example image, spectrum, catalogue, IFU cube, etc.

Automated scheduler improvements and generalizations for the Automated Planet Finder

Bradford P. Holden, Jennifer Burt, William T. S. Deich, Univ. of California Observatories (United States)

The Automated Planet Finder (APF), designed as a single purpose facility to search for exoplanets, has become a general use observatory that is used by observers the world over. We describe the improvements of our software for operations to both optimize work for finding planets and supporting a much broader community of astronomers with a variety of interests and requirements. These include a variety of observing modes beyond the originally envisioned fixed target lists, such as time dependent priorities to meet the needs of rapid varying targets, and improved tools for simulating observing cadence for the planet hunting teams. None of the changes resulted in lost observing time, and were implemented by the only permanent staff member for the APF. The of implementation of these additions illustrates the power and flexibility of the underlying software infrastructure.

9910-89, Session PWed

Trends and developments in VLT data papers as seen through telbib

Uta Grothkopf, Silvia Meakins, Dominic Bordelon, Michael Sterzik, European Southern Observatory (Germany)

The ESO Telescope Bibliography (telbib) is a database of refereed papers published by the ESO users community. It links data in the ESO Science Archive with the published literature, and vice versa. Developed and maintained by the ESO library, telbib also provides insights into the organization's research output and impact as measured through bibliometric studies.

Numerous reports, statistics, and visualizations derived from telbib help to understand the way in which the user community uses ESO/VLT data in publications. Based on selected use cases, this contribution will showcase recent trends and developments.

Optimizing the observational efficiency of the Southern African Large Telescope (SALT) using dynamic scheduling

Paul Kotze, Petri Vaisanen, Christian Hettlage, Encarni Romero Colmenero, Steve M. Crawford, Brent Miszalski, Chris Coetzee, South African Astronomical Observatory (South Africa)

The Southern African Large Telescope (SALT) is a fully queue schedule telescope. Observations are executed using observing blocks which contain target and instrument configuration information. Observing blocks are assigned priorities by principle investigators according to the scientific priority categories assigned to the program by the time allocation committee. The dynamic scoring algorithm used by the SALT Operations Team aims to maximize the number of high priority observing blocks completed during an observing semester.

There are a number of static parameters in the dynamic scoring algorithm. The priority of blocks are converted to a score, as are the program-internal rankings supplied by the PI. Since SALT time is allocated by consortium partner shares, an adjustment is made to the score based on how much time the partner in question has received to date.

Dynamic parameters in the algorithm aim at taking into account the likelihoods of getting an observation done as well as the completeness of programs. i.e. the aim is to observe those blocks first which are disappearing first, those with more stringent Moon and Seeing conditions, as well as completing visits to a given target already started, not to waste observing time in partial observations. Object availability is determined from the total number of nights a target is still visible during the remainder of the semester. Completeness of blocks and programs are simply calculated by summing up the time in accepted blocks vs. the allocated times. These schemes also take into account monitoring programs with repeated visits necessary over a given time, as well as pools of optional targets.

The aim of the scoring algorithm is to give the observer and indication which block would be most efficient to observe at the given time to maximize the high-priority block completeness over the whole semester. Previously, the SALT Astronomer made these decision based solely on the present conditions and the scientific priority of the blocks available at the given time.

We discuss the limitations and future development of the algorithm. At present, the scheduling essentially follows a greedy search algorithm. It is the best solution for changing conditions since one only considers the next available target, although it is not necessarily the optimal global solution for a whole night. Rapidly changing weather conditions and unpredictable mirror alignments make it difficult to schedule a whole night. However, the present algorithm already can be used effectively by using it to recreate the queue during the night as conditions change.

Finally, we discuss development of semester long simulations of the SALT observing queue, and how it has represented actual observations during the latter half of 2015. We also have given the PIs tools to estimate the probabilities of getting their observations done with the constraints that they define for the blocks.

9910-92, Session PWed

Large collaboration in observational astronomy: the Gemini Planet Imager exoplanet survey case

Franck Marchis, SETI Institute (United States); Paul R. Kalas, Univ. of California, Berkeley (United States); Marshall D. Perrin, Space Telescope Science Institute (United States); Quinn M. Konopacky, Univ. of California, San Diego (United States); Dmitry Savransky, Cornell Univ. (United States); Bruce A. Macintosh, Stanford Univ. (United States); James R. Graham, Univ. of California, Berkeley (United States)

The Gemini Planet Imager (GPI) is a next-generation high contrast imager constructed for the Gemini Observatory. It is one of the most advanced planet-imaging systems in operation – an order of magnitude more sensitive than any previous AO systems, capable of detecting and spectroscopically characterizing young Jovian planets 106 times fainter than their parent star at separations of 0.5 arcseconds as well as studying debris disks.

Our team initiated the GPI Exoplanet Survey (GPIES) in November 2014. Our goal is to observe ~600 stars in 850 h of telescope time in three years to look for young Jupiter-like exoplanets and debris disks. The team includes ~90 researchers from ~35 institutions located mostly in North and South America, a rather unique case in ground-based astronomy but probably the future of all major instrumentation-based survey in astronomy. Significant efforts, including a task-oriented structure of the team, a detailed campaign policies and data rights document will be described. Our team focused on using modern communication tools (wiki website, project management, telecon, mailing lists, shared documents), optimized scheduler and data processing pipelines (data sharing, several algorithms to search for planets and disk). Our goal is to optimize operation management and improve the technical and scientific productivity of this campaign while maintaining its cost. We will describe lessons learned, progress made and future ideas to conduct such long-term surveys in collaboration with large telescope observatories.

9910-93, Session PWed

Data reduction pipelines for the Keck Observatory archive

Hien D. Tran, Richard W. Cohen, Andrew Colson, Jeffrey A. Mader, W. M. Keck Observatory (United States); Graham B. Berriman, Christopher R. Gelino, NASA Exoplanet Science Institute (United States)

The Keck Observatory Archive (KOA) currently serves 40 TB of data spanning over 20 years from all ten past and current facility instruments at Keck.

Although most of the available data are in the raw (level-0) form, one of KOA's goals is to produce quick-look, browse reduced (level-1) products for all of the instruments so that users can better assess the scientific content and quality of the data.

It is necessary to develop completely hands-off, automated data reduction pipelines (DRPs) for this purpose. Our approach is to adapt existing pipelines and algorithms where possible, and use languages that do not require special environments or commercial licenses, in order to maximize their utility and usefulness to the user community as well.

We describe what level-1 data products are currently available in KOA, review the existing reduction tools for Keck data, and present our plans and anticipated priorities for the development of automated DRPs and release of reduced data products for the current and future instruments in KOA. In addition to the raw data, KOA currently serves quick-look, level-1 products generated by automated pipelines for four instruments (HIRES, NIRC2, OSIRIS, LWS).

KOA underwrote the update of the MAKEE software to support reduction of the CCD upgrade to HIRES, developed scripts for reduction of NIRC2 data and automated the existing OSIRIS and LWS data reduction packages. We recently completed the development of a fully automated pipeline written in Python for NIRSPEC. This DRP will be used to create level-1 products for KOA, and made available for use by the community through open source repositories such as Github. The challenges encountered in designing this pipeline include fully automating the wavelength calibration, which was solved by using an algorithm that performs a two-dimensional fit to sky lines. We also anticipate that Keck's newest instrument NIRES, which will be delivered with a fully automated DRP, will be the first to have both raw and level-1 data ingested at commissioning.

HIRES the high resolution spectrograph for the E-ELT: integrated data flow system

Guido Cupani, Stefano Cristiani, Valentina D'Odorico, INAF - Osservatorio Astronomico di Trieste (Italy); Emanuele Pomante, Univ. degli Studi di Trieste (Italy); Giorgio Calderone, Paolo Di Marcantonio, INAF - Osservatorio Astronomico di Trieste (Italy); Alessandro Marconi, Univ. degli Studi di Firenze (Italy)

The current E-ELT instrumentation plan foresees a High Resolution Spectrograph conventionally indicated as HIRES whose Phase A study will start in 2016. An international consortium (called the "HIRES initiative") is conducting a a preliminary study of a modular E-ELT instrument able to provide high-resolution spectroscopy (R~100,000) in a wide wavelength range (0.37-2.5 ?m). For the aims of data treatment (which encompasses both the reduction and the analysis procedures) an end-to-end approach has been adopted, to directly extract scientific information from the observations with a coherent set of interactive, properly-validated software modules. This approach is favoured by the specific science objectives of the instrument, which pose unprecedented requirements in terms of measurement precision and accuracy. In this paper we present the architecture envisioned for the HIRES science software, building on the lessons learned in the development of the data analysis software for the ESPRESSO ultra-stable spectrograph for the VLT (currently at the integration phase).

9910-95, Session PWed

Aircraft avoidance for laser propagation at the Large Binocular Telescope Observatory: life under a busy airspace

Gustavo Rahmer, Julian C. Christou, Michael J. Lefebvre, Large Binocular Telescope Observatory (United States)

A key aspect of LGS operations is the implementation of measures to prevent the illumination of airplanes flying overhead. The most basic one is the use of "aircraft spotters" in permanent communication with the laser operator. Although this is the default method accepted by the FAA to authorize laser propagation, it relies on the inherent subjectivity of human perception, and requires keeping a small army of spotters to cover all the nights scheduled for propagation.

Following the successful experience of other observatories (Keck and APO), we have installed an automatic aircraft detection system developed at UCSD known as TBAD (Transponder-Based Aircraft Detection). The system has been in continuous operation since April 2015, collecting detection data every night the telescope is open.

We present a description of our system implementation and operational procedures. We also describe and discuss the analysis of the TBAD detection data, that shows how busy our airspace is, and the expected impact on the operation efficiency of the observatory.

9910-96, Session PWed

Genetically optimizing weather predictions

Stephen B. Potter, South African Astronomical Observatory (South Africa); Kai Staats, African Institute for Mathematical Sciences (South Africa)

For the past ~7 years the Southern African Large Telescope (SALT) has archived its live weather data (temperature, humidity, air pressure, wind speed and wind direction). Built upon this database, we have developed a remarkably simple approach to derive a functional weather predictor. The aim is to provide up to the minute local weather predictions in order to prepare dome environment conditions ready for night time operations or plan, prioritise and update weather dependent observing queues.

We take the current live weather readings, then search the entire archive for similar conditions. Predictions are made against an averaged, subsequent 24 hours of the closest matches for the current readings. We use Genetic Programming and Genetic Algorithms to optimise our formula through weighted parameters.

The accuracy of the predictor is routinely tested and tuned against the full, updated archive to account for seasonal trends and total, climate shifts.

The live (updated every 5 minutes) SALT weather predictor can be viewed here:

http://www.saao.ac.za/~sbp/suthweather_predict.html

Opto-mechanical design of a deployable tertiary mirror for the Keck I telescope

Christopher T. Ratliff, Univ. of California Observatories (United States) and W.M. Keck Observatory (United States); Gerald Cabak, Jason X. Prochaska, Univ. of California Observatories (United States); Sean M. Adkins, W. M. Keck Observatory (United States); David J. Cowley, Jerry Nelson, Andrew C. Phillips, Michael Peck, James Ward, William T. S. Deich, Michael Bolte, Dale Sandford, Alex Tripsas, Univ. of California Observatories (United States)

The new deployable tertiary mirror for the Keck I telescope at the W. M. Keck Observatory presents unique challenges for opto-mechanical design. The mirror needs to either reflect the beam to one of six positions around the telescope elevation ring or retract out of the way to allow the use of Cassegrain instruments. At the same time, the in-beam pointing of the mirror must be repeatable to less than 11.5 arcseconds. This paper addresses the mechanical designs developed to meet these functional requirements. One key consideration is gravitational deformations of the mirror support structure. Since gravitational forces vary with telescope orientation, we performed extensive analyses where deformation and mirror pointing error are predicted to confirm that pointing can meet requirements with a non-vignetting instrument profile.

To achieve a non-vignetting profile, the mirror assembly, which exceeds 100 Kg, has to retract into a narrow 300mm thick volume outside of the Cassegrain field of view and inside the shadow of the M1 to M2 optical path. To address the repeatability of mirror pointing, we use kinematic mechanisms for deployment positioning, mirror azimuth positioning and mirror assembly mounting. The repeatability of the kinematic coupling was confirmed with a test bed. The use of high precision displacement sensors showed that our position repeatability at each kinematic interface was less than 2 microns. We are currently in the detailed design phase of this project. Construction will follow with installation at the observatory approximately 1 year later.

DAG telescope site studies and infrastructure for possible international co-operations

Sinan Kaan Yerli, Middle East Technical Univ. (Turkey); Cahit Yesilyaprak, Atatürk Üniv. (Turkey); Onur Keskin, Isik Üniv. (Turkey)

The selected site for the 4 m DAG (Eastern Anatolian Observatory in Turkish) telescope is “Karakaya Tepeleri”, at 3170m altitude. The telescope’s optical design is performed by the DAG technical team to allow infrared observation at high angular resolution, with its adaptive optics system to be built in Turkey. In this paper; a brief introduction about DAG telescope design; planned instrumentation; the meteorological data collected from 2008, clear night counts, short-term DIMM observations; current infrastructure to hold auxiliary telescopes; auxiliary buildings to assist operations; the observatory design; and coating unit plans will be presented along with potential collaborations in terms of instrumentation and science programs.

9910-100, Session PWed

An autonomous observation and control system of BSST in Antarctic

Peng-yi Tang, Jian Wang, Guangyu Zhang, Ming-hao Jia, Jie Chen, Shu-cheng Dong, Fengxin Jiang, Hong-fei Zhang, Univ. of Science and Technology of China (China)

Many astronomy telescopes are built in remote sites such as high altitude plateau and mountain, Antarctic, and outer space, because they offer better seeing, less atmospheric water vapour, and reduced light pollution. But these areas are not suitable for human habitation for its harsh environments. Hence the ability of autonomous observation and control for astronomical telescope is highly required. This paper describes the design of an Antarctic autonomous observation and control system with remote operation, which is aimed at the Antarctic Bright Star Survey Telescope (BSST) which will be built in 2016 at Zhongshan Station, Antarctic.

BSST is a small telescope with 30cm aperture, which is used to study extrasolar planet. Its field of view is wide, so it can observe many targets simultaneously, which has advantage of bright star survey. After its construction, BSST will take advantage of polar night to make observation on wide scope sky area.

An EPICS (Experimental Physics and Industrial Control System) and RTS2(Remote Telescope System, 2nd Version) based autonomous observation and control system with remoted operation is designed for BSST. EPICS is a set of Open Source software tools, libraries and applications developed collaboratively and used worldwide to create distributed soft real-time control systems for scientific instruments while RTS2 is an open source environment for control of a fully autonomous observatory. Using the advantage of EPICS and RTS2 respectively, a combined integrated software framework for autonomous observation and control is established that use RTS2 to fulfill the function of astronomical observation and use EPICS to fulfill the device control of telescope.

The structure of the autonomous observation and control system for telescope in Antarctic is designed and developed based on RTS2 and EPICS. Observation control models are designed based on RTS2. A command and status interface for EPICS and RTS2 is designed to make the EPICS IOC (Input/Output Controller) components integrate to RTS2 directly. For the specification and requirement of control system of telescope in Antarctic, core components named Executor and Auto-focus for autonomous observation is designed and implemented with remote operation user interface based on Browser-Server mode.

To realize autonomous observation of BSST, we investigate the need of observation and define several observation mode and observation plan. Executor can automatically load plans from database and execute them. Status Monitor and alarm mechanism is designed for the automatic control of telescope.

The whole system including the telescope is tested in Lijiang Observatory in Yunnan Province for practical observation to complete the autonomous observation and control, including telescope control, camera control, dome control, weather information acquisition with the local and remote operation.

Education and public engagement in observatory operations

Pavel Gabor, Vatican Observatory Research Group (United States); Louis Mayo, NASA Goddard Space Flight Ctr. (United States); Dennis Zaritsky, The Univ. of Arizona (United States)

Education and public engagement (EPE) is an essential part of astronomy's mission. New technologies, remote observing and robotic facilities are opening new possibilities for EPE. A number of projects (e.g., NASA-sponsored Global Telescopes In Education, UNC's Skynet) have developed new infrastructure, a number of observatories (e.g., University of Arizona's "full-engagement initiative" towards its astronomy majors, Vatican Observatory's collaboration with high-schools) have dedicated their resources to practical instruction and EPE. Some of the facilities are purpose built, others are legacy telescopes upgraded for remote or automated observing. Networking among institutions is most beneficial for EPE, and its implementation ranges from informal agreements between colleagues to advanced software packages with web interfaces. The deliverables range from reduced data to time and hands-on instruction while operating a telescope. EPE represents a set of tasks and challenges which is distinct from research applications of the new astronomical facilities and operation modes. In this paper we examine the experience with several EPE projects, and some lessons and challenges for observatory operation.

Monitoring the performance of the Southern African Large Telescope

Christian Hettlage, Chris Coetzee, Petri Vaisanen, Encarni Romero Colmenero, Steven M. Crawford, Paul Kotze, Paul Rabe, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa); Stephen Hulme, Southern African Large Telescope (South Africa); Janus Brink, Deneys S. Maartens, Keith R. J. Browne, Ockert Strydom, South African Astronomical Observatory (South Africa) and Southern African Large Telescope (South Africa); David De Bruyn, Amazon (South Africa)

The efficient running of a telescope requires both engineers and scientists to be aware of operational successes and problems on a daily and on a long-term basis. In this paper the authors present the Fault Tracker, Nightlogs and Dashboard, which achieve this goal for the Southern African Large Telescope (SALT).

Most operational errors are automatically entered into the SALT database by the telescope control software along with the relevant details like subsystem, time of occurence and severity. The list of faults can be viewed for a user-selected night via a web-based interface called the Fault Tracker (FT). The FT also gives the user access to the full details of individual faults.

Users can add new, edit existing and comment on faults in the FT. Previous revisions of faults are kept in the database.

In order to allow for easier classification of faults the FT allows tags to be added to faults either manually or automatically based on the affected subsystem or an error code.

The SALT Astronomer and SALT Operator use their Nightlogs to record the weather details, engineering time and telescope downtime throughout the night, and this information is automatically entered into the database.

All this allows SALT's efficiency to be measured by various metrics like technical and weather downtime, observation efficiency and number of observations. These are collectively displayed by another web-based interface called the Dashboard for the last night, the last week, the last 31 nights, the last six months and the semester to date.

Depending on the time period and metric, bar charts, dials, pie charts or line charts are used. Colour coding (red, yellow, green) is employed to show whether the value for a metric is within the required range. Trend curves are included with the bar charts.

In order to maintain awareness and encourage discussions about SALT's operational status, the Dashboard offers a kiosk mode which rotates through slides with the plots of key metrics. This is displayed on a public screen at the telescope in Sutherland and at the South African Astronomical Observatory in Cape Town.

Most of the tools are browser-based single page applications, using libraries and frameworks like jQuery, AngularJS and D3. Flask is used to provide the server-side API functionality. The data are stored in a MySQL database. The merits and drawbacks of the libraries as well as possible applications for other telescopes are discussed.

Gaia uplink commanding system at work: VPU SW on-board commissioning

Juanma Martin-Fleitas, Jose Osinde, Hassan Siddiqui, Asier Abreu, Alcione Mora, Cian M. Crowley, Neil Cheek, Rocio Guerra, Emmanuel Joliet, European Space Astronomy Ctr. (Spain)

Gaia is a spinning spacecraft designed to observe every star in the magnitude range G = [3.0 - 20.0], being partially complete only on very high-density areas of the sky. It will create the most detailed 3D map of the Galaxy, comprising a billion stars.

The Gaia observes using two telescopes sharing a common focal plane. This Focal Plane Array (FPA) comprises 106 CCDs aligned in 7 rows and 17 functional strips. Each of the 7 CCD rows is controlled by one Video Processing Unit (VPU) that operates each CCD in TDI mode synchronized with the spacecraft's 6-hour spin period around its z-axis.

The observation strategy is defined by a scanning law and the configuration of the VPUs. The scanning law describes the attitude of the spacecraft as a function of time. The VPUs are hybrid microprocessor-FPGA systems in charge of detecting, confirming and observing any object crossing the focal plane in the nominal magnitude range. The VPU algorithms are highly parametrized so their behaviour is highly customisable.

The Gaia uplink commanding system's main tasks are to generate the commanding to modify the configuration of the VPU parameters on-board, properly schedule each parameter modification and maintaining a CDB (Configuration Data Base) on-ground with all those configurations timestamped per VPU.

The input to the Gaia uplink commanding system is the calibration activity. The commanding of an activity is based on a set of fixed templates comprising consecutive time-stamped telecommand sequences. Only a subset of the sequences defined in the Operations Data Base (ODB) are used: VPU memory patches, EEPROM patches, dumps and dump-checksums, Service Interface Function (SIF) and VPU mode changes (service, operational, used/unused by the Attitude and Orbit Control System). The template is filled using 'calibration activity data sets', containing the VPU memory patches. The scheduler operation is thus limited to program the execution of a given template and data set at a particular time. A Payload Operations Request (POR) file is then produced and sent to the Mission Operations Centre (MOC) for uplink and execution on-board. In addition, a record of the transaction and any patched data is stored in the CDB for its consumption by the Data Processing and Analysis Consortium (DPAC).

During the nominal mission the VPU algorithms software were updated on-board to include new capabilities. All those new capabilities were tested, commissioned and optimised. Intense commanding to modify the VPU parameters in a limited period of time was required. All the calibrations and tests were performed using the Gaia uplink commanding system.

In this talk, the key elements of the Gaia uplink commanding system will be illustrated using an example that took place during the Commissioning phase of the spacecraft, in which a new software version of the VPUs on-board Gaia. The full process of an activity generation to its commanding, the tools and restrictions imposed to the scheduling, telecommand budget and configuration maintenance will be explained through this example. Finally, the lessons learned for future survey missions will be discussed.

Data flow operations and quality control of SPHERE

Wolfgang Hummel, European Southern Observatory (Germany); Julien H. V. Girard, Julien Milli, Zahed Wahhaj, European Southern Observatory (Chile); Lars Lundin, European Southern Observatory (Germany); Arthur Vigan, European Southern Observatory (Chile) and Lab. d'Astrophysique de Marseille (France)

ESO operates since April 2015 the new planet finder instrument SPHERE with three partly simultaneously operating arms supported by a common path coronograph with extreme AO. Observing modes include differential beam imaging, long slit spectroscopy, IFS and high contrast polarimetry. We report on the implementation of the SPHERE dataflow and quality control system and operational highlights in the first year of operations: This includes some unconventional parts of the SPHERE calibration plan like attached science observations, special rules for the selection of filters and the measures for an optimized calibration of the two polarimetric channels of the ZIMPOL arm. Finally we report on the significance of SPHERE quality control system, its relation to the data reduction pipeline and which unreported instrumental features have been revealed so far.

9910-106, Session PWed

Development of QuickPhot: an automated data acquisition and processing pipeline for observing AGNs

Vaibhav Savant, Niall Smith, Cork Institute of Technology (Ireland)

This reports the development of "QuickPhot", an automated data acquisition and reduction pipeline. Cork Institute of Technology – Blackrock Castle Observatory (CIT-BCO) operates two nodes of remotely operated robotic telescopes based in California, US and Cork, Ireland. The observatories have been installed by BCO labs and are primarily used as a tool to facilitate STEM promotion (Project TARA) and as a testbed for automation and instrumentation. The node at BCO consists of two optical telescopes – 6" and 16" OTAs housed separately while the one at California is its 6" replica. QuickPhot is an automated data reduction pipeline aimed at studying the microvariability of blazars. The telescopes constantly monitor the skies in search of optical photometric variability in predefined targets whenever observing conditions are favourable. After carrying out aperture photometry, if any interesting behaviour is observed, the telescopes report the source and follow up with multi band observations using one or more nodes that are located in strategically separated timezones for continuous monitoring of astrophysical phenomenon.
We investigate the conformance of Shock-in-jet and the Geometric models, which try to explain the processes at work in AGNs which result in the formation of jets, by looking for temporal variability in these 2 band observations. Two-channel Optical PHotometric Imaging CAMera (TO?CAM) has been optimised for two band photometry on 16" OTA using two 1k ? 1k EMCCDs. Plans are underway for mounting TO?CAM on a larger OTA for precision photometry which may use LuckyPhot to further improve results by doing away limitations posed by atmospheric disturbances. The Telescope ARrAy (TARA) nodes work in conjunction with TO?CAM as one system to examine the most appropriate model interpreting the optical variability exhibited by AGNs by searching for variability and carrying out precision photometry continuously in an automated mode.

9910-107, Session PWed

Taking the San Pedro Martir National Astronomical Observatory into the era of time domain and massive data astronomy

Mauricio Reyes-Ruiz, Joel Castro, Enrique Colorado, David Hiriart, Elena Jimenez, William H. Lee, Manuel Nunez, Michael G. Richer, Alan M. Watson, Univ. Nacional Autónoma de México (Mexico)

We present the operational measures taken and the infrastructure recently constructed and under development at the Observatorio Astronomico Nacional in San Pedro Martir, Mexico (OAN-SPM), to equip it in order to address the challenges of time domain astronomy and the handling of large amounts of data resulting from wide field, high cadence observations.

These include the construction of infrastructure for high bandwidth data transmission to the observatory via fiber optics, and the installation or upgrade of 5 new robotic, meter-class telescopes to study a wide range of problems, from Kuiper Belt occultations (TAOS-2) to GRB followup (RATIR and GFT). In addition, several smaller aperture, robotic telescopes, dedicated to rapid follow-up of transient phenomena (BOOTES-5), diffraction limited imaging (COATLI) and very wide field observations (DDOTI), are currently being constructed. The design and construction of massive data storage facilities to host the results of these projects, reaching 1 PB in the next few months, and its integration with the OAN-SPM, are also discussed.

9910-108, Session PWed

Versatile quality control scheme for the adaptive optics instruments at the VLT

Julien H. V. Girard, European Southern Observatory (Chile)

The Paranal Observatory and its large instrument suite is unique in the world and leader in ground-based astronomy. There are many Adaptive Optics (AO) fed instruments on Paranal and more to come. To monitor their performances and assess the quality of the scientific data, we have developed a scheme and a set of tools and metrics adapted to each flavour of AO and each data product. Our decisions to repeat observations or not depends heavily on this immediate quality control "zero" (QC0). Atmospheric parameters monitoring can also help predict performances . At the end of the chain, the user must be able to find the data that correspond to his/her needs translated into a set of requirements based on simulations done with an exposure time calculator (ETC). Predictions and real performances must match and the assessment must be intelligible to the community. We will emphasis on the difficulties encountered to perform quality control with SPHERE and the need for different metrics at various levels of wavefront: i.e Strehl ratio and FWHM for SCAO/LTAO/MCAO, contrast for an xAO, EE for GLAO, etc.

9910-110, Session PWed

Model-based fault detection and diagnosis in ALMA subsystems

José L. Ortiz, ALMA (Chile); Rodrigo Carrasco, Univ. Adolfo Ibañez (Chile); Jaime Fariña, ALMA (Chile)

The Atacama Large Millimeter/Submillimeter Array (ALMA) observatory, with its 66 individual radiotelescopes and other central equipment, generates a massive set of monitoring data every day, collecting information on the performance of a variety of critical and complex electrical, electronic and mechanical components. This data is crucial for most troubleshooting efforts performed by engineering teams. More than 5 years of accumulated data and expertise allow for a more systematic approach to fault detection and diagnosis. This paper presents model-based fault detection and diagnosis to support corrective and predictive maintenance in an 24/7 minimum-downtime observatory.

9910-111, Session PWed

Investigating the effect of atmospheric turbulence on mid-IR data quality with VISIR

Mario van den Ancker, European Southern Observatory (Germany); Daniel Asmus, European Southern Observatory (Chile); Christian Hummel, Hans-Ulrich Käufl, Florian Kerber, European Southern Observatory (Germany); Alain Smette, European Southern Observatory (Chile); Julian Taylor, European Southern Observatory (Germany); Konrad Tristram, European Southern Observatory (Chile); Jakob Vinther, Burkhard Wolff, European Southern Observatory (Germany)

Accurately predictions of image quality -- typically taken as the FWHM of an unresolved point-source -- which can be achieved under a range of atmospheric conditions is an important prerequisite for queue-based scheduling at modern observatories. However, investigations of the relation between seeing at different wavelengths has so far been limited to wavelengths between 0.36 to 4.5 microns. Here we extend the relation between optical seeing and mid-infrared (7.8-19.5 micron) image quality using data from VISIR, the mid-infrared imager and spectrometer at ESO's Very Large Telescope. We find that the equations used so far to estimate mid-IR data quality from the optical seeing under-estimate the effect of atmospheric turbulence in the N-band (7-13 microns). We explore several options to align model predictions with the achieved mid-IR image quality. Adopting a larger outer length scale for the median atmospheric turbulence for Cerro Paranal than the so far adopted value of 23 m improves the agreement between measured and predicted image quality for VISIR, while it only has a modest effect on the predicted image quality at shorter wavelengths.

9910-112, Session PWed

Dispatch scheduling to maximize exoplanet yield

Samson Johnson, Harvard-Smithsonian Ctr. for Astrophysics (United States) and Univ. of Montana (United States); Nate McCrady, The Univ. of Montana (United States)

The MINiature Exoplanet Radial Velocity Array (MINERVA) is a dedicated exoplanet survey using radial velocity measurements of nearby (< 75 pc) stars to detect small planets. MINERVA will be a completely robotic facility, with a goal of maximizing the number of exoplanets detected. This requires a unique application of dispatch scheduling due to its automated nature and the requirement of high cadence observations. A dispatch scheduling algorithm is employed to create a dynamic and flexible selector of targets to observe, in which stars are chosen by assigning values through a weighting function. I designed and have begun testing a simulation which implements the functions of a dispatch scheduler and records observations based on target selections through the same principles that will be used at the commissioned site. These results will be used in a larger simulation that incorporates weather, planet occurrence statistics, and stellar noise to test the planet detection capabilities of MINERVA. This will be used to heuristically determine an optimal observing strategy for the project. The high precision RV spectrograph (1m/s) is being commissioned in the winter of 2015, and the results will be compared to the intentions of the implementation to this point. The choreography of the entire robotic site will also be commented on.

9910-113, Session PWed

DAG: a new observatory and a prospective observing site for other potential telescopes

Cahit Yesilyaprak, Atatürk Üniv. (Turkey); Sinan Kaan Yerli, Middle East Technical Univ. (Turkey); Onur Keskin, Isik Üniv. (Turkey)

DAG (Eastern Anatolian Observatory in Turkish) is the newest and largest (4 m) observatory of Turkey with the optical and near-infrared telescope and its robust observing site infrastructure. This national project consists of three phases: DAG: Telescope, Enclosure, Buildings and Infrastructures; FPI: Focal Plane Instruments and Adaptive Optics; and MCP: Mirror Coating Plant. The Ministry of Development of Turkey and Atatürk University supports all three phases. The tenders of telescope and enclosure have been completed in 2014 and 2015, respectively. The final design of telescope and building and almost all the infrastructure (roads, geological and atmospherical surveys, electricity, fiber optics, cable car, water, generator, etc.) of DAG site (which is at an altitude of 3,170 m in Erzurum/Turkey) have been completed. This poster is about the recent developments of DAG and about the future possible collaborations for various telescopes which can be constructed at the DAG site.

9910-114, Session PWed

FACT: from remote to robotic operation of an Imaging Atmospheric Cherenkov Telescope

Dominik Neise, ETH Zürich (Switzerland)

The First G-APD Cherenkov Telescope (FACT) is installed at the Canary island La Palma. Since Summer 2012, it is the first Imaging Atmospheric Cherenkov Telescope (IACT) being operated remotely without the need for data-taking personnel on site.

In order to achieve a robust and reliable remote operatable system, reliable monitoring and control of all subsystems is a necessity.

All components of FACT, including the drive, power supplies, trigger and data acquisition system as well as auxiliary systems are connected via the same layer of interprocess communication. The homogeneity of the communication layer by the Distributed Information Management System (dim) developed at CERN greatly simplifies operation.

In case of emergencies like complete power loss or sudden loss of network connection, it is agreed that the crew of the nearby MAGIC telescopes can be contacted for help.

Due to the large mirror area intrinsic to an IACT, the highest risk poses a nonfunctional drive system, leaving the telescope pointing towards the sun.

In such case, it is possible to park the telescope manually in less than 10 minutes.

Over time, the system was converted from a remotely operated to a remotely monitored Cherenkov observatory. This includes two distinct tasks.

First, the operation of each subsystem must be monitored and actions being taken in case of any malfunction. The low-level software or firmware does react in case of any parameter being outside predefined limits and takes necessary actions to bring the subsystem into a safe state or restart the operation. In rare cases, the situation has to be investigated by the shifter and experts on call.

The second task is taking physics data as well as special data for monitoring the performance of the full system.

The nightly observation schedule and technical runs are defined in advance and stored in a dedicated database.

The main physics task of FACT is the monitoring of a set of extragalactic sources of very high energy gamma-rays. In case of bright flaring activity of such a source, alerts have to be sent to the community as soon as possible.

Currently, the shifters role during the observation consists of monitoring the system status, visual inspection of the night sky conditions using all-sky cameras and additional weather input as well as examining the sources flux state. An inclusion of all-sky camera images into an autonomous weather condition assessment based on computer vision techniques is currently being developed.

To reduce the load on humans, an automatic alert system has been developed and is currently being tested by running it in parallel to remote operation by a shifter. In case of any malfunction or of a flare of the observed source, phone calls to a predefined list of people are initiated. To reduce single points of failure in such a safety related task as much as possible, a similar but independent second system is currently under development.

We will present the implementation of and experience from the remote and robotic operation of FACT from the past four years of successful operation.

9910-116, Session PWed

JWST guide star pipeline data products

Daryl A. Swade, Howard A. Bushouse, Pierre Chayer, Edmund P. Nelan, Space Telescope Science Institute (United States)

Science data products for James Webb Space Telescope (JWST) observations will be generated by the Data Management Subsystem (DMS) within the JWST Science and Operations Center (S&OC) at the Space Telescope Science Institute (STScI). A Guide Star Pipeline will process data from the JWST Fine Guidance Sensor (FGS) guide star acquisition process.

FGS data are generated on-board by four guide star functions associated with the guide star acquisition and tracking sequence; Identification, Acquisition, Track, and Fine Guide. The Identification function obtains an image of the sky in the FGS 2.3'x2.3' field of view and identifies the designated guide star based on its position and intensity by pattern matching the observed scene to the scene predicted by the ground system. The Acquisition function images the guide star using first an 8.8"x8.8" and then a 2.2"x2.2" window, providing the attitude control system (ACS) with the guide star's location to eliminate most of the coarse pointing error. The FGS next executes the Track function, imaging the guide star in a 2.2"x2.2" window, providing ACS with guide star centroids every 64 milliseconds in closed loop. When ACS places the guide star at the desired position on the FGS detector, the FGS transitions to the Fine Guide function, imaging the guide star in a 0.55"x0.55" window, providing guide star centroids to ACS every 64 milliseconds. Data from all four guide functions are captured to the on-board solid state recorder and downlinked with the science data.

The DMS generates Flexible Image Transport System (FITS) Guide Star Pipeline products that capture FGS data from the guide star functions and provide detailed information on spacecraft jitter. Additional inputs to the Guide Star Pipeline include Observatory Status Files, the Proposal and Planning Subsystem Database, and the DMS Engineering Database. The Identification function images the field of view by taking of a set of detector subarray "strips" that collectively cover most of the detector. The Acquisition function locates the guide star in 128x128 subarray images and then in smaller 32x32 subarray images. The Track function repositions the 32x32 subarray to keep guide star centered. During the Track function the guide star location is provided to ACS at 16 Hz. In Fine Guide the FGS flight software measures the guide star location in a fixed 8x8 subarray and provides it to ACS at 16 Hz. All FGS guide star images employ the Correlated Double Sample (CDS) image technique, except for Fine Guide, which uses Fowler-4 integration. All of the data are run through a calibration pipeline. The guide star position on the FGS detector is captured in FITS tables every 64 milliseconds for the Track and Fine Guide functions. The Fine Guide function will generate the largest data file with a typical Fine Guide data file containing approximately 200 MB of data.

Data products from the Guide Star Pipeline will be generated for each JWST visit and archived to the Mikulski Archive for Space Telescopes (MAST) along with all other JWST science data products.

9910-117, Session PWed

The JWST-MIRI MRS calibration pipeline

Alvaro Labiano-Ortega, ETH Zürich (Switzerland); Ruyman Azzollini, Mullard Space Science Lab. (United Kingdom); Alistair C. H. Glasse, UK Astronomy Technology Ctr. (United Kingdom); Steven M. Beard, Vincent Geers, UK Astronomy Technology Ctr. (United Kingdom); Adrian M. Glauser, ETH Zürich (Switzerland); Karl D. Gordon, Space Telescope Science Institute (United States); Kay Justtanont, Chalmers Univ. of Technology (Sweden); Fred Lahuis, SRON Netherlands Institute for Space Research (Netherlands); Pamela Klaassen, UK Astronomy Technology Ctr. (United Kingdom); David R. Law, Space Telescope Science Institute (United States); Jane Morrison, The Univ. of Arizona (United States); Michael Muller, Univ. of Groningen (Netherlands); Daniel Dicken, CEA-Ctr. de SACLAY (France); George H. Rieke, The Univ. of Arizona (United States); Bart Vandenbussche, KU Leuven (Belgium); Gillian S. Wright, UK Astronomy Technology Ctr. (United Kingdom)

The Mid-Infrared Instrument (MIRI) Medium Resolution Spectrometer (MRS) is the only mid-IR Integral Field Spectrometer on board James Webb Space Telescope. Even though the JWST pipeline will be built by the Space Telescope Science Institute, the European Consortium that developed MIRI is responsible for designing a calibration pipeline that ensures the users will have available the best quality data for their science. The complexity of MIRI, and in particular the MRS, required a very specialised pipeline with steps specific for the MRS such as fringe corrections, wavelength offsets, etc. The pipeline results and steps will be different also for point or extended source observations. On top of that, the pipeline will have two different variants: the "default", automatic pipeline, optimized for most forseen science cases, and the "advanced", more specific pipeline, where extra steps will be needed for different science cases, and expert users can interact with the structure of the pipeline. All versions of the MRS pipeline will be presented by the MRS team lead, as well as the different steps and algorithms used, structure of the input and output science data, accesory data, etc

9910-118, Session PWed

Three axis feed array correlator for the 21cm radiation detection coming from early universe

Rosario F. Cimmino, Consorzio Nazionale Interuniversitario per i Transporti e la Logistica (Italy); Francesco Romano, EExSKA (Italy); Alessandro Trifiletti, Sapienza Univ. di Roma (Italy); Antonio Saitto, Consorzio Nazionale Interuniversitario per i Transporti e la Logistica (Italy)

The SKA Radio Telescope program detects 21 cm signals which represent a probe of Early Universe.

The 21 cm radiations transfers both cosmological as well astrophysical information. Such radiation is composed by three dimensional signal components, fitting the three dimensional representation model developed by the last generation numerical simulator.

Currently, since only a bi-dimensional detection is implemented during observation, part of the signal information are lost or made unavailable for the processor.

A three-dimensional retrieval to efficiently detect all the radiation information would be useful in order to reconstruct extremely large scale as well small scale spectrum.

Such detection has to be compliant with the last generation three dimensional numerical simulator to a better interpretation of complex events.

The paper examines 21 cm radiation characteristics. Additionally, the work focuses on effective three dimensional Feed Array Correlator performances required to: perform ambiguity immunity, increase dynamic range and increase sensitivity.

The paper shows as the three dimensional Feed Array Correlator detection may be useful to optimize the complexity of the the simulators needed to interpret the observations data coming from the deep dark.

9910-119, Session PWed

Evolution of operations for the survey telescope at Paranal

Cristian M. Romero, Steffen Mieske, Andres Pino, Susana Cerda, Stéphane Brillant, European Southern Observatory (Chile)

Since 2009 began operations Surveys Telescopes at Paranal Observatory, which aim to make observations using a large field of view through which you can detect how much fainter sources also cover wide areas of sky quickly. The first to enter the telescope operations was VISTA (Visible and Infrared Survey Telescope for Astronomy) and subsequently the VST Telescope (VLT Survey Telescope). The survey telescopes were a change of the operational model adopted until then, they had the distinction of being 100% operated by an operator of telescope and instruments without the support of a support astronomer. This prompted the gradual and steady improvement of tools for the operation of the observatory within both generally and in particular these Telescopes, Examples of these enhancements include control systems for image quality, selection of Obs, logging in evening activities among others. However the new generation instruments on the Very Large Telescope (VLT) propose a new challenge to our observatory from scientific and operational point of view, as these new systems would be more demanding and complex and it would be more complicated to operate and require additional support.

That is why the focus of this study aims to explore the possible development and optimization of the operations of Surveys telescopes, which would give greater operational flexibility given the new situation looming, and to determine the feasibility of redistribution of their operators if necessary during periods of increased demand from other systems from the VLT.

9910-120, Session PWed

PHOENIX: the production line for science data products at ESO

Reinhard Hanuschik, European Southern Observatory (Germany)

In the past two years ESO has installed a production line for level 2 science data products. Focussing on spectroscopic observations, these in-house generated data products are complementary to the externally provided data products from the imaging and spectroscopic surveys. The production line combines mass production (more than one million spectra have been generated so far), previews, and quality control concepts.

9910-121, Session PWed

The ESO science data product standard for 1D spectral products

Alberto Micol, Magda Arnaboldi, Nausicaa A. R. Delmotte, Laura Mascetti, Joerg Retzlaff, European Southern Observatory (Germany)

Since 2011, ESO operates the Phase 3 process that closes the loop with the community following Phase 1 (propoosal submission) and Phase 2 (preparation and definition of the observations). Phase 3 allows the upload, validation, storage, and publication of science data products through the ESO Science Archive Facility (SAF).

Via the Phase 3 process, nearly 2 million data products have been archived and published to date; a large fraction of them, more than 80%, are one-dimensional extracted and calibrated spectra. Central to the Phase 3 process is the ESO science data product standard that defines the data format and the metadata information of any data product type.

This contribution describes the ESO science data product standard for 1d spectra, along with the operational and legacy value such standard brings to the SAF, its adoption for the routine publication of the ESO in-house generated reduced science spectra of selected spectroscopic instrument modes (currently UVES echelle, HARPS, Xshooter echelle, FLAMES-Giraffe Medusa, more to come). The usage statistics for the data access and dowload will also be provided, highlighting the legacy value of the ESO spectroscopic public surveys (PESSTO, GAIA-ESO) and of the ESO large programmes.

9910-122, Session PWed

Building a pipeline of talent for operating radio observatories

Lory M. Wingate, National Radio Astronomy Observatory (United States)

In the U.S., as around the world, there is a strong desire to develop further our human capacity in the Science, Technology, Engineering, and Mathematics (STEM) fields, especially within traditionally under-represented groups. Within the mandate and mission statement of NRAO we define under-represented groups to mean all of the following but not limited to people of color, women, economically disadvantaged and first-generation college students.

The National and International Non-Traditional Exchange Program (NINE) is part of the NRAO Office of Diversity and Inclusion. It is geared towards increasing under-represented participation in STEM fields associated with radio astronomy through enticing the best and brightest, both nationally and internationally, into high quality programs designed to benefit the participant, each partnering location, and the radio astronomy community as a whole.

The NINE's primary objectives are to 1) provide supported short programs (up to three month's duration) designed to teach sustainable skills in any STEM functional area associated with radio astronomy that can ultimately be applied in the home location, 2) to form long-term mentor/mentee relationships with staff at NRAO, and 3) position the participant to successfully develop a NINE Hub, capable of providing training in the STEM field of experience at their home location.

The Program provides learning opportunities throughout all disciplines affecting the full spectrum of activities associated with designing, constructing, and operating, radio astronomy observatories (Human Resources, Education and Public Outreach, Electronics, Engineering, Technicians, Operators, Project Management, Systems Engineering, and many others). The anticipated outcome of this program is worldwide partnerships with fast growing radio astronomy communities designed to facilitate the exchange of faculty and the co-mentoring of under-represented groups of students, thereby developing a strong pipeline of global radio astronomy talent.

Specifically, the NINE Program consists of process learning, hands-on experience, mentoring/teaching techniques, NINE Hub Program development, and NINE Hub Program exchanges. Process learning includes preparing for and completing an international standard processes certification used to achieving successful project outcomes and optimize science results. Hands-on learning includes learning associated with radio astronomy during construction of radio equipment, testing, commissioning, and observations. Mentoring/teaching includes learning the basics on how to instruct and mentor other participants, and understanding how to provide training events to be provided at the home site. NINE Hub Program development includes the identification and securing of tools, physical space, and processes needed at the home location. And the NINE Hub Program exchanges include developing the processes to identify potential students and postdocs, faculty/instructors and other professionals and facilitating their engagement in the NINE Program.

Participation in the NINE Program is through a competitive process. Participants are selected by a panel that assesses fitness for the Program through application review, discussions with references, and mentor and budget availability.

This presentation describes the Program and its elements, as well as the lessons learned in implementing the program in the international environment.

Training telescope operators and support astronomers at Paranal

Henri M. J. Boffin, European Southern Observatory (Germany); Dimitri A. Gadotti, Joe Anderson, Andres Pino, Julien H. V. Girard, Willem-Jan de Wit, European Southern Observatory (Chile)

The operations model of the ESO Paranal Observatory relies on the work of efficient telescope and instrument operators as well as astronomers to carry out all the day- and night-time tasks. This is highly dependent on adequate training of the staff. The Science Operations department of the ESO Paranal Observatory (SciOps) has a training group that devises a well-defined and continuously evolving, training plan for new staff, in addition to broadening and reinforcement courses for the whole department. This paper presents the training activities for and by SciOps, including recent astronomical and quality control training for operators, as well as adaptive optics and interferometry training of all staff.

Characterizing silicon pore optics stacks

Giuseppe Vacanti, Nicolas M. Barrière, Abdelhakim Chatbi, cosine Science & Computing B.V. (Netherlands); Max Collon, cosine B.V. (Netherlands); Ramses Günther, Roy van der Hoeven, Boris Landgraf, Mark Vervest, Alex Yanson, cosine Science & Computing B.V. (Netherlands); Marcos Bavdaz, Eric Wille, European Space Agency (Netherlands)

In this paper we describe how the data obtained at the XPBF is processed in an automatic fashion to generate a large number of diagnostic and characterization data results. The pipeline can be run live, during the measurement, so that within a few minutes of a measurement being completed a complete X-ray characterizaion is available for immediate feedback.

9910-126, Session PWed

A schedule optimizer for astronomical observations under constraints

Anne-Marie Lagrange, Pascal Rubini, Institut de Planétologie et d'Astrophysique de Grenoble (France); Nadia Brauner-Vettier, UJF/G-SCOOP (France); Hadrien Cambazard, Nicolas Catusse, Pierre Lemaire, G-INP/G-SCOOP (France); Laurence Baude, Institut de Planétologie et d'Astrophysique de Grenoble (France)

Telescope time is precious; the scheduling of observations must be as efficient as possible in terms of time usage and obtained data quality. The optimization of the schedules of observations, which include hundreds of targets to be observed in different runs, with sometimes tricky and/or time-dependant constraints cannot be done manually. In addition, this optimization must be fast for real-time use. This is the case, for instance, for big surveys spanning several years to search for extrasolar planets, which rely on the use of Angular Differential Mode (ADI).

In this context, we have developed a software (SPOT) that can compute long term (months, years) and short term (night) optimized schedules of such surveys, taking into account constraints that include all classical astronomical constraints plus specific constraints related to ADI observations. SPOT is now routinely used to schedule GTO SPHERE observations on the VLT. It is also used to determine the best observing dates given a list of targets, or, alternatively, to optimize a list of targets, once the dates of observations are known.

We are now investigating possible coupling i/ with weather forecast for short term response to atmospheric conditions and ii/ with long term meteorological data to improve the target list preparation.

SPOT could be easily used for queue-scheduling, or could be extended to integrate new and more complex types of constraints.

9910-35, Session 8

Getting NuSTAR on target: predicting mast motion

Karl Forster, Kristin K. Madsen, Hiromasa Miyasaka, California Institute of Technology (United States); William W. Craig, Space Sciences Lab. (United States); Fiona A. Harrison, Vikram R. Rana, California Institute of Technology (United States); Craig B. Markwardt, NASA

Goddard Space Flight Ctr. (United States)

The Nuclear Spectroscopic Telescope Array (NuSTAR) is the first focussing high energy (3-79 keV) X-ray observatory operating for four years from low Earth orbit. The X-ray detector arrays are located on the spacecraft bus with the optics modules mounted on a flexible mast of 10.14m length. The motion of the telescope optical axis on the detectors during each observation is measured by a laser metrology system and matches the pre-launch predictions of the thermal flexing of the mast as the spacecraft enters and exits the Earths shadow each orbit. However, an additional motion of the telescope field of view was discovered during observatory commissioning that is associated with the spacecraft attitude control system and an additional flexing of the mast correlated with the Solar aspect angle for the observation. We present the methodology developed to predict where any particular target coordinate will fall on the NuSTAR detectors based on the Solar aspect angle at the scheduled time of an observation. This may be applicable to future observatories that employ optics deployed on extendable masts. The automation of the prediction system has greatly improved observatory operations efficiency and the reliability of observation planning.

9910-36, Session 8

Oprimizing GESE operations by orbit selection and system design

Sara R. Heap, Lloyd R. Purves, NASA Goddard Space Flight Ctr. (United States)

Operation of a small survey telescope in space is markedly simpler than operations of ground-based telescopes driven by user selection or transient events. Nevertheless, both types of telescopes share two common challenges: maximizing the integration time on target, while minimizing operation costs including communication costs and staffing on the ground. We use the example of the Galaxy Evolution Spectroscopic Explorer (GESE) to show how these challenges can be met through a custom orbit and a system design emphasizing simplification and leveraging information from ground-based telescopes.

9910-37, Session 8

Feature-based telescope scheduler

Elahesadat Naghib, Robert J. Vanderbei, Princeton Univ. (United States); Christopher W. Stubbs, Harvard Univ. (United States)

In the era of expensive astronomical instruments, efficient scheduling of their operation is receiving increasing attention. For a telescope similar to the Large Synoptic Survey Telescope (LSST) with operating costs of approximately $40M/year, a mis-scheduling of only 5% (around 50 visits a night) would be equivalent to a loss of 20 million dollars over a decade of operation. Thus, an appropriate maximization of the number of visits seems to be necessary. Moreover, not only the number of observations is important, but also the cadence of observations, airmass distribution, and depth will characterize the performance of the telescope. The challenge is to devise a scheduling algorithm that maximizes the scientific return of the system, given a complex set of constraints and scientific merit that includes sky coverage, co-added depth, and sampling in the time domain across the survey filters.

This study proposes an efficient scheduler that consists of a fast (sub-linear) online controller, and an offline supervisory control-optimizer. The online control law is computed at the moment of decision for the next visit, t, and has a much faster response than the timescale of changes in operational conditions such as the weather, visibility, and sky brightness. Accordingly, these inherently unpredictable variables can in fact be considered as deterministic inputs for the controller at t. This feature eliminates concerns about the sub-optimality caused by probabilistic representation of the above-mentioned disturbances in the decision process. The offline control optimizer is designed to carry most of the computational burden, and accordingly time consumption of the scheduler. Although the efficiency of the supervisory system is not as critical as that of the online controller, in order to reduce the cost of implementation, a variant of Differential Evolution (specially designed for this scheduler) is used which is particularly conducive to parallel computation. The supervisory optimizer trains the controller using a telescope simulator by maximizing a performance function. In this procedure, the controller is exposed to different possible environments and observation histories to learn the optimal response to different real-time scenarios. The performance function is computable at the end of the simulated observations and accounts for all scientific/engineering constrains, as well as the high-level, long-term mission objectives (such as almost uniform coverage of the sky for the case of LSST). Moreover, any constraint or preference can be easily added or removed at any time which makes the scheduler flexible to changes in the scientific metrics or mission objectives. This approach is also capable of feedback-based self-adjustments.

In order to produce a tractable problem for the offline optimization, a reduced approximate state-space called feature-space is also introduced in this study. Preliminary results for a model of LSST, implemented in Python 2.7, is promising in terms of both optimality (100 visits per hour), and the computational cost (8.5 hours for optimizing the controller over an average night using a 2.7 GHz Intel Core i5 CPU with 8 GB 1333MHz memory).

9910-38, Session 8

Ongoing evolution of proposal reviews in the Spitzer warm mission

Lisa J. Storrie-Lombardi, Nancy Silbermann, Luisa M. Rebull, John R. Stauffer, Megan Crane, Seppo Laine, Lee Armus, Spitzer Science Ctr. (United States) and California Institute of Technology (United States); Suzanne R. Dodd, Jet Propulsion Lab. (United States)

The Spitzer Space Telescope is executing the seventh year of extended warm mission science. From launch in 2003, Spitzer cryogenic mission operations lasted until May of 2009 when the cryogen was depleted. Warm operations have continued since July 2009 using the 3.6 and 4.5 micron channels of the IRAC instrument. The observatory still executes 7000 hour of science per year but the size of the operations staffing has been reduced by 70%.

During the cryogenic mission the proposal reviews were week-long, in-person meetings of 80-100 scientists that met in topical science panels followed by a time allocation committee to review and discuss the proposals. When warm operations began we introduced panel reviews via telecon. The panels recommended the awards for the smaller proposals. This was followed later by an in-person time allocation committee meeting to recommend awards for the larger proposals. Introducing the telecon panel reviews reduced the cost of the annual process substantially as only 10-15% of the reviewers need to travel to the time allocation committee meeting.

In 2014 the process for the solicitation and selection was further compressed due to changes in the mission funding profile, leading to another change in the review process for the smaller proposals. The large proposals are still reviewed by a time allocation committee that meets in person to discuss and review the proposals but the smaller proposals are no longer discussed by a topical science panel. For the 2014 cycle we solicited a larger pool of reviewers who are guaranteed they will receive no more than 20 proposals that they read, grade, rank, and provide comments for, and that completes their service. The advantages are that proposals can be better targeted to expert reviewers because there are no issues with potential conflicts with other panel members. It is also substantially easier to get reviewers to say yes to a process with a small number of proposals to read and no travel or telecon commitment. The disadvantages are that disparate opinions from the reviewers are not resolved in a panel discussion. The SSC does the merge of the grades and comments to create the final ranked list of proposals.

This new process has been utilized for two observing cycles and we discuss here our experience with it so far and the pros and cons of this methodology.

9910-109, Session 8

Sharing the skies: the Gemini Observatory international time allocation process

Steven J. Margheim, Gemini Observatory (United States)

Gemini Observatory serves a diverse community of four partner countries (United States, Canada, Brazil, and Argentina), two hosts (Chile and University of Hawaii), and limited-term partnerships (currently Australia and the Republic of Korea). Observing time is available via multiple opportunities including Large and Long Programs, Fast-turnaround programs, and regular semester queue programs. The primary factors that inform the overall schedule of observing programs are a desire to allocate the available observing time in proportion to a partner's financial contribution (partner share), and to reach target completion rates as set by the Gemini Board. The slate of programs for observation each semester must be created by merging programs from these multiple, conflicting sources. This paper describes the time allocation process used to schedule the overall science program for the semester, with emphasis on the International Time Allocation Committee and the software applications used.

Each partner (or host) has an independent peer-review process to assess their community's proposals. The outcome of these National Time Allocation Committees (NTACs) are ranked lists of approved programs and the desired partner's time allocation. These are forwarded to the observatory for consideration by the International Time Allocation Committee (ITAC). The ITAC is composed of a representative from each partner (or host) country and led by a member of the observatory's scientific staff, the ITAC Chair.

The ITAC Chair merges the programs forwarded by each NTAC to produce a draft queue. The merging process primarily involves stepping through each partner's ranked programs and distributing the time in proportion to each partner's share; while also ensuring that any particular observing constraint, such as Right Ascension or Cloud Cover, is not over-subscribed. This process is primarily accomplished through the use of a custom software package, the "ITAC Software", detailed in this paper.

Draft queues are shared with the ITAC members and the Heads of Science Operations, who construct the semester telescope schedule in parallel. This draft queue is analyzed for many factors including instrument availability, duplication of observations, and the distribution of targets and observing constraint requests. The ITAC chair incorporates feedback from each draft queue and additional iterations are completed until the ensemble of proposals approaches the optimal queue, for both the partners and observatory. Typically, this process occurs over a 2-3 week period, and involved 6-10 major iterations within the ITAC. Once the members of the ITAC have agreed upon a proposal slate of programs, it is forwarded to the Gemini Director for approval.

9910-39, Session 9

The LSST Scheduler from design to construction

Francisco Delgado, LSST (United States)

The Large Synoptic Survey Telescope (LSST) will be a highly robotic facility, demanding a very high efficiency during its operation. To achieve this, the LSST Scheduler has been envisioned as an autonomous software component from the Observatory Control System (OCS) that drives the survey selecting the sequence of targets in real time by optimizing a dynamic cost function of more than 200 parameters. Multiple science programs produce thousands of candidate targets for each visit, and multiple telemetry measurements are received to evaluate the external and the internal conditions of the observatory. The design of the LSST Scheduler started early in the project supported by Model Based Systems Engineering, detailed prototyping and scientific validation of the survey capabilities required. In order to build such a critical component, an agile development path in incremental releases is presented, integrated to the development plan of the Operations Simulator (OpSim) to allow constant testing, integration and validation in a simulated OCS environment. The final product is a Scheduler that is also capable of running 2000 times faster than real time in simulation mode for survey studies and scientific validation during commissioning and operations.

9910-40, Session 9

Determining the direct and indirect impact of commercial aircraft on LSST observing efficiency

Rose K. Gibson, Wellesley College (United States); Chuck Claver, LSST (United States); Christopher W. Stubbs, Harvard Univ. (United States); Michael Warner, Cerro Tololo Inter-American Observatory (Chile)

The Large Synoptic Survey Telescope (LSST) is a ten-year survey that will map the southern sky in six different filters 800 times before the end of its run. We explore the primary effect of airline traffic on scheduling the LSST observations in addition to the secondary effect of condensation trails, or contrails, created by the presence of the aircraft. The large national investment being made in LSST implies that small improvements in observing efficiency through aircraft and contrail avoidance can result in a significant improvement in the quality of the survey and its science. A Software Defined Radio (SDR) received Automatic Dependent Surveillance-Broadcast (ADS-B) signals from commercial aircraft in order to monitor and record plane activity over the LSST site. We installed an ADS-B ground station on Cerro Pachón, Chile consisting of a 1090Mhz antenna on the Andes Lidar Observatory feeding a RTL2832U SDR. The Python software dump1090 converted the ADS-B telemetry into Basestation format, and we found that even during the busiest time of the night there were only 4 signals being received each minute on average, which will have very small direct effect, if any, on the LSST observing scheduler. We are also able to use the the ADS-B data in combination with a correlation between a glitch on 3 channels of the LSST sky-brightness sensor with aircraft beacons to avoid pointing LSST towards contrails, reducing the systematic error in photometry during otherwise photometric conditions.

9910-41, Session 9

Survey strategy optimization for the Atacama Cosmology Telescope

Francesco De Bernardis - for the ACT collaboration, Cornell Univ. (United States)

In recent years there have been significant improvements in the sensitivity and the angular resolution of the instruments dedicated to the observation of the Cosmic Microwave Background (CMB). ACTPol is the first polarization receiver for the Atacama Cosmology Telescope (ACT) that is observing the CMB sky with arcmin resolution over ~ 2000 sq. deg. Its upgrade, Advanced ACTPol, will observe the CMB in five frequency bands and over a larger area of the sky. We describe the optimization and implementation of the ACTPol and Advanced ACTPol surveys. The

selection of the observed fields is driven mainly by the science goals, that is, small angular scales CMB measurements and cross-correlation studies. For the ACTPol survey we have observed patches of the southern galactic sky with low galactic foregrounds emission while maximizing the overlap with several galaxy surveys to allow unique cross-correlation studies. A wider and less deep field in the northern galactic cap ensures significant additional overlap with the BOSS spectroscopic survey. The exact shapes and footprints of the fields are optimized to achieve uniform coverage and to obtain cross-linked maps by observing the fields at orthogonal scan directions. We have maximized the efficiency of the survey by implementing a close to 24 hour observing strategy, switching between a daytime and a nighttime observing plan and minimizing the telescope idle time. We describe the challenges represented by the survey optimization for the significantly wider area observed by Advanced ACTPol and the software package used to optimize and implement the ACT surveys.

9910-42, Session 9

SNR-based queue observations at CFHT

Daniel Devost, William Mahoney, Claire Moutou, Canada-France-Hawaii Telescope (United States)

The Canada-France-Hawaii Telescope has been observing in Queued Service Observing (QSO) mode since 2000. The QSO system has proven to be quite efficient compared to classical observing since CFHT is now routinely complete more than 75 percent of its high priority science programs. In an effort to optimize the night time utilizing the exquisite weather on Maunakea, CFHT is now moving it's QSO based observations toward Signal to Noise (SNR) observing. In this new mode, individual exposure times for a science program are determined using an estimate of the seeing conditions. The science program is considered completed when the depth required by the scientific requirements is reached. This way, the good seeing conditions on Maunakea are used more effectively, allowing for the completion of more programs. I will review the concept of SNR observations and show how the concept is implemented with CFHT's instruments.

9910-44, Session 9

Pandeia: a multi-mission exposure time calculator for JWST and WFIRST

Klaus M. Pontoppidan, Timothy E. Pickering, Victoria G. Laidler, Karoline Gilbert, Christopher D. Sontag, Christine Slocum, Mark J. Sienkiewicz Jr., Christopher Hanley, Nicholas M. Earl, Laurent Pueyo, Swara Ravindranath, Diane M. Karakla, Massimo Robberto, Alberto Noriega-Crespo, Elizabeth Barker, Space Telescope Science Institute (United States)

Exposure time calculators (ETCs) are integral parts of any large observatory. They are often one of the first places new users go to explore and familiarize themselves with the capabilities of a new facility, and one of the last tools that are used before submitting an observing program for evaluation by a time allocation committee. As such, there is a strong drive to develop ETCs that accurately model a telescope/instrument combination, as well as provide the user with an intuitive, easy-to-use, yet powerful interface. The JWST ETC system -- Pandeia -- is the environment in which a user will explore an observing concept, before deciding to write a proposal, and then craft specific observation sequences.

During the JWST era, users will benefit from features that go well beyond what has previously been offered as part of an exposure time calculator. Such features include algorithms that closely model data's acquisition, structure, and post-processing; advanced, interactive graphical user interfaces (GUIs), more powerful tools to visualize a large parameter volume, and functionality to share work efficiently. The JWST ETC is required to support instrument modes that generate large amounts of information, including integral field unit (IFU) spectroscopy and multi-object spectroscopy with the NIRSpec Multi-Shutter Array (MSA). Calculations must be accurate for modern observational modes that depend on high signal-to-noise and high contrast data, including exoplanet spectroscopy, coronagraphy and non-redundant aperture masking.

A common property of JWST observations is that they are recorded as sets of two-dimensional detector exposures; all information is at some point stored in discrete detector pixels. Different observing modes fundamentally differ in two aspects: First, how light is projected and/or dispersed onto a detector and second, how observational products are extracted from a set of exposures, typically by a linear combination of pixel values. The ETC generalizes both of these steps by adopting a three-dimensional, pixel-based approach. The user can create complex astrophysical scenes consisting of multiple sources with different spectral and spatial properties. By modeling individual detector pixels the ETC can explicitly mimic many of the steps taken in the calibration and reduction of actual JWST data, leading to more accurate results that are easier to test and interpret. To facilitate extensive forward-model parameter explorations, the ETC engine is optimized for calculations of small "postage-stamp" regions on angular scales of a few arcseconds. This approach can generally lead to processing times as fast as a few seconds per calculation, depending on observing mode.

Key features of the Pandeia ETC include: Full support of a wide variety of imaging, coronagraphic and spectroscopic instrument modes, MULTIACCUM readout modes, correlated noise, advanced astronomical scene creation, an interface to the JWST background model, fully data-driven with verified reference data, including throughputs, point spread functions and detector properties, and extensible and modular Python engine. While developed for JWST, Pandeia is currently also extended for use with the WFIRST imager and IFU instruments as they are currently prototyped.

9910-45, Session 9

Proposal creation, submission, and evaluation: the OPAL example

Jill Rathborne, Jessica Chapman, Phillip G. Edwards, Arkadi Kosmynin, Douglas C. Bock, CSIRO Astronomy and Space Science (Australia)

The Australia Telescope National Facility (ATNF) operates a suite of radio telescopes in Australia and receives ~350 proposals per year from the international scientific community eager to use these telescopes. Since 2006 OPAL, the Online Proposal Applications and Links, has been used to handle all proposals received by the ATNF. OPAL is a web-based application that provides a set of tools that allow users to (1) create, modify, save, submit, update and withdraw proposals during an application period, (2) access their own current and previous proposals, and (3) see grades and comments provided by ATNF's Time Assignment Committee (TAC). OPAL also provide a critical link to our data archives. In addition, OPAL also provides tools for the TAC and telescope scheduler that are integral to the proposal review and time allocation process. In this talk I will provide an overview of OPAL's capabilities, highlight its key features, and showcase its versatility from the perspective of both users and support staff.

9910-46, Session 9

Hinode/EIS science planning and operations tools

Jonn A. Rainnie, STFC Rutherford Appleton Lab. (United Kingdom)

We present the design, implementation and maintenance of the suite of software enabling scientists to design and schedule Hinode/EIS operations. The total of this software is the EIS Science Planning Tools (EISPT), and is predominately written in IDL (Interactive Data Language), coupled with SolarSoft (SSW), an IDL library developed for solar missions.

Hinode is a multi-instrument and wavelength mission designed to observe the Sun. It is a joint Japan/UK/US consortium (with ESA and Norwegian involvement). Launched in September 2006, its principal scientific goals are to study the Sun's variability and the causes of solar activity.

Hinode operations are coordinated at ISAS (Tokyo, Japan). A daily Science Operations meeting is attended by the instrument teams and the spacecraft team. Nominally, science plan uploads cover periods of two or three days. When the forthcoming operations have been agreed, the necessary spacecraft operations parameters are created. These include scheduling for spacecraft pointing and ground stations.

The Extreme UV Imaging Spectrometer (EIS) instrument, led by the UK (the PI institute is MSSL), is designed to observe the emission spectral lines of the solar atmosphere.

Observations are composed of reusable, hierarchical components, including lines lists (wavelengths of spectral lines), rasters (exposure times, line list, etc.) and studies (defines one or more rasters).

Studies are the basic unit of 'timeline' scheduling. They are a useful construct for generating more complex sequences of observations, reducing the planning burden. Instrument observations must first be validated.

An initial requirement was that operations be shared equally by the 3 main EIS teams (Japan, UK and US). Hence, a major design focus of the software was 'Remote Operations', whereby any scientist in any location can run the software, schedule a science plan and send it to the spacecraft commanding team. It would then be validated and combined with the science plans of the other instruments. Then uploaded to the spacecraft.

As for any space mission, telemetry size and rate are important constraints. For each planning cycle the instruments are issued a maximum data allocation. EISPT interactively calculates the telemetry requirements of each observation and plan.

Autonomous operations was a challenging concept designed to observe the early onset of various dynamic events, including solar flares. The planning cycle precluded observers responding to such short-term events.

Hence, the instrument can be run in a (low-telemetry) 'hunter' mode at a suitable target. Upon detecting an event the current observation ceases and another automatically begins at the event location. This 'response' observation involves a smaller field-of-view and higher cadence. It's impossible to predict if this mechanism will be activated, and if so how much telemetry is acquired.

The EISPT has operated successfully since it was deployed in November 2006. Nominally it is used six days a week. It has been maintained and updated as required to take account of changing mission operations. A large update was made in 2013/14 to develop the facility to coordinate observations with other solar missions (SDO/AIA and IRIS).

9910-48, Session 9

An optical to IR sky brightness model for the LSST

Peter Yoachim, Univ. of Washington (United States); Michael Coughlin, Harvard Univ. (United States); George Z. Angeli, Chuck Claver, LSST (United States); Andrew J. Connolly, Univ. of Washington (United States); Kem H. Cook, Cook Astronomical Consulting (United States); Scott Daniel, Zeljko Ivezic, R. Lynne Jones, Univ. of Washington (United States); Catherine E. Petry, LSST (United States); Michael A. Reuter, LSST (United States); Christopher W. Stubbs, Harvard Univ. (United States); Bo Xin, LSST (United States)

To efficiently survey the night sky requires a detailed knowledge of the sky brightness and how it evolves as a function of time, position of the moon, and solar activity. To develop this knowledge the Large Synoptic Survey Telescope (LSST), as part of its simulations program, has developed an open-source python code to calculate the expected night sky emission on Cerro Pachon. This code uses the ESO SkyCalc Sky Model Calculator (Noll et al. 2012; Jones et al. 2013) to generate a suite of 3,500 template spectra that can be interpolated to arbitrary observing conditions. These template spectra include components for scattered moonlight, zodiacal light, airglow, scattered starlight, and upper and lower atmosphere emission. To determine how far into twilight the LSST can observe (in the z and y filters) we have extended the sky model to predict twilight sky conditions. This model is an analytic fit to observations made with a Canon all-sky camera located at the LSST site. These observations have been run through a photometry pipeline to generate a database with 91.5 million measurements of the sky brightness spanning a range of 311 days. From these data we find that, for sun altitudes between -11 and -20 degrees and airmasses less than 2.5, the twilight component of the sky can be fit with a model with only 4 free parameters. Early validation of the LSST sky model shows that dark-time zenith predictions match the observations with an RMS of 0.2 magnitudes. We attribute most of this variation to random variations in the weather, as the residuals show no significant trend with time of night or time of year.

9910-49, Session 9

Measurements of airglow at Gemini Observatory on Maunakea in the optical and infrared

Adam Smith, Katherine C. Roth, Andrew Stephens, Olesja Smirnova, Gemini Observatory (United States)

Gemini Observatory on Mauna Kea has been collecting optical and infrared science data for almost 15 years. We have analyzed imaging data from two of the original facility instruments, GMOS and NIRI, in order to measure sky brightness levels in multiple infrared and optical broad-band filters. We present measured background levels as a function of several operational quantities (e.g. moon-phase, hours after/before twilight, seasons). We find that airglow is a significant contributor to background levels in several filters. Gemini is primarily a queue scheduled telescope, with observations being optimally executed in order to provide the most efficient use of telescope time. However, without any means to schedule observations as a function of airglow we find that some imaging observations may not be meeting the expected sensitivity requirements. We suggest that in order to improve the delivered queue data quality an airglow monitor could be adopted and airglow brightness be incorporated into the Integration Time Calculator as part of the sky background quantity used to schedule observations.

9910-50, Session 10

Two years of LCOGT network operations: the challenges of a global observatory

Nikolaus Volgenau, Las Cumbres Observatory Global Telescope Network (United States)

With 18 telescopes distributed over 6 sites, and more telescopes being added in 2016, Las Cumbres Observatory Global Telescope Network is a unique resource for time-domain astronomy. The Network began providing observations for members of its Science Collaboration and other partners in May 2014. In the two years since then, LCOGT has made a number of improvements to increase the Network's science yield. We also now have two years' experience monitoring observatory performance; effective

monitoring of an observatory that spans the globe is a complex enterprise. This presentation describes LCOGT's efforts to monitor site conditions, instrument performance, the quality of science data, and the efficiency of the scheduling software.

The Network's continuous coverage of the night sky, and the optimization of the observing schedule over all sites simultaneously, have enabled LCOGT-users to produce significant science results. However, practical challenges to maximizing the Network's science output remain. Overcoming some of these challenges will require increasing the sophistication of our Network scheduling. Some examples are the following: Long-duration observations, which can benefit studies of exoplanet transits, microlensing events, and lensed quasar time delays, should be automatically passed from one site to another. Requests to observe in multiple filters simultaneously should be linked, so that either all observations are attempted or rejected (and so can be rescheduled at another site). And requests for immediate (target-of-opportunity) observations, which are critical for GRB and SN-progenitor investigations, should be acted on as quickly as possible but be otherwise minimally disruptive.

Weighing the priorities of observing requests for large and small projects is a thorny issue. On the one hand, thousands of hours have been allocated to LCOGT's (high priority) key projects, dedicated to exoplanet microlensing (PI: R. Street), supernova characterization (PI: D. Howell), and AGN reverberation mapping (PI: K. Horne). But on the other hand, some key project data are more important than others, and smaller projects that request a few hours to observe a few events shouldn't repeatedly be squeezed out of the schedule.

In 2015, new Sinistro cameras, which were designed and built in-house, replaced commercial SBIG cameras on the Network's 1-meter telescopes. The need to develop the necessary site infrastructure and install the Sinistros had to be balanced against the need to keep sufficient telescopes available for science observations. LCOGT is facing this challenge again with future instrument upgrades, including the 2016 deployment of the Network of Robotic Echelle Spectrographs (NRES, see contribution by Siverd).

9910-51, Session 10

Dark energy survey operations: years 1 to 3

H. Thomas Diehl, Fermi National Accelerator Lab. (United States)

The Dark Energy Survey (DES) is a next generation optical survey aimed at understanding the accelerating expansion of the universe using four complementary methods: weak gravitational lensing, galaxy cluster counts, baryon acoustic oscillations, and Type Ia supernovae. To perform the 5000 sq-degree wide field and 30 sq-degree supernova surveys, the DES Collaboration built the Dark Energy Camera (DECam), a 3 square degree, 570 Megapixel CCD camera that was installed at the prime focus of the Blanco 4-meter telescope at the Cerro Tololo Inter-American Observatory in 2012. A DES season comprises 105 nights of observations from August to mid February. DES "Year 1" (of 5) was 2013 to 2014. We will finish "Year 3" in February 2016. This presentation will describe DES, the strategy and goals for the first three season's data, the performance of the camera, and the efficiency of survey operations.

9910-52, Session 10

Lessons from and methods for surveying large areas with the Hubble Space Telescope

John W. MacKenty, Space Telescope Science Institute (United States)

Although the imagers on the Hubble Space Telescope only provide fields of view of a few square arc minutes, the telescope has been extensively used to conduct large surveys. These range of relatively shallow mappings in a single filter, multi-filter and multi-epoch surveys, and a series of increasingly deep exposures in several carefully selected fields. HST has also conducted extensive "parallel" surveys either coordinated with a prime instrument (typically using two cameras together) or as "pure" parallel observations to capture images of areas on the sky selected by another science programs(typically spectroscopic observations). We compare various strategies and outcomes from these pure parallel observations. Recently, we have tested an approach permitting much faster mapping with the WFC3/IR detector under GYRO pointing control and avoiding the overhead associated with multiple target observations. This results in a four to eight fold increase in mapping speed (ad the expense of shallower exposures). This approach enables 250 second exposures (reaching H~25th magnitude) covering one square degree in 100 orbits.

9910-53, Session 10

Development of the Arizona Robotic Telescope Network

Benjamin Weiner, Dennis Zaritsky, The Univ. of Arizona (United States); Pavel Gabor, Vatican Observatory Research Group (United States); Nathan Smith, Scott Swindell, Chris Johnson, The Univ. of Arizona (United States); Petr Kubánek, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Victor Gasho, Buell T. Jannuzi, The Univ. of Arizona (United States)

The Arizona Robotic Telescope Network project is a long term effort to develop a system of telescopes that can carry out a flexible program of PI observing, survey projects, synoptic observing, and time domain astrophysics including monitoring, rapid response, followup and characterization of transients and targets of opportunity. Steward Observatory operates and shares in several 1-3m class telescopes with quality sites and instrumentation, largely operated in classical modes. Science programs suited to these telescopes become limited by scheduling flexibility and people-power of available observers. Our goal is to adapt these facilities for multiple co-existing queued programs, interrupt capability, remote/robotic operation, and delivery of reduced data. In the long term, planning for the LSST era, we envision an automated system coordinating across multiple telescopes and sites, where alerts can trigger followup on one telescope + instrument, automated characterization, and triggering of further observations if required, such as followup imaging that automatically triggers spectroscopy when criteria are met. We are updating telescope control systems and software to implement this system in stages, beginning with the Kuiper 61" and the Vatican Observatory's 1.8m telescopes. We present science requirements for the telescope network and the technical requirements derived therefrom, and discuss issues adopting legacy facilities, scheduling, data pipelines, and maintaining capabilities for a diverse user base.

9910-54, Session 10

Spectral calibration for the Maunakea Spectroscopic Explorer: challenges and solutions

Nicolas Flagey, Alan W. McConnachie, Richard Murowinski, Kei Szeto, Canada-France-Hawaii Telescope (United States); Shan B. Mignot, Observatoire de Paris à Meudon (France)

The Maunakea Spectroscopic Explorer (MSE) will each year obtain millions of spectra in the optical to near-infrared, at low (R~2,500) to very high (R~40,000) spectral resolution by obtaining ~3000 spectra per pointing via a highly multiplexed fiber-fed system. Key science programs for MSE include black hole reverberation mapping, stellar population analysis of faint galaxies at high redshift, and sub-km/s velocity accuracy for stellar astrophysics. This requires highly precise, repeatable and stable spectral calibration over long timescales. To meet these demanding science goals and to allow MSE to deliver data of very high quality to the broad community of astronomers involved in the project, a comprehensive and efficient calibration strategy is being developed. In this paper, we present the different challenges we face to properly calibrate the MSE spectra and the solutions we are considering to address these challenges.

9910-55, Session 10

Calibration development strategies for the Daniel K. Inouye Solar Telescope (DKIST) data center

Fraser Watson, Kevin Reardon, Steven J. Berukoff, Daniel Speiss, Scott Wiant, Tony Hays, National Solar Observatory (United States)

As telescopes have grown larger and data rates have increased, so have the challenges in providing reliable and accurate calibration strategies for transforming raw data into useful science-ready outputs. The Daniel K. Inouye Solar Telescope (DKIST), currently under construction on Haleakal?, in Maui Hawai`i will be the largest solar telescope in the world and will use adaptive optics to provide the highest resolution view of the Sun. Its data acquisition rates will be in the hundreds of thousands of frames per day, and it will deliver an average of 12TB of raw solar data on a daily basis. It is expected that DKIST data will enable significant and transformative discoveries that will dramatically increase our understanding of the Sun and its effects on the Sun-Earth environment. As a result of this, it is a priority of the DKIST Data Center team at the National Solar Observatory (NSO) to be able to deliver timely and accurately calibrated data to the astronomical community for further analysis.

The first light suite consists of five unique instruments, which are all expected to begin operations within a short window at the start of operations. These instruments are designed to work in parallel, taking simultaneous observations of a single part of the Sun in multiple wavelengths and with multiple observational schemes at the same time. As such, the calibration development effort for each instrument will involve efforts from the NSO Data Center team, the instrument developers, and the broader community. This allows us to leverage the similarities between some instruments, identify calibration processes that are common among instruments, and make use of the accumulated domain knowledge. By modularizing these steps, we will be able to increase the efficiency and effectiveness of our calibration strategy.

The facility will execute a variety of investigator-driven observing programs, which will produce day-to-day variations in the types of acquired data. In combination with large data rates and limited personnel, this will require some degree of automation to be incorporated into the calibration workflows to facilitate the generation of scientifically useful data. The heterogeneity of the data and the unpredictable variations in the seeing conditions (on timescales of seconds or minutes) introduce complexity, which requires a self-adapting, extensible calibration pipeline. In addition, our knowledge of the instrument performance and telescope characteristics will grow rapidly as the telescope begins operations, and continuously through the facility lifetime. So the automated calibration pipelines will need to be capable of modification and improvement to incorporate the new information about the DKIST system, as well as potential improvements provided by the DKIST user community.

This paper will detail the current calibration processing development strategies being used by the Data Center team at the National Solar Observatory to manage this calibration effort, so that we can deliver timely and accurately calibrated data to the DKIST user community, with as much scientific value as possible.

9910-56, Session 10

ALMA quality assurance: concepts, procedures, and tools

A. Maurizio Chavan, European Southern Observatory (Germany); Stephane L. Tanne, ALMA (Chile); Eiji Akiyama, National Astronomical Observatory of Japan (Japan); Robert Kurowski, Suzanna Randall, European Southern Observatory (Germany); Baltasar Vila Vilaro, ALMA (Chile); Eric Villard, Joint ALMA Observatory (Chile)

Data produced by ALMA for the community undergoes a rigorous quality assurance process, from the initial observation (“QA0”) to the final science-ready data products (“QA2”), to the QA feedback given by the PIs when they receive the data products (“QA3”). Calibration data is analyzed to measure the performance of the observatory and predict the trend of its evolution (“QA1”).

The procedure develops over different steps and involves several actors across all ALMA locations; it is made possible by the support given by dedicated software tools and a complex database of science data, meta-data and operational parameters. The life-cycle of each involved entity is well-defined, and it prevents for instance that “bad” data (that is, data not meeting the minimum quality standards) is ever processed by the ALMA pipeline.

9910-58, Session 10

Data mining spacecraft telemetry: towards generic solutions for automatic health monitoring and status characterization

Pierre Royer, Joris De Ridder, Bart Vandenbussche, Sara Regibo, Rik Huygen, Wim De Meester, KU Leuven (Belgium); David J. Evans, Jose Martinez, European Space Agency (Germany)

Context: As the number of spacecraft telemetry parameters and telecommands keeps increasing, and the manpower for operating the ground systems keeps being reduced, there is an increasing need for automating the health monitoring and status characterization of all on-board subsystems.

Goal: we present the first results of a joint study between KU Leuven and ESA aiming at finding new and efficient ways to automatically process spacecraft telemetry as it is down-linked. The goal is to detect anomalous behavior as well as early signs of new trends or discrepancies that are worth checking by an operations engineer. We aim at reducing the load on the flight control team while extending the “checkability” to the entire telemetry database, and provide efficient, faster and more accurate detection of anomalies in near real time. Special care is taken to define robust methods, i.e. to avoid false alarms as much as possible.

Means: we have performed a study of the statistical properties of the signal, regarding each parameter in the telemetry as an independent time series. We also analyzed binned time series of the signal properties themselves. Finally, we have completed the dataset with auxiliary parameters derived from the telecommand history, the event reports, the spacecraft attitude, etc.

For this study, we received a full year of Venus Express telemetry from

ESA, without description, enforcing a purely data-centric approach, without any a priori knowledge. We have developed and recommended a set of methods that were then validated against a second year of telemetry from Venus Express, namely the last one, where a series of peculiar operations took place before the mission was finally lost.

Results: We present a set of effective methods to (a) detect outliers in the telemetry or in its statistical properties, (b) uncover and visualize special properties of the telemetry and (c) detect new behavior. Our results are structured around two main families of solutions.

For parameters visiting a restricted set of signal values (i.e. all status parameters and about one third of all the others), we focus on a transition analysis. We show how Poincaré plots and transition probabilities can be used to uncover special properties of the signal and very efficiently detect anomalies and new behavior.

For parameters with an arbitrarily high number of possible signal values, we describe the statistical properties of the signal via its Kernel Density Estimate. We demonstrate that this allows for a generic and dynamic approach of the soft limit definition. Thanks to a much more accurate description of the signal and of its time evolution, the method provides more sensitive and much more responsive outlier detection capabilities than the traditional checks against hard limits.

The methods we present are generic for assisting in health monitoring of complex systems with large amounts of diagnostic sensor data. Not only spacecraft systems, but also present day astronomical observatories can benefit from using these techniques.

9910-59, Session 11

The evolution of observing modes at ESO telescopes

Stéphane Marteau, Olivier R. Hainaut, European Southern Observatory (Germany); George Hau, European Southern Observatory (Chile); Ferdinando Patat, Marina Rejkuba, European Southern Observatory (Germany); Ivo Saviane, Steffen Mieske, European Southern Observatory (Chile); Lowell E. Tacconi-Garman, European Southern Observatory (Germany)

Traditionally astronomers traveled to the telescopes to observe. With the start of space operations this has changed, and soon the large ground based observatories have followed along, introducing in addition to the traditional (visitor) also the service (in some observatories also known as queue) observing mode. When observing in service mode, the astronomers interact with the observatory staff who take the observations on behalf of the Principle Investigators and their team. The fundamental concepts behind these modes have not radically changed since they were introduced. However, the emergence of new scientific rationales and observing strategies and the will to take advantage of improving IT technologies have spawned new variants of these observing modes over the past 20 years. From the implementation of Service Mode at the NTT in 1997 to the recent “designated” Visitor Mode observations for short runs, we review how the palette of observing modes and the types of programs has evolved at ESO, responding to the requests of the user community. In more detail, we present how the evolution of tools at the disposal of external astronomers and the Observatory staff has enabled ESO to implement new types of observations (monitoring programs, time-constrained observations, rapid response mode, etc.) and to improve their efficiency. Also, we describe some of the challenges that are still ahead of us. Instruments currently in their construction or design phase, such as ESPRESSO or 4MOST, will once again shuffle the cards and force us to re-invent part of the operations and observation system to address the new constraints that these facilities bring. Scientific optimization of observing strategy including on-the-fly adjustments to the planned observations, or the necessity to multiplex several observing programs into a single slot of observing time will challenge our current implementation of flexible scheduling and will require solutions that do not jeopardize the rest of the observations. Recent feedback from the community has indicated that both visitor and service observing modes are highly rated for current and future observing sites, but that there is also interest for further evolution. In particular, we look at some first steps being done towards the possibility of performing remote observations at ESO telescopes: it is a perspective which has to be considered for the future, and one for which the user community has expressed clear interest.

9910-60, Session 11

New facilities, new challenges: the telescopes and instruments operators evolution

Andres Pino, Steffen Mieske, Stéphane Brillant, Susana Cerda, Cristian M. Romero, Antoine Mérand, Alain Smette, European Southern Observatory (Chile)

Observatories and operational strategies are evolving in connection with the facilities that will be built. For those new facilities, the strategy for dealing with the telescopes, instrumentation, data-flow, reduction process and relationship with the community is more or less handled from its conception. However, for those Observatories already in place, the challenge is to adapt the processes and prepare the existing people for these changes.

The scope of this talk will show how Paranal Observatory is working by improving the continuous development of the Telescopes and Instruments Operator Group (TIO), preparing them with regards to the evolution of the instruments, operational techniques and the technical and engineering support for these new facilities.

When Paranal started with Science Operations activities during the late 1990s, the implemented operational model was standard among big observatories. All the technical procedural area about telescope operations was completely handled by Telescopes Operators and the activities related with the instrument (instrument acquisition and data acquiring, observational queues preparation, data quality control and calibrations completion) where mostly performed by the Astronomers on site.

Keeping in mind the requirements for more specific skills, the profile for selecting new TIOs and the involvement on operational activities changed during these years. With the implementation of the current operational scheme (SciOps 2.0), a more dynamic interaction culture between TIOs and Astronomers was born.

Today, Science Operations activities are directly handled by TIOs during daytime and nighttime. During nighttime, operational activities are performed collaboratively between astronomers and TIOs, and during the last part of the night, the Operators perform the full process independently. For those high level or more astrophysical dedicated decisions to be taken during the night, a Senior Astronomer (Nighttime Shift Coordinator) is always available at the Control Room, in order to keep offering the standard services of the Observatory. During daytime, the activities related with calibration completeness and data quality assurance are also part of the TIO duties.

Arriving to this level of involvement required the full support from the Observatory and the proactive support from Astronomers and other related groups under the Directorate of Operations.

This talk will show detailed information about current activities, the implemented training plan, the definition of the current operational model, the involvement of the group in projects towards improving in operational processes and efficiency, and what new challenges will be involved during the definition of the strategies for the new generation instruments to be installed.

9910-61, Session 12

Operations of the Thirty-Meter-Telescope (TMT) International Observatory

Christophe Dumas, Hanne Buur, Kim Gillies, Angel Otarola, Matthias Schoeck, Warren Skidmore, Tony Travouillon, Thirty Meter Telescope (United States)

The construction of the Thirty-Meter-Telescope International Observatory (TIO) is scheduled to take about eight years, with first-light currently planned for 2024 and start of operations soon after. Its innovative design, the unequaled astronomical quality of its location, and the scientific capability that will be offered by its suite of instruments, all contribute to position TIO as a major ground-based astronomical facility of the next decade.

In this talk, we will present the details of our operations plan, focusing in particular on the aspects of science operations and data-management, but describing as well our plans for managing technical operations, instrument development and logistics support.

After some initial periods dedicated to AIV and observatory commissioning, steady state operations will require a science and technical staff of about 120 persons. Daytime technical presence on the summit will address the support of all engineering and maintenance activities, while only a minimal nighttime crew will be present at the telescope to secure safe night-operations of the equipment. The telescope will be operated remotely at night from the TIO headquarters and science operations are expected to meet a wide range of observing needs. Observing support associated with ‘classical’ and ‘queue’ modes will be offered, including various flavors of remote observing, which will allow – when needed – ‘virtual’ (‘eavesdropping’) connection with the observatory staff by the team members of science programs. It is also planned that remote observing sites, operated by trained TIO staff, will be available across the partner countries. Such sites will support observation preparation, execution, and possibly data-reduction/analysis. The execution of the approved science programs will be implemented in the schedule in a manner to optimize scientific outputs. Science programs with stringent observing constraints, or time-critical components (e.g. ‘Target of Opportunity’ programs), will be fully supported as well. All science data, and their associated calibration frames, will be archived and available for download to the community of TIO users, and access to a wider community is currently being discussed.

The international TIO partnership includes Canada, China, India, Japan, Caltech, the University of California, and funding is also provided by the Gordon and Betty Moore Foundation. AURA is an associate member of TIO, on behalf of the US national community. Through a cooperative agreement with the NSF, TIO and a US-TMT Science Working Group are developing a model for potential US national partnership in the TIO.

9910-62, Session 12

Science operations at Gemini Observatory

Andrew J. Adamson, Gemini Observatory (United States); Rene Rutten, Gemini Observatory (Chile); Sandy Leggett, Gemini Observatory (United States)

Gemini Observatory operates two 8-m telescopes, one on Cerro Pachón in Chile and one on Maunakea Hawaii, supporting via a distributed model a multiple-member, international partnership. The telescopes, their software and supporting IT infrastructure (and some of the instrumentation) are identical at the two sites, affording economies of scale and staff-sharing opportunities in many technical and scientific areas. The aim of this paper is to describe the observatory’s operations in context of the >20% budget reduction incurred due to the withdrawal of the UK from the international partnership, other changes in the partnership itself and increasing use of short-term “limited-term partnership” arrangements via which interested potential full partners may “test the water”.

Recent initiatives such as the Large and Long Program and Fast Turnaround Program proposal modes, increased time for Visiting Instruments and the new Priority Visitor observing mode, have been successful from the point of view of the user community. We describe the integration of these initiatives into the regular operation and note some of the impacts which needed to be controlled.

Gemini operates a distributed user support model in which National Gemini Offices in each Partner country are responsible for a significant amount of user support, particularly in the early stages of the lifecycle of a science program. We discuss recent adjustments in this support model, driven by budget and effort constraints and the needs of the user community.

Finally, we describe science outcomes in terms of science program completion rates and publications, and make some comparisons with targets set early in the life of the observatory.

9910-63, Session 12

The 4MOST operations system

Tom Dwelly, Andrea Merloni, Max-Planck-Institut für extraterrestrische Physik (Germany); Jakob C. Walcher, Leibniz-Institut für Astrophysik Potsdam (Germany); Nicolas Clerc, Alain Gueguen, Thomas Boller, Max-Planck-Institut für extraterrestrische Physik (Germany); Roelof S. de Jong, Cristina Chiappini, Leibniz-Institut für Astrophysik Potsdam (Germany)

The 4MOST multi-object spectroscopic instrument to be mounted on the ESO/VISTA telescope will be used to conduct an ambitious multi-year wide area sky survey. A disparate set of science goals, requiring observation of tens of millions of galactic and extragalactic targets, must be satisfied by a unified program of observations. The 4MOST Operations System is designed to facilitate this complex task by i) providing sophisticated simulation tools that allow the science team to plan and optimise the 4MOST survey, ii) carrying out optimised medium-term scheduling using survey forecasting tools and feedback from previous observations, and iii) producing sets of observation blocks ready for execution at the telescope. We present an overview of the Operations System, highlighting the advanced facility simulator tool and the novel strategies that will enable 4MOST to achieve its challenging science goals.

9910-64, Session 12

Planning JWST NIRSpec MSA spectroscopy using NIRCam pre-images

Tracy Beck, Leonardo Ubeda, Diane M. Karakla, Susan Kassin, Space Telescope Science Institute (United States)

The Near-Infrared Spectrograph (NIRSpec) is the work-horse spectrograph at 1-5microns for the James Webb Space Telescope (JWST). A showcase observing mode of NIRSpec is the multi-object spectroscopy with the Micro-Shutter Arrays (MSAs), which consist of a quarter million tiny configurable shutters 0.”2x0.”45 in size. The NIRSpec MSA shutters can be opened in adjacent rows to create flexible and positionable spectroscopy slits on prime science targets of interest. Because of the very small shutter width, the NIRSpec MSA spectral data quality benefits significantly from very accurate astrometric knowledge of the positions of planned science sources. Images acquired with the Hubble Space Telescope (HST) have the optimal 5milli-arcsec accuracy for NIRSpec planning astrometry. However, galactic fields can have moderate proper motions beyond the 5mas source position knowledge, and extragalactic images with HST may have inadequate source information at NIRSpec wavelengths beyond 2 microns. Thus, optimal NIRSpec spectroscopy planning may require pre-imaging

observations with the Near-Infrared Camera (NIRCam) on JWST to properly establish source positions. We describe operational philosophies and programmatic considerations for acquiring JWST NIRCam pre-image observations for NIRSpec MSA spectroscopy planning within the same JWST observing Cycle.

9910-65, Session 12

Moving toward queue operations at the Large Binocular Telescope Observatory

Michelle L. Edwards, Douglas M. Summers, Joseph A. Astier, Igor Suarez Sola, Christian Veillet, Jennifer Power, Andrew Cardwell, Shane Walsh, Large Binocular Telescope Observatory (United States)

The Large Binocular Telescope Observatory (LBTO), a joint scientific venture between the Instituto Nazionale di Astrofisica (INAF), LBT Beteiligungsgesellschaft (LBTB), University of Arizona, Ohio State University (OSU), and the Research Corporation, is one of the newest additions to the world's collection of large optical/infrared ground-based telescopes. With its unique, twin 8.4m mirror design providing a 22.8 meter interferometric baseline and the collecting area of a 11.8m telescope, LBT has a narrow window of opportunity to exploit its singular status as the "first" of the next generation of Extremely Large Telescopes (ELTs).

Prompted by urgency to maximum scientific output during this favorable interval, LBTO recently re-evaluated its operations model and developed a new strategy that augments classical observing with queue. Run by trained observatory staff, queue mode will allow for flexible, multi-instrument observing responsive to site conditions. Our plan is to implement a staged rollout that will provide many of the benefits of queue observing sooner rather than late -- with more bells and whistles coming in future stages.

In this paper, we outline LBTO's new scientific model, focusing specifically on our "lean" resourcing and development, reuse and adaptation of existing software, challenges presented from our one-of-a-kind binocular operations, and lessons learned. We also outline further stages of development and our ultimate goals for queue.

9910-66, Session 12

4MOST: science operations for a large spectroscopic survey program with multiple science cases executed in parallel

Jakob C. Walcher, Leibniz-Institut für Astrophysik Potsdam (Germany); Thomas Boller, Tom Dwelly, Max-Planck-Institut für extraterrestrische Physik (Germany); Michael J. Irwin, Institute of Acoustics (United Kingdom); Roelof S. de Jong, Leibniz-Institut für Astrophysik Potsdam (Germany); Andrea Merloni, Max-Planck-Institut für extraterrestrische Physik (Germany); Nicolas A. Walton, Institute of Acoustics (United Kingdom); Olga Bellido-Tirado, Cristina Chiappini, Leibniz-Institut für Astrophysik Potsdam (Germany); Sofia Feltzing, Univ. Lund (Sweden); Olivier Schnurr, Leibniz-Institut für Astrophysik Potsdam (Germany)

The 4MOST instrument is a multi-object spectrograph to be mounted to the VISTA telescope at ESO La-Silla-Paranal observatory. 4MOST will deliver several 10s of millions of spectra from surveys typically lasting 5 years. 4MOST will address Galactic and extra-galactic science cases simultaneously, i.e. by observing targets from a large number of different surveys within one science exposure. This parallel mode of operations as well as the survey nature of 4MOST require some 4MOST-specific operations features within the overall operations model of ESO. These features are necessary to minimize any changes to the ESO operations model at the La-Silla-Paranal observatory on the one hand, and to enable parallel science observing and thus the most efficient use of the instrument on the other hand.

I will describe the operations model for 4MOST as seen by the consortium building the instrument. Among others this encompasses: 1) A joint science team for all participating surveys (i.e. including community surveys as well as those from the instrument building consortium). 2) Common centralized tasks in observing preparation and data management. 3) Transparency of all decisions to all stakeholders. 4) Close interaction between science and facility operations. 5) Strategies to minimize complexity and coordination overhead.

Overall I will show that parallel observing mode is efficient, flexible, and manageable.

9910-67, Session 12

Optimizing parallel observations for the JWST/MIRI instrument

Macarena Garcia-Marin, European Space Agency (United States); Stacey Alberts, The Univ. of Arizona (United States); Alvaro Labiano-Ortega, ETH Zürich (Switzerland); Marcia Rieke, George H. Rieke, Christopher Willmer, The Univ. of Arizona (United States); Gillian S. Wright, UK Astronomy Technology Ctr. (United Kingdom)

Using unprecedented sensitivity and angular resolution, the Mid-Infrared Instrument (MIRI) for the JWST will provide imaging, coronagraphy, low-resolution slit spectroscopy, as well as integral-field spectroscopy at medium spectral resolution for a broad variety of science observations. Observing programs that use MIRI in parallel with other instruments (either as a prime or secondary instrument) are an optimal way to better exploit the observatory capabilities.

It is expected that the JWST operational observatory design will include parallel modes. We have therefore been studying the intricacies of combining MIRI (5-28 microns) and NIRCam (0.6-5microns) imaging observations for a deep imaging use-case. Such programmes present particular challenges from an operations point of view.

These collaborative programs pose some interesting challenges from the operations point of view. New dither patterns need to be designed that optimally work for both instruments and take into account their individual detector characteristics, field of views and relative orientations. They also need to consider the difference in PSF between instruments. The MIRI PSF is Nyquist sampled at wavelengths larger than about 6.3 microns, and sub-pixel sampling may be needed for the shorter wavelengths. For the long wavelengths, ideally dithers should be of the order of 2 or 3 FWHM. NIRCam will need sub-pixel sampling for for almost all wavelengths bluer than 2 microns in the Short wavelength detector and 4.4 microns in the Long wavelength one.

From a purely operational perspective, the way instrument events are planned and organized (e.g. changing filter wheels) needs to be taken into account as well; one instrument's mechanisms cannot be moved while other is exposing. In this sense the dwelling time on each dither position is another aspect to consider. For MIRI, the detector performance and the radiation environment at the L2 orbit will dictate for how long we can integrate on each dither position.

All this, along with the difference in sensitivity between instruments, (e.g. MIRI does not reach as deep as NIRCam for a given exposure time) are the main drivers for the design of joint science programs.

In general the design and execution of MIRI parallel observations needs to be carefully choreographed, and that requires close collaboration and compromise with other instrument teams. In this contribution we present the overall design of the MIRI observations in parallel with NIRCam, opening the path to a wealth of collaborative science opportunities between MIRI and the rest of JWST instruments.

9910-68, Session 12

Through thick and thin: quantitative classification of photometric observing conditions on Paranal

Florian Kerber, European Southern Observatory (Germany); Richard R. Querel, National Institute of Water and Atmospheric Research (New Zealand); Bianca Neureiter, Ludwig-Maximilians-Univ. München (Germany); Reinhard Hanuschik, European Southern Observatory (Germany)

A Low Humidity and Temperature Profiling (LHATPRO) microwave radiometer is used to monitor sky conditions over ESO's Paranal observatory. It provides measurements of precipitable water vapour (PWV) at 183 GHz, which are being used in Service Mode for scheduling observations taking advantage of favourable conditions for infrared observations. The instrument also contains an IR camera measuring sky brightness temperature at 10.5 ?m. It is capable of detecting very cold and very thin, even sub-visual, cirrus clouds. We present a diagnostic diagram that, based on a sophisticated time series analysis of these IR sky brightness data, allows for the automatic classification of photometric observing conditions over Paranal. The method is highly sensitive to the presence of even very thin clouds but robust against other causes of sky brightness variations. The diagram has been validated across the complete range of conditions that occur over Paranal and we find that the automated process provides correct classification at the 95% level.

9910-69, Session 12

A daily task manager for Paranal science operations

Cristian M. Romero, Steffen Mieske, Stéphane Brillant, European Southern Observatory (Chile); Myriam Rodrigues, Observatoire de Paris à Meudon (France); Andres Pino, Leonel Rivas, European Southern Observatory (Chile)

Paranal Observatory has a department called Science Operations and is in charge of operates the instrument within the global scheme established for the Very Large Telescope. This scheme was improved on what was called SciOps 2.0. The main operational goals of this new scheme were strengthen the coordination of science operations activities within, and between, the department groups, by increasing the time allocated to "high-level" activities. Also improve the efficiency of the core science operations support to service mode (SM) and visitor mode (VM) observations, and the quality of the astronomical data delivered to the community of Paranal users.

In this context of efficiency and quality improvement of operations within the SciOps department, we had identified a strong need to optimize the management of daily operation tasks, via the development of a daily activity monitoring integrated tool, so this paper details the findings of the Daily Activity Monitoring Integrated Tool (DAMIT), the proof of Concept phase and the first delivered phase. The technical proof of concept was the first phase in development of a daily operation-monitoring tool for the science operation department. The primary objective of this phase was to evaluate the viability and impact of such a tool to improve the quality and efficiency of SciOps at Paranal.

We present the preparation of this study followed an on-site technical analysis of the SciOps daily operation (day and night), the current procedures to certify the completeness and quality of the daily operations, and requirements for a new daily operation-monitoring tool.

9910-71, Session 12

Delivering data reduction pipelines to science users

Wolfram Freudling, European Southern Observatory (Germany)

The ultimate objective of astronomical observations is to produce science data products that can be used to extract science. The complexity of modern instruments requires highly specialized algorithms for data organization and data reduction. Data visualization and user interaction, both to fine tune individual algorithms and to modify the data flow itself, are essential for the production of science grade products that fully exploits the potential of the raw data.

The European Southern Observatory has a long history of providing specialized algorithms called recipes for each of its instruments. However, calling these recipes in sequence and providing the proper input to each of the recipes is a challenging and time consuming task. The efficiency of data reduction can vastly be improved by using automatic workflows to organise data and execute a sequence of data reduction steps. To realize such efficiency gains, we designed a system called ESOREFLEX that allows intuitive representation, execution and modification of the data reduction workflow, and has facilities for inspection of and interaction with the data. ESOREFLEX uses a number of innovative concepts and has been described in Freudling et al., 2013, Astronomy and Astrophysics 559, 96. In October 2015, the complete system was released to the public. It includes systems for automatic data organization and visualization, interaction with recipes, and the exploration of the provenance tree of intermediate and final data products. ESOREFLEX is highly efficient, using its internal bookkeeping database to recognize and skip previously completed steps during subsquent processing of the same or similar data sets.

ESOREFLEX workflows encapsulate the best practice data reduction for the data from a particular instrument mode, and at the same time can easily be modified by users. Where necessary, several alternative reduction flows are offered in a single workflow. Currently, about 20 different workflows for most of the instruments on ESO's Very Large Telescope (VLT) have been released or are under development.

ESOREFLEX executes the same recipes that have been developed for other operational purposes, such as data quality control and archive processing.These highly controlled operational environments have substantially different requirements. In particular, they run these recipes mostly unsupervised in a static manner. ESOREFLEX allows to deliver these operational pipelines to science users that use them in a highly interactive and dynamic manner.

Conference 9911: Modeling, Systems Engineering, and Project Management for Astronomy VI

Sunday - Tuesday 26–28 June 2016

Part of Proceedings of SPIE Vol. 9911 Modeling, Systems Engineering, and Project Management for Astronomy VI

9911-1, Session 1

Daniel K. Inouye Solar Telescope: the latest integration, testing, and commissioning plan

Simon C. Craig, Kerry L. Gonzales, Robert P. Hubbard, Chang Liang, Ruth A. Kneale, William R. McBride II, Predrag Sekulic, Timothy R. Williams, National Solar Observatory (United States)

The Daniel K. Inouye Solar Telescope (DKIST) has been in its construction phase since 2010, anticipating the onset of the integration, test, and commissioning (IT&C) phase in early 2017, and the commencement of science verification in 2019. The works on Haleakal? are progressing at a phenomenal rate and many of the various sub-systems are either through or about to enter their Factory (or Laboratory) acceptance. The delays in obtaining site planning permissions, while a serious issue for Project Management, has allowed the sub-systems to develop well ahead of their required delivery to site. We have benefited from the knowledge that many sub-systems will be on site and ready for integration well before affecting the critical path. Opportunities have been presented for additional laboratory/factory testing which, while not free, significantly reduce the risks of potential delays and rework on site. From the perspective of IT&C this has provided an opportunity to develop the IT&C plans and schedules free from the pressures of imminent deployment.

In this paper we describe the ongoing planning of the Integration, Testing and Commissioning (IT&C) phase of the project in particular the detailed planning phase that we are currently developing.

9911-2, Session 1

Two years of nominal science operations: experiences from the Gaia science ground segment

Sebastian G. Els, Gaia Data Processing and Analysis Consortium (Spain) and Ruprecht-Karls-Univ. Heidelberg (Germany); Anthony G. A. Brown, Leiden Observatory (Netherlands); Neil Cheek, Gabriele Comoretto, Maria Garcia-Reinaldos, Hassan Siddiqui, European Space Astronomy Ctr. (Spain); Antonella Vallenari, INAF - Osservatorio Astronomico di Padova (Italy)

With its launch at the very end of 2013, ESA's astrometry satellite Gaia began its endeavor to compile astrometric and photometric measurements of at least one billion objects, as well as high resolution optical spectra of hundred million objects. The Gaia catalog therefore results in a wealth of coherently determined astrophysical parameters of these objects.

After its extensive commissioning phase, Gaia entered the nominal mission phase in July 2014. The science ground segment, which is formed by the Gaia Data Processing and Analysis Consortium (DPAC), has since then started its operations. DPAC is a large, multi-national, science consortium which has to handle and process the dense and complex Gaia data stream. With its decentralized management and its distributed infrastructure, the Gaia DPAC is a remarkable undertaking. In this paper we will summarize some of the experiences of the DPAC facing the real Gaia data, compare this to the pre-launch expectations, and critically review the development phase. By comparing the pre-launch expectations with the real life experiences, we will draw the limitations of a requirements driven development approach for such large scale science software projects, in particular in view of the human factor.

9911-3, Session 1

The Large Synoptic Survey Telescope (LSST) materials test facility (MTF)

David K. Gilmore, Aaron J. Roodman, Kevin A. Reil, Tim Bond, SLAC National Accelerator Lab. (United States)

This paper outlines the design, construction and performance of the Large Synoptic Survey Telescope (LSST) camera Materials Test Facility (MTF) that was built and developed at Stanford/SLAC/KIPAC in compliance with government, industry standards and specifications to ensure that the contamination-critical and sensitive items in the LSST Camera are fabricated, assembled and operated in a way that reduces the likelihood of damage or loss of function due to contamination.

The Large Synoptic Survey Telescope (LSST) project is the most ambitious currently planned in the optical wavelengths. A vast array of science will be enabled by this single wide-deep-fast sky survey, and LSST will have unique survey capability in the faint time domain. The telescope will have an 8.4m (6.5m effective) primary mirror, a 9.62 field of view and a 3.2 gigapixel camera. The system is designed to yield high image quality as well as supurb astrometric and photometric accuracy. To achieve these goals, part of the design requires that the electronics for the camera CCDs operate at -40C inside the cryostat. Given over 3K video channels, each of the 82 electronics boards contain over 1800 active and passive components, along with many connectors and cables that could compromise data quality by deposition of molecular contaminants on the surface of the 4kx4k 201 CCDs in the focal plane as well as the vacuum side of the 1m cryostat window.

Molecular contamination on focal plane CCDs is a major potential source of uncertainty for any astronomical camera performance. This paper seeks to gain leverage on this issue by directly measuring the molecular outgassing rates, at a very sensitive level (10-13 torr), of electronic components, connectors, cable and mechanical assemblies and a fully populated electronics board. The resultant analysis of the MTF data will inform the LSST camera instrument model which is of paramount importance for analyzing eventual LSST throughput data and selection of low outgassing materials.

The LSST MTF is a UHV system designed to measure two types of contamination levels, rate-of-rise and throughput with a conductance (or orifice). On each side of the conductance, the system contains a Stanford Research System 200amu Residual Gas Analyzer (RGA), a 20l s-1 ion pump, and a 200l turbo pump. The system also has the provision for plasma cleaning which involves the removal of impurities and contaminants from surfaces through the use of an energetic plasma created from gaseous species (the LSST MTF uses hydrogen and oxygen).

The prioritized risk scenarios for the LSST camera contamination levels based on the effect on performance and the difficulty of recovery from a "contamination event" are:

1. Non-Evaporable Residue (NVR-molecular contamination) in the vacuum of the cryostat that accumulates on critical surfaces (input window lens surface and sensor surfaces).

2. Accumulation of condensable materials on optical surfaces that are cold relative to their surrounding environment (water on sensor surfaces or the first or second surfaces of the input window lens).

3. Non-evaporable substances that accumulate on optical or CCD surfaces.

4. Accumulation of particulate matter on optical or CCD surfaces.

Quantitative analysis of contamination levels and the effect on camera performance is used to define milestone cleanliness and exposure durations of the critical components. Such analysis is also used to establish cleanliness requirements for associated sensitive hardware.

This paper will describe the detailed design and implementation of the LSST MTF, review the various configurations and procedures involved with making high precision RGA measurements, explain the rationale and results of plasma cleaning and give an overall evaluation of cryostat measured, in-situ component outgassing rates.

9911-4, Session 1

Mission-level performance verification approach for the Euclid space mission

Roland Vavrek, European Space Astronomy Ctr. (Spain); René J. Laureijs, Jose Lorenzo Alvarez, European Space Research and Technology Ctr. (Netherlands); Jérôme Amiaux, Commissariat à l'Énergie Atomique (France); Guillermo Buenadicha, John Hoar, European Space Astronomy Ctr. (Spain); Yannick Mellier, Institut d'Astrophysique de Paris (France); Giuseppe D. Racca, Gonzalo Saavedra Criado, Jean-Christophe Salvignol, Luis Miguel Gaspar Gaspar Venancio, European Space Research and Technology Ctr. (Netherlands)

ESA's Dark Energy Mission Euclid will map the 3D Dark Matter distribution by measuring two Dark Energy probes: Weak Lensing (WL) and Galaxy Clustering (GC). The extreme accuracy required for both probes can only be achieved by observing from space in order to limit all observational biases in the measurements of tracer galaxies. Weak Lensing requires an extremely high precision measurement of galaxy shapes realised with the Visual Imager (VIS) as well as photometric redshifts using near-infrared photometry provided by the Near Infrared Spectrometer Photometer (NISP) complemented by additional ground based visible photometry. Galaxy Clustering requires very accurate redshift measurements (0.1%) of galaxies to be obtained by the NISP Spectrometer.

Performance requirements on spacecraft, telescope assembly, scientific instruments and the ground data-processing have been carefully budgeted to meet the very demanding top level cosmology requirements. As part of the mission development, the verification of scientific performances needs mission level end-to-end analyses in which the Euclid systems are modelled from as-designed to final as-built flight configurations. We present the plan to carry out end-to-end analysis coordinated by the ESA project and the Euclid Consortium in collaboration, including the definition of key performance parameters and their process of verification, the input and output identification and the management of applicable mission configurations in the parameter database.

9911-5, Session 1

Bottom-up laboratory testing of the DKIST Visible Broadband Imager (VBI)

Andrew Ferayorni, Andrew Beard, B. Scott Gregory, Wes Cole, Friedrich Wöger, National Solar Observatory (United States)

The Daniel K. Inouye Solar Telescope (DKIST) is a 4-meter solar observatory under construction at Haleakala, Hawaii. The Visible Broadband Imager (VBI) is a first light instrument that will record images at the highest possible spatial and temporal resolution of the DKIST at a number of scientifically important wavelengths. The VBI is a pathfinder for DKIST instrumentation and a test bed for developing processes and procedures in the areas of unit, systems integration, and user acceptance testing. These test procedures have been developed and repeatedly executed during VBI construction in the lab as part of a "test early and test often" philosophy aimed at identifying and resolving issues early thus saving cost during integration test and commissioning on summit.

The VBI team recently completed a bottom up end-to-end system test of the instrument in the lab that allowed the instrument's functionality, performance, and usability to be validated against documented system requirements. The bottom up testing approach includes four levels of testing, each introducing another layer in the control hierarchy that is tested before moving to the next level. First the instrument mechanisms are tested for positioning accuracy and repeatability using a laboratory position-sensing detector (PSD). Second the real-time motion controls are used to drive the mechanisms to verify speed and timing synchronization requirements are being met. Next the high-level software is introduced and the instrument is driven through a series of end-to-end tests that exercise the mechanisms, cameras, and simulated data processing. Finally, user acceptance testing is performed on operational and engineering use cases through the use of the instrument engineering graphical user interface (GUI).

In this paper we present the VBI bottom up test plan, procedures, example test cases and tools used, as well as results from test execution in the laboratory. We will also discuss the benefits realized through completion of this testing, and share lessons learned from the bottoms up testing process.

9911-6, Session 2

Gaia challenging performances verification: combination of spacecraft models and test results *(Invited Paper)*

Eric Ecale, Frederic Faye, François Chassat, Airbus Defence and Space (France)

To achieve the ambitious scientific objectives of the Gaia mission, extremely stringent performance requirements have been given to the spacecraft contractor (Airbus DS). For a set of those key-performance requirements (e.g. end-of-mission parallax, maximum detectable magnitude, maximum sky density or attitude control system stability), this paper describes how they are engineered during the whole spacecraft development process, with a focus on the end-to-end performance verification. As far as possible, performances are usually verified by end-to-end tests on-ground (i.e. before launch). However, the challenging Gaia requirements are not verifiable by such a strategy, principally because no test facility exists to reproduce the expected flight conditions. The Gaia performance verification strategy is therefore based on a mix between analyses (based on spacecraft models) and tests (used to directly feed the models or to correlate them). Emphasis is placed on how to maximize the test contribution to performance verification while keeping the test feasible within an affordable effort. In particular, the paper highlights the contribution of the Gaia Payload Module Thermal Vacuum test to the performance verification before launch. Eventually, an overview of the in-flight payload calibration and in-flight performance verification is provided.

9911-7, Session 2

Integration and verification testing of the Large Synoptic Survey Telescope camera

Tim Bond, James Chiang, David K. Gilmore, Seth Digel, Richard Dubois, Tom Glanzman, Tony Johnson, Travis Lange, Margaux Lopez, Scott P. Newbry, Martin E. Nordby, Andrew P. Rasmussen, Kevin A. Reil, Aaron J. Roodman, SLAC National Accelerator Lab. (United States)

We present an overview of the Integration and Verification Testing (I&T) activities of the Large Synoptic Survey Telescope (LSST) Camera at the SLAC National Accelerator Lab (SLAC). The LSST Camera, the sole instrument for LSST and under construction now, is comprised of a 3.2 Giga-pixel imager and a three element corrector with a 3.5 degree diameter field of view. LSST Camera I&T will be taking place over the next five years with final delivery to the LSST observatory anticipated in early 2020. We outline the planning for I&T, describe some of the key verification hardware systems being developed, and identify some of the more complicated assembly/integration activities. Specific details of integration and verification hardware systems will be discussed, highlighting some of the technical challenges anticipated.

9911-8, Session 2

OAJ 2.6m survey telescope: optical alignment and on-sky evaluation of IQ performances

Grégory P. Lousberg, Christian Bastin, Vincent Moreau, Olivier Pirnay, Carlo Flebus, AMOS Ltd. (Belgium); Sergio Chueca, César Iñiguez García, Alessandro Ederoclite, A. Javier Cenarro Lagunas, Ctr. de Estudios de Física del Cosmos de Aragón (Spain)

AMOS has recently completed the alignment campaign of the 2.6m telescope for the Observatorio Astrofisico de Javalambre (OAJ). Installed on the Pico del Buitre (Aragon, Spain), the telescope is primarily intended to be used for deep-sky photometric surveys. It is equipped with two mirrors, which are arranged in a Ritchey-Chretien configuration, and with a three-lens aspherical field-corrector. It exhibits a wide field-of-view of +/- 1.5° associated to a large aperture of 2.6m that endow the telescope with a large etendue.

Due to its low focal-ratio (f/# = 3.5), the alignment of the telescope is a complex and challenging process that aims at providing an outstanding image quality over the focal plane of 500mm diameter. In order to reach that optical quality, the positions of the secondary mirror and of the instrument focal plane are adjustable with the help of dedicated hexapods. In that framework, AMOS developed an innovative alignment technique for wide field-of-view telescopes that has been successfully implemented on the OAJ 2.6m telescope with the active support of the team of CEFCA (Centro de Estudios de Física del Cosmos de Aragón).

The alignment relies on two fundamental techniques: (1) the wavefront-curvature sensing (WCS) for the evaluation of the telescope aberrations at arbitrary locations in the focal plane, and (2) the coma-free point method for the adjustment of the position of the secondary mirror (M2) and of the focal plane (FP). The wavefront curvature sensing technique consists in reconstructing the telescope wavefront error from the measurement of the intensity of two out-of-focus images of a star, while the alignment with the coma-free point method allows to perform a sequential alignment of the telescope, with a step-by-step minimization of independent aberrations (coma, field-astigmatism, spherical aberration and focus). Since it does not require the use of traditional Shack-Hartmann wavefront sensors, the proposed method can be readily implemented in any telescope focal plane at a reasonable cost.

For the alignment and commissioning purposes, a dedicated verification camera is installed on the focal plane of the 2.6m telescope. The verification camera features two off-the-shelf CCD sensors that are mounted on two translations stages. The sensors can be positioned at any locations in the focal plane and are able to move along the optical axis. The verification camera thus allows to perform intra- and extra-focal image acquisitions for the WCS, as well as an assessment of the image quality in the telescope focal plane.

The alignment campaign unfolded in three steps: (a) analysis of the repeatability of the WCS measurements, (b) assessment of the sensitivity of telescope WFE to M2 and FP position adjustments, (c) optical alignment of the telescope and (d) evaluation of image quality in the overall focal plane. At the end of the campaign, seeing-limited performances were easily demonstrated in the complete focal plane. With the help of CEFCA team, the image quality of the telescope has been further investigated with a lucky-imaging method. Image sizes of less than 0.3 arcsec FWHM are obtained, and this excellent image quality is observed over the complete focal plane.

9911-9, Session 2

Limiting JWST momentum accumulation: strategies and simulation results

Ronald Henry, Mark Giuliano, Space Telescope Science Institute (United States)

On the James Webb Space Telescope (JWST) mission, the Observatory's large sunshield and uncertainty about exact center of mass makes momentum management a major operations challenge. As observations are executed at different attitudes, varying pitch and roll torques cause momentum buildup, requiring occasional propulsive maneuvers to unload momentum. The JWST propulsion system is sized for a 10-year science mission. Depending on still-uncertain torque magnitudes, momentum unloads could be needed as frequently as once a week on average, making momentum buildup reduction an important operations objective to improve efficiency and extend mission lifetime. JWST uses a two-phase planning and scheduling system. First, observations are assigned to limited "plan windows" (typically 10-60 days) based on a variety of constraints and criteria. Next, short-term scheduling proceeds using the subset of candidates whose plan windows overlap a ~1-week scheduling interval. Several strategies are available to limit momentum buildup. These include momentum balancing during long-range planning, momentum balancing during short-term scheduling, and (to the extent that science constraints permit) adjustments to Observatory orientation. With development of the operational JWST planning and scheduling system, empirical investigation has become possible using realistic mission simulations that vary these strategies. This paper presents results of mission simulations using the Science Operations Design Reference Mission (SO-DRM), a scientifically diverse suite of programs resulting in over 10,000 schedulable units (visits), which have been performed to compare the effectiveness of the above momentum reduction strategies over ~1-year intervals. Detailed investigation is continuing, but scheduling experiments have already demonstrated significant reductions in momentum buildup. Balancing observations during long-range planning appears the most powerful approach because this is the phase with the most global view of the pool of schedulable visits and can generate well-balanced sets of plan windows that facilitate short-term optimization. However, effective short-term scheduling strategies are also essential. For optimal results, all three of the above approaches should be pursued in combination.

9911-10, Session 2

Earthquake survivability tests and analysis for a Thirty Meter Telescope primary segment assembly

Peter M. Thompson, Systems Technology, Inc. (United States); M. Mark Colavita, Jet Propulsion Lab. (United States); Douglas G. MacMartin, California Institute of Technology (United States); Mark J. Sirota, Thirty Meter Telescope (United States)

Shake tests were conducted January 2015 in El Segundo, California of a single Primary Segment Assembly to verify compliance with earthquake

survivability requirements for a 200 Average Return Period earthquake. The test results were also used to validate a dynamic model of combined response of the segment and soft actuators. Both the model and extrapolation of the data were used to predict compliance of earthquake survivability requirements for 1000 Average Return Period earthquake. Requirements for acceleration at the mirror surface in both the vertical and horizontal directions are based on buckling limits and safety factors. The soft actuators that control piston and tip-tilt motion of the mirror surface amplify earthquake vertical acceleration at the mirror cell resulting in larger acceleration at the mirror surface. A snubber limits the travel of the soft actuator, which thereby limits the acceleration at the mirror surface, but the dynamic interaction is complicated, and testing was considered to be necessary. The test results and analysis verified compliance with earthquake survivability requirements. The test results, dynamic model, and model-based predictions will be presented. Diagrams of the vertical and horizontal test setup are shown in Figure 1. A short movie of the shake test will be presented.

9911-11, Session 3

Creating system engineering products with executable models in a model-based engineering environment *(Invited Paper)*

Robert Karban, Frank G. Dekens, Jet Propulsion Lab. (United States); Nerijus Jankevicius, No Magic, Inc. (Lithuania); Maged E. Elaasar, Jet Propulsion Lab. (United States)

The system engineering life-cycle creates a number of products built from interdependent sources of information using different kinds of system level analysis. This paper focuses on leveraging the Executable System Engineering Method (ESEM) that automates some system level analysis (e.g. requirements verification, power and mass budget margins, duration analysis of operational modes) using executable SysML modeling patterns that involve structural, behavioral and parametric diagrams, and the open source Model Based Engineering Environment (openMBEE).

Executable system models provide the data to create required products (e.g. operational concept document) for the Alignment and Phasing System (APS) within the Thirty Meter Telescope (TMT), under development by the TMT International Observatory (TIO).

9911-12, Session 3

Model-based system engineering approach for the Euclid mission to manage scientific and technical complexity

Jose Lorenzo Alvarez, European Space Agency (Netherlands); Jérôme Amiaux, Commissariat à l'Énergie Atomique (France); Gonzalo Saavedra Criado, Luis Miguel Gaspar Venancio, Jean-Christophe Salvignol, René J. Laureijs, Roland Vavrek, European Space Agency (Netherlands); Harold Metselaar, European Space Research and Technology Ctr. (Netherlands)

In the last years, the system engineering field is coming to terms with a paradigm change in the approach for complexity management. Different strategies to cope with highly interrelated systems, system of systems and collaborative system engineering have been proposed and a significant effort is in place into standardization and ontology definition. In particular, Model Based System Engineering (MBSE) intends to introduce methodologies for a systematic system definition, development, validation, deployment, operation and decommission based on logical and visual relationship mapping, rather than traditional 'document based' information management.

The practical implementation in real large-scale projects is not uniform across fields. In space science missions the usage has been limited to subsystems or sample projects with modelling performed 'a-posteriori' in many cases. The main hurdle for the introduction of MBSE practices in new projects is still the difficulty to demonstrate the value added to a project and whether the benefit is commensurate with the level of effort required.

In this paper we present the implemented Euclid modelling activities, and the benefits identified to support in particular requirement break-down and allocation and verification planning at mission level.

Euclid is the second medium class mission (M2) of the ESA Cosmic Vision program. Its primary goals are to determine the nature and distribution of dark matter and dark energy using two main cosmological probes: Weak Lensing (WL) and Galaxy Clustering (GC). These objectives plan to be achieved with a survey of more than 15,000 deg2 of the extragalactic sky performed by a single spacecraft with a 1.2 m entrance pupil telescope equipped with a visible imager (VIS) and a near infrared spectrophotometer (NISP). The WL probe involves the measurement of galaxy shear of a large number of sources, driving performance requirements beyond traditional image quality and sensitivity to include also ellipticity, PSF stability and control of any systematic bias that could introduce errors in the cosmological signal of interest. The required level of residual errors depends not only on the performance of the telescope, instruments, spacecraft pointing, etc, but also to a significant extent on calibration data, external data (from other space and/or ground missions) and the science data processing algorithms performance. These different contributors are developed and under responsibility of different entities both within ESA project and its direct contractors and as part of a Euclid Consortium composed of institutions across different nations.

The complex interrelationship between the different contributors to the system performance and the number of involved stakeholders led early to the decision to adopt a MBSE approach in Euclid to control requirement flow-down, architecture selection, verification and operations definition. Specifically System Modelling Language (SysML) was selected to build a representation of the system and capture the complete traceability of the mission break-down from science objectives to verification and full life-cycle planning.

This is, to our knowledge, the first full application of MBSE in an ESA science project in development and it has generated an important number of lessons learned and recommendations for modelling in future missions that will be presented.

9911-13, Session 3

Using model based systems engineering for the development of the Large Synoptic Survey Telescope's (LSST) concept of operations

Brian M. Selvy, Charles Claver, LSST (United States)

In this paper we provide an overview of the methodology and tools we are using to develop the concept of operations (ConOps) for operational phase of the Large Synoptic Survey Telescope (LSST). LSST's Project Systems Engineering (PSE) team's is using a model-based approach ConOps development to: 1) capture the top-down stakeholders' needs and functional allocations defining the scope, required tasks, and personnel needed to for operations, and 2) model a bottom-up, Use Case-driven approach capturing known operations and maintenance activities required to conduct the LSST survey across its distributed operations sites for the full ten year survey duration. The top-down view is being used to support a team writing the operations proposal, where the bottom-up view will be used in the future as the basis for developing the detailed work procedures required to by each activity. To accomplish these complimentary goals

and ensure that they result in self-consistent results, we have developed a holistic approach using the Sparx Enterprise Architect modeling tool and Systems Modeling Language. This approach utilizes SysML Use Cases, Actors, associated relationships, and Activity Diagrams to document and refine all of the major operations and maintenance activities that will be required to successfully operate the observatory and meet stakeholder expectations. Additionally, we have customized the tool and extended the SysML language to meet the our unique needs; customizations that have resulted in the creation of a custom stereotyped Use Case element with unique tagged values, as well as unique association connectors and actor stereotypes. Our approach allows for continual refinement utilizing the systems engineering spiral method to expose higher levels of detail as necessary. We demonstrate the methodology described here, has the ability to define: 1) the rolls each human actor must take on to successfully carry out the activities associated with the Use Cases; 2) the skills each actor must possess; 3) the functional allocation of all required stakeholder activities and use cases to organizational entities tasked with carrying them out; and 4) the organization structure required to successfully execute the operational survey.

9911-14, Session 3

Operational modes, health, and status monitoring

Cornelius Taljaard, SKA Organisation (United Kingdom)

System Engineers must fully understand the system, its support system and operational environment to design & develop a system. Support & Maintenance Managers must also identify the correct metrics to measure the performance and manage the support organisation.

Model-based Systems Engineering (MBSE) is a systems engineering methodology which focuses on creating models as the means of information exchange. Logistic Engineering and Support Analysis provides methods to design a Support & Maintenance System and to optimize the Operational Availability of a complex system. Availability modeling and Failure Analysis during the design is intended to influence the design and to develop an optimum maintenance strategy for a system.

The remote site locations of the SKA Telescopes place emphasis on availability and Failure identification information is critical to the success of the project.

This paper describes the used of MBSE on the SKA project to model the Telescope's operational modes and health monitoring information. It describes the use of Failure Analysis and a Support Database to design a Support & Maintenance strategy. It also describes the used of modeling to develop an availability dashboard and performance metrics.

9911-15, Session 4

Optical error budgeting using linearized ray-trace models

David C. Redding, John Z. Lou, Jet Propulsion Lab. (United States)

Design of optical telescopes and instruments increasingly relies on "STOP" modeling methods, which combine detailed structural, thermal, and optical models to generate realistic simulated data and make accurate system performance predictions. By also incorporating models of key mechanisms, actuators, alignments, and closed-loop controls, such models can accurately predict the impact of component and subsystem errors on total system performance. STOP models can be very time consuming to create and exercise, however, making them inefficient for common system design and engineering tasks such as error budgeting.

We present the mathematical framework for an alternative approach that preserves the accuracy of the full-up STOP model, but in a computationally efficient spreadsheet form. The method builds on earlier work in linearized ray-trace methods [1]. It directly incorporates system kinematics, alignments, sensors and controls, and other key elements. It propagates statistical representations of component and subsystem errors, misalignments and aberrations, to compute metrics such as wavefront error, Strehl ratio, encircled energy, and line-of-sight error, as a function of design and error specifications.

Examples from space and ground-based active telescopes illustrate the approach.

9911-16, Session 4

Systems budgets architecture and development for the Maunakea Spectroscopic Explorer

Shan B. Mignot, Observatoire de Paris à Meudon (France); Nicolas Flagey, Kei Szeto, Rick Murowinski, Alan W. McConnachie, Canada-France-Hawaii Corp. (United States)

The Maunakea Spectroscopic Explorer (MSE) project is an enterprise to upgrade the existing Canada-France-Hawaii observatory into a spectroscopic facility based on a 10 meter-class telescope. As such, the project relies on engineering requirements not limited only to its instruments (the low, medium and high resolution spectrographs) but for the whole observatory. The science requirements, the operations concept, the project management and the applicable regulation are the basis from which these requirements are initially derived, yet they do not form hierarchies as each may serve several purposes, that is, pertain to several budgets. Completeness and consistency are hence the main systems engineering challenges for such a large project as MSE. Special attention is devoted to ensuring the traceability of requirements via parametric models, derivation documents, simulations, and finally maintaining KAOS diagrams and a relational database under IBM Rational DOORS® linking them together. This paper will present the architecture of the main budgets under development and the associated processes, expand to highlight those that are interrelated and how the system, as a whole, is then optimized by modelling and analysis of the pertinent system parameters.

9911-17, Session 4

Automatic performance budget: a global process for instrumentation

Philippe Laporte, Observatoire de Paris à Meudon (France); Hermine Schnetler, Philip Rees II, UK Astronomy Technology Ctr. (United Kingdom)

Whatever the wavelength domain, projects in astronomy evolve towards larger dimensions and higher complexity. In the meantime, risks in terms of safety, cost and operability have to be reduced to the minimum, to maintain a reasonable maintenance cost, while the time to perform the different phases shortens. From the system engineer point of point, this evolution is an important challenge. Big instruments imply to manage interfaces within large consortia and to deal with the time dedicated for the design phases which necessitates having an efficient and rapid interaction between all the stakeholders to ensure that the design fits all the requirements. Such an interaction is mandatory to rapidly answer any question of the engineer and maximising the time devoted to the design.

In this context, tools can participate to provide solutions. We present in the

first section the development of an automatic performance budget that helps the system engineer to estimate in a few minutes how a change in the design may impact the scientific performance. This capability without the help of simulations during the phase A allows a faster interaction between, first, the engineers and the system engineer and, secondly, between the latter and the instrument scientist on the other hand. We summarise in a second section how tobuild an automatic performance budget while in the three following sections the examples of EAGLE, MOONS and SST-GATE are described in order to illustrate how this mechanism has been used in projects in astronomy.

9911-18, Session 4

E-ELT requirements flow from top-level requirements through level 1 requirements down to procurement specifications

Juan C. Gonzalez, Herve Kurlandczyk, Christian Schmid, Dominik Schneller, European Southern Observatory (Germany)

One of the critical activities in the systems engineering scope of work is managing requirements. In order to be able to implement the system and attending not only to technical but also to programmatic aspects, systems engineering has to split the whole thing in several parts that have to match each other to fulfil the user needs. Properly specifying these parts (that are procured separately) to make sure that they will run as a whole when integrated together is not an easy task, in particular when dealing with complex systems.

In line with this, E-ELT systems engineering devotes a significant effort to this activity, which follows a well-established process. The goal is to optimally derive requirements from the user (Top-Level Requirements) through the system Level 1 Requirements and from here down to subsystems procurement specifications.

This papers describes the process, which is illustrated with some practical examples. To help in understanding this process, the E-ELT documentation tree, showing the relationship between the several requirements specifications at different levels, is presented. Particular attention is given to the Level 1 Requirements specification, which is the highest level engineering document describing the actual baseline of the E-ELT. To provide the complete picture a short overview of its parent document (Top-Level Requirements) and of a typical (children) subsystem specification is given.

The special role of the technical budgets as tools to manage the critical Top-Level Requirements and to derive requirements on subsystems is also addressed. To better understand this role a summary of the technical budgets that are maintained at system level is given.

In addition, the way that requirements specifications are reviewed as the final step before releasing for procurement is explained. To close the process, the provisions taken at system and subsystem level for the verification of requirements along the several milestones of the procurement contracts are discussed.

Apart from the already mentioned technical budgets, other tools helping in the requirements management process (e.g., database, review files, compliance matrix) and the way they are used is described.

9911-19, Session 4

DESI systems engineering: throughput and signal-to-noise

Robert W. Besuner, Univ. of California, Berkeley (United States)

The Dark Energy Spectroscopic Instrument (DESI) is under construction to measure the expansion history of the Universe using the Baryon Acoustic Oscillation technique. The spectra of tens of millions of galaxies over 14,000 square degrees will be measured over the planned five-year survey. A new prime focus corrector for the KPNO Mayall telescope will deliver light to 5000 fiber optic positioners. The fibers in turn feed ten broad-band spectrographs.

Managing light throughput and noise in all elements of the instrument is key to achieving the high-level DESI science requirements over the planned survey area and depth within the planned survey duration. The DESI high-level science requirements flow down to instrument performance requirements on system throughput and operational efficiency. Signal-to-noise requirements directly affect minimum required exposure time per field, which dictates the pace and duration of the entire survey. The need to maximize signal (light throughput) and to minimize noise contributions and time overhead due to reconfigurations between exposures drives the instrument subsystem requirements and technical implementation.

Throughput losses arise from several effects, including blurred galaxy images, lateral misplacement of galaxy images relative to fiber tips, losses at air/glass interfaces, reflection and transmission losses in optics and fibers, fiber focal ration degradation (FRD), diffraction grating inefficiency, and CCD quantum efficiency. Throughput losses are managed with subsystem requirements on: optics manufacturing and alignment tolerances; fiber positioner accuracy; system structural stability; guiding accuracy; transmission and reflectivity of optics; fiber system FRD; and spectrograph and CCD performance.

Noise contributors include stray light and ghosts, night sky background light, and CCD read noise. Mitigation of noise is achieved by requirements on: design of optics and baffling based on ghosting and stray light analysis; corrector f-ratio and fiber diameter optimized to balance maximizing galaxy light while minimizing sky background; and CCD and readout electronics noise.

The interexposure time is minimized by choreography of the entire reconfiguration sequence and with specific time requirements on: CCD readout; telescope slewing and settling; fiber positioner reconfiguration; corrector hexapod motion; and atmospheric dispersion compensator re-alignment.

Throughput, noise, and interexposure reconfiguration time are budgeted, tracked, and managed as a DESI Systems Engineering responsibility. Current best estimates of throughput losses and noise contributions from each individual element of the instrument are tracked together in a master budget to calculate overall margin on completing the survey within the allotted time.

9911-21, Session 5

Project management and control of the Daniel K. Inouye Solar Telescope (DKIST) *(Invited Paper)*

Joseph P. McMullin, Mark Warner, Thomas R. Rimmele, Simon C. Craig, Andrew Ferayorni, Bret D. Goodrich, Robert P. Hubbard, Rex Hunter, Paul Jeffers, Erik M. Johansson, Heather Marshall, William R. McBride II, William McVeigh, LeEllen Phelps, Steve Shimko, Alexandra Tritschler, Timothy R. Williams, Friedrich Wöger, National Solar Observatory (United States)

We provide a brief update on the construction status of the Daniel K. Inouye Solar Telescope, a $344M, 10-year construction project to design and build the world's largest solar physics observatory. We review the science drivers along with the challenges in meeting the evolving scientific needs over the course of the construction period without jeopardizing the systems engineering and management realization. We review the tools, processes and performance measures in use in guiding the development as well as the risks and challenges as the project transitions through various developmental phases. We elaborate on environmental and

cultural compliance obligations in building in Hawai'i. We discuss the broad "lessons learned" along with the "lessons that were known but not fully learned/implemented". Finally, we discuss the project in the context of the evolving management oversight within the US (in particular under the NSF).

9911-22, Session 5

Multivariable parametric cost model for space and ground telescopes

H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States); Todd M. Henrichs, Missile Defense Agency (United States)

Parametric cost models can be used by designers and project managers to perform relative cost comparisons between major architectural cost drivers and allow high-level design trades; enable cost-benefit analysis for technology development investment; and, provide a basis for estimating total project cost between related concepts. This paper summarizes our ground and space telescope cost models. While space telescopes are 50X to 100X more expensive than ground telescopes, their respective scaling relationships are similar. An interesting speculation is that the role of technology development may be different between ground and space telescopes. For ground telescopes, the data indicates that technology development tends to reduce cost by approximately 50% every 20 years. But for space telescopes, there appears to be no such reduction because we do not re-fly similar systems. Thus, instead of reducing cost, 20 years of technology development may be required to enable a doubling of capability. Other findings include: mass should not be used to estimate cost; spacecraft and science instrument costs account for approximately 50% of total mission cost; and, integration and testing accounts for only about 10% of total mission cost.

9911-23, Session 5

The seven habits of highly effective project managers

Mark Warner, Richard T. Summers, National Solar Observatory (United States)

Why do some astronomy projects succeed, while others fail? There are obviously many different factors that can and do influence the outcome of any given project, but one of the most prevalent among successful projects is the combined skills and qualifications of the project manager (PM) at their helms. But this begs an obvious question: what exactly makes a project manager "skilled and qualified?" Asked another way, are there common traits, philosophies, and techniques that successful PMs share, and if so, what are they? The short answer is yes, the majority successful engineering project managers have significant things in common. The longer answer is there are at least seven of these key traits, or "habits" that many successful PM share and, more importantly, implement within their respective projects. This paper will present these seven key factors, including thoughts on scope and quality management, cost and schedule control, project team structures, risk management strategies, stakeholder management, and general project execution.

9911-27, Session 5

Agile software development in an earned value world: a survival guide

Jeffrey Kantor, LSST (United States); Mario Juric, Univ. of Washington (United States); Kevin Long, BCF Solutions (United States); Jacek Becla, SLAC National Accelerator Lab. (United States); Frossie Economou, LSST (United States); Margaret Gelman, Univ. of Illinois at Urbana-Champaign (United States); Ron Lambert, LSST (Chile); K. Simon Krughoff, Univ. of Washington (United States); John D. Swinbank, Princeton Univ. (United States); Xiuqin Wu, California Institute of Technology (United States)

Agile methodologies are current best practice in software development. They are favored for, among other reasons, preventing premature optimization by taking a somewhat short-term focus, and allowing frequent replans/reprioritizations of upcoming development work based on recent results and current backlog. At the same time, funding agencies prescribe earned value management accounting for large projects which, these days, inevitably include substantial software components. Earned Value approaches emphasize a more comprehensive and typically longer-range plan, and tend to characterize frequent replans and reprioritizations as indicative of problems. Here we describe the planning, execution and reporting framework used by the LSST Data Management team, that navigates these opposite tensions.

9911-20, Session 6

The LSST project execution plan for construction *(Invited Paper)*

Victor L. Krabbendam, LSST (United States)

The Large Synoptic Survey Telescope (LSST) Project is a public-private partnership that has entered full construction as a United States National Science Foundation (NSF) and Department of Energy (DOE) multi-agency project. The lead Federal Agency is the NSF which has approved construction under it Major Research Equipment for Federal Construction (MREFC) budget. The DOE Office of Science has taken the responsibility to build the LSST camera and has approved their element of the project as a Major Item of Equipment (MIE). The two federal agencies recognize the early investment of the LSST Corporation that provided significant initial funding from non-federal sources that directly supported design, fabrication of mirrors, and early site work. LSST has developed a unique Project Execution Plan to conduct the complex construction effort as a single project with a unique set of tools and processes to manage the effort, to support the necessary oversight, and to satisfy the reporting requirements for the multiple stakeholders. The plan includes earned value management for assessing progress against the plan, risk evaluation tools to guide the use of contingency resources for technical mitigations and opportunities, and extensive systems engineering tools to manage the technical configuration. The LSST management structure has been developed to addressed the scientific, engineering, and project challenges as well as the details of communication across a significantly distributed team. LSST is in full construction and scheduled for full science operation in 2022.

9911-24, Session 6

CARMENES: management of a schedule-driven project

María Luisa García-Vargas, FRACTAL S.L.N.E (Spain); Jose A. Caballero, Ctr. de Astrobiología (Spain); Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain); Pedro J. Amado González, Instituto de Astrofísica de Andalucía (Spain); Walter Seifert, Landessternwarte Heidelberg (Germany); Marco Azzaro, Ctr. Astronómico Hispano-Alemán (Spain); Holger G. Mandel, Andreas Quirrenbach, Landessternwarte Heidelberg (Germany); Ignasi Ribas, Institut de Ciències de l'Espai (Spain); Ansgar Reiners, Georg-August-Univ. Göttingen (Germany); Eike Guenther, Thüringer Landessternwarte Tautenburg (Germany); Lluis Gesa, Institut d'Estudis Espacials de Catalunya (Spain); David Galadi-Enriquez, Jesus Aceituno, Ctr. Astronómico Hispano-Alemán (Spain)

CARMENES (Calar Alto high-Resolution search for M dwarfs with Exoearths with Near-infrared and optical Échelle Spectrographs) is a two high resolution (R~82,000) spectrographs covering simultaneously the visible (0.5 – 1.0μm) and near-IR (1.0 - 1.7μm) ranges and long-term stability to provide high-accuracy radial-velocity measurements (?1 m/s). CARMENES has been built for the 3.5m telescope at the Centro Astronómico Hipano-Alemán (CAHA), Calar Alto Observatory (Almería, Spain). CAHA is jointly operated by the Max-Planck-Society (MPG) and the Spanish National Research Council (CSIC). CARMENES was the initiative of a consortium of eleven German and Spanish institutions.

In February 2013, the project passed a Final Design Review. Six months later, the MPG and CSIC, the observatory's owners, made an independent evaluation concluding that CARMENES had to be ready for operations at the end of 2015. Since then, fulfilling the calendar was the driver of all project decisions. Moreover, the observatory's survival was linked to the instrument's success: should the instrument fail, the observatory would be closed. On the contrary, the instrument's success would give unique capabilities to the Observatory for Big Science. Such a challenge became to be our private Olympic Games: we had to be on time. This decision definitively impacted on the project dynamics, there was no room for a delay. The deadline, December 31st, 2015, was controlled by a strict tracking of the critical path; calendar deviations were corrected with risky decisions and fast tracking or even crashing methods were applied.

The management scenario was far from optimum. Most key people in the project shared their time with other duties; the observatory funding cuts; the tight budget, globally controlled by the project manager but distributed among the 11 partner centers with their own different rules, etc. Despite these difficulties, the close coordination among the project manager, the system engineer and the work package managers, the hard work of the whole team, and the support from the observatory were our best bets.

Two frenetic years after the calendar decision, we had manufactured, integrated and tested the two spectrographs and we were commissioning the instrument. The instrument first light took place on November, 9th, 2015. This paper describes the keys to success.

9911-25, Session 6

Management of the camera electronics programme for the World Space Observatory ultraviolet WUVS instrument

Gayatri S. Patel, Nick R. Waltham, Matthew J. Clapp, Mike A. Salter, Sarah K. Beardsley, STFC Rutherford Appleton Lab. (United Kingdom)

World Space Observatory Ultra-Violet (WSO-UV) is a major international collaboration led by Russia, scheduled for launch in 2020. It will study the universe at ultra-violet wavelengths between 115 nm and 310 nm, exceeding the current capabilities of ground-based instruments. The WSO Ultra-Violet Spectrograph (WUVS) subsystem is led by a consortium of Russian institutes and consists of three spectrographs capable of high resolution spectroscopy (R>50,000) and long-slit low-level spectroscopy (R≈ 1,000).

RAL Space is contracted by e2v technologies Ltd to provide the CCD readout electronics for each of the three WUVS channels. The programme involves the design, manufacturing, assembly and testing of each Camera Electronics Box (CEB), it's associated Interconnection Module (ICM), Electrical Ground Support Equipment (EGSE) and harness.

An overview of the programme will be presented, from the initial design phase culminating in the development of an Engineering Model (EM) through qualification whereby an Engineering Qualification Model (EQM) will undergo environmental testing to characterize the performance of the CEB against the space environment, to the delivery of the Flight Models (FMs). The paper will discuss the challenges faced managing a large, dynamic project. This includes managing significant changes in fundamental requirements mid-programme as a result of external political issues which forced a complete re-design of an existing CEB with extensive space heritage but containing many ITAR controlled electronic components to a new, more efficient solution, free of ITAR controlled parts. The methodology and processes used to ensure the demanding schedule is maintained through each stage of the project will be presented including an insight into planning, decision-making, communication, risk management, and resource management; all essential to the continued success of the programme.

9911-26, Session 6

ALMA software releases versus quality management: and the winner is...

Erik Allaert, Moreno Pasquato, European Southern Observatory (Germany); Rubén Soto, ALMA (Chile)

The Atacama Large Millimetre /submillimetre Array (ALMA) consists of 66 high-precision radio-antennas, located on the Chajnantor plateau in the Chilean Andes, at an elevation of 5000 metres. Its construction and operation is a joint effort from partners on 3 different continents: the European Southern Observatory (ESO), the U.S. National Science Foundation (NSF) and the National Institutes of Natural Sciences (NINS) of Japan. The development of the software to operate this sophisticated array, acquire, monitor and evaluate scientific data is equally distributed over these 3 continents, involving many institutes and software engineers.

The ALMA Observatory was inaugurated in March 2013, and the construction phase has formally been completed, but the software development effort continues at roughly the same level as during construction, to cope with the capabilities offered to the scientific community in the context of ALMA's yearly Observing Cycles. This implies that in the course of a year several software releases have to be prepared, dealing with everything from proposal preparation and submission software up to the deployment of the online software commanding the array at the official start of a new cycle at the observatory. These software releases follow a pre-defined process; there are several quality aspects followed up continuously as part of this process, providing a quality status overview to the developers, end-users (scientists and engineers), plus the Release and Acceptance Managers. The corresponding report assessing the software quality of a new release is submitted to the Acceptance Review.

As the ALMA observatory is fully operational, it is used on a daily basis to produce scientific data for the approved projects, and also by engineering teams to extend existing capabilities or to diagnose and fix problems. Hence the preparation of new software releases up to their deployment is "just one more activity", competing for resources with all other activities. Testing a new release and ensuring its quality is acceptable to the observatory is of course fundamental, but can on the other hand not monopolize the observatory's resources or jeopardize its commitments to the scientific community, such as publicly announced milestones for the start of new observation cycles.

In this paper we describe the tools and metrics used so far to monitor the quality of ALMA software releases, and the results this has produced. After having applied this for a number of releases, we have also identified several areas within the release or acceptance process where improvement is desired or needed, and where the stumbling blocks are.

9911-28, Session 6

Project management of DAG: Eastern Anatolia Observatory

Onur Keskin, Isik Üniv. (Turkey); Lorenzo Zago, HEIG-VD (Switzerland); Cahity Yesilyaprak, Atatürk Üniv. (Turkey); Sinan K. Yerli, Middle East Technical Univ. (Turkey)

The four meter DAG (Eastern Anatolia Observatory in Turkish) telescope is not only the largest telescope in Turkey but also the most promising telescope in the northern hemisphere with a potential to offer scientific observations with its cutting edge technology. DAG is designed to be an AO telescope which will allow both infrared and visible observations with its two Nasmyth platforms dedicated to next generation focal plane instruments. In his paper, status updates from DAG telescope will be presented in terms of; (i) in house optical design of DAG, (ii) tender process of telescope, (iii) tender process of enclosure, and (iv) tender process of the observatory building. Also status updates from the focal plane instruments project and possible collaboration activities will be presented.

9911-29, Session 7

Managing engineering in a science project: lessons for SKA from MeerKAT *(Invited Paper)*

François Kapp, SKA South Africa (South Africa)

The SKA is a large science project - planning to commence construction after 2018 - to construct the world's largest Radio Telescope. MeerKAT is one of the precursor projects to the SKA, based on the same site that will house the SKA Mid array in the arid central Karoo area of South Africa. Taking the perspective of signal processing hardware development, we analyse the challenges that MeerKAT encountered and extrapolate them to SKA in order to prepare the System Engineering and Project Management methods that could contribute to a successful completion of SKA.

Using the MeerKAT Digitiser, Correlator/Beamformer and Time and Frequency Reference Systems as an example, we will trace the risk profile and engineering approaches of these systems over time and show the effects of varying levels of System Engineering rigour on the evolution of their risk profiles. It will be shown that the most rigorous application of System Engineering discipline resulted in the most substantial reduction in risk over time.

At the start of the MeerKAT project, the Digitiser was the only of the three systems under consideration was a first-of-kind development, and, as a result, it dominated the MeerKAT risk registers. It was also a driver of the project critical path. As an engineering response, the team used rigorous System Engineering processes and principles in order to manage the risks - both technical and schedule. These processes were implemented early in the project and in spite of the perceived impacts on schedule. Over time, the Digitiser has reduced in significance as a contributor to the technical risk profile of the MeerKAT telescope. It is in full production and not on the critical path of the higher level system.

Since the challenges faced by SKA are not limited to that of MeerKAT, we also look into how that translates to a system development where there is substantial complexity in both the created system as well as the creating system. Since the SKA will be designed and constructed by consortia made up from the ten member countries, there are many additional complexities to the organisation creating the system - a factor that MeerKAT did not face. Factors outside of engineering, for instance procurement models and political interests, also play a more significant role, and add to the project risks of SKA when compared to MeerKAT.

9911-30, Session 7

Gemini Observatory base facility operations: systems engineering process and lessons learned

Andrew W. Serio, Martin Cordova, Gemini Observatory (Chile); Gustavo Arriagada, Atsuko Nitta, Madeline Close, Andrew J. Adamson, Arturo J. Nunez, Gemini Observatory (United States)

The Gemini Observatory Base Facility Operations (BFO) project began in 2013, with the goal of having both telescopes operating from their respective sea level base facilities by the end of 2015. Due to resource constraints, it was decided that Gemini North BFO would be implemented first, as it would generate the most cost savings and user benefits due to the more harsh operating environment of Maunakea. Gemini South (Cerro Pachon, Chile) BFO implementation will follow in 2016.

Gemini North Observatory successfully began nighttime remote operations from the Hilo Base Facility control room in November 2015. As this project was a major observatory-wide undertaking, the implementation of GN BFO was a great learning experience for many of our employees, especially the author of this paper, the BFO Systems Engineer.

In this paper I discuss the key factors that led to the successful implementation of the GN BFO project, the tailored Systems Engineering processes used for the project, the various software tools used in both project management and systems engineering support, and finally discuss the lessons learned from the Project Management team.

The GN BFO project was challenging both in terms of technical and managerial complexity and also at the human level, as it represented a major change to the routine of the Gemini operations. The GN BFO project was separated into 17 individual Work Packages of varying degree of technical complexity. As there was only a single dedicated Systems Engineer to the project, this necessitated a tailored systems engineering approach at both the project top-level and on an individual Work Package level. The less complex work packages received little to no systems engineering involvement, while the more complex work packages (in terms of their technical complexity and level of interfacing with existing observatory systems) required a much more rigorous systems engineering approach.

The Project Management team identified early on that because this project covered many areas of the Observatory, it meant it involved people from many backgrounds and expertises. Therefore we made a decision early on that any software tools used during the project would be simple enough that everyone could use. As a result several software tools were used for requirements management, tracking Work Package progress, risk identification, tracking and mitigation, project level and Work Package issue tracking, and finally for change management. Some of these tools overlapped in their functionality and became too cumbersome to manage, while others were modified from their initial purpose and successfully met our needs.

Both the tailoring of the level of systems engineering involvement at the individual work package level and the tools used yielded many important lessons learned, that will no doubt aid us in our Gemini South BFO implementation in 2016, as well as in future technical projects at Gemini Observatory.

This paper will focus on the Systems Engineering practices and processes used during the lifecycle of the Gemini North BFO project, and how those practices and processes will be further tailored based on the experience and lessons learned, for the upcoming Gemini South BFO project.

9911-32, Session 7

European Extremely Large Telescope (E-ELT) availability stochastic model: integrating FMEA, influence diagram, and Bayesian network together

Gianluca Verzichelli, European Southern Observatory (Germany)

The paper presents the description and use of a Telescope Availability Stochastic Model developed in the GeNIE environment based on SMILE (Genie has been developed at the Decision Systems Laboratory, University of Pittsburgh).

The E-ELT will be the largest optical/near-infrared telescope in the world. Its design comprises an Alt-Azimuth mount reflecting telescope with a 39-metre-diameter segmented primary mirror, a 4-metre-diameter secondary mirror, a 3.75-metre-diameter tertiary mirror, adaptive optics and multiple instruments.

The model is used for several purposes depending on the development stages of the Programme. In the early phases of the development it is used to define quantitative achievable and cost effective availability, reliability and maintainability (RAM) requirements for the procurement of Sub-systems and for availability budget definition as well for evaluating "what-if" scenarios.

Later on it is adopted as a framework where - as soon as new information related to Contractor's detailed design solutions is provided - it is embedded and a refined assessment of the Telescope Availability can be made.

Furthermore, when first reliability and maintainability data become available, either from a Highly Accelerated Life Test (HALT) campaign or from field data, the adoption of Bayesian Network allows updating the prior distributions with posterior distributions and thus re-compute the overall Telescope Availability.

The major points to be covered in the paper include:

• Introduction of the European Extremely Large Telescope

- Key reliability, availability and maintainability (RAM) Observatory Top Level Requirements

- Overview of Telescope Procurement and Design & Development Business Models

- Definition and Verification of RAM Requirements in a Contractual Framework

- Highlights of Telescope Operations and Maintenance Activities

• Definition of Failures and Faults

• Overview of different types of Availability

- Inherent, Operational and Achieved Availability

- Availability is not Reliability...

- Implications on Telescope Acquisition vs Ownership Costs

• Introduction of Degradation-Based Reliability

• Model Description

- Telescope Product Breakdown Structure

- Overview of the RAM items considered in the Model: Operating Time, Standby Time, Administrative and Logistics Down Time (ALDT) and Mean Time Between Failures (MTBF), Mean Time to Repair (MTTR), etc.

- Modular Approach Development

- Introduction of FMEA elements and Degradation-Based Reliability

• Model Results

- E-ELT Availability Results

• Model Use

- Availability Apportionment Verification

- Prior and Posterior Distributions Updating

- Telescope Master Minimum Equipment List Definition (T-MMEL) Definition

- Telescope Failure, Detection, Isolation and Recovery (FDIR) Control Strategy Definition

• Possible Further Development

• Conclusions

The paper has highlighted the key features of the E-ELT Telescope Availability Stochastic Model. It has outlined the various steps and assumptions that have been used for developing the model. It has demonstrated how the use of such model may reduce the risk of introducing unrealistic or non-cost effective reliability, availability and maintainability requirements into specifications for the definition of the System and procurement of Sub-systems. Finally it has shown how the information and knowledge contained in the model may be seamlessly reused for the definition of the Telescope Master Minimum Equipment List (T-MMEL) and the Telescope Failure, Detection, Isolation and Recovery (FDIR) Control Strategy.

9911-33, Session 7

Considerations regarding system engineering in large scale projects with heterogeneous contexts

Andrea Cremonini, Maria Grazia Labate, Marco Caiazzo, Rodrigo A. Oulgin, Juande Santander-Vela, Tim Stevenson, SKA Organisation (United Kingdom)

With This paper I would like to share some considerations and lessons learned based on my direct experience as system engineer at the SKA project. This is a very wide and ambitious program, which involves several stakeholders, heterogeneous as cultural background, technological heritages, disciplines, motivations and competences as never before. My role is to amalgamate efforts in order to deliver the "MID telescope" and often I discovered that, "system engineering", assume a wider meaning than purely being a disciplined sets of processes

9911-34, Session 7

GESE mission concept optimization

Lloyd R. Purves, Sara R. Heap, NASA Goddard Space Flight Ctr. (United States)

Here we describe the work and results of a study that we have undertaken to optimize the mission concept for the Galaxy Evolution Spectroscopic Explorer (GESE) space telescope. We define mission concept optimization as the development of a combination of science return and overall mission cost that has the highest probability of successful implementation. We approach this optimization by inserting a specification for "quantitative measurement capabilities" between the two conventional mission definition phases of: 1) establishing science requirements; and 2) developing a mission concept to achieve that science. Examples of quantitative measurement capabilities include characterizations of measurement range and resolution in the spectral, temporal, intensity, and spatial/angular domains that are required to achieve science objectives but are independent of instrument and mission design. Separating the science and engineering phases in this manner facilitates the use of automated engineering tools to efficiently estimate the direct and indirect costs of design options such as instrument collecting area, mission orbit, and mission duration. This separation also simplifies the process of down- (or up-) scoping science and measurement requirements to obtain an implementable combination of science return and mission cost.

9911-51, Session PSMon

Dynamical compensation for the optical aberrations from a telescope with a large-single-piece primary mirror: modeling and control of the dynamical systems for its active optics, supporting and positioning

Eloy Edmundo Rodríguez Vázquez Jr., Jorge Luis Iglesias Medina Sr., Gengis Kangh Toledo Ramirez Sr., ctr. de Ingenieria y Desarrollo Industrial (Mexico); Israel Mejia Alonso, CIDESI (Mexico)

This paper describes a mathematical model for the optics and supporting systems which has been gotten from the basic design of the new San Pedro Mártir optical telescope which is going to be developed by UNAM, INAOE and CIDESI in collaboration with others international institutions.

These model considers both static and dynamic states of the entire opto-mechatronic system of the telescope, because its intention is to work as reference for the detailed design of the robotics for the supporting and positioning of the optical system.

The mathematical model output is the wavefront at the image plane, which is simulated to analyze aberrations and compensate them through the robotic support and the active optics of the primary mirror.

Simulations of the entire system have solved by commercial programs but the algorithm has been developed based into the spatial and dynamic response of the opto-mechatronics system, by considering the fundamental equations for optics, mechanical vibrations, kinematics and mechanisms dynamics.

The algorithm developed solves the mathematical equations of the physics involved, but it starts from a multi-variable linear model raised like a dynamic state space, then it is discretized and it is converted in a finite element model with dynamical border conditions.

All solver algorithm is described and some recommendations for the telescope design are done considering the simulations results.

9911-52, Session PSMon

Using integrated multi-body systems for dynamical-optical simulations

Johannes Störkle, Peter Eberhard, Univ. Stuttgart (Germany)

In order to investigate and analyse the dynamical-optical behavior of high precision optics, integrated modeling strategies and methods are proposed. For instance, this optical systems can be an astronomical telescope or a lithographic objective. In order to derive a simplified mechanical model for time simulations with low computational cost, the method of elastic multibody systems in combination with model order reduction methods is used. Mechanical and optical simulation models are derived and implemented. In order to clarify these methods, an academic mirror example is chosen.

Ground-based telescopes are highly resoluting optical systems consisting of precise mirrors. They are accurately mounted and they are very sensitive with respect to vibrations. During the observation time, small mechanical vibrations can be sufficient to produce inacceptably aberrated images. Even the adaptive optical unit or other motion systems can unintentionally excite the whole construction. The mechanical behavior of such optical systems can be described by a combination of rigid body motions and small deformations.

The mechanical model is based on elastic multibody systems with the floating frame of reference. In contrast to a detailed and large global model based on the finite element method, a reduced and modular elastic multibody system leads to low computational effort for simulations in the time domain. Furthermore, the system can be analysed and assembled step by step and it is able to include only the relevant dynamical behaviour due to appropriate model order reduction methods. For sequential ray tracing through several lenses and mirrors during the optical simulation, a continuous description of the mechanically deformed surfaces is required. Thereby, the line of sight describes the displacement of the center of intensity and the wavefront aberrations characterise the blurring and image quality. In order to take also wave optical effects during an image simulation into account, Fourier optical methods are utilized.

The influence of different model order reduction methods will be presented and analysed for an exemplary integrated model. It is based on an annular lightweight mirror with a parabolic shape made of aluminum. Here, the influence of the model order reduction methods is analysed and the mechanical-optical transfer behaviors of different wavefront aberrations are investigated. It is shown, that the mechanical-optical sensitivities depend on the frequency of excitation. Moreover it is investigated, whether the sensitivities can be used during the model order reduction in order to describe the overall behavior with an optimized model. Finally, the performance of different simulation strategies is assessed and the application limits are identified.

9911-53, Session PSMon

A feasibility study for conducting unattended nighttime operations at Keck Observatory

Paul J. Stomski Jr., W. M. Keck Observatory (United States); Sarah Gajadhar, Consultant (Canada); Carolyn Jordan, Thomas Nordin, W. M. Keck Observatory (United States)

In 2015, W. M. Keck Observatory conducted a feasibility study for conducting nighttime operations on Maunakea without any staff on the mountain. The study was motivated by the possibility of long term operational costs savings as well as other expected benefits. The goals of the study were to understand the technical feasibility and risk as well as to provide labor and cost estimates for implementation. The results of the study would be used to inform a decision about whether or not to initiate a project aimed at the development of this new unattended nighttime operating mode. In this paper we will describe the study process as well as a brief summary of the results including the identified viable design alternatives, the risk analysis, and expected scope of work. We will also share the decisions made as a result of the study and the current status of related follow-on activity.

9911-54, Session PSMon

STABLE: fine pointing control approach for image stabilization of balloon-borne telescopes

Carl R. Seubert, Milan Mandic, Herrick Chang, Jet Propulsion Lab. (United States)

The Astro2010 decadal survey places the study of dark matter and the accelerating expansion of the Universe at the top of its priorities for the next decade. At the same time, NASA strategic goals also focus on studies of the chemical composition of galaxies as well as the race to find Earths exoplanet counterpart. For these scientific objectives, a common requirement is an ultra-stable pointing system (sub-arcsecond) for long exposure imaging supported by space and ground based telescopes. A promising alternative is to use high altitude balloons as a telescope observation platform.

High altitude balloons enable two key advantages over conventional observatories: 1) they raise the telescope above more than 99% of the Earth's atmosphere which significantly reduces atmospheric seeing and 2) they avoid the high cost of space observatories by avoiding the expensive spacecraft development and launch services. However, one of the major technical challenges to perform scientific observations is precision pointing.

This paper describes the design of fine pointing control system as a balloon-borne payload for precision pointing observations. This fine pointing architecture used in combination with a balloon-borne coarse pointing gimbal stage can provide sub-arcsecond focal-plane image precision. This is achieved over a 60 second exposure time, while targeting relatively dim stars of magnitudes 10-12.

The foundation of the fine pointing architecture is based on two sensors; a focal plane image camera sampled at 50 Hz, and a Dynapak 14 triaxial attitude rate sensor (ARS). The high-rate ARS measures ultra-low level angular jitter in the sub-microradian regime, with low noise equivalent angles and large integration bandwidth. The actuation is done by a PI S-330 fast steering mirror (FSM), sampled at 1000 Hz, and featuring custom, low-noise strain gauge sensing electronics. The fine pointing control architecture blends these pieces together with image-based measurements in feedback and ARS measurements in feedforward to expand the measurement bandwidth from 0-200 Hz. This sensing bandwidth allows control bandwidth beyond 35 Hz with significant disturbance attenuation in lower frequencies, to capture typical balloon platform disturbances, such as azimuth reaction wheels.

The control design follows strict design principles, maintaining system stability with healthy gain and phase margins. In addition, this paper will cover the development of auxiliary algorithms, for processing ARS measurements, which is necessary when using ARS in feedforward, as well as for computing the centroid value of the target star on the camera focal plane array.

Extensive analysis and expected flight performance of the system is presented. While the fine pointing control architecture is decoupled from the balloon coarse pointing stage (making it a generic payload viable for balloon telescope systems), a representative coarse loop is simulated using previous balloon flight data. Results of high fidelity simulations show performance to better than 100 milliarcsecond RMS in 2 axes. This is achieved while using lab tested performance data of the sensors and actuators. In addition, preliminary results from limited closed loop tests performed within the lab environment are also presented.

9911-55, Session PSMon

Requirements management at Gemini Observatory: a small organization with big development projects

Madeline Close, Gemini Observatory (United States)

Gemini Observatory is continuously engaged in development projects to enhance scientific capabilities and improve operational efficiency. Historically, these development projects have been supported by a very limited systems engineering infrastructure. In seeking to mature this infrastructure, the Gemini Systems Engineering Group started studying requirements management. The team identified several steps necessary to implement requirements management: role definition, process definition, requirement data definition, change control definition, and finally tool selection. In this paper, these five steps will be presented and expanded upon, with reference to the team's personal experience in selecting and configuring a dedicated requirements management tool. Key activities are described for each step, and guidance on tailoring each step to the particular project characteristics (size, internal or external, etc.) is provided. The paper will also address requirements reuse across multiple projects and the implications for requirements management.

9911-56, Session PSMon

AST3-3 IR camera for the Kunlun infrared sky survey (KISS): thermal optimization and system performance

Jessica R. Zheng, Jonathan S. Lawrence, Robert Content, Vladimir Churilov, Australian Astronomical Observatory (Australia); KaiYuan Zhang, Xiangyan Yuan, Haiping Lu, Nanjing Institute of Astronomical Optics & Technology (China)

AST3-3 IR camera is designed for the Kunlun Infrared Sky Survey (KISS) with an infrared camera for the AST3-3 wide field telescope; it will provide the comprehensive exploration of the time varying Universe in the infrared and is going to be located at Kunlun Station (Dome A), Antarctic plateau, one of the most unique low sky background in K-dark band (2.4μm). KISS is the first deep and wide K dark survey, a path finder for future.

In this paper, we present that the thermal optimization design and system performance evaluation for the KISS infrared camera design. To take full advantage the unique low sky background at Dome A, the thermal emission from telescope and IR camera needs to be carefully investigated. We examined different IR camera design options by using different thermal control methods by either adding narcissus mirror or controlling pad behind telescope secondary mirror. It becomes clear that full cold-stop within the camera is a feasible, less risk and economical solution for this kind of survey telescope.

After the design of IR camera is decided, we setup the full thermal analysis model for the camera optimization with commercial software FRED. Since the sky emission becomes very low comparing to temperate site, it becomes necessary to examine thermal self-emission from telescope and its instrument carefully as they could emit prodigiously in the infrared. The major sources of the background radiation against the faint astronomical sources are black-body thermal emissions from the atmosphere and the telescope. They are mostly composed of atmospheric emissivity, emission of telescope mirrors and structure in beam, warm windows and surfaces within the cryostat and scattered light within instrument.

Using FRED, we are able to calculate the solid angle from all critical and illuminated objects; hence the thermal emission from all structures can be calculated at different ambient temperature. The size of the cold stop and temperature of the camera body are therefore optimized respectively. Different emissivity of black surfaces with different methods is compared and it is found that Acktar vacuum black can be used for all camera body internal mechanical surfaces which provide good thermal and low outgas performance. We also examine the PST (Point source transmission) of the system by using scattered light model and found that we can obtain the 10^3 suppression of scattering light within the telescope field of view.

To evaluate the system performance, a telescope exposure time calculator is setup in which the signal to noise ratio for an observed astronomical object is calculated based on sky transmission, spectral responses of different components and thermal emission from telescope and instrument at different ambient temperature. It is found that the IR camera can achieve 18.5 mag at K dark band at 235K with 25s exposure time for 1? operation, for 10 ? with exposure time of 1 hour, it can go up to 18.7mag which meets the system design requirements.

Using tailored methodical approaches to achieve optimal science outcomes

Lory Mitchell Wingate, National Radio Astronomy Observatory (United States)

Project management is an effective and widely adopted methodology used to control cost, schedule, and scope for a specific activity. The successful use of project management in manufacturing and production has been shown to provide such a competitive advantage that the discipline has spread to use in other parts of the lifecycle such as research and development, and more recently into operations management.

Systems engineering is a standardized, disciplined process with a mission to ensure that the outcomes of a project match the intent of the customer, or if they diverge in any way, that the changes are understood, captured, and controlled from both the component and the systems perspectives. The role of Systems Engineering is to provide a comprehensive view of how all the pieces fit together, to ensure that each piece actually works as specified as a unique component, and as an integral part of the system as a whole.

Systems engineering complements project management in that it assumes direct responsibility for the development and control of some activities for which the project manager is also responsible, but at a much deeper level. Systems engineering provides a management service to the project manager ensuring that the project comes together as a whole. And it provides a technical service to the project manager to ensure that the design, development, production, or other technical project activities meet specifications and ultimately worked as planned. The technical processes used by systems engineers include modeling and simulation, which help establish measureable parameters for the requirement(s) and often also provide performance specifications. This is imperative for science projects that may start out with vague high-level science requirements. In situations where choices among technology could be adopted, these activities also help clarify the costs, benefits and constraints of each proposed solution.

Within the scientific realm, these disciplines provide structure to help define and carefully control the evolution of requirements so that science outcomes can be optimized within the costs and schedule provided by the customer. An *appropriate application* of these disciplines can be the foundation upon which success in scientific endeavors can be achieved. Both project management and systems engineering disciplines require tailoring to fit the project and to ensure that the appropriate level or rigor is applied; that the right amount of each discipline is applied to the project so that it is not be burdened, yet helps optimize the project performance. For standard projects (which fit all the traditional project management criteria such as a defined schedule, budget, and scope), tailoring involves consideration of the entire framework, and then scaling the framework down to fit project needs. For scientific research and development projects, tailoring generally involve a progressively increasing application of these processes.

This presentation provides insights into the challenges, lessons learned, and potential applications associated with applying project management and systems engineering disciplines onto scientific research and development projects in order to increase the potential for achieving optimal science results.

SALT tracker upgrade utilizing aerospace processes and procedures

Raoul van den Berg, Southern African Large Telescope (South Africa); Chris Coetzee, South African Astronomical Observatory (South Africa); Ockert Strydom, Janus Brink, Keith R. J. Browne, Eben P. Wiid, Wouter Lochner, Grant Nelson, Paul Rabe, Martin Wilkinson, Vic Moore, Adelaide Malan, Southern African Large Telescope (South Africa); Jonathan Love, South African Astronomical Observatory (South Africa); Anthony R. Koeslag, Southern African Large Telescope (South Africa)

The SALT Tracker was originally designed to carry a payload of approximately 1000 kg. The current loading exceeds 1300 kg and more instrumentation, for example, the Near-Infrared (NIR) arm of the Robert Stobie Spectrograph (RSS), is being designed for the telescope. In general, provision also had to be made to expand the envelope of the tracker payload carrying capacity for future growth as some of the systems on SALT are currently running with small safety margins.

As part of the RSS-NIR development project it was decided to upgrade the SALT Tracker to be able to carry a payload of 1875 kg.

A pre-project study showed that in order for the SALT Tracker to carry this higher payload, a number of upgrades are required on the sub-systems of SALT. These were defined as three Project Stages called Y-Upgrade, Rho-Upgrade and Hexapod-Upgrade, respectively.

Before the project “Kick-Off” it became evident that neither SALT nor SAAO had the required standard of processes and procedures to execute a project of this nature. The Project Management, Mechanical Design and Review processes and procedures were adopted from the Aerospace Industry and tailored for our application. After training the project team in the application of these processes/procedures and gaining their commitment, the Tracker Upgrade Project was “Kicked-Off” in early May 2013.

It was clear during the first stage of the project that the learning curve for the project team to adapt to these new processes and procedures was steep, but they coped extremely well. By the second stage of the project the team started seeing the benefits of executing a design and development project in a more structured and organised manner. Today, even new projects on SALT bear testimony to the benefits of following these processes and procedures.

The application of these aerospace-derived processes and procedures, as used during the Tracker Upgrade Project, were very successful in that:

1. It ensured the generation and quality of complete/configured/traceable engineering and manufacturing data packs.

2. All designs of systems and sub-systems have been extensively tested and found to have met, or in some cases even exceed, the requirements and specifications.

3. The Y-Upgrade system has been installed on SALT and is operating successfully.

4. The technical and project risks have been reduced to acceptable levels with mitigation plans in place during the execution of the project.

5. After 32 months the Tracker Upgrade Project is still within budget and only 3% behind schedule.

Truly remarkable achievements for such a design and development project.

In this paper the authors highlight some of the details of the implemented processes and procedures as well as specific challenges that needed to be met while executing a project of this nature and technical complexity. All while remaining within a limited budget and schedule.

9911-59, Session PSMon

PSF simulations as part of the on-ground calibration of the NISP infrared spectrometer instrument for Euclid

Cyril Jomni, Anne Ealet, William Gillard, Ctr. de Physique des Particules de Marseille (France); Eric Prieto, Lab. d’Astrophysique de Marseille (France); Frank U. Grupp, Max-Planck-Institut für extraterrestrische Phyisk (Germany)

EUCLID is a telescope dedicated to the understanding of the acceleration of the expansion of the Universe with the measure of large surveys of the sky in the visible and near infrared ranges. Its payload is composed of a 1.2 m aperture telescope with two instruments: a visual imager (VIS) and a near-infrared spectrometer and photometer (NISP). The NISP integration is under LAM responsibility and the CPPM is in charge of the reception, integration and individual characterization of all detectors. One of the main objectives of the test campaign is the on-ground calibration of the NISP which is also a responsibility of these laboratories.

The test campaign will regroup functional tests of the payload, performance tests of the instrument, calibration procedure validation and observation scenario tests, all done at LAM.

A specific GSE will be used to simulate the telescope (VGS) and will be put in front of the NISP. This VGS will produce measured PSFs during the test campaign. The campaign includes in particular a precise determination of the focus position of the NISP instrument with respect to the EUCLID object plane.

In order to prepare this test, a tolerance model (Zemax) including the NISP and the VGS contributions will be developed, adjusting focal length, to generate a PSF database. This database will allow to develop the test procedure, based on simulated PSFs, and related analysis tools for the test ground campaign and will be further used to validate the calibration procedure verification. This simulated PSF database will be also used in pixel simulation to evaluate the performance of the instrument up to the science level.

After a description of the main objectives of the NISP calibration, we will focus on the method developed to realize and validate the NISP focus test, based on PSF simulations i.e.:

• Method to fit the PSF on the basis of the Markov Chain Monte Carlo (MCMC) method, or to be more specific, on the slice sampling method;

• Establishment of a PSF database base on a Zemax model;

• Procedure to minimize the PSF for a test of the focus.

9911-61, Session PSMon

Problem reporting and tracking system: a systems engineering challenge

Vasco Cortez Montero, ALMA (Chile)

In the ALMA observatory, in average, are reported 12 unexpected problems daily, which can affect the observations, software, planned maintenance, infrastructure, instrumentation, equipment or any other operational component. These problems are generated and managed by different groups, with dissimilar backgrounds and some cases different locations around the world. The tracking of these problems becomes in a very interesting challenge, at the moment to address them and applying a systemic view.

The problem reporting and tracking system (PRTS) is the ALMA system based in JIRA to register and track all problems and investigations arisen in operation. In the JIRA project PRTSPR are created the tickets of problems, where it is included all information available about them, such as: the event times of the failure and the system overview at the moment when the failure happened. On the other hand, the investigations are tracked separately, in another JIRA project PRTSIR, where are included all outcomes of the analyses carried out to determine the root causes, the affected components, the verification and validation of the solutions implemented.

At the end of 2014 the number of PRTSIR tickets unresolved assigned to the ALMA department of engineering (ADE) was more than 800, number extremely large to get a proper tracking considering the size of the ADE staff. In this work, we shall present a set of concrete actions applied at the basis of understanding the complexity of the problem, which finally got to improve the interactions between different subsystems and enhance the communication at different levels. Currently, the number of ticket unresolved has been considerably decreased and the tracking of the problems has presented clear improvements among the groups. Even so, there are a lot of challenges to be addressed and enhancements to be applied, in order to have a robust and functional PRTS that ALMA needs.

Daniel K. Inouye Solar Telescope: computational fluid dynamics analysis and evaluation of the air knife model

Isaac McQuillen, LeEllen Phelps, Mark Warner, Robert P. Hubbard, National Solar Observatory (United States)

Implementation of an air curtain at the thermal boundary between conditioned and ambient spaces allows for observation over wavelength ranges not practical when using optical glass as a window. The air knife model of the DKIST project, a 4-meter solar observatory that will be built on Haleakala, Hawaii, deploys such an air curtain while also supplying ventilation through the ceiling of the coudè lab. The findings of CFD analysis and subsequent changes to the air knife model are presented. Major design constraints include adherence to the Interface Control Document (ICD), separation of ambient and conditioned air, unidirectional outflow into the coudè lab, integration of a deployable glass window, and maintenance and accessibility requirements. Optimized design of the air knife successfully holds full 12 Pa back pressure under temperature gradients of up to 20 °C while maintaining unidirectional outflow. This is a significant improvement upon the .25 Pa pressure differential that the initial configuration, tested by Phelps, indicated the curtain could hold. CFD post-processing, developed by Vogiatzis, is validated against interferometry results of initial air knife seeing evaluation, performed by Hubbard. This is done by developing a CFD simulation of the initial experiment and using Vogiatzis' method to calculate error introduced along the optical path. A Kolmogorov model is applied in order to convert from seeing in arc seconds to rms wavefront error in nm and thus obtain congruity between units in the CFD model and units in the initial experiment. Seeing error, for both temperature differentials tested in the initial experiment, match well with seeing results obtained from the CFD analysis and thus validate the post-processing model. Application of this model to the realizable Air Knife assembly yield seeing errors that are well within the error budget under which the air knife interface falls, even with a temperature differential of 20 °C between lab and ambient spaces. With ambient temperature set to 0 °C and conditioned temperature set to 20 °C, representing the worst-case temperature gradient, the phase analog to the OPD-based rms wavefront error in units of wavelength is 0.0774 (38.7 nm at ? = 500 nm).

Conceptual design of the TMT instruments cryogenic cooling system

Nan Peng, Lianyou Xiong, Liqiang Liu, Bin Dong, Jing Li, Jiancheng Tang, Technical Institute of Physics and Chemistry (China); Hugh A. Thompson, Brent L. Ellerbroek, Thirty Meter Telescope (United States)

In order to ensure that the Thirty Meter Telescope (TMT) will achieve the expected image quality and detection ability for adaptive optics assisted observation, it is essential that mechanical vibration from all sources in the observatory be minimized. This includes the cryogenic cooling systems used to maintain near infra-red and visible science detectors, and other components contained in vacuum dewars, at temperatures as low as 70 K.

Recently, a conceptual design of a facility cryogenic cooling system for the TMT observatory has been developed by the Technical Institute of Physics and Chemistry of the Chinese Academy of Sciences (TIPC, CAS). This novel design approach is based upon the Brayton cycle which has the characteristics of long life, wide temperature range, large cooling capacity and low vibration. This cryogenic cooling system consists of two warm compressors, two cold boxes, three cryogenic valve boxes, warm transfer lines and vacuum jacketed cryogenic transfer lines. In this system, pressurized room temperature helium is delivered to the heat exchangers

and turbine expanders located in the cold boxes on the Nasmyth platforms. And the cold helium gas is then distributed to each instrument via the cryogenic valve boxes. This cryogenic system design produces 2.9 kW of cooling power at 65K and 0.4 kW of cooling power at 160 K. This paper presents the results of trade studies, process design, system layout, cooling power, operating modes and reliability estimates.

Dynamic position accuracy analysis of fiber positioner

Feng Cheng, Yonggang Gu, Hongzhuan Hu, Chao Zhai, Univ. of Science and Technology of China (China)

The Large Sky Area Multi-Object Fiber Spectroscopic Telescope (LAMOST) is a special quasi-meridian reflecting Schmidt telescope installed with 4000 optical fibers, which require precise alignment with the celestial target during the astronomical observation. Therefore, the fiber positioning system is the key to ensure effective observations. In order to reduce the loss of the coupling efficiency due to the misalignment between a target and a fiber, the fiber must be positioned within 40?m of the target. For the purpose of improving the positioning accuracy of fiber ends, it is essential in both theory aspect and practical aspect to study the sources and compensation method of the positioning error. In this paper, the sources of the positioning error, including dimensional deviation and joint clearance, are taken into consideration, and the corresponding error model is established respectively. The influences of different error sources are analyzed through appropriate simulation method. First, the model of positioning error caused by dimensional deviations is established based on the vector chain analysis method, and the numerical solution of the model is obtained through Monte Carlo numerical simulation method. Second, two virtual prototype models of fiber positioner, one of which contains joint clearance while the other one is zero-clearance, are built on multi-body dynamics simulation program ADAMS. Positioning error of fiber positioner caused by joint clearance is obtained by comparing the computational results of the two different models. Finally, the comprehensive positioning error is derived by coupling the two errors caused by dimensional deviations and joint clearances. Precise position measurement experiments of fiber ends are conducted , then a comparison is made between experimental and theoretical analysis to confirm the rationality of simulation models. Some conclusion is obtained, which can avail in further study.

Development of the space telescope mirror construction

Nadezhda D. Tolstoba, Daria Butova, ITMO Univ. (Russian Federation)

Nowadays mapping is an important task in the everyday and military purposes, performs a quick update and supply of high-quality images with the help of space telescopes. The better the image quality, the larger the telescope in size, and therefore require more capacity and investments to launch these telescopes into orbit. Because of this reasons there are happens works of making components of the telescope easier in mass.

The purpose of this paper is to find the most optimal design of the main mirror of a space telescope with preassigned characteristics and for a known material. The optimal design implies a set of minimum mass and maximum rigidity. The scheme to facilitate mirrors: edge-ring.

We study the dependence of the values ??of displacements [m] and static stress [N / m2] in the mirror of the different configurations of edge-ring design, different kinds and value of load on mirror: it must be resistant not only to its weight on the Earth, but also to forces appeared at the moment of rocket start.

From the totality of the results will be made conclusions of the optimal design of the primary mirror of the telescope with the specified parameters.

Meeting the challenges of bringing new base facility operation model to Gemini Observatory

Atsuko Nitta, Gemini Observatory (United States); Gustavo Arriagada, Gemini Observatory (Chile); Andrew J. Adamson, Scot J. Kleinman, Gemini Observatory (United States)

The aim of the Gemini Base Facilities Project is to provide the capabilities to perform routine night time operations with both telescopes and their instruments from their respective base facilities with no one at the summit. Tightening budget constraints prompted this as both a mean to save money and an opportunity to move toward increasing remote operations in the future.

Key challenges included: (1) Managing parallel work within the project while sharing resources with opeartions. (2) Testing commissioning and introducing new tools to operational systems without adding significant disruptions. (3) Staff buy-in to the new operational model given their involvement as both labor resources and users. There were two principles we applied to overcome these challenges and successfully complete the project ahead of schedule at Gemini North "Bare Minimum" and "Gradual Descent" I will discuss how we managed the cultural and human aspects of the project through these concepts. The other management aspects will be presented by Gustavo Arriagada, the Project Manager.

Application of the ALMA Observatory experience with software engineering tools to the system engineering design process for SKA

Rodrigo A. Olguin, SKA Organisation (United Kingdom); Tzu-Chiang Shen, ALMA (Chile)

The Software Group of the ALMA Observatory during the construction stage implemented a set of tools belonging to the discipline of Software Engineering with aim of successfully managing the complexities and problems proper of a large system as ALMA which is currently the world's largest radio telescope in operation.

The SKA Observatory, actually in the pre construction phase, is being designed following a tailored Systems Engineering approach. The design process is being carried out by more than 300 people conforming 7 design consortia and the SKA Organisation. The complexities in the design coming from the ambitious science goals and integrating such a large organisation sets not only technical, but also organisational and information sharing challenges. It is envisioned to learn from the ALMA experience with Software Engineering tools to explore and develop a plan to apply them in the SKA system engineering process aiming to mitigate the different design process risks. A set of potential implementations for SKA will be presented.

9911-68, Session PSMon

The use of information technology tools in the system engineering design process of SKA

Rodrigo A. Olguin, Juande Santander-Vela, Andrea Cremonini, Maria Grazia Labate, Marco Caiazzo, Daniel Hayden, Susan Nel, SKA Organisation (United Kingdom)

The SKA Observatory, presently in the Pre-Construction phase, is being designed following a tailored Systems Engineering approach. Large-scale engineering design projects are characterised by an equally large set of documentation and a complex configuration management structure, with design resources also spread across more than 10 different countries. SKA is innovating the way that astronomy projects are designed by making use of the new generation of Information Technologies to manage the System Engineering and design processes. SKA is hosting services for requirements management (JAMA), Model-Based Systems Engineering using SysML tools (Cameo) and Configuration Management (eB), and is engaging the SKA community activities by the use of on-the-cloud systems for reporting (JIRA) and discussion (Confluence). In this contribution we report how these tools are being used, what is the impact they are having in the SKA design process, their limitations, and the solutions to work around them.

9911-69, Session PSMon

Management aspects of Gemini's base facility operations project

Gustavo Arriagada, Andrew W. Serio, Arturo J. Nunez, Atsuko Nitta, Martin Cordova, Gemini Observatory (United States)

Gemini's Base Facilities Operations (BFO) Project provided the capabilities to perform routine nighttime operations without anyone on the summit. The expected benefits it were to achieve money savings and to become an enabler of the future development of remote operations.

Managing this project represented several challenges:

It was a schedule driven project.

With limited resources we managed a large number of concurrent work packages.

We had to implement new capabilities without disrupting operations.

And we needed to succeed introducing the new operational model, where operators would rely on technology to assess summit conditions.

The project was executed using a tailored version of Prince 2 project management methodology. We spent a good portion of time early in the project, collecting or learning about user's needs. This was done through close interaction with Telescope Operators and Observers.

Once we had a clear understanding of the requirements and since the project was schedule driven, we took the approach of implementing the "bare minimum" necessary technology that would meet the requirements and that would be maintainable in the long term.

BFO was divided in several smaller projects called work packages (WP). We executed them independently, introduction another important concept called "gradual descent". With this idea in mind, we increasingly provided tools to the night staff to prevent them from going outside the control room during nighttime operations. Also, by using them at an early stage, we had plenty opportunity for debugging and problem fixing.

The main technical areas that BFO tackled were:

• The preservation of safe daytime and nighttime operations. We implemented 3 observatory modes called "Summit, Standby and Base". During the day the observatory remains in Summit mode making the remote operations of the critical systems from the base, impossible. At night the observatory is in Base mode enabling full remote control of the above-mentioned systems and during the period of time that nobody is operating, the observatory is left in Standby mode.

• The creation of a virtual summit operator through the Facility Protection System (FPS) that takes autonomous actions under 3 well identified scenarios: precipitation, earthquake and network loss. In each case the actions and their immediacy is different. For instance, precipitation triggers an immediate dome closing sequence; earthquakes on the other hand are notified if they are small, but systems are stopped if the earthquake is large and in the case of summit-base network loss, FPS waits for few minutes before initiating a closing sequence.

• The replacement of operator's eyes and ears was achieved by adding Video/Audio and Cloud Sensing systems that provide full remote inspection capabilities and nighttime fog and cloud presence assessment. We also implemented redundant weather sensors to monitor conditions that were critical for the safety of the observatory as a whole.

To assure proper BFO overall performance, all WPs products were tested at a system level before releasing them to operations.

Work packages were documented and in each case a formal handover protocol was followed.

We finally conducted 3.5 months of trial operations before declaring the project done.

9911-70, Session PSMon

Diffraction modeling of finite subband EFC probing on dark hole contrast with WFIRST-AFTA shaped pupil coronagraph

Hanying Zhou, John E. Krist, Bijan Nemati, Jet Propulsion Lab. (United States)

Both shaped pupil coronagraph (SPC) and hybrid Loyt coronagraph (HLC) are of the primary architecture in current coronagraph instrument (CGI) design that is under intense development for a proposed NASA WFIRST-AFTA mission. The SPC operates in two modes: discovery/disk science mode which has a disk shape dark hole region but relatively larger inner working angle (IWA), and characterization mode for Integral filed spectroscopy (IFS) which has sets of bow-tie shaped dark hole regions but smaller IWA. While the current design bandpass of science filter for non-IFS imager has a 10% bandwidth at each band, it generally requires multiple narrow bandpass (subband) filters for accurate E field estimation through a pairwise image plane probing to achieve designed dark hole contrast, in a high contrast coronagraph that uses Electric Field Conjugation (EFC) algorithm for wavefront sensing and control. On the other hand to contain system complexity and cost, it is desirable to have as smaller number of mechanisms as possible. Current CGI design allocates two subband filters per full band. In this paper we investigate, through diffraction modeling with realistic AFTA optics and finite bandwidth EFC probing, the adequacy of such limited number of subband filters in achieving the designed contrast for SPC imager configuration. Multiple subband choices and probing strategies are explored, including standard subband probing; mixed wavelength and/or weighted Jacobian matrix; subband probing with intensity subtraction; and extended subband probing with intensity subtraction. Overall, the investigation shows that the achievable contrast with limited number of finite subband EFC probing is about 2-2.5x worse than the designed post-EFC contrast for current SPC design. Detailed results are included and discussed.

9911-71, Session PSMon

Radiometric model for the stereo-camera STC onboard the BepiColombo ESA mission

Vania Da Deppo, IFN-CNR Padova (Italy) and INAF - Osservatorio Astronomico di Padova (Italy); Elena Martellato, INAF - Osservatorio Astronomico di Padova (Italy); Emanuele T. Simioni, IFN-CNR Padova (Italy); Giampiero Naletto, Univ. degli Studi di Padova (Italy); Gabriele Cremonese, INAF - Osservatorio Astronomico di Padova (Italy)

BepiColombo is the fifth cornerstone mission of the European Space Agency (ESA) foreseen to be launched in 2017 with the aim of studying in great detail the Mercury planet.

One of the BepiColombo instruments is the STereoscopic imaging Channel (STC), which is part of the Spectrometers and Imagers for MPO BepiColombo Integrated Observatory SYStem (SIMBIOSYS) suite: an integrated system for imaging and spectroscopic investigation of the Mercury surface.

The main scientific STC objective is the 3D global mapping of the entire surface of Mercury with a scale factor of 60 m per pixel at periherm.

To determine the design requirements and to model the on-ground and in-flight performance of STC, a radiometric model has been developed.

STC optical design, mirrors and lenses specifications together with focal plane assembly (FPA) characteristics have been used as input data to the model for defining the spectral instrument response function. Depending on the applications (i.e. simulation of the instrument behavior in-flight or on-ground during the calibration) different sources can be taken into account as input for the model. Mercury expected radiance, as derived from current available data, or the measured OGSE integrating sphere radiance, or calibrated stellar fluxes can be considered.

Primary outputs of the model are: the expected integration times used on-ground during the calibration campaign and the in-flight exposure time to be used both for surface imaging along the orbit around Mercury and during stellar calibration acquisitions. In addition the expected signal-to-noise ratio (SNR) has been evaluated.

This paper describes the radiometric model structure philosophy, the input and output parameters and presents the radiometric model derived for STC. The predictions of the model will be compared with some measurements obtained during the Flight Model (FM) ground calibration campaign. In particular, the results show that the foreseen values are in good agreement with the measurements.

Finally, the radiometric model can be further improved using the experimental results of the on-ground calibration to better simulate the in-flight performance prediction.

9911-72, Session PSMon

Cooling a solar telescope enclosure: plate coil thermal analysis

Michael M. K. Gorman, Syracuse Univ. (United States); LeEllen Phelps, Guillermo Montijo Jr., Chriselle Galapon, National Solar Observatory (United States); Gaizka Murga, IDOM Ingenieria y Consultoria S.A. (United States)

The climate of Haleakal? requires the observatories to actively adapt to changing conditions in order to produce the best possible images. Observatories need to be maintained at a temperature closely matching ambient or the images become blurred and unusable. The Daniel K. Inouye Solar Telescope (DKIST) is a unique telescope as it will be active during the day as opposed to the other night-time stellar observatories. This means that it will not only need to constantly match the ever-changing temperature during the day, but also during the night so as not to sub-cool and potentially affect the view field of nearby telescopes while they are in use. Being located approximately twenty-five (25) meters from operational telescopes, this becomes an issue that should be managed. Currently, there are many systems designed to manage the thermal environment of the observatory. However, the scope of this research was on the carousel cooling system of the DKIST.

The telescope enclosure surface, as mentioned, will be kept near ambient temperature. To accomplish this task, plate heat exchanger panels will be installed on the DKIST enclosure that are designed to keep the temperature at ambient temperature +0°C/-4°C. To verify the feasibility of this and to validate the design models, a test rig has been installed at the summit of Haleakal?. The project's purpose is to confirm that the plate coil panels are capable of maintaining this temperature throughout all seasons and involved collecting data sets of various variables including pressures, temperatures, flows of coolant, solar radiations and wind velocities during typical operating hours. Using MATLAB, a script was written to observe the plate coil's thermal performance. The system did not perform as expected, achieving a surface temperature that was generally 2ºC above ambient temperature. This isn't to say that the plate coil does not work, but the small chiller used for the experiment was undersized resulting in coolant pumped through the plate coil that was not supplied at a low enough temperature. Calculated heat depositions were about 23% lower than that used as the basis of the design for the chillers to be used for the full system, a reasonable agreement given the fact that many simplifying assumptions done in the model. These were not carried over into the testing.

The test rig performance showing a 23% margin provides a high degree of confidence for the performance of the full system when it is installed. If time allows, additional testing could be done that includes additional incident angles and times of day. This would allow a more complete analysis. If additional testing is performed, it's also recommended to use a larger chiller for the plate coil or to set the coolant flowing through the plate coil to a lower temperature. The test rig design could also be optimized in order to bring the plate coil up to its maximum efficiency. In the future, the script could be rewritten in a different computer language, so that the data could be solved for quicker. Further analysis could also include different types of coolants.

9911-73, Session PSMon

The Atacama Large Millimeter/sub-millimeter Array (ALMA) band-1 receiver

Yau-De Huang, Oscar Morata, Patrick Michel Koch, Ciska Kemper, Yuh-Jing Hwang, Chau-Ching Chiong, Institute of Astronomy and Astrophysics - Academia Sinica (Taiwan); Chi-Den Huang, Ching-Tang Liu, National Chung-Shang Institute of Science and Technology (Taiwan); Satoru Iguchi, Shin'ichiro Asayama, Daisuke Iono, Álvaro Gonzalez, National Astronomical Observatory of Japan (Japan); John E. Effland, Kamaljeet S. Saini, Marian W. Pospieszalski, National Radio Astronomy Observatory (United States); Doug W. Henke, NRC - Herzberg Astronomy & Astrophysics (Canada); Ricardo Finger, Univ. de Chile (Chile)

The Academia Sinica Institute of Astronomy and Astrophysics (ASIAA) is currently responsible to contribute the Band 1 (35-50 GHz) receiver system to the ALMA project. Together with the Herzberg Institute of Astrophysics in Canada (HIA), the National Radio Astronomy Observatory (NRAO) in the USA, the University of Chile (UCh) in Chile, and the National Astronomical Observatory of Japan (NAOJ). ALMA Band 1 will be able to study a very broad range of astrophysical environments, from nearby stars

to the re-ionization edge of the Universe. The two main scientific cases of ALMA Band 1 are also two of the ALMA Level One Science Goals: 1) the study of grains in protoplanetary disks to sizes as large as ~1 cm; and 2) the detection of the CO (3--2) line from nearby to high-redshift galaxies (6 < z <10). But, the scientific case for ALMA Band 1 is much more extended: studies of the cold molecular ISM, through the observation of many molecular lines close to their fundamental rotational transitions, which will allow the study of star formation processes in nearby galaxies; the study of the Sunyaev-Zel'dovich effect to probe the physics of galaxy clusters; the study of protoplanetary disks; detection of spinning dust; study of chemical differentiation in cloud cores; solar observation of flares in the Sun; or study of magnetic fields through the use of the Zeeman effect. Band 1 will allow ALMA to bridge the gap between the mm/sub-mm and cm radio astronomy and, given the large ratio of the available bandwidth to frequency, it will be able to study a large range of energy regimes.

The plan is to complete and deliver all 73 receiver units by the end of 2019. Not only are the technical requirements for the receivers far more stringent than any existing receiver system at this frequency band, but also the development and delivery schedule is challenging. To meet this requirement, the integration/test infrastructure and human resources must be planned to sustain the requirements over the next several years. Industrial involvement is also one of the important elements in the project planning. This document will present an overview of the Band 1 receiver project, the status of receiver development, and the progress of establishing the infrastructure and the projected project time-line.

Simulation analysis of the photographic noncoincidence between fiber ends and light spots under integrating sphere light source

Juan Luo, Yonggang Gu, Ye Zhu, Chao Zhai, Univ. of Science and Technology of China (China)

Fiber spectroscopic telescopes, such as LAMOST, require accurate alignment between the fiber ends and their corresponding celestial targets, and thus accurate position measurement of the fiber ends becomes a key problem. Due to the huge amounts and extremely small diameter of the fibers, photogrammetry is the most appropriate technology to measure the positions of all the fiber ends at the same time. In the measurement, the center of a light spot obtained through gray centroid method is regarded as the center of a fiber end. Nevertheless, we've observed that these two centers don't coincide under wide visual angles when integrating sphere is used as light source.To be more specific, there are two phenomena: 1) Under the image coordinate, the center of a light spot is always roughly on the extension line of the image center and the center of an optical fiber end; 2) The shape of captured light spotsturns into approximate ellipse while the visual angle increases. Basing on these phenomena we observed, this paper proposes a hypothesis that the maximum intensity of the light transmitted by the optical fiber to the end of the optical fiber is not in the end of the fiber, but outside the end of the fiber. The intensity distribution at the output end of fibers under integrating sphere light source is simulated by using ZEMAX. ZEMAX is a new type of optical ray tracing program, which can simulate the optical system of light transmission. So the photographic noncoincidence between fiber ends and light spots under integrating sphere light source is simulated and analyzed on ZEMAX.

Point spread function computation in normal incidence for rough optical surfaces

Kashmira Tayabaly, INAF - Osservatorio Astronomico di Brera (Italy) and Politecnico di Milano (Italy); Daniele Spiga, INAF - Osservatorio Astronomico di Brera (Italy); Michele Lavagna, Politecnico di Milano (Italy); Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy)

The Point Spread Function (PSF) allows specifying the angular resolution of optical systems, a key parameter used to define the performances of most of the optics. A prediction of the system's PSF is therefore a powerful tool to assess the design and manufacture requirements of complex optical systems. Usually well-established ray-tracing routines based on a geometrical optics are used for that purpose. However, those ray-tracing routines either lack of real surface defects (figure errors or microroughness) considerations in their computation, or they include a scattering effect modeled separately that requires assumptions difficult to verify. Facing an increasing demand for tighter angular resolution, the problem of surface finishing could drastically damage the optical performances of the system and must be taken seriously, including in optical telescopes systems.

In that context, a purely physical optics approach is more appropriate as it remains valid regardless of the shape and size of the defects appearing on the optical surface. However, such a computation, when performed in the two-dimensional space, is memory and time consuming as it requires one to process a surface map with a few micron resolution, sometimes extending the propagation to multiple-reflections. Fortunately, the computation is significantly simplified in the far-field configuration as it involves only a sequence of Fourier Transforms. In this paper, we show how to account for measured surface defects and roughness in order to predict the performances of the optics in single reflection.

4MOST systems engineering: from conceptual design to preliminary design review

Olga Bellido-Tirado, Steffen Frey, Samuel C. Barden, Roger Haynes, Olivier Schnurr, Jakob C. Walcher, Roland Winkler, Joar G. Brynnel, Roelof S. de Jong, Leibniz-Institut für Astrophysik Potsdam (Germany)

The 4MOST Facility is a very high-multiplex, wide-field, fibre-fed spectrograph system for the ESO VISTA telescope. Its aim is to create a world-class spectroscopic survey facility that is unique in its combination of wide-field multiplex, spectral resolution, spectral coverage, and sensitivity.

In such a complex instrumentation project, in which design and development activities are geographically distributed through several international institutions, a formal system engineering approach is essential for the success of the project.

After a successful concept optimization design phase, 4MOST entered at the end of 2014 into its Preliminary Design Phase. During this phase, 4MOST Systems Engineering have been challenged to accommodate evolving technical requirements, incomplete definitions of the interfaces with the VISTA Telescope, and undefined operational procedures in a tight schedule. Here we will present the process and tools adopted during the Preliminary Design Phase to perform the requirements analysis and define the subsystems specifications, coordinate the interface control documents and draft the system verification procedures. We will also present the plan

for the main systems engineering activities planned for the Final Design Phase.

9911-77, Session PSMon

Preliminary design of the HARMONI science software

Laure Piqueras, Aurélien Jarno, Arlette Pécontal-Rousset, Johan Richard, Observatoire de Lyon (France); Noah Schwartz, UK Astronomy Technology Ctr. (United Kingdom); Jean-François Sauvage, ONERA (France); Benoît Neichel, Carlos M. Correia, Lab. d'Astrophysique de Marseille (France); Thierry Fusco, ONERA (France)

HARMONI is one of the two first-light instruments that will be installed on the European Extremely Large Telescope (E-ELT) in 2024. It is a visible and near-infrared integral field spectrograph, operating in the wavelength range 0.47–2.45µm. Coupled with two different adaptive optics (AO) systems, it will offer a set of spatial scales and resolutions to optimize observations for a wide range of science programs and observing conditions.

In this paper we present the science software that is being developed for the HARMONI instrument.

The Instrument Numerical Model (INM) simulates the instrument from the optical point of view, in order to provide synthetic exposures simulating detector readouts, and includes the whole chain of acquisition from the atmosphere down to the telescope and including the detectors. It is based on Fourier optics formalism taking into account both optical aberrations and diffraction effects, by propagating a wavefront through the instrument. The adaptive optics simulation is provided by a dedicated model delivering PSFs.

The Data Reduction Software (DRS) removes most of the instrumental signature from raw data frames, corrects the data from the environmental effects (e.g. atmospheric refraction, sky background) and converts them into a fully calibrated, scientifically usable data cube. To improve the data quality it will use only a single re-sampling step from the raw data to the reduced data-cube.

These two software packages benefit from being developed together in a closed loop. The INM transforms data-cubes containing astrophysical scenes or test data into simulated detector exposures, and the DRS turns them back into a data-cube. By comparing a specially created data-cube at the INM entrance with the output at the DRS level it becomes possible to validate the simulation and the reduction of each effect individually. However these two software packages will be developed in different contexts. The INM is a living software evolving as the instrument is being designed and built, and thus must be flexible enough to easily simulate new effects. The DRS has to be developed within an ESO framework, and will be available to every observer who needs to reduce data taken with HARMONI.

This paper presents the functionalities and the preliminary design of this software, describes some of the methods and algorithms used and highlights the challenges that we will have to face.

9911-78, Session PSMon

CARMENES: system engineering during manufacturing and AIV phases

Ana Pérez-Calpena, FRACTAL S.L.N.E (Spain); Walter Seifert, Landessternwarte Heidelberg (Germany); Pedro J. Amado González, Instituto de Astrofísica de Andalucía (Spain); Andreas Quirrenbach, Landessternwarte Heidelberg (Germany); María Luisa García Vargas, FRACTAL S.L.N.E (Spain); Jose A. Caballero, Ctr. de Astrobiología (Spain); Lluis Gesa, Institut de Ciències de l'Espai (Spain); Eike Guenther, Thüringer Landessternwarte Tautenburg (Germany); Santiago Becerril, Miguel Andrés Sánchez Carrasco, Instituto de Astrofísica de Andalucía (Spain); Gerardo Veredas, Landessternwarte Heidelberg (Germany); Ignasi Ribas, Institut de Ciències de l'Espai (Spain); Ansgar Reiners, Georg-August-Univ. Göttingen (Germany)

CARMENES (Calar Alto high-Resolution search for M dwarfs with Exoearths with Near-infrared and optical Échelle Spectrographs) is a high resolution spectrograph built for the 3.5m telescope at the Calar Alto Observatory (Almería, Spain), which is operated jointly by the Max-Planck-Society (MPG) and the Spanish National Research Council (CSIC). CARMENES consists of two separated highly stabilized spectrographs covering both the visible, from 0.5 to 1.0 µm, and the near-IR, from 1.0 to 1.7 µm, wavelength ranges and long term stability with spectral resolution of R=82,000 to provide high-accuracy radial-velocity measurements (?1 m/s) and long-term stability.

CARMENES has been built by a consortium formed by five German institutions, five Spanish institutions and the Calar Alto observatory itself. The instrument first light took place on November, 9th 2015 to start operations on January 1st 2016.

The technical and managerial complexity of the instrument demanded a strong system engineering control during the system development, manufacturing, assembly, integration and verification. The goal was to ensure that the demanding high level requirements were met. The MPG and CSIC, the observatory's owners, imposed CARMENES to be ready for operations at the end of 2015, which was an important constrain that impacted on all technical decision taken during the last project phases.

The system engineering activities carried out during those project phases included a) preparing the specifications of low-level subsystems and components, and implementing traceability of the high-level requirements to the low-level ones, b) follow up of components manufacturing to verify that low-level specifications were fulfilled, c) definition and control of the interfaces between subsystems and components developed by the different teams and external providers, d) coordination of the preparation of the observatory rooms to be ready for receiving the instrument, e) preparation and control of the AIV plans followed at the different centers before acceptance and delivery of the main subsystems to the observatory and f) coordination of the AIV phase at system level at the observatory.

This article summarizes how these activities were carried out in order to have CARMENES fully operational on the imperative date.

ALMA software release management: a practical approach

Rubén Soto, Tzu-Chiang Shen, ALMA (Chile); Jorge Ibsen, European Southern Observatory (Germany); Norman Saez, ALMA (Chile); Erich Schmid, A. Maurizio Chavan, European Southern Observatory (Germany)

The ALMA software is a large collection of modules implementing all the functionality needed for the observatory's day-to-day operations from proposal preparation to the scientific data delivery. ALMA software subsystems include among many others: array/antenna control, correlator, telescope calibration, submission and processing of science proposals and data archiving.

The implementation of new features and improvements for each software subsystem must be in close coordination with observatory milestones, the need of rapidly respond to operational issues, regular maintenance activities and testing resources available to verify and validate new and

improved software capabilities. This paper described the main issues detected managing all these factors together and the different approaches used by the observatory in the search of an optimal solution.

We describe the software delivery process adopted by ALMA since the construction phase and its further evolution in early operations. We also present the acceptance mechanism implemented by the observatory for the validation of the software before it can be used for science operations. We provide details of the main roles and responsibilities in the software delivery and validation and their participation at the process for reviewing and approving changes into the accepted software versions.

Finally, we present ideas on how these processes should evolve in the near future, considering the operational reality of the ALMA observatory as it moves into full operations. We summarize the progress implementing some of these ideas and lessons learnt.

9911-80, Session PSMon

NELIOTA: ESA's new NEO lunar impact monitoring project with the 1.2m telescope at the National Observatory of Athens

Alexios Liakos, Alceste Bonanos, Manolis Xilouris, Panayotis Boumis, Ioannis Bellas-Velidis, Athanassios Marousis, Anastasios Dapergolas, Anastasios Fytsilis, Andreas Noutsopoulos, Vassilis Charmandaris, National Observatory of Athens (Greece); Kleomenis Tsiganis, Aristotle Univ. of Thessaloniki (Greece); Kanaris Tsinganos, National and Kapodistrian Univ. of Athens (Greece); Sebastian G. Els, Gaia Data Processing and Analysis Consortium (Spain); Detlef Koschny, European Space Research and Technology Ctr. (Netherlands); Timothy F. Lock, Vicente Navarro, European Space Astronomy Ctr. (Spain)

NELIOTA is a new ESA activity launched at the National Observatory of Athens in February 2015 aiming to determine the distribution and frequency of small near-earth objects (NEOs) via lunar monitoring. The project involves: (i) a complete refurbishment of the 40 year old 1.2m Kryoneri telescope at the National Observatory of Athens, (ii) development of a Lunar imager for the prime focus with two fast-frame sCMOS cameras, and (iii) procurement of servers for data processing and storage. Furthermore, we have developed a software system that controls the telescope and the cameras, processes the images and automatically detects lunar flashes. NELIOTA provides a web-based user interface, where the impact events, after their verification and characterization, will be reported and made available to the scientific community and the general public. The objective of this 3.5 year activity is to design, develop and implement a highly automated lunar monitoring system, which will conduct an observing campaign for 2 years, starting in the Summer 2016, in search of NEO impact flashes on the Moon. The novelty of this project is the dedication of a large, 1.2m telescope for lunar monitoring, which is expected to characterize the frequency and distribution of NEOs weighing as little as a few grams.

9911-81, Session PSMon

Design and test of a tip-tilt controller for an image stabilization system

Albert Casas, José María Gómez, Manuel Carmona, David Roma, José Bosch, Manel López, Josep Sabater, Atilà Herms, Univ. de Barcelona (Spain); Reiner Volkmer, Jörg Baumgartner, Thomas Berkefeld, Frank Heidecke, Monika Ellwarth, Christoph Kiess, Thorsten Maue, Eiji Nakai, Wolfgang Schmidt, Dirk Soltau, Kiepenheuer-Institut für Sonnenphysik (Germany)

This work consists on the description of the whole development process of a tip-tilt controller. This controller will be part of an Image Stabilization System of the PHI instrument of the Solar Orbiter mission. The main characteristics of this controller are high output voltage levels and a high resolution. The development process includes the design, tests and verification steps.

Simulations have been carried out for supporting the design step and allowing for the consecution of the specified requirements for the mission. Simulation results will be compared to the measurements obtained for the engineering model.

A thorough test of the controller has been performed. The controller output achieves a minimum output resolution of ±14mV and a maximum current consumption of 13mA rms.

9911-82, Session PSMon

SIMCADO: how to use the end-to-end model of the E-ELT's first-light near-infrared wide-field imager

Kieran Leschinski, Oliver Czoske, Werner Zeilinger, João Alves, Wolfgang Kausch, Univ. Wien (Austria); Rainer Köhler, Univ. of Innsbruck (Austria); Gijs Verdoes Kleijn, Univ. of Groningen (Netherlands); Richard Davies, Max-Planck-Institut für extraterrestrische Physik (Germany)

The era of the ELTs will soon be upon us and with it the ability to observe smaller, fainter and more distant objects than ever before. MICADO will be the E-ELT's first-light near-infrared wide-field camera, providing diffraction limited imaging over a ~50 arcsec field of view. During the development of such an instrument it is imperative that all parties (i.e. the design, calibration, and science teams) have a platform with which to exchange information regarding the current state of instrument. In this context we are developing an end-to-end instrument data simulator for MICADO - SimCADO.

SimCADO is able to simulate the entire optical path between a source and the MICADO focal plane array. To do this we have used a modular array-based approach (instead of a ray tracing approach), implemented in python in order to minimize computation time and maximize the potential user base. The array based approach means that SimCADO can be run on everyday computers in a "usable" time frame (seconds to minutes). The intrinsic modularity means that we are able to update SimCADO with the newest optical design as soon as the data becomes available. Naturally we provide data for the current design of the E-ELT/MICADO optical train, however the user may use her or his own instrumental data and still retains complete control over the whole system.

Here we present an overview of how to use the SimCADO package, both for the quick-use case where the user would like to visualise an object of interest as seen by MICADO, as well as for the advanced case, where the user would like to simulate MICADO output images under varying conditions and instrument configurations.

9911-83, Session PSMon

Simulating the LSST OCS for conducting survey simulations using the LSST scheduler

Michael A. Reuter, LSST (United States); Kem H.

Cook, Cook Astronomical Consulting (United States); Francisco Delgado, Catherine E. Petry, LSST (United States); Stephen T. Ridgway, National Optical Astronomy Observatory (United States)

During the past 10+ years of project definition, the Operations Simulator was used to prototype the LSST Scheduler. Moving towards operations, the Scheduler is being developed as a separate project to interface with the LSST Observatory Control System (OCS). A new Simulator is under concurrent development to adjust to this change of architecture. It consists of the Scheduler and a package that will simulate enough of the OCS interfaces to allow execution of realistic schedules. This new package is called the Simulated OCS (SOCS).

The SOCS is responsible for collecting control (time, downtime, mode, etc.), configuration (observatory, proposals, etc.) information and environmental conditions (seeing, clouds, etc.) and transmitting the data to the Scheduler. The Scheduler performs the operations necessary to produce the next target or targets for observation. The SOCS then carries out the observation and returns that observation (visit) back to the Scheduler. The SOCS will also record target, observation, Scheduler telemetry, observatory state and other information into a simulated survey database.

This paper will detail the construction plan for SOCS and provide information about its package structure and use of the LSST communication middleware platform that is built on top of the Data Distribution Service (DDS) standard. It will also describe some interesting use cases that the separated architecture allows. The software engineering practices used during the code development process will also be elaborated.

9911-84, Session PSMon

Quality initiative at ESO

Gero Rupprecht, Robin Arsenault, Maximillian Kraus, Paola Sivera, Gianluca Verzichelli, Arnout Tromp, Reinhard Hanuschik, European Southern Observatory (Germany)

An initiative is under way at ESO Headquarters to streamline operations, in particular in the engineering, technical and associated management areas. A systematic approach to strengthen the operating processes is in preparation, starting with a mapping of the extensive existing process network. Processes identified as sufficiently important and complex to merit an in-depth analysis will be properly specified and their implementation optimised to strike a sensible balance between organisational overhead (documentation) and efficiency. By applying methods and tools tried and tested in industry we expect to achieve a more unified approach to address recurrent tasks. This will enable staff to concentrate more on new challenges and improvement rather than spending effort on issues already resolved in the past.

9911-85, Session PSMon

SHARK-NIR system design analysis overview

Valentina Viotto, Jacopo Farinato, Maria Bergomi, Andrea Baruffolo, INAF - Osservatorio Astronomico di Padova (Italy); Alexis Carlotti, Institut de Planétologie et d'Astrophysique de Grenoble (France); Elena Carolo, Valentina D'Orazi, INAF - Osservatorio Astronomico di Padova (Italy); Davide Greggio, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli Studi di Padova (Italy); Demetrio Magrin, Luca Marafatto, INAF - Osservatorio Astronomico di Padova (Italy); Lars Mohr, Max-Planck-Institut für Astronomie (Germany); Roberto Ragazzoni, INAF - Osservatorio Astronomico di Padova (Italy); Daniele Vassallo, INAF - Osservatorio Astronomico di Padova (Italy) and Univ. degli Studi di Padova (Italy); Christophe Vérinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France)

In this paper, we present an overview of the System Design Analysis carried on for SHARK-NIR, the coronagraphic camera designed to take advantage of the outstanding performance that can be obtained with the FLAO facility at the LBT, in the near infrared regime. Born as a fast-track project, the system now foresees both coronagraphic direct imaging and spectroscopic observing mode, together with some wavefront correction tools. The analysis we report here includes several trade-offs for the selection of the baseline design, in terms of optical and mechanical engineering, and the choice of the coronagraphic techniques to be implemented, to satisfy both the main scientific drivers and the technical requirements set at the level of the telescope. Further care has been taken on the possible exploitation of the synergy with other LBT instrumentation, like LBTI. A set of system specifications is then flown down from the upper level requirements to finally ensure the fulfillment of the science drivers. The preliminary performance budgets are presented, both in terms of the main optical planes stability and of the image quality, including the contributions of the main error sources in different observing modes.

9911-86, Session PSMon

Integrated opto-dynamic modeling of the 4m DAG telescope image quality performance

Lorenzo Zago, Benjamin Guex, HEIG-VD (Switzerland)

The Turkish DAG 4-m telescope is currently through the final design stage with major optics parts already ordered.

It is to be located on a 3000 m mountain top in Easter Anatolia.

The telescope will be a state-of-the art device, alt-az mount with active primary and adjustable secondary and tertiary mirrors. Its optics design is specially aimed at being compatible with advance adaptive optics instrumentation.

The ultimate performance of such a telescope results of multiple concurrent effects from many different components and active functions of the complex system.

The paper presents a comprehensive integrated (end-to-end) model of the telescope, comprising in one computational sequence all structural, electrodynamics and oactive optics performance that produce the image quality at the focal plane.

The model is entirely programmed in Matlab/Simulink and comprises a finite element model or structure and mirrors, dynamics modal reduction, deformation analyses of structural and optical elements, active optics feedback control in the Zernike modal space.

9911-87, Session PSMon

SysML model of exoplanet archive functionality and activities

Solange Ramírez, California Institute of Technology (United States)

The NASA Exoplanet Archive is an online service aimed to promote and enable astronomical research related to search for and characterization of extrasolar planetary systems. We are dedicated to collect and serve

important public data sets and provide tools to work with these data. Data include stellar parameters, exoplanet parameters, time series, images, and spectra. Tools provided are interactive tables, plotting and histogram tool, time series viewer, transit predictor, periodogram service, and application program interfaces. There are many interfaces and interactions between data in our database and file systems and the tools we provide to the users. Our weekly additions of data and updated to the services are complex and need to be managed efficiently. The SysML model presented here help us through the weekly update process. The model includes Package Diagrams to show the overall structure of the model, block definition diagrams to present the logical architecture, and behavioral diagrams (activity and sequence) to describe the weekly update process.

9911-88, Session PSMon

Optomechanical design software for segmented mirrors

Juan Marrero, European Southern Observatory (Germany)

The design of an optomechanical system, especially of large telescopes, involves the consideration of thousands of highly interrelated parameters. Many commercial tools like Matlab, Ansys, Zeemax or Inventor, covering various disciplines like Mathematical analysis, Finite Element Modelling, Optical Design or CAD modelling, need to be employed in a certain order to obtain final conclusions on the performances of the system.

The description of a software tool under development is presented in this article. This tool pretends to ease the parametric analysis of large structures, allowing on the fly results at the change of a paremeter, without the need for going from one software package to another.

A brief summary of the most important features implemented on the described application follows:

- Solid and segmented mirrors analysis
- Ray tracing
- AIV errors analysis
- Collision detection
- 3d graphical representation
- Adaptable on-the-fly structure creation
- Supports analysis
- Deflections computation (through Ansys)
- Analysis of segmented mirror related components: Edge Sensors misalignments, Position Actuators stroke optimization, Warping Harness wavefront maps, etc.
- Export CAD models
- Accessibility analysis

At present, the tool is being very useful on the analysis of the various E-ELT error budgets, together with many other aspects.

9911-89, Session PSMon

Making the most of MBSE: pragmatic model-based engineering for the SKA Telescope Manager

Gerhard Le Roux, SKA South Africa (South Africa); Alan Bridger, Michael J. MacIntosh, Mark Nicol, Hermine Schnetler, Stewart J. Williams, UK Astronomy Technology Ctr. (United Kingdom)

Many large projects including major astronomy project are adopting a Model Based Systems Engineering approach. How far is it possible to get value for the effort involved in developing a model that accurately represents a significant project such as SKA? Is it possible for such a large project to ensure that high-level requirements are traceable through the various system-engineering artefacts? Is it possible to utilize the tools available to produce meaningful measures for the impact of change?

This paper shares one aspect of the experience gained on the SKA project. It explores some of the recommended and pragmatic approaches developed, to get the maximum value from the modelling activity while designing the Telescope Manager for the SKA. While it is too early to provide specific measures of success, certain areas are proving to be the most helpful and offering significant potential over the lifetime of the project.

The experience described here has been on the Cameo Systems Modeller tool set, supporting a SysML based System Engineering approach; however the concepts and ideas covered would potentially be of value to any large project considering a Model based approach to their Systems Engineering.

9911-90, Session PSMon

Tolerancing a radial velocity spectrometer within Zemax

Steven R. Gibson, Univ. of California, Berkeley (United States); Steven R. Gibson, Space Sciences Lab. (United States)

Techniques are described for tolerancing a radial velocity spectrometer system within Zemax, including: how to set up and verify the tolerancing model, performance metrics and tolerance operands used, as well as post-Zemax analysis methods. Use the tolerancing model for various analyses will be discussed, such as: alignment sensitivity, radial velocity sensitivity, and sensitivity of the optical system to temperature changes. Tolerance results from the SHREK project (a precision radial velocity spectrometer of asymmetric white pupil design) will be shown.

9911-91, Session PSMon

A method for generating a synthetic spectrum within Zemax

Steven R. Gibson, Edward Wishnow, Space Sciences Lab. (United States); the SHREK collaboration ., UC Berkeley Space Sciences Laboratory (United States)

A method using non-sequential Zemax to produce a pixelated synthetic spectrum is described. This simulation was developed for the SHREK project (a precision radial velocity spectrometer of asymmetric white pupil design). The synthetic spectrum will prove useful for engineering performance analyses (instrument stability, stray light, cross-talk between orders, camera distortion, line shape profile, etc.). It has also provided a base set of synthetic spectra to be used during the development of the data pipeline. Various aspects concerning the construction of the spectrum are described, including: converting a model from sequential to non-sequential Zemax, the creation of Zemax coating files for echelle blaze functions and overall system efficiency, and the generation of spectrum source files (solar, thorium-argon, incandescent, Fabry-Perot etalon and laser frequency comb).

9911-92, Session PSMon

LSST telescope modeling overview

Jacques Sebag, LSST (United States); Michael Warner, LSST (Chile); William J. Gressler, Constanza Araujo Hauck, John Andrew, Ming Liang, Douglas Neill, Felipe Daruich, Sandrine J. Thomas, Myung Kyu Cho, George Z. Angeli, LSST (United States)

During this early stage of construction of the LSST telescope, modeling has become a crucial system engineering process to ensure that the final detailed design of all the sub-systems that composed the telescope meet requirements and interfaces. This activity is particularly important because of the increased complexity of the telescope systems. Modeling includes multiple tools and type of analyses that are performed to address specific technical issues. 3D Computer-aided Design (CAD) modeling has become central for controlling interfaces between subsystems and identifying potential interferences. In addition, maintenance and handling requirements can be verified using 3D models.

The LSST Telescope dynamic requirements are challenging because of the nature of the LSST survey which requires a high cadence of rapid slews and short settling times. Combination of finite element modeling (FEM) coupled with control system dynamic analysis has proven to provide a method to validate these specifications. The output of the structural FEM analysis is key to provide the matrices for the nodal or modal model of the subsystem response. The dynamic analyses are implemented in Matlab using the object-oriented Simulink environment.

These challenging slewing requirements have a direct impact on the LSST primary/tertiary mirror support system that must be able to prevent excessive loads on the six locating actuators to maintain the mirror in place in real time. Modeling the behavior of the pneumatic actuators that support the mirror is required to develop the control strategy to counteract for these dynamic forces during slewing.

An overview of these modeling activities will be given in this paper including specific cases relevant to LSST.

9911-93, Session PSMon

Daniel K. Inouye Solar Telescope systems engineering update

Robert P. Hubbard, Simon C. Craig, Ruth A. Kneale, National Solar Observatory (United States)

The Daniel K. Inouye Solar Telescope (DKIST), formerly the Advanced Technology Solar Telescope (ATST), is now in its sixth year of construction. During the two years that have elapsed since our last systems engineering update we have been through factory acceptance of several major subsystems including the enclosure, telescope mount assembly, and the primary mirror. With these major milestones behind us, site assembly in progress, and with the integration, test, and commissioning phase about to begin, we will discuss what has been working well in terms of DKIST systems engineering processes along some things we could have done better and would do differently if given another chance. The paper examines examples of successes including full-scale factory assembly of major mechanical components and some less optimum outcomes. We explore the reasons for success or failure, including the early delivery and level of detail in factory acceptance test procedures.

9911-94, Session PSMon

End-to-end modeling: a new modular and flexible approach

Matteo Genoni, INAF - Osservatorio Astronomico di Brera (Italy) and Univ. degli Studi dell'Insubria (Italy); Marco Riva, Marco Landoni, Giorgio Pariani, INAF - Osservatorio Astronomico di Brera (Italy)

In this paper we present an innovative philosophy through which develop the End-to-End model for astronomical observation projects, i.e. the architecture which allows physical modeling of the whole system from the light source to the reduced data. This new philosophy foresees the development of the physical model of the different modules, which compose the entire End-to-End system, directly during the project design phase. This approach is strongly characterized by modularity and flexibility; these aspects will be extremely required in the next generation astronomical observation projects like E-ELT (European Extremely Large Telescope) because of the high complexity and long-time design and development. With this approach it will be possible to keep the whole system and its different modules efficiently under control during every project phase and to exploit a reliable tool at a system engineering level to evaluate the effects on the final performance both of the main parameters and of different instrument architectures and technologies. This philosophy will be important to allow scientific community to do in advance simulations and tests on the scientific drivers. This will translate in a continuous feedback to the (system) design process with a resulting improvement in the effectively achievable scientific goals and consistent tool for efficiently planning observation proposals and programs. We present the application case for this End-to-End modeling technique, which is the high resolution spectrograph at the E-ELT (E-ELT HIRES). In particular we present the definition of the system modular architecture, describing the interface parameters and detailed model of the modules.

Concept of operations (a day in the life) of the COSMO large coronagraph

Phillip H. Oakley, Steven Tomczyk, Scott Sewell, Dennis J. Gallagher, Brandon Larson, Alice R. Lecinski, Greg L. Card, Rob Graves, National Ctr. for Atmospheric Research (United States)

The COronal Solar Magnetism Observatory (COSMO) Large Coronagraph is a proposed facility with unique capabilities for magnetic field measurements in the solar corona. This paper summarizes the preliminary concept of operations of this facility. Specifically we detail a "day in the life" of the observatory discussing both the synoptic program and guest program. We also detail the daily schedule of the observer, facility, and scientific instrument. Lastly community interaction with the facility is discussed from the perspective of observation planning, proposing, observing, data pipeline processing, and data delivery.

Systems engineering overview of the COSMO large coronagraph

Phillip H. Oakley, Steven Tomczyk, Scott Sewell, Dennis J. Gallagher, Brandon Larson, Alice R. Lecinski, Gregory L. Card, Rob Graves, National Ctr. for Atmospheric Research (United States)

The COronal Solar Magnetism Observatory (COSMO) Large Coronagraph is a proposed facility with unique capabilities for magnetic field measurements in the solar corona. This paper summarizes the systems engineering plan for this facility. In particular we detail the flow of science requirements to engineering requirements, and discuss an overview of requirements management, configuration management and overall verification and compliance processes.

9911-97, Session PSMon

An optical toolbox for astronomical instrumentation

Brian M. Sutin, Thirty Meter Telescope (United States)

The author has open-sourced a program for optical modeling of astronomical instrumentation. The code allows for optical systems to be described in a programming language. An optical prescription may contain coordinate systems and transformations, arbitrary polynomial aspheric surfaces and complex volumes. Rather than using a plethora of rays to evaluate performance, all the derivatives along a ray are computed by automatic differentiation. By adaptively controlling the patches around each ray, the system can be modeled to a guaranteed known precision. The code currently consists of less than 10,000 lines of C++/stdlib code.

Reduced order transfer function for a radio-telescope

Gengis Kangh Toledo Ramirez Sr., CIDESI (Mexico); Isrel Mejia Alonso, Ctr. de Ingeniería y Desarrollo Industrial (Mexico); Eloy Edmundo Rodríguez Vázquez Jr., Ctr. de Ingenieria y Desarrollo Industrial (Mexico); Jorge Luis Iglesias Medina, CIDESI (Mexico)

A frequency response analysis for the identification of the dynamical model for a 34 meters radiotelescope was performed. The model identified is a 18th-order linear transfer function, which has its main resonances into the range from 1 to 10 Hz.

In this work just the nearby resonances of the frequency response and their modal shapes were considered to get a reduced order model, by performing a new methodology which its main concern is to reproduce the embodied frequency response.

This methodology consists of a set of steps which were embodied in a Transfer Function Reconstruction algorithm. The application of this function shows systematically how the identification, classification, and treatment of truncation unwanted factors from the frequency response analysis is performed.

The model validation was made by performing responses analysis: time and frequency. Here a second iterative algorithm was used to relocate the poles of the reduced order transfer function to mitigate the magnitude of the oscillations from time step inputs, like a fine tuning of these poles.

A second validation for the reduced order transfer function of the radio telescope model was controlled by simulating the sun tracking from position commands based on NOAA Solar Position Algorithm. The simulation results show that this complete methodology is competitive with others documented before.

Optical parametric evaluation model for a broadband HIRES at E-ELT

Matteo Genoni, INAF - Osservatorio Astronomico di Brera (Italy) and Univ. degli Studi dell'Insubria (Italy); Marco Riva, Manuele Moschetti, Matteo Aliverti, INAF - Osservatorio Astronomico di Brera (Italy)

We present the details of a paraxial parametric model of an high resolution spectrograph which can be used as a tool, characterized by good approximation and reliability, at a system engineering level. This model can be exploited to perform a preliminary evaluation of the di?erent parameters as long as di?erent possible architectures of high resolution spectrograph like the E-ELT HIRES. The detailed equations flow concerning the first order e?ects of all the spectrograph components is described; in addition a comparison with the data of a complete physical ESPRESSO spectrograph model is presented as a model proof.

9911-100, Session PSMon

A green observatory in the Chilean Atacama desert

Michael Ramolla, Christian Westhues, Moritz Hackstein, Ruhr-Univ. Bochum (Germany); Klaus W. Hodapp, Univ. of Hawai'i (United States); Rolf Chini, Martin Haas, Ruhr-Univ. Bochum (Germany); Angie Barr Domínguez, Univ. Católica del Norte (Chile); Roland Lemke, Luftfahrt-Bundesamt (Germany); Miguel G. Murphy, Univ. Católica del Norte (Chile)

Since 2007, the Ruhr-Universität Bochum, Germany and Universidad Catolica del Norte, Chile jointly operate the Observatory Cerro Armazones, which is located in direct neighborhood of the future E-ELT of ESO. It is the only observatory that relies completely on green energy. Our electricity is produced by solar panels and windmills. Excess power is stored in batteries that allow uninterrupted operation even in windless nights.

The scientific equipment consists of three robotic optical telescopes with apertures ranging from 15 cm (RoBoTT) over 25 cm (BEST II) to 40 cm (BMT) and one 80 cm (IRIS) infra-red telescope. The optical telescopes are equipped with Johnson and Sloan broad band filters together with a large number of narrow and intermediate bands. In the infrared, J, H and K filters are available, accompanied by several narrow bands near the K band wavelength. A switch of nasmyth foki in the 80 cm telescope allows to use a high resolution echelle spectrograph similar to the FEROS instrument of ESO. This variety has evolved from different collaborations, i.e. with the University of Hawaii which provided the near-infrared-camera of the IRIS telescope, or with the "Deutsches Zentrum für Luft- und Raumfahrt" (DLR) which provided the whole BEST II telescope. The highly automatized processes on all telescopes enable a single person to run the whole facility, providing the high cost efficiency required for an university observatory.

While the comparatively small apertures are not efficient for observing faint sources, the excellent site conditions allow projects that require continuous daily reobservations of astronomical objects over epochs of several months or even years. Such observations are time allocation-wise impossible on the large multinational observatories. We can show that a small collaboration between universities is able to design and operate a green observatory. This enables us to do competitive science, such as studies of young stellar objects, multiplicity of stars, quasar variability or the hunt for exo-planets.

9911-101, Session PSMon

Vibration measurements of the DKIST mount, Coude rotator, and enclosure assemblies

William R. McBride II, Paul Jeffers, Heather Marshall, National Solar Observatory (United States)

The Daniel K. Inouye Telescope (DKIST) will be the largest solar telescope in the world, with a 4-meter off-axis primary mirror and 16 meter rotating coude laboratory within the telescope pier. The off-axis design requires a mount similar in size to an 8-meter on-axis telescope. Both the telescope mount and the coude laboratory utilize a new bearing technology in place of hydrostatic bearings. The telescope enclosure utilizes a crawler

mechanism for the altitude axis. As these mechanisms have not previously been used in a telescope, understanding the vibration characteristics and the potential impact on the telescope image is important.

This paper presents the methodology used to perform jitter measurements of the enclosure and the mount bearings and servo system in high-noise environments utilizing seismic accelerometers and high dynamic-range data acquisition equipment, along with digital signal processing (DSP) techniques. Data acquisition and DSP were implemented in MATLAB.

In the telescope mount tests, multiple accelerometers were strategically located to capture the six axes-of-motion of the primary and secondary mirror dummies. The optical sensitivity analysis was used to map these mirror mount displacements and rotations into units of image motion on the focal plane.

Testing was performed by recording accelerometer data while the telescope control system performed tracking operations typical of various observing scenarios. The analysis of the accelerometer data utilized noise-averaging FFT routines, spectrograms, and periodograms. To achieve adequate dynamic range, the use of special filters and advanced windowing functions were necessary. Multiple automated over-night tests were performed and compared to find and select the data sets with the lowest level of external interference.

Similar testing was performed on the telescope enclosure during the factory test campaign. The vibration of the enclosure altitude and azimuth mechanisms are characterized.

9911-102, Session PSMon

Quality management in Laboratory of Space Studies and instrumentation in astrophysics

Didier Zeganadin, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France) and Ctr. National de la Recherche Scientifique (France) and Observatoire de Paris (France)

From the design of astronomical instruments to the exploitation of results, scientific themes developed at LESIA cover many areas of astrophysics. The activities are organized around projects (ground, space or modeling) whose many accomplishments demonstrate the laboratory's reputation.

The technical quality culture is transmitted between our engineers and technicians mainly through our space projects.

Product assurance management is a main activity in the development of space projects.

The principal activity of a product assurance manager (PAM) in the design phase is to demonstrate that quality applied to product design is under control.

It also has the role:

- to assist the project manager in the mastery of design (support for procurement activities, mastery of changes, risk management...)

- to work with the engineer system to preserve quality performance and reduce risk

In AIT phase (assembly, integration, test) the principal activity of a PAM is to define a quality program that demonstrates that quality controls are carried out and that the quality structure works.

It also has the role:

- to assist the project manager in the mastery of production (support for configuration changes and traceability of equipment, checking supplies comply with the requirements, available documentation preparation coordination)

- to monitor compliance with the requirements

To strengthen this activity, the CNES (French national space research center) and INSU (Universe Sciences National Institute) support the establishment of a quality framework, established by a head quality manager mandated by the laboratory director to coordinating quality activities in the lab.

The main objectif of the Head quality manager is to consolidate, track and reliable "best practices" on lab projects to ensure the satisfaction and the trust of customers, and in particular national and international agencies

Also he can be a guide by simplifying information searches (normative or other) and keep alive the quality system in inter-project periods

Production of ELZM mirrors: performance coupled with attractive schedule, cost, and risk factors

Antoine Leys, SCHOTT AG (Germany); Tony B. Hull, The Univ. of New Mexico (United States); Thomas Westerhoff, SCHOTT AG (Germany)

Extreme Lightweighted ZERODUR® Mirrors (ELZM) have been developed to exploit the superb thermal characteristics of ZERODUR®. Coupled with up to date mechanical and optical fabrication methods this becomes an attractive technical approach. However the process of making mirror substrates has demonstrated to be unusually rapid and especially cost-effective. ELZM is aimed at the knee of the cost as a function of lightweighting curve. ELZM mirrors are available at 88% lightweighted. Together with their low risk, low cost production methods, this is presented as a strong option for NASA Explorer and Probe class missions.

9911-104, Session PSMon

A database for TMT software interface control documents

Kim Gillies, Scott C. Roberts, John Rogers, Thirty Meter Telescope (United States)

The TMT Software System consists of software components that interact with one another through a software infrastructure called TMT Common Software (CSW). CSW consists of software services and library code that is used by developers to create the subsystems and components that participate in the software system. CSW also defines the types of components that can be constructed and their roles. The use of common component types and shared middleware services allows standardized software interfaces for the components.

A software system called the TMT Interface Database System was constructed to support the documentation of the interfaces for components based on CSW. The programmer describes a subsystem and each of its components using JSON-style text files. A command interface file describes each command a component can receive and any commands a component sends. The event interface files describe status, alarms, and events a component publishes and status and events subscribed to by a component. A web application was created to provide a user interface for the required features. Files are ingested into the software system's database. The user interface allows browsing subsystem interfaces, publishing versions of subsystem interfaces, and constructing and publishing interface control documents that consist of the intersection of two subsystem interfaces. All published subsystem interfaces and interface control documents are versioned for configuration control and follow the standard TMT change control processes. Subsystem interfaces and interface control documents can be visualized in the browser or exported as PDF files.

The web application is implemented in the Scala using the Play web application framework. The JSON model files are stored as binary files in the MongoDB document database system. The user interface is created

using Scala.js. All the implementation products are open-source. The source code for the TMT Interface Database System is available on Github.

9911-105, Session PSMon

Stress and thermal optical effects in large refracting corrector elements for the GMT

Sean Lin, Andrew P. Rakich, GMTO Corp. (United States)

The Giant Magellan Telescope (GMT) will consist of seven 8.4 m aperture telescopes mounted as a phased radially symmetrical array in a common mount. One of the observing modes offered by the telescope has a 20 arc minute diameter field, corrected for seeing limited observation. In this mode a large aberration and atmospheric dispersion corrector (C-ADC), with refracting elements of the order of 1.5 m in diameter, provides correction for both the optical design residual astigmatism and atmospheric dispersion. A refracting corrector of this size is unique, and due to its scale, the large refracting components can produce significant wavefront error via mechanisms that are often not significant in smaller correctors. This paper focusses on two of these potential error sources; varying stress within the material leading to birefringence effects, and inhomogeneous thermal distributions leading to deltas in refractive index through the material.

Little work has been done in the area of stress optical modeling of astronomical refracting correctors. For smaller correctors, using standard optical glasses, these effects are often negligible. Variable stresses can arise in the large refractive components from both their variable orientation with respect to gravity and from differential thermal expansions within the correct element material. We have found that there are non-negligible contributions from stress induced wavefront error in elements of our ADC. These stresses have been modeled for a variety of cases with finite element tools, and the resultant wavefront error analyzed with SigFit™ and Zemax™. Details of this integrated modeling approach and the results are presented here.

In a similar integrated modeling approach, ANSYS™ software has been used to produce a transient thermal analysis, and the resultant temperature distribution of the optical elements at specific time has been fed into the SigFit™ Thermo-Optic module and the resultant OPD map fit with Zernike polynomials.

After presenting the results of this analysis we will discuss how the results have informed and guided the opto-mechanical design process, particularly for lens-to-cell interfaces, and how predicted residuals of wavefront error contribute to the overall wavefront error budget for the corrector.

Observatory building design: a case study of DAG with infrastructure and facilities

Ali Erkan Sahmali, GÜNARDA A? (Turkey); Cahity Yesilyaprak, Atatürk Üniv. (Turkey); Sinan K. Yerli, Middle East Technical Univ. (Turkey); Onur Keskin, Isik Üniv. (Turkey)

DAG (Eastern Anatolia Observatory in Turkish) site is located at 3170 m altitude in one of the well-known mountain ridges of Erzurum, Turkey. As well as erecting the largest telescope of Turkey, the DAG project aims to establish an observatory complex both small in size and functional enough to give service to all astronomy community. In this paper, the challenge is explained in details: geological limitations, usage distribution of building base area, concept of green-building, astronomical services (both on-site and remote), and of course give chance to out-reach of astronomy.

9911-107, Session PSMon

High-contrast imaging and high dispersion spectroscopy observation of exoplanets and brown dwarfs

Ji Wang, Dimitri Mawet, California Institute of Technology (United States)

Characterizing exoplanet atmospheres is the logical next step after an overwhelming number of discoveries. Current challenges for exoplanet atmosphere characterization are (1), high contrast between and host star and its planet; (2), degeneracy between models at low spectral resolution. High contrast imaging (HCI) and high dispersion spectroscopy (HDS) observation is a promising technique to meet these two challenges. We study system performance of HCI+HDS instrument by exploring a broad range of instrumental and astrophysical parameter spaces. We discuss the implications of this study in two scientific cases: (1) measuring atmospheric chemical composition, (2), probing surface non-uniformity caused by clouds.

9911-108, Session PSMon

AETC: a powerful web-tool to simulate astronomical images

Michela C. Uslenghi, INAF - IASF Milano (Italy); Renato Falomo, Daniela Fantinel, INAF - Osservatorio Astronomico di Padova (Italy)

We present the capabilities of the Advanced Exposure Time Calculator (AETC), a tool, publicly available via a web interface (http://aetc.oapd.inaf.it/), aimed to simulate astronomical images obtained with any (given) telescope and instrument configuration. The tool includes the possibility of providing an accurate modelling of PSF variations in the FoV, a crucial issue for realistic simulations and which makes AETC particularly suitable for simulations of adaptive optics instruments.

The input configuration includes the characteristics of the telescope, instrument and the detector. For selected targets (stars, galaxies, complex objects) the tool provides estimate of S/N for given observations parameters (exposure time, number of exposures, sky conditions, etc). Pre-configured templates are also available for several sets of telescope/instrument, both existing and future, usable as is or as a starting point for a new configuration. In addition AETC produces simulated images of the observations taking into account the instrument configuration and the observation parameters. The observed fields can include not only stars and galaxies, but also any kind of complex object, modelled by convolution with the instrumental PSF.

The PSF can be modelled by a simple function (Gaussian or Moffat), using a radial average brightness profile or a fits image. We will describe how AETC can manage PSFs variable in the FoV and what kinds of input are required. In particular, the user can choose between two options of input data: one (a map that describes the changes of a reference PSF model in terms of ellipticity, FWHM and position angle) well suited for existing instruments, for which the variability of the PSF can be characterized analyzing real images, and one more useful for instruments in development, a data cube of fits images of PSF computed (e.g. with ray-tracing tools) at various positions of the FoV.

The simulated images can be used to estimate the performance of a novel system, but also fed to the analysis tools to characterize the accuracy of the measurements of the science parameters on the real data. In the context of design and concept study of new telescopes and instrumentation, AETC offers the possibility to evaluate the science capability, performing end-to-end simulations of specific science cases. To exemplify the AETC capabilities we will present a number of simulations for specific science cases, useful for studying the capabilities of next generation AO imaging cameras for Extremely Large Telescopes.

9911-35, Session 8

Evaluation of the alignment plan for the Thirty Meter Telescope using optical modeling

Byoung-Joon Seo, Carl R. Nissly, Mitchell Troy, Jet Propulsion Lab. (United States) and California Institute of Technology (United States); John Rogers, Scott C. Roberts, Thirty Meter Telescope (United States)

We present an estimate of the optical performance of the Thirty Meter Telescope (TMT) after execution of the full telescope alignment plan. The TMT alignment is performed by the Global Metrology System (GMS) and the Alignment and Phasing System (APS). The GMS first measures the locations of the telescope optics and instruments as a function of elevation angle. These initial measurements will be used to adjust the optics positions and build initial elevation look-up tables.

After this step, the telescope is aligned using starlight as the input for the APS at multiple elevation angles. APS measurement is used to refine the telescope alignment to build elevation and temperature dependent look-up tables. Due to the number of degrees of freedom in the telescope (over 10,000), the ability of the primary mirror to correct aberrations on other optics, the tight optical performance requirements and the multiple instrument locations, it is challenging to develop, test and validate these alignment procedures. In this paper, we consider several GMS and APS operational scenarios. We apply the alignment procedures to the model-generated TMT, which consists of various quasi-static errors such as polishing errors, passive supports errors, thermal and gravity deformations. Using an integrated optical model and Monte-Carlo framework, we evaluate TMT's aligned states using optical performance metrics at multiple instrument and field of view locations. The optical performance metrics include the Normalized Point Source Sensitivity (PSSN), RMS wavefront error before and after Adaptive Optics (AO) correction, pupil position change, and plate scale distortion.

9911-36, Session 8

An extensive coronagraphic simulation applied to LBT

Daniele Vassallo, Elena Carolo, Jacopo Farinato, Maria Bergomi, INAF - Osservatorio Astronomico di Padova (Italy); Mariangela Bonavita, The Royal Observatory, Edinburgh (United Kingdom); Alexis Carlotti, Institut de Planétologie et d'Astrophysique de Grenoble (France); Davide Greggio, Demetrio Magrin, Dino Mesa, INAF - Osservatorio Astronomico di Padova (Italy); Enrico Pinna, Alfio Timothy Puglisi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Christophe Vérinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France); Valentina Viotto, INAF - Osservatorio Astronomico di Padova (Italy); Marco Stangalini, INAF - Osservatorio Astronomico di Roma (Italy)

Coronagraphy is a widely adopted technique in current direct imaging instruments to address any scientific case that requires high contrast very close to a bright target, where diffraction usually prevents from achieving it. A coronagraph is characterized by a few key parameters: contrast, inner working angle, throughput and sensitivity to low-order aberrations. The large number of techniques currently known basically address in different ways the fundamental problem of the trade-off among them.

This article summarizes the results of a simulation program aimed at exploring different coronagraphic solutions for SHARK NIR, an instrument approved to proceed to the final design phase at Large Binocular Telescope. For the purpose, a dedicated simulation tool has been developed. The code is written in IDL language and makes use of the Physical Optics Propagation (POP) library PROPER. As a POP code, it performs propagation of electric field wavefronts through SHARK optical train according to scalar theory of diffraction, in an end-to-end fashion. The best Fresnel propagator at any position along the propagation axis is automatically selected by means of simultaneous propagation of a Gaussian pilot beam. The fully reflective design currently foreseen for the camera, as well as the absence of highly aspherical surfaces, make PROPER an optimal tool for the undergoing study.

The tool currently implements a set of coronagraphic techniques that have been identified as conceptually suitable for SHARK: from the classical Lyot and its variants (such as focal plane masks with Gaussian transmission profile in place of hard edge ones), to more advanced concepts such as Shaped Pupil or Apodized Lyot coronagraphs. However, any kind of technique can be easily implemented, with the only requirement of compatibility with the optical design.

As input, simulations use synthetic data-cubes of wavefront residuals after AO correction specifically generated for FLAO (the LBT XAO system) and corresponding to different values of seeing and guide star magnitudes, spanning a Strehl range going from ≥90% down to ≈30%. Optical aberrations not sensed by the AO system (NCPA) can be also introduced in a flexible way, via adjustable input parameters such as total amount in rms, power spectrum shape and temporal evolution law. The latter property is as critical as difficult to model, so particular attention has been dedicated to it.

Finally, the tool allows to generate multiple coronagraphic images in sequence, ready then to be processed by differential imaging pipelines (e.g. ADI) in order to compute ultimate detection limits of the camera in a given configuration. Real-time AO correction through the entire sequence ensures a realistic estimation of atmospheric speckles contribution to noise after post-processing (at the expense of computational time).

9911-37, Session 8

Measurement of vibration source amplitudes including a low-vibration centralized cryocooling system against the TMT AO performance vibration budget

Hugh A. Thompson, Douglas G. MacMartin, Thirty Meter Telescope (United States)

A key item element in the TMT AO image quality budget is an allocation of AO-corrected wavefront error to vibration (both image jitter due to relative motion of main optical elements and the effects of dynamic motion of individual primary mirror segments). This system allocation has been further subdivided into contributions from individual vibration sources at various locations in the TMT observatory both on and off the telescope. This vibration budget was allocated based on the results of finite element modelling of the system and guesses about the relative source strength of different vibrating equipment. Since that initial allocation, we have measured force amplitudes for a number of potential sources of vibration that may be installed at the TMT observatory. We report these results evaluating them against the specific frequency filter used in the TMT vibration budget. These include an evaluation of a range of possible cryocooling systems for the TMT instruments. These results help us to determine both the suitability of the equipment for TMT and the feasibility of our current vibration budget allocations.

9911-38, Session 8

Using frequency response functions to manage image degradation from equipment vibration in the Daniel K. Inouye Solar Telescope

William R. McBride II, National Solar Observatory (United States); Daniel R. McBride, Univ. of California, Davis (United States)

The Daniel K Inouye Solar Telescope (DKIST) will be the largest solar telescope in the world, providing a significant improvement in the resolution of solar images and magnetic field data available to the scientific community.

As with any large-aperture high-performance telescope, vibration of the telescope optics can degrade image quality. In fact, it is not unusual for this vibration to be the limiting factor in the resolution of a large telescope. Vibration mitigation is even more critical in long focal-length telescopes such as the Inouye Solar Telescope, especially when adaptive optics are employed to correct for atmospheric seeing.

An approach to managing this problem is described in the literature including the concept of a vibration error budget along with techniques to measure the mechanical transfer functions.

We have pieced together, from these and other sources, a method to quantify the transfer function, called the compliance frequency response function, between equipment mount points and telescope image motion. This method uses a large instrumented inertial-mass shaker to vibrate the telescope structure over a range of frequencies, while simultaneously using accelerometers to measure the response of the system at the mirror mounts (with dummy mirrors in place).

We then take the data, apply statistical and filtering methods for noise suppression and perform a discrete fast Fourier transform (FFT) to convert it to the frequency domain.

Using digital signal processing techniques, we estimate the transfer function between the shaker location and the various mirror mounts. Utilizing the sensitivity matrix from the telescope optical analysis, these displacements and rotations are transformed directly into units of image motion on the focal plane.

The results of these analyses are a set of frequency response functions between vibration source locations and image motion. These data are then used to determine the sensitivity of various locations in and around the telescope mount so that vibration error budgets can be established for each piece of equipment on the telescope mount.

This approach allows the DKIST engineers to design vibration-reducing solutions with accurate knowledge of the level of mitigation that must be achieved to realize the diffraction-limited image quality requirement.

Measurements were taken on the Inouye Solar Telescope mount assembly during the factory acceptance campaign. In this paper, we describe the data acquisition equipment, measurement approach, data analysis, results, and lessons learned.

9911-39, Session 8

Analysing the impact of vibrations on E-ELT primary segmented mirror

Babak Sedghi, Michael Müller, Martin Dimmler, European Southern Observatory (Germany)

The E-ELT primary mirror is 39m in diameter composed of 798 segments. It is exposed to external large but slow amplitude perturbations, mostly gravity, thermal and wind. These perturbations are efficiently rejected by a combination of edge sensor loop and adaptive optics (AO) in order to leave a small residual wavefront errors (WFE).

Vibrations induced by various equipment in the observatory are typically smaller amplitude but often higher frequency perturbations exceeding the rejection capabilities of these control loops. They generate both, low spatial frequency and high spatial frequency WFE. Especially segment phasing errors, i.e. high spatial frequency errors, cannot be compensated by AO. The effect of vibrations is characterized by excitation sources, transmission of the telescope structure and segment support, they all together define the WFE caused by M1 due to vibrations. It is important to build a proper vibration error budget and specification requirements from an early stage of the project.

This paper presents the vibration analysis and budgeting approach developed for E-ELT M1 and addresses the impact of vibrations onto WFE.

9911-40, Session 9

On the precision of aero-thermal simulations for TMT

Konstantinos Vogiatzis, Hugh A. Thompson, Thirty Meter Telescope (United States)

Environmental effects on the Image Quality (IQ) of the Thirty Meter Telescope (TMT) are estimated by aero-thermal numerical simulations. These simulations utilize Computational Fluid Dynamics (CFD) to estimate, among others, thermal (dome and mirror) seeing as well as wind jitter and blur. As the design matures, guidance obtained from these numerical experiments can influence significant cost-performance trade-offs and even component survivability.

The stochastic nature of environmental conditions results in the generation of a large computational solution matrix in order to statistically predict Observatory Performance. Moreover, the relative contribution of selected key subcomponents to IQ increases the parameter space and thus computational cost, while dictating a reduced prediction error bar.

The current study presents the strategy followed to minimize prediction time and computational resources, the subsequent physical and numerical limitations and finally the approach to mitigate the issues experienced. In particular, the paper describes a mesh-independence study, the effect of interpolation of CFD results on the TMT IQ metric, and an analysis of the sensitivity of IQ to certain important heat sources and geometric features.

9911-41, Session 9

Initial computational fluid dynamics modeling of the Giant Magellan Telescope site and enclosure

Ryan Danks, William Smeaton, Rowan Williams Davies & Irwin Inc. (RDWI) (Canada); Bruce C. Bigelow, William S. Burgett, GMTO Corp. (United States)

In the era of extremely large telescopes (ELTs), with telescope apertures growing in size and tighter image quality requirements, maintaining a controlled observation environment is critical. This means that the geometry of the telescope's enclosure now plays an increasingly important role, thus requiring a more detailed understanding of how a proposed enclosure design will interact with the local wind microclimate on site.

Image quality is directly influenced by thermal gradients and the level of turbulence present in the incoming ambient air flow. Both of these factors decrease with height above grade, so a key function of any ELT enclosure is to minimize the infiltration of the ground layer air into the enclosure. Because wind forces on the telescope and its optics increase with the size of the telescope, a second key function of the enclosure of an ELT is to provide a means of modulating the velocity and direction of airflow through the enclosure and on the telescope. However, gaining an a priori

understanding of the wind environment's impacts on a proposed telescope can be challenging. It is complicated by the fact that telescopes are usually located in remote, mountainous areas. Such locations often do not have high quality historic records of the wind conditions, and can be subject to highly complex flow patterns that may not be well represented by the traditional analytic approaches used in the design of typical buildings.

As part of the design process for the planned Giant Magellan Telescope (GMT) at Cerro Las Campanas, Chile; the authors have conducted parametric design study to assess how the telescope's position on the leveled mesa, its ventilation configuration and the design of the enclosure and windscreens could be optimized to minimize the infiltration of grade level ambient air. The study consisted of several dozen computational fluid dynamics (CFD) simulations. These simulations initially investigated the wind microclimate on the mesa under existing conditions to understand the naturally occurring variations in wind flows across the site. Further simulations were then conducted of two enclosure concepts with various enclosure venting and windscreen options employed, at three locations on the mesa. The air flow rates into the telescope enclosure from each of the simulations was then predicted and compared. This comparative data set was then used to inform decision making related to the design and siting of the GMT.

9911-42, Session 9

Site and enclosure CFD modeling and analysis for the Giant Magellan Telescope

John A. Ladd, Jeffrey Slotnick, William P. Norby, The Boeing Co. (United States); Bruce C. Bigelow, William S. Burgett, GMTO Corp. (United States)

The Giant Magellan Telescope (GMT) is currently planned for construction at a summit at the Las Campanas Observatory (LCO) in Chile. As one of the next generation of extremely large telescopes (ELTs), GMT will be one of the most powerful ground-based telescope in operation in the world. Due to the larger aperture envisioned for GMT, characterization and control of the air flow entering and circulating within the enclosure will be required to maintain the highest possible image quality. Aero-thermal interactions between the site topography, enclosure, internal systems, and optics are complex. A key parameter for optical quality is the thermal gradient between the terrain and the air mass entering the enclosure, and how quickly that gradient can be dissipated to equilibrium. Because the thermal gradients are highest near the ground, an important function of the GMT enclosure is to minimize the flow of ground-layer air entering the enclosure. Moreover, the enclosure must also provide a means to modulate the magnitude and direction of the flow velocity on the telescope optical system to minimize wind loading and vibration. Thus, to ensure the highest quality GMT optical performance, computational fluid dynamics (CFD) models and specialized analyses are utilized to examine airflow over the leveled mesa on the peak at LCO, the airflow conditions around two GMT enclosure concepts located at three possible sites on the summit mesa, and the impacts of enclosure soffit geometry, ventilation configurations, and windscreens on airflow through the telescope and enclosure.

High-fidelity Reynolds-Averaged Navier Stokes (RANS) CFD analysis of the GMT, enclosure, and LCO terrain is performed using the Ansys Fluent software package. In this work, CFD is used to specifically study (a) the impact of either an open or closed enclosure base soffit external shape design, (b) the effect of telescope/enclosure location on the mountain summit, and (c) the effect of enclosure venting patterns and windscreens on the airflow entering the enclosure. In the final paper, details on geometry modeling of the GMT telescope, enclosure, and LCO terrain, and associated unstructured mesh discretization are first described. Then, results from a set of flow solutions are shown to quantify the quality of the airflow entering the GMT enclosure based on soffit, site location, and venting and windscreen considerations. Based on the results, conclusions on GMT soffit design, site location, and enclosure venting will be discussed and presented.

9911-43, Session 9

Thermal control modeling approach for GRAPE (GRAntecan PolarimEter)

Igor DiVarano, Klaus G. Strassmeier, Manfred Woche, Leibniz-Institut für Astrophysik Potsdam (Germany)

GRAPE is the polarimeter planned to be installed on the main Cassegrain focus of GTC (Gran Telescopio Canarias), having an equivalent entrance pupil of 10.4 m, located at the Observatorio del Roque de los Muchachos , in La Palma, Canary Islands. It's meant to deliver full Stokes (IQUV) polarimetry covering the spectral range 0.420-1.6 um, in order to feed the HORS instrument (High Optical Resolution Spectrograph), mounted on the Nasmyth platform, which has a FWHM resolving power of about 25,000 (5 pixel) designed for the wavelength range of 380-800 nm. Two calcite blocks and a BK-7 prism arranged in a Foster configuration are splitting the Ø12.5mm collimated beam into the ordinary and extraordinary components. The entire subunit from the Foster prisms down to the input fibers is rotated by steps of 45 degrees in order to retrieve Q, U components. By inserting a quarter wave retarder plate before the entrance to the Foster unit circular polarization is measured too.

The current paper consist of two main parts: at first thermal analysis simulations are introduced, which have been run compliant to the specifications derived by the environmental conditions and the transient thermal gradients (°C/h) taking into account the motors and lamps installed; then a thermal control model is proposed to minimize the image quality degradation at different exposure times when compensation via passive insulation is not enough. The tools deployed to achieve such goal are the ANSYS Multiphysics and Fluent package, Zemax and several Python/Matlab scripts to import into Zemax the surface motions and the different refractive indices values depending on the temperature distribution.

9911-44, Session 9

Improvements in optomechanical analysis techniques for segmented mirror arrays

Gregory J. Michels, Victor L. Genberg, Gary R. Bisson, Sigmadyne, Inc. (United States)

The employment of actively controlled segmented mirror architectures has become increasingly common in the development of current astronomical telescopes. Optomechanical analysis of such hardware presents unique issues as compared to that of monolithic mirror designs. The work presented here is a review of current capabilities and improvements in the methodology of the analysis of mechanically induced surface deformation of such systems. The recent improvements include capability to differentiate surface deformation at the array and segment level. This differentiation allowing surface deformation analysis at each individual segment level offers useful insight into the mechanical behavior of the segments that is unavailable by analysis solely at the parent array level. In addition, capability to characterize the full displacement vector deformation of collections of points allows analysis of mechanical disturbance predictions of assembly interfaces relative to other assembly interfaces. This capability, called racking analysis, allows engineers to develop designs for segment-to-segment phasing performance in assembly integration, 0g release, and thermal stability of operation. The performance predicted by racking has the advantage of being comparable to the measurements used in assembly of hardware. Approaches to all of the above issues are presented and demonstrated by example with SigFit, a commercially available tool integrating mechanical analysis with optical analysis.

9911-45, Session 10

End-to-end (E2E) simulations for small space telescopes: a case study

Sara R. Heap, NASA Goddard Space Flight Ctr. (United States); Tony B. Hull, The Univ. of New Mexico (United States); Lloyd R. Purves, NASA Goddard Space Flight Ctr. (United States)

Large astronomical missions are usually general-purpose telescopes with a suite of instruments optimized for different wavelength regions, spectral resolutions, etc. Their E2E simulations are typically photons-in to flux-out calculations made to verify that each instrument meets its performance specifications. In contrast, smaller space missions are usually single-purpose telescopes, and their E2E simulations start with the scientific question to be answered and end with an assessment of the effectiveness of the mission in answering the question. Thus, E2E simulations for small mission concepts are broader in scope than for large missions, as they include not only the telescope and instrumentation, but also the spacecraft, orbit, and external factors such as coordination with other telescopes. We will illustrate the strategy and organization of small-mission E2E simulations using the Galaxy Evolution Spectroscopic Explorer (GESE) as a case study. GESE is an Explorer/Probe-class space mission concept with the primary aim of answering the scientific question of why star formation in galaxies started to decline after reaching a peak when the universe was only 3 billion years old and continues to decline to this day.

9911-46, Session 10

An integrated modeling framework for the Large Synoptic Survey Telescope (LSST)

George Z. Angeli, Bo Xin, Charles Claver, LSST (United States); Myung Kyu Cho, Christoph Dribusch, National Optical Astronomy Observatory (United States); John Ku, SLAC National Accelerator Lab. (United States); Douglas G. MacMartin, California Institute of Technology (United States); Douglas Neill, LSST (United States); Martin E. Nordby, SLAC National Accelerator Lab. (United States); John Peterson, Purdue Univ. (United States); Jacques Sebag, Sandrine J. Thomas, LSST (United States)

All of the components of the LSST subsystems (Telescope and Site, Camera, and Data Management) are in production, either by vendors or by in-house engineering teams. The major systems engineering challenges in this early construction phase are establishing the final technical details of the observatory, and properly evaluating the change and deviation requests due to financial and technical constraints emerging from the detailed design and manufacturing process. To meet these challenges, the LSST Project Systems Engineering team established an Integrated Modeling (IM) framework including (i) a high fidelity optical model of the observatory, (ii) an atmospheric aberration model, and (ii) perturbation interfaces capable of accounting for quasi static and dynamic variations of the optical train. The IM can also be coupled to a comprehensive astronomical sky model, making it feasible to image individual bright or faint stars (point sources), or generating a fully populated focal plane image with stars and galaxies.

The model described is integrated in the sense that it constitutes a joint simulation of optics, structure, and control in an integrated fashion. This integrated model supports the periodic evaluation of two key LSST Measures of Performance: image quality and ellipticity, i.e. the size and shape of the system PSF across the 3.5 degrees field of view. Image quality is characterized by two connected, but not equivalent metrics: the (i) real FWHM of the PSF, and the (ii) effective FWHM characterizing the background limited photometric depth (detection limit) of the system. The latter one is equivalent to the system Point Source Sensitivity (PSSN), relating the expected photometric depth to the absolute atmospheric detection limit.

At the front end, the IM is linked to environmental and operational parameters, as well as to the structural and thermal finite element models of the system. Manufacturing, assembly, and alignment tolerances are included, together with the open loop (LUT) corrections and compensations for these errors. Furthermore, the feedback loops utilizing mechanical (encoder) and thermal sensors, and optical (guider and WFS) information can be investigated by the tools developed.

The paper will include actual examples for applying the established framework. LSST has four curvature wavefront sensors to monitor and control its image quality. In a recent trade study, the separation of their intra and extra focal images was optimized by applying the high fidelity optical and atmospheric IM tools. The envisioned control strategy for the LSST Active Optics System (AOS) was verified by extensive simulations in the presence of the expected atmosphere and system perturbations. A brief summary of the methods and results will demonstrate the comprehensive nature of the framework. Finally, the investigation of the feasibility of additional structural dampers will be reported, as an example for the dynamic application of the tool.

9911-47, Session 10

Science yield modeling with EXOSIMS

Christian Delacroix, Dmitry Savransky, Daniel Garrett, Cornell Univ. (United States)

Estimating the science yield of a space mission constitutes an essential way of selecting and refining the most appropriate technologies or instruments. In the case of an exoplanet imaging mission, it identifies specification cases likely leading to zero detections, and allows avoiding a worst case scenario. The Exoplanet Open-Source Imaging Mission Simulator (EXOSIMS) is designed to allow for systematic exploration of expected science yields over the course of a specific mission, and is currently being developed as part of the WFIRST-AFTA Preparatory Science investigation. Here, we report on our ongoing development of EXOSIMS and mission simulation results for WFIRST-AFTA. We present the interface control and the modular structure of the software, along with corresponding prototypes and class definitions for each of the modules, e.g. planet population, star catalog, optical system, background sources, post-processing, etc. This modular structure allows users to investigate multiple missions or system designs by only modifying individual modules without having to redefine the unaffected ones. More specifically, we also provide a full set of modules dedicated to WFIRST-AFTA. In that context, we show and discuss the results of some preliminary WFIRST-AFTA simulation ensembles, i.e. collections of a large number of survey simulations, using different envisioned coronagraph instruments. We focus on simulating a mission using both the Hybrid Lyot Coronagraph (HLC) and the Shaped Pupil Coronagraph (SPC) for detection and characterization, respectively. The analysis of such simulation ensembles leads to decisive conclusions regarding the coronagraph instrument operation, such as (i) optimal target selection, (ii) optimal time spent on imaging known planets vs. detecting new ones, (iii) optimal operating points in terms of detection band. EXOSIMS will continue to be further developed through the final release in May of 2017, and will be used to continuously refine the modeling of the WFIRST-AFTA coronagraph science.

9911-48, Session 10

Structural, thermal, and optical performance (STOP) modeling and results for the James Webb Space Telescope integrated science instrument module

Renee Gracey, Ball Aerospace & Technologies Corp. (United States); Andrew E. Bartoszyk, NASA Goddard Space Flight Ctr. (United States); Emmanuel Cofie, SGT, Inc. (United States); Brian J. Comber, Genesis Engineering Solutions, Inc. (United States); George F. Hartig, Space Telescope Science Institute (United States); Derek S. Sabatke, Ball Aerospace & Technologies Corp. (United States); Greg W. Wenzel, Sierra Lobo, Inc. (United States); Raymond G. Ohl IV, NASA Goddard Space Flight Ctr. (United States)

The James Webb Space Telescope (JWST) is a general astrophysics mission which consists of a 6.6m diameter, segmented, deployable telescope for cryogenic IR space astronomy (~40K). The JWST Observatory architecture includes the Optical Telescope Element and the Integrated Science Instrument Module (ISIM) element. ISIM contains four science instruments (SI) and a Guider mounted to a composite metering structure. ISIM is optically tested at NASA Goddard Space Flight Center using a telescope simulator (Optical telescope element SIMulator; OSIM). OSIM is a high-fidelity, cryogenic JWST telescope simulator that features a ~1.5m diameter powered mirror.

We performed extensive Structural, Thermal, and Optical Performance (STOP) modeling in support of all phases of ISIM development. In this paper, we focus on modeling and results associated with test and verification. While ISIM's ground testing is comprehensive, a perfect, on-orbit test environment does not exist or would be difficult to create (e.g., 0-g effects, flight-like thermal gradients). We used STOP modeling to predict system performance in 0g and various temperature environments. The on-orbit predictions are used to translate ground test results to on-orbit performance. We used tests to validate our models (i.e., g-release, co-boresight, and jitter testing) to build confidence in our predictions for on-orbit performance.

The integrated STOP model is composed of structural, thermal and optical models. The OSIM and SI teams developed structural (i.e., finite element model; FEM) and optical (i.e., ray trace) models that were delivered to ISIM. We developed NASTRAN, CodeV, and Thermal Desktop models of ISIM's composite metering structure, OSIM, and other test equipment. We defined and added six degree of freedom reference "nodes" to the structural and optical models. The nodes were located at the critical opto-mechanical positions. The structural models were offset by the changes induced by thermal changes and the resultant node offsets were used to alter the optical models and predict performance.

STOP analysis started early in the JWST program and its role evolved. For example, the nodes were initially set prior to SI integration and test. As the SIs progressed through their builds, the models were updated to represent as-built locations. Each SI model delivery was tracked through configuration management and the STOP models were revised and tracked.

We report the STOP analysis results used for g-release, jitter, co-boresight, boresight, pupil shear/roll, wavefront error, and focus, including the alignment mechanism offsets needed to account for ground to orbit changes. Early in the development of the ISIM ground test program, we used this analysis to understand the impact of the cryogenic test environment on these parameters. For example, ISIM has a co-boresight alignment requirement that is challenging to measure via test. We used STOP analysis to design the co-boresight test and predict the output. After the test was complete, we used the results to validate the STOP model. Similarly, an ambient g-release test was performed on ISIM using metrology, validating the structural model. These validation tests were a check against possible workmanship errors that might contribute to systematic error in our on-orbit performance predictions.

9911-49, Session 10

Exploring possible Large Synoptic Survey Telescope (LSST) surveys with the LSST operations simulator and delivering a reference simulated survey

Kem H. Cook, Cook Astronomical Consulting (United States) and LSST (United States); Francisco Delgado, Catherine E. Petry, Michael A. Reuter, LSST (United States); Stephen T. Ridgway, National Optical Astronomy Observatory (United States); R. Lynne Jones, Peter Yoachim, Andrew J. Connolly, ?eljko Ivezic, Univ. of Washington (United States)

The operation simulator (OpSim) for the Large Synoptic Survey Telescope (LSST) models the sequences of observations that might be undertaken by the survey given the properties of the site, telescope and camera, and the science goals of the project. OpSim simulations have been used to inform the LSST site selection process and drove the move from the originally proposed 3 degree field-of-view to the current 3.5 degrees. OpSim simulations have also been used to optimize mechanical specifications of the LSST including various motor power capabilities, heat dissipation and cable wrap details. OpSim reads database tables for cloud cover and seeing, calculates sky brightness values across the sky and references internal science proposals which request observations under conditions appropriate to the science case. The requested observations are weighted with relatively simple algorithms and the most highly valued observation is taken. There is no look-ahead and this algorithm is commonly described as a 'greedy' algorithm (see Delgado et. al. SPIE_9150-39 for more details). All aspects of an observation are saved in MySQL database tables. The output is analyzed using a custom tool, the Metrics Analysis Framework (MAF). Two sets of metrics are typically run on a simulation's output, one focussing on the performance and behavior of OpSim and another set focussing on a science analysis.

Recent simulations have focussed on exploring different science proposal sets and science proposal parameters. There are two basic types of science proposals, time domain and area, with a wide range of variations within each depending upon the values of hundreds of parameters. The key proposal is the Wide Fast Deep proposal (WFD) which attempts to collect 18,000 square degrees with 825 visits to each field in 10 years in sets to optimize NEO detection. This proposal meets a primary design goal of the LSST Science Requirements Document. The requested WFD observations leave about 20% of the 10 year survey available for other proposal. The main non-WFD proposals we have been investigating cover the Milky Way plane, the South Celestial Pole, the region of the ecliptic north of the WFD area and various sets of fields with intense sampling (Deep Drilling fields) for depth and time sampling.

We present the MAF analyses (which are available via web browser) of a set of simulations exploring various combinations of these proposals as well as variations in parameters governing the proposals (eg airmass, seeing, sky brightness limits). These runs are available to the community for analyses specific to a particular investigator's interests. Both MAF and OpSim are publicly available.

Finally, we describe the 2015 baseline LSST survey simulation, the assumptions that go into this simulation, and the resulting observational characteristics of such a survey. In subsequent years, we expect to publish updated baselines as we better understand the properties of the delivered LSST system, the response of the science to different observing strategies, and enhancements in the algorithms used to schedule the telescope.

9911-50, Session 10

Creating the right atmosphere: analyzing extensive telemetry data to create more realistic, computationally efficient atmosphere models for end-to-end simulations

Srikar Srinath, Univ. of California, Santa Cruz (United States); Lisa A. Poyneer, Lawrence Livermore National Lab. (United States); Donald T. Gavel, Alexander R. Rudy, Univ. of California, Santa Cruz (United States); S. Mark Ammons, Lawrence Livermore National Lab. (United States)

End-to-end simulation of the next generation of telescopes, their adaptive optics systems, instrumentation, and control systems is a necessity given their high cost and complexity. Underpinning all simulations is the atmosphere model through which wavefronts from artificial (i.e. simulated) sources accumulate phase errors and are then propagated through a representation of the telescope's optics to observe the effect on the system's point spread function (PSF). At the level of detail required for error budgets in large, complex systems standard assumptions like Kolmogorov (or von Karman) turbulence and Taylor frozen flow are no longer adequate representations of reality. In our prior work we have demonstrated that adding even small amounts of "boiling" to atmosphere models results in drastic degradations in figures of merit such as contrast ratio for direct exoplanetary imagers (like the Gemini Planetary Imager (GPI)) or PSF spatial variability for wide field telescopes (e.g. Large Synoptic Survey Telescope or LSST). GPI attributes a four-fold increase in on-sky bandwidth error versus estimated performance to simplistic atmosphere models used in simulations.

Using an autoregressive (AR) model to fit extensive telemetry data gathered by GPI and the ShaneAO system at Lick Observatory, we demonstrate the utility of an atmospheric model with multiple degrees of freedom to match real-world conditions. Phase screens generated using the AR method have power spectral densities (PSD) tailored to match measured PSDs, incorporate stochastic content at each time step to simulate "boiling", accommodate multiple wind layers of varying wind velocity and direction, set statistical parameters like coherence length (r0) and outer scale (L0) for each wind layer, and evolve them in time in a manner consistent with measured data. By operating primarily in the Fourier domain, this model creates realizations of phase screens that are computationally efficient and sparing in their use of memory, thus enabling simulations of long exposures, telescopes with large apertures or wide fields of view. The addition of stochastic content at each timestep also mitigates periodicity issues associated with sample-based phase screen generation methods. The method is simple to implement in any optical simulation environment and source code is readily available and freely licensed for immediate use. It has extended the capabilities of the GPI adaptive optics simulator by enabling long-exposure simulations that model the effect of slow time-varying aberrations. LSST simulations exploit the AR method's memory efficiency to reduce the size of phase screens used and the ability to introduce stochastic variations to observe their effect on PSF stability.

Conference 9912: Advances in Optical and Mechanical Technologies for Telescopes and Instrumentation

Sunday - Friday 26–1 July 2016

Part of Proceedings of SPIE Vol. 9912 Advances in Optical and Mechanical Technologies for Telescopes and Instrumentation II

9912-1, Session 1

A prototype of the NFIRAOS to instrument thermo-mechanical interface

Alexis Hill, Peter W. G. Byrnes, Glen Herriot, Vladimir A. Reshetov, Kei Szeto, Joeleff Fitzsimmons, Evan Poulton, Sam Lambert, National Research Council Canada (Canada); Calvin Winter, Yan Pennec, Quantum Technology Corp. (Canada)

The Narrow Field InfraRed Adaptive Optics System (NFIRAOS) is the first-light facility Adaptive Optics (AO) system for the Thirty Meter Telescope (TMT), located on the Nasmyth platform. NFIRAOS accepts light from the telescope, corrects it and selectively feeds it to a collection of client instruments at dedicated instrument ports, including planned science instruments: IRIS and IRMS. NFIRAOS optical components are maintained in a controlled cold environment; the NFIRAOS enclosure provides this function by using a refrigeration system embedded in its walls to intercept heat from its surroundings. NFIRAOS also includes three sealed instrument interface ports.

In order to meet the optical performance and stability specifications, all of the optical components within NFIRAOS are protected within the large enclosure maintained at -30°C ± 0.5°C, as well as staying clean and dry. The walls of the enclosure consist of thermally insulated panels with actively cooled aluminum thermal conduction plates to intercept the heat flux from the environment. Three of the insulated panels are modified to be used as dedicated instrument ports. Instruments are not permitted to disrupt the internal environment of the NFIRAOS enclosure. This is complicated by the fact that NFIRAOS and the instruments do not have a window to separate them and because instruments rotate with respect to NFIRAOS on a large mechanism. Sealing from the external TMT environment at this interface is accomplished using a set of rotating seals. Additionally, due to long warm-up and cool-down times for NFIRAOS, the instruments must be installed and removed while at -30°C without allowing any influx of warm, humid, dirty air creating concerns about humidity/frost and contamination during instrument changes. It was decided that a prototype of both the instrument interface and the enclosure wall panel would be a cost-effective risk reduction strategy.

The prototyping activity was separated into two stages. The first stage was to build one section of the enclosure wall, integrate it into an existing freezer room and assess performance and manufacturability. Temperature homogeneity was measured over the length of the wall panel while freezer simulated the internal NFIRAOS environment. Temperature stability over time was also measured. The second stage of activity was to build the instrument side of the interface and test for temperature stability (of the rotating seal), frost accumulation and the instrument change process. Of particular interest was to find out whether rotating seals in the interface would leak or freeze. Issues have been identified which are being flowed into the final design of the enclosure and the interface to the instruments. For example, while testing for frost accumulation, it was determined that there needs to be a localized re-heat cycle at the instrument port to avoid frost build-up on the NFIRAOS side of the interface.

Enclosure prototyping effort has been performed to reduce risk and identify design, operational and manufacturing issues. One wall panel of the actively cooled enclosure and a half-scale version of the instrument interface have been prototyped at NRC-Herzberg. Results of testing and lessons learned from prototyping are presented here.

9912-2, Session 1

Polarization dOTF: on-sky focal plane wavefront sensing

Matthew A. Kenworthy, Keira Brooks, Leiden Observatory (Netherlands); Laure Catala, South African Astronomical Observatory (South Africa); Steven M. Crawford, South African Astronomical Observatory (South Africa) and Leiden Observatory (Netherlands); Johanan L. Codona, The Univ. of Arizona (United States)

Differential Optical Transfer Function (dOTF) is a focal plane wavefront sensing method that uses a diversity in the pupil plane to generate two different focal plane images. The difference of their Fourier transforms recovers the complex amplitude of the pupil to the spatial scale of the diversity. We produce two simultaneous PSF images with diversity using a polarizing filter at the edge of the telescope pupil, and a Polarization Camera to simultaneously record the two images. Here we present the first on-sky demonstration of polarization dOTF at the 1.0m South African Astronomical Observatory telescope in Sutherland, and our attempt to validate it with simultaneous Shack-Hartmann wavefront sensor images.

9912-3, Session 1

Electromagnetic deformable mirror development at TNO

Stefan Kuiper, Jet Human, TNO Technical Sciences (Netherlands); Niek Doelman, TNO Technical Sciences (Netherlands) and Leiden Observatory (Netherlands)

Modern astronomy often relies on adaptive optics to improve the overall imaging performance, utilizing a deformable mirror (DM) to compensate for aberrations stemming from for instance turbulences in the atmosphere. Over the last decade TNO developed a deformable mirror concept using electromagnetic actuators with the main advantages of having very low non-linearity and hysteresis, low power consumption, and the inherent high reliability of these actuators. The latter is due to the fact that the electromagnetic actuators do not suffer from any material aging or depolarization.

TNO recently started a program to redesign the electromagnetic actuator to improve the actuator efficiency, allowing higher actuator force per volume and per unit electrical power. This is achieved by changing the actuator configuration to allow separated flux paths between the driving coil and permanent magnets used to pre-magnetize the circuit. The resulting DM design is highly scalable, with an actuator pitch from 4mm up to more than 30mm. The increased actuator efficiency can be utilized to further optimize the behavior of the deformable mirror depending in the target application. By tuning the stiffness of the actuator structure an optimal balance can be found between dynamical performance, actuation range, and power dissipation.

Another major advantages of the newly developed actuator configuration is that it allows relatively straightforward refurbishment of the mirror membrane without the need for completely dismantling the actuator structure. This will reduce the overall operating cost and risks at for the end user.

With this technology various applications in the fields of ground-based

astronomy can be targeted, and also for space missions, including both earth observation and science missions. Especially for such highly costly and critical missions, the reliability and low-power consumption of the novel DM design are considered main assets. A separate design study is conducted to evaluate and improve the DM design for the space environment.

In order to validate the actuator performance several actuator breadboards are being built and tested, demonstrating the improved actuator response. In this paper the concept of the newly developed electromagnetic DM will be explained, the results from the actuator tests will be presented, and an outlook will be given on the development of the improved electromagnetic DM concept.

9912-4, Session 1

NFIRAOS beam splitters subsystems optomechanical design

Frédéric Lamontagne, Nichola Desnoyers, Reston Nash, Louis Buteau-Vaillancourt, François Châteauneuf, INO (Canada); Marc-André Boucher, OMP inc. (Canada); Jenny Atwood, National Research Council of Canada (Canada); Alexis Hill, National Research Council Canada (Canada); Peter W. G. Byrnes, National Research Council of Canada (Canada); Glen Herriot, Jean-Pierre Véran, NRC - Herzberg Astronomy & Astrophysics (Canada)

The early-light facility adaptive optics system for the Thirty Meter Telescope (TMT) is the Narrow-Field InfraRed Adaptive Optics System (NFIRAOS). The science beamsplitter changer mechanism and the visible light beamsplitter are subsystems of NFIRAOS. The beamsplitter changer mechanism allows selection between the science beamsplitter and an engineering beamsplitter for use with the high-resolution wavefront sensor (HRWFS) during system integration. The visible light beamsplitter divides the visible light in two paths, one for the Natural Guide Star (NGS) wavefront sensor (WFS) and another for the Laser Guide Star (LGS) WFS.

This paper presents the optomechanical design of the beamsplitters subsystems. Also, the integrated optomechanical analysis approach used to evaluate the optical performance of the mounted beamsplitters under environmental constraints is detailed.

First, the transmitted and reflected wavefront error of the beamsplitters must be kept as low as possible. The size and weight of the optical components coupled with the low operating temperature of -30°C represents a challenge for the mounting strategy. Special care is taken to deal with the coefficient of thermal expansion (CTE) mismatch between the fused silica beamsplitters and the steel table structure. Also, the mass budget allowed for the science and engineering beamsplitter changer mechanism requires optimization to ensure compliance with the minimum natural frequency, handling acceleration and seismic requirements. Finally, tip/tilt alignment and positional stability over time also influence the optomechanical design solutions.

The selected mounting method for the beamsplitters uses room temperature vulcanizing (RTV) adhesive to bond each beamsplitter in its respective steel cell. The high CTE of the RTV allows to compensate for the CTE mismatch between the fused silica beamsplitters and the steel cell. The beamsplitters are bonded with RTV dots that are optimized in terms of quantity, diameter and thickness in order to minimize the WFE while maximizing the natural frequency. This mounting approach allows to use steel for all mechanical parts, providing an assembly with matched CTE from the optical cell to the table structure. This simple design imparts very low optical surface deformation on the beamsplitters and has the advantage to avoid the use of invar and flexures, which are more expensive.

A finite element model using Ansys is developed to optimize the design and to verify that all the requirements are met. In addition to the modal and the structural analyses, the beamsplitter surface deformations are computed considering the environmental constraints during operation. Surface deformations are fit to Zernikes polynomials using SigFit software. Rigid body motion as well as residual RMS and peak to valley surface deformations are calculated. Finally, deformed surfaces are exported to Zemax to evaluate transmitted and reflected wavefront error. The simulation results of this integrated optomechanical analysis have shown compliance with all optical requirements.

9912-5, Session 2

Development and test of the Ball Aerospace optical frequency comb: a versatile measurement tool for aerospace applications

Jordan Wachs, James W. Leitch, J. Scott Knight, Bob Pierce, Michael Adkins, Ball Aerospace & Technologies Corp. (United States)

The Ball Fiber Optical Comb Demo is a lab-based system which is used to develop space applications for optical frequency combs. These developments utilize the broadband optical coherence of the frequency comb to expand the capabilities of ground test and orbital systems used for optical wave-front measurement, control of adaptive optics, precision ranging, and reference frequency stabilization. The development expands upon a NIST-developed all-fiber frequency comb that exhibits high stability in a compact, enclosed package.

Previously demonstrated applications for frequency combs, include: spectroscopy, distance and velocity measurement, frequency conversion, and timing transfer. Results from the Ball system show the characterization and performance of a frequency comb system with a technological path-to-space. Demonstrations in high precision metrology and long-distance ranging are also presented for application in adaptive and multi-body optical systems.

9912-6, Session 2

A soft actuator for prototype segmented mirror telescope

Prasanna Deshmukh, Padmakar S. Parihar, Indian Institute of Astrophysics (India); Deepta Sundar Mishra, Manipal Institute of Technology (India); Ajin Prakash, Madan Mohan Kemkar, Indian Institute of Astrophysics (India)

Segmented mirror telescopes (SMT) are built using small hexagonal mirror segments placed side by side so that it works like a monolithic mirror of very large size. Optical figure of such a segmented primary mirror need to be maintained against external disturbances introduced by gravity, temperature, wind as well as structural vibration. This very important task is done by the three position actuators combined with six edge sensors per segment working at few nano-meter scale. In this paper we describe our effort to develop a force/position soft actuator for a Prototype Segmented Mirror Telescope (PSMT), under development in Indian Institute of Astrophysics, Bangalore. PSMT is a 1.3m effective diameter, seven segment test bed telescope which requires twenty one precision actuators. Our actuator is a compact, light weight, soft actuator, uses similar technology adopted in upcoming extremely large telescopes like TMT and E-ELT. We have chosen soft actuator, because it is subjected to low mechanical losses and provide high bandwidth with the ability to correct wind and vibration disturbances. The prime mover of our actuator is a Voice Coil Motor (VCM) which takes care of dynamic load on the actuator and generates required force to correct for disturbances. VCM combined with high resolution linear position encoder provides very accurate positioning ability. The output shaft of actuator is isolated from its rigid frame with the help of a

Disc Spiral Flexures (DSF) made of very thin metallic discs. This actuator also consist of an offloading mechanism which in turn offloads the static load on VCM to reduce the overall power consumption. Although, almost all components required for the actuator are custom design and built, however, we put our best efforts to minimize the production cost as much as possible and made it affordable for the PSMT which is relatively low budget project.

The VCM and DSF are designed using numerical simulation and FEM analysis technique. Detailed control analysis has also been carried out to understand the performance of the actuator in different conditions i.e. closed loop, open loop, with and without external disturbance. Based on results obtained from simulation and parametric sensitivity analysis, stable design parameters are obtained and used in the mechanical design. The actuator is designed to provide the output stroke of 2.5mm and the track rate of 324nm/s (6.5mN/s) with tracking accuracy better than 25nm. In addition to these it is also expected to have high reliability and long life. In this paper we describe electromechanical design aspects of the device and provide details on our works carried out toward modelling and simulation. Finally we present preliminary experimental results obtained from prototype actuator developed for the PSMT.

9912-7, Session 2

ZERODUR strength modeling with Weibull statistical distributions

Peter Hartmann, SCHOTT AG (Germany)

The decisive influence on breakage strength of brittle materials such as the low expansion glass ceramic ZERODUR® is the surface condition. For polished or etched surfaces it is essential if micro cracks are present and how deep they are. Ground surfaces have many micro cracks caused by the generation process. Here only the depths of the micro cracks are relevant. In any case presence and depths of micro cracks are statistical by nature.

The Weibull distribution is the model used traditionally for the representation of such data sets. It is based on the weakest link ansatz. The use of the two or three parameter Weibull distribution for data representation and reliability prediction depends on the underlying crack generation mechanisms. Before choosing the model for a specific evaluation, some checks should be done. Is there only one mechanism present or is it to be expected that an additional mechanism might contribute deviating results? For ground surfaces the main mechanism is the diamond grains' action on the surface. However, grains breaking from their bonding might be moved by the tool across the surface introducing a slightly deeper crack. It is not to be expected that these scratches follow the same statistical distribution as the grinding process. Hence, their description with the same distribution parameters is not adequate. Before including them a dedicated discussion should be performed.

If there is additional information available influencing the selection of the model, for example the existence of a maximum crack depth, this should be taken into account also. Micro cracks introduced by small diamond grains on tools working with limited forces cannot be arbitrarily deep. For data obtained with such surfaces the existence of a threshold breakage stress should be part of the hypothesis. This leads to the use of the three parameter Weibull distribution. A differentiation based on the data set alone without preexisting information is possible but requires a large data set. With only 20 specimens per sample such differentiation is not possible. This requires 100 specimens per set, the more the better.

The validity of the statistical evaluation methods is discussed with several examples. These considerations are of special importance because of their consequences on the prognosis methods and results. Especially the use of the two parameter Weibull distribution for high strength surfaces has led to non-realistic results. Extrapolation down to low acceptable probability of failure covers a wide range without data points existing and is mainly influenced by the slope determined by the high strength specimens. In the past this misconception has prevented the use of brittle materials for stress loads, which they could have endured easily.

9912-8, Session 2

Development and final design of the FAME active array

Szigfrid Farkas, MTA Research Ctr. for Astronomy and Earth Sciences (Hungary); Tibor Agócs, Gabby Aitink-Kroes, Felix C. M. Bettonvil, ASTRON (Netherlands); Emmanuel Hugot, Lab. d'Astrophysique de Marseille (France); Hermine Schnetler, UK Astronomy Technology Ctr. (United Kingdom)

FAME (Freeform Active Mirror Experiment - part of the FP7 OPTICON/FP7 development programme) intends to demonstrate the huge potential of active mirrors and freeform optical surfaces that can help to address the new challenges of next generation astronomical instruments, which are bigger, more complex and have tighter specifications than their predecessors.

The FAME design consists of a pre-formed, deformable thin mirror sheet with an active support system. The thin face sheet provides a close to final surface shape with very high surface quality. The active array provides the support, and through actuation, the control to achieve final surface shape accuracy.

In the current paper the development path, trade-offs and demonstrator design of the active array of FAME is presented. The key steps of the development process of the active array are the design of the mechanical structure and especially the optimization of the actuation node positions, where the actuator force is transmitted to the thin mirror sheet. This is crucial for the final performance of the mirror where the aim is to achieve accurate surface shapes, with low residual (high order) errors using the minimum number of actuators. The activities are based on the coupling of optical and mechanical engineering, by using analytical and numerical methods, which results an active array with optimized node and surface shape design.

The research of the design and development of a special actuator and control for FAME can be found in the paper "Thermal expansion used as a precision actuator" of this conference.

9912-9, Session 2

Stressed mirror anular polishing for scale-down TMT segments

Xinnan Li, Zibo Jiang, Xuefei Gong, Haiying Zhang, Kunxing Chen, Yi Zheng, Bo Li, Binbin Yu, Chen Xu, Bo Ji, Qiuyun Xu, Nanjing Institute of Astronomical Optics & Technology (China)

A new Stressed Mirror Polishing technology carried out on Annular polishing machine has been developed in NIAOT. Since three or more pieces of segments can be polished simultaneously on one annular polishing machine, this SMAP technology will provide higher efficiency for massive production of Off-axis segments of the extremely large telescope. With the help of a 3.6m in diameter annular polishing machine, two scale-down TMT segments have been polished using SMAP technology. Both of two segments are 1100 mm in diameter, with the radius of curvature of 60 m in the vertex and aspheric constant K=-1.000953. The off-axis distance is 8 m and 12 m respectively. After SMAP the reasonable surface accuracy is reached. The final surface accuracy is 1.12 mm PV, 0.23 mm RMS for OAD 8m segment, and 1.22 mm PV, 0.26 mm RMS for OAD 12m segment.

9912-10, Session 2

Research on key issues of large diameter off-axis aspheric segments testing

Zibo Jiang, XinNan Li, YongJun Liang, Bo Li, BinBin Yu, Zhe Chen, Nanjing Institute of Astronomical Optics & Technology (China)

The research works are summarized on 1.1m off-axis aspheric segments which are scaled-down TMT segments polished by NIAOT using SMAP (Stressed Mirror Annular Polishing) method in the previous phase and testing preparations for 1.45m mirrors. The detailed introduction is given on result of errors analysis in contact detection testing of segments. Those errors include supporting deformation caused by gravitation, detection error of reference mirror counting in interference testing by temperature gradients of air and corresponding restrain measurements, mirror alignment error in contact detection, simulation and statistics on random error of length gauges. In the second part, the selected basis of sampling number for contact-type detector arrays and the terms number of Zernike polynomials we need are studied. And the situations on orthogonality destruction of Zernike polynomials in discrete points sampling case and spectral analysis for each order Spherical aberrations in continuous sampling are introduced. Next, the selection strategy and the results of unified best-fitting sphere for dozens segments which may be processed are presented. Finally, a brief introduction is made on detection system for 1.45m segments being installed at the present stage.

9912-11, Session 3

Diamond machining of large ZnSe grisms for the Rapid Infrared/Imager Spectrograph (RIMAS)

Paul J. Kuzmenko, Steve L. Little, Lawrence Livermore National Lab. (United States); Alexander S. Kutyrev, NASA Goddard Space Flight Ctr. (United States); John I. Capone, Univ. of Maryland, College Park (United States)

The Rapid Infrared Imager/Spectrograph (RIMAS) is an instrument designed to observe gamma ray burst afterglows following initial detection by the SWIFT satellite. Operating in the near infrared between 0.9 and 2.4 μm, it has capabilities for both low resolution (R~25) and moderate resolution (R~4000) spectroscopy. Dispersion in the moderate resolution mode is provided by a pair ZnSe grisms: one covering the Y and J bands and the other covering the H and K. Each has a clear aperture of 40 mm. The YJ grism has a blaze angle of 42.8º and a periodicity of 25 lines/mm. For the HK grisms the blaze is 57º with a 20 line/mm periodicity.

The grisms are being diamond machined on the Precision Engineering Research Lathe (PERL) at LLNL. Details of the fabrication and results of optical testing will be reported.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

9912-12, Session 3

Polishing techniques for MEGARA optics

Rafael Izazaga-Pérez, Esperanza E. Carrasco-Licea, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Alfonso J. Salas-Sánchez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico) and Univ. Autónoma de Sinaloa (Mexico); Daniel Aguirre-Aguirre, Univ. Nacional Autónoma de México (Mexico) and Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico (Mexico); Armando Gil de Paz, Jesús Gallego Maestro, Univ. Complutense de Madrid (Spain); Jorge Iglesias-Páramo, Instituto de Astrofísica de Andalucía (Spain)

MEGARA (Multi-Espectrógrafo en GTC de Alta Resolución para Astronomía) is the new integral-field and multi-object optical spectrograph for the 10.4m Gran Telescopio Canarias, now under the construction. It will offer spectral resolutions in the range of R=6000-20000.The dispersive elements are volume phase holographic (VPH) gratings, sandwiched between two flat Fused Silica windows of high optical precision in large apertures. The design, based in VPHs in combination with prisms made of Ohara PBM2Y optical glass allows to keep the collimator and camera angle fixed. Seventy three optical elements are being built in Mexico at INAOE and CIO. For the low resolution modes, the VPHs windows specifications in irregularity is 1 fringe in 210mm x 170mm and 0.5 fringe in 190mm x 160mm for a window thickness of 30mm. For the medium and high resolution modes the irregularity specification is 2 fringes in 220mm x 180mm and 1 fringe in 205mm x 160mm for a window thickness of 20mm. In this work we present a description of the polishing techniques developed at INAOE optical workshop to manufacture the 36 Fused Silica windows and 24 PBM2Y prisms that allows us to achieve such demanding specifications. We include the processes of mounting, cutting, blocking, polishing and optical interferometric testing.

9912-13, Session 3

A large size ion beam figuring system for 1.2m astronomical telescopes fabrication

Xuhui Xie, Bing Yang, Lin Zhou, Ci Song, Hao Hu, National Univ. of Defense Technology (China)

A large ion beam figuring system has been build to figure large size optics with maximum dimensions of 2.0?2.0?0.6m at National University of Defense Technology (NUDT) in China. This system can realize five-axial motion of ion resource. This paper main introduce how to machine a 1.2m SiC optics using this IBF system, which includes different ion grids selection of ion source, dwell time algorithm and scan path planning etc. The final figuring contour accuracy is 9nm.

9912-14, Session 3

Manufacturing of super-polished large aspheric/freeform optics

Daewook Kim, Chang Jin Oh, The Univ. of Arizona (United States); Andrew E. Lowman, College of Optical Sciences, The Univ. of Arizona (United States); Greg A. Smith, Maham Aftab, The Univ. of Arizona (United States); James H. Burge, College of Optical Sciences, The Univ. of Arizona (United States)

Very large optical systems targeting diffraction-limited high spatial resolution and/or more light collecting efficiency have been increasingly popular in advanced optical system concepts and designs such as Giant Magellan Telescope and Large Synoptic Survey Telescope. Number of next generation astronomical telescopes or large optical systems utilize aspheric/freeform optics since they enable segmented optical system creating a combined large optical surface or off-axis optical design avoiding obscurations, which could be a source of stray-light noise. For instance, in order to avoid light scattering from the secondary mirror structure, the Daniel K. Inouye Solar Telescope (DKIST) adopts a 4.2 m in diameter off-axis primary mirror using Zerodur thin substrate. The DKIST primary mirror has been successfully completed in 2015 at the Optical

Engineering and Fabrication Facility (OEFF), University of Arizona. As the telescope looks at the brightest object in astronomy, our own Sun, the primary mirror surface quality needs to meet comprehensive and extreme specifications. While most optical systems often have only two major specifications defining i) low spatial frequency error (e.g. overall optical surface figure error RMS) and ii) very high spatial frequency error (e.g. surface finish within 1 by 1 mm local area) the DKIST optical surface specification covers broad range of surface error spectrum in terms of the overall surface error, bidirectional reflectance distribution function (BRDF) associated with its power spectral density (PSD) and micro-roughness. Four powerful metrology systems have been researched, developed and used to provide measurement data covering the required low-to-mid-to-high spatial frequency information about the 4.2 m optical surface. Customized interferometry using computer generated hologram (CGH) and the Software Configurable Optical Testing System (SCOTS) deflectometry system have been used to measure the overall surface figure. The newly developed Slope Measuring Portable Optical Test System (SPOTS) covers the mid-spatial frequency metrology. In order to measure the local micro-roughness, Micro Finish Topographer (MFT) using temporal phase shifting interferometry has been used on various local spots on the DKIST mirror surface. All measurements are converted to PSD plots and combined in spatial frequency domain. The measured PSD covering the wide surface error spectrum without missing bands shows an excellent super-polished surface quality of the large aspheric mirror, which is going to enable a new level of solar science.

9912-15, Session 3

Freeform and advanced optics for ELT instrumentation

Roland Geyl, REOSC (France)

The E-ELT will be equiped with advanced instrumentation and Reosc wish you highlight recent technology developments that shall allow the design and realization of more performant optical instrumentation than ever.

Freeform surfaces : Recent development in freeform optics for space application will be presented with their potential application to spectrographic instrumentation.

R-SiC polishing layer: This new SiC substrate cladding and polishing technology will be presented. It shall allow a much more easy and less expensive use of SiC material in advanced instrumentation, including cryogenic one.

Extreme aspheric: A demonstration of extreme aspheric optic has recently been made with a 500 mm aperture OAP with 90° deviation and F/2.5 output NA polished to laser quality. This example shall push more far away the technological limitations the instrument designers take into account in their design work.

9912-16, Session 3

Fabrication of an ultra-lightweight Zerodur mirror

Martin J. Valente, James H. Burge, Justin P. Hoover, Arizona Optical Systems, LLC (United States); Tony B. Hull, The Univ. of New Mexico (United States)

A 1.2-m mirror ultra-lightweight mirror was manufactured by Schott from Zerodur glassy ceramic. This mirror was machined from the back to achieve 85% lightweighting with respect to a solid mirror. A pressure-balanced technique is being used for grinding and polishing the optical surface that limits the print-through effect of the thin facesheet. This paper presents the design of the mirror and its mount, as well as the manufacturing steps to generate the blank and finish the optical surface.

9912-17, Session 3

TIF and material removal characteristics of SiC mirror materials using OVT

Jeong-Yeol Han, Korea Astronomy and Space Science Institute (Korea, Republic of); Myung K. Cho, Gary A. Poczulp, National Optical Astronomy Observatory (United States); Dong-Kyun Kim, Jinho Kim, Green Optics Co., Ltd. (Korea, Republic of); Hyunju Seo, Korea Astronomy and Space Science Institute (Korea, Republic of); Sehyun Seong, Sug-Whan Kim, Yonsei Univ. (Korea, Republic of); Min-Gab Bog, Jong-Su Jeon, Kiuk Nam, Yoon Seul (Korea, Republic of); Jeonggun Lee, Sungyeop Han, Green Optics Co., Ltd. (Korea, Republic of); Jihun Kim, Young-Soo Kim, Jakyoung Nah, Uk-Won Nam, Bongkon Moon, Je Heon Song, Korea Astronomy and Space Science Institute (Korea, Republic of); Geon-Hee Kim, Min Woo Jeon, Sangwon Hyun, Korea Basic Science Institute (Korea, Republic of)

TIF (Tool Influence Function) has been a representative parameter to quantify the material removal characteristics for optical surfaces. We generated a pseudo Gaussian-like TIF on Silicon Carbide (SiC) mirrors with different machine input parameters using Orthogonal Velocity Tool (OVT). The OVT was a polishing tool implemented with orthogonal velocity fields and SiC materials fabricated by diverse production methods. In addition, material removal coefficient of Preston Equation can be calculated by the experimental contact area and relevant translation. Both the TIF and the coefficient could be used as a parameter to characterize the optical surface for various SiC materials. In this paper, we present technical details of experiments and results.

9912-18, Session 4

ZERODUR thermo-mechanical modelling and advanced dilatometry for the ELT generation *(Invited Paper)*

Ralf Jedamzik, Clemens Kunisch, Thomas Westerhoff, SCHOTT AG (Germany)

Large amounts of low thermal expansion material are required for the upcoming ELT projects. The main mirror is designed using several hundreds of hexagonal 1.4 m sized mirror blanks. The M2 and M3 are monolithic 4 m class mirror blanks. The mirror blank material needs to fulfill tight requirements regarding the CTE specification and homogeneity. Additionally the mirror blanks need to be dimensionally stable for more than 30 years. In particular, stress effects due to the changes in the environment shall not entail shape variation of more than 0.5 ?m PV within 30 years. In 2010 SCHOTT developed a physical model to describe the thermal and mechanical long time behavior of ZERODUR®. The model enables simulation of the long time behavior of ZERODUR® mirror blanks under realistic mechanical and thermal constraints. This presentation shows FEM simulation results on the long time behavior of the ELT M1, M2 and M3 mirror blanks under different loading conditions. Additionally the model results will be compared to an already 15 years lasting long time measurement of a ZERODUR® sample at the German federal physical standardization institute (PTB). In recent years SCHOTT pushed the dilatometer measurement technology to its limit. With the new Advanced Dilatometer CTE measurement accuracies of +- 3 ppb/K and reproducibility's of better 1 ppb/K have been achieved. The new Advanced Dilatometer exhibits excellent long time stability. New CTE measurements based on the advanced dilatometer confirm the excellent CTE homogeneity in the single digit ppb/K level on short and long scales.

9912-19, Session 4

Fused silica challenges in sensitive space applications

Josephine Criddle, Heraeus Quartz UK, Ltd. (United Kingdom) and Heraeus Quarzglas GB (United Kingdom)

Space bound as well as earthbound spectroscopy of extra-terrestrial objects finds its challenge in light sources with low intensities. High transmission for every optical element along the light path requires optical materials with outstanding performance to enable the measurement of even a one-photon event. Using the Lunar Laser Ranging Project and the VIRGO Gravitational Wave Detector as examples, the influence of the optical properties of fused silica will be described. The Visible and Infrared Surveillance Telescope for Astronomy (VISTA) points out the material behaviour in the NIR regime, where the chemical composition of optical materials changes the performance. Special fibres are often used in combination with optical elements as light guides to the spectroscopic application. In an extended spectral range between 350 and 2,200 nm Heraeus developed STU fibre preforms dedicated for broad band spectroscopy in astronomy. STU fibres in the broad spectral range as well as SSU fibres for UV transmission (180 – 400 nm) show also high gamma radiation resistance which allows space applications.

9912-20, Session 4

Manufacturing zero thermal expansion cordierite ceramics aspheric mirrors with Magneto-Rheological Finishing (MRF)

Jun Sugawara, Krosaki Harima Corp. (Japan); Chris Maloney, QED Technologies, Inc. (United States)

Advanced Cordierite (2MgO-2Al2O3-5SiO2) ceramics have both an ultra-low CTE (coefficient of thermal expansion) of 0.03 ppm/K or less at room temperature and a pore-less microstructure. In addition, advanced cordierite ceramics have strong mechanical properties and high, long term dimensional stability for enduring heat cycles. These properties make it a perfect candidate to be used for lightweight satellite mirrors for geostationary earth observation with high spatial resolution and for mirrors for ground-based astronomical metrology; more specifically, an infrared spectroscope. The properties of advanced cordierite ceramics are not only being utilized for structural components of steppers for LSI lithography but also as primary standards and laser mirrors in the field of precision metrology. The advanced cordierite ceramics laser reflecting flat-mirrors with light-weight boxed structures made by diffusion bonding technology were reported in a previous paper. The paper shows that the pore-less microstructure achieved by the polishing realizes a smooth surface with averaged-roughness (Ra) of around 0.3 nm and a flatness of less than lambda/10. To expand upon this previous work to the field of astronomy, aspheric shapes are required for mirrors.

To realize the high precision aspheric shapes made of advanced cordierite ceramics, the deterministic aspherization and figure correction capabilities of Magneto-Rheological Finishing (MRF) will be tested. The first phase of the testing is a material compatibility study. Two types of the advance cordierite ceramics have been prepared and then finished by MRF. The first cordierite (N117B) is a polycrystalline ceramics consisting of one crystal phase. The second (CD107) is a polycrystalline ceramics consisting of main and sub crystal phases. For the MRF material compatibility, a Q-flex 100 machine (QED Technologies) and 4 types of fluid have been used. CD107 with D20 fluid (diamond abrasive fluid) is the best performing combination of MRF fluid and material, resulting in the lowest surface roughness of RMS ~0.8 nm after MRF.

The second phase of testing will start with a conventionally polished 100 mm diameter sphere made of CD107 and MRF will be used to polish in a hyperbolic shape to the mirror as well as provide high precision figure correction. Based on these results, we conclude that MRF polishing has a strong possibility to be a very promising technique for producing the advanced cordierite aspheric mirrors.

9912-21, Session 4

Silicon carbide main structure for EUCLID NISP instrument in final development

Tony Pamplona, Jean Luc Gimenez, William Ceria, Aurélien Febvre, Lab. d'Astrophysique de Marseille (France)

The Euclid project is part of ESA's Cosmic Vision program with its launch planned for 2020. The Euclid mission main scientific goal is to understand the accelerated expansion of the Universe by mapping the geometry of the dark Universe. The mission will investigate the distance-redshift relationship and the evolution of cosmic structures by measuring shapes and redshifts of galaxies and clusters of galaxies out to redshifts ~2, or equivalently to a look-back time of 10 billion years. The NISP (Near Infrared Spectro-Photometer) is one of the two Euclid instruments operating in the near-IR spectral region (0.9-2?m) as a photometer and spectrometer. The development of the instrument is currently in phase C.

LAM has in charge the development of the main structure of the NISP instrument. This mechanical assembly will support six main optomechanical modules and work at 132 K. These modules require very high positioning accuracy and a very high stability in operation (a few tens of microns) to achieve the required optical performances and so the scientific goals.

In this context, a structure made of Silicon Carbide (SiC) supporting by an invar hexapod, ensuring a very high stability with a very good mass stiffness ratio, is developed at LAM.

This article describes the challenging design of this optomechanical concept taken into account the complexity of the interfaces and the very high accuracy of the manufacturing tolerances. Static, dynamic and thermomechanical associated analyses have been performed. These studies, allowing to demonstrate the thermomechanical strength of the structure and so validate the design choice, are documented and detailed. Finally, future vibrations tests planned at Centre Spatial de Liège (CSL) on the hardware, currently realized by sub-contractor, will be presented.

9912-22, Session 4

A study on a fabrication process for CFRP mirror

Young-Soo Kim, Jeong-Gyun Jang, Jihun Kim, Je Heon Song, Jeong-Yeol Han, Jakyoung Nah, Uk Won Nam, Korea Astronomy and Space Science Institute (Korea, Republic of)

Most favorable materials for telescope mirrors are Zerodur, Clearceram-z, Astrosital, and ULE, as they have low thermal expansion values and easy production. However, they need careful manipulations as they are brittle. Especially when they are applied to space telescopes, deeper attentions should be paid during the harsh launch environments.

CFRP material has a great potential for a next generation mirror especially for space telescopes. The stiff and light-weight mirror will reduce the risk of launches and the production costs eventually. Efforts have been poured to produce CFRP mirrors worldwide, and the key success factor looks fabrication method and process. In this paper, a fabrication process is presented. When the CFRP mirror becomes available, it would benefit mobile equipment as well as space telescopes.

9912-23, Session 5

Fabrication and testing of the 4.2m off-axis primary mirror of DKIST

Chang Jin Oh, Andrew E. Lowman, Greg A. Smith, Run Huang, Tianquan Su, Peng Su, Daewook Kim, Chunyu Zhao, James H. Burge, College of Optical Sciences, The Univ. of Arizona (United States)

Daniel K. Inouye Solar Telescope (formerly known as Advanced Technology Solar Telescope) is the largest optical solar telescope ever built to provide greatly improved image, spatial and spectral resolution and to collect sufficient light flux of Sun. To meet the requirements of the telescope the design adopted a 4m aperture off-axis parabolic primary mirror with challenging specifications of the surface quality including the surface figure, irregularity and BRDF. The mirror has been completed at the College of Optical Sciences in the University of Arizona and it meets every aspect of requirement with margin. In fact this mirror may be the smoothest large mirror ever made.

The fabrication and metrology support has been developed using 118 hydraulic actuators with force calibration for the 75mm thick and 4m aperture membrane mirror and the support demonstrated the extremely accurate and stable performance. During the grinding stage the fabrication process has been guided by a large spherometer and Laser Tracker. During the fine grinding stage IR deflectometry played a critical role revealing the entire ground surface in sub micron level. for the final polishing two redundant metrology systems have been applied. one is Highly accurately calibrated Visible Deflectometry and the other is an Interferometry using a CGH. To achieve efficient progress in fabrication and extremely fine surface finish, computer controlled fabrication has been applied.

The completed mirror presents less than 20nm RMS figure in the full clear aperture, less than 5nm RMS irregularity over 100mm-1mm spatial scale, 1Angstrom micro surface roughness and particularly BRDF is better than 0.6steradian, which is only fraction of the specification.

This paper presents the detail fabrication process and metrology applied to the mirror from the grinding to finish, that include extremely stable hydraulic support, IR and Visible deflectometry, Interferometry and Computer Controlled fabrication process developed at the University of Arizona.

9912-24, Session 5

New and improved technology for manufacture of GMT primary mirror segments

Daewook Kim, The Univ. of Arizona (United States); James H. Burge, College of Optical Sciences, The Univ. of Arizona (United States); Jonathan M. Davis, Hubert M. Martin, Michael T. Tuell, Logan Graves, Steve C. West, The Univ. of Arizona (United States)

The Giant Magellan Telescope (GMT) primary mirror consists of seven 8.4 m light-weighted honeycomb mirrors that are being manufactured at the Richard F. Caris Mirror Lab (RFCML), University of Arizona. Since the first off-axis segment was successfully completed in 2012, the second and third off-axis segments have been cast and the only on-axis center segment is in the process of spin casting. In order to manufacture the largest and most aspheric astronomical mirrors in human history various high precision fabrication and testing technologies have been developed, researched and implemented at the RFCML. It includes a 28 m tall test tower with Computer Generated Hologram (CGH) interferometer, laser tracker, pentaprism scanning system and direct slope measuring deflectometry system. The 8.4 m (in mirror diameter) capacity fabrication facilities are also fully equipped with large optical generator (LOG), large polishing machine (LPM), stressed lap, rigid conformal lap (RC lap) and their process simulation/optimization intelligence called MATRIX. While the core capability and key manufacturing technologies have been well demonstrated by completing the first GMT off-axis segment, there have been significant hardware (H/W) and software (S/W) level improvements in order to maximize GMT primary mirror manufacturing efficiency. Major fabrication system upgrades include LOG H/W and S/W improvement allowing 8.4 m in diameter freeform surface generating, Micro Diamond Finishing (MDF) process, fast fine grinding and polishing process leveraging Trizact diamond pads, MATRIX with multiple tool optimization feature, and stressed lap with orbiting stroke motion. The metrology systems have been also enhanced in many aspects. The interferometric principal test has been thoroughly reviewed and updated using up-to-date technologies such as higher spatial resolution interferometers. For ground surface measurements (during grinding phase) laser tracker system with a new calibration tools and infrared deflectometry system have been developed and tested. The data processing S/W for various GMT deflectometry systems has been continuously enhanced by applying more robust calculations and systematic data handling methods. The new and improved manufacturing technology plays a key role to realize GMT, the next generation extremely large telescope, with high efficiency and confidence.

9912-25, Session 5

Polishing and testing of the 3.4 m diameter f/1.5 primary mirror of the INO telescope

Tapio K. Korhonen, Perttu Keinänen, Mikko Pasanen, Opteon Oy (Finland); Ahmad Darudi, Iranian National Observatory (Iran, Islamic Republic of); Jonathan Maxwell, Optical Consultant (United Kingdom)

Polishing and testing methods used in manufacture of the 3.4 m INO primary mirror are described and the test results of the finished mirror are presented.

Mirror lapping and polishing was performed using several rectangular non-rotating tools arranged in a linear array across the mirror radius. Each tool is equipped with two computer controlled force actuators for regulating the surface pressure and removal efficiency during the lapping and polishing operations. The same tool system was used from the beginning of the lapping phase to the end of the final polishing.

During lapping phase the mirror surface errors were measured with a profilometer to accuracy of about 1 micron RMS. During polishing mirror measurements were made with pentaprism test to verify the correct conic constant of the mirror. The principal optical test method was the interferometric Hartmann test with the aid of a two component null lens in the mirror center of curvature. In the test arrangement the miniature Hartmann mask is behind the second element of the null lens and in the final tests it has about 7500 holes with equal spacing in a rectangular grid. The sampling spacing on the mirror surface is about 33 mm. In a complete test procedure the mirror is measured in 12 different rotational positions with increases the number of the sampling points to about 22500. The rotation also eliminates effects originating from possible alignment errors of the null lens. In each rotational position a large number of measurement images are averaged to eliminate the effects from air turbulence and vibrations.

The mirror was finished to extremely good surface accuracy. After subtraction of some low frequency aberrations of very small amplitude the residual high frequency mirror surface error is 4 nm RMS. Also the smoothness of the surface is very good and uniform. The micro-roughness within measured areas of about 1 mm diameter is 0.6 nm RMS and it is uniform within +- 0.1 nm.

9912-26, Session 5

Modern technologies of fabrication and testing of large convex secondary mirror

Chang Jin Oh, College of Optical Sciences, The Univ. of Arizona (United States); Eric Frater, The Univ. of Arizona (United States); Matthew B. Dubin, Andrew E. Lowman, Greg A. Smith, James H. Burge, College of Optical Sciences, The Univ. of Arizona (United States)

Modern large telescopes such as TAO, LSST, TMT and EELT require 0.9m-4m monolithic convex secondary mirrors. The fabrication and testing of these large convex secondary mirrors of astronomical telescopes is getting challenging as the aperture of the mirror is getting bigger. The biggest challenge is to measure the large aspheric convex surfaces to a few nanometers, while maintaining the testing and polishing cycle to be efficient. For the last a couple of decades there has been a huge advancement in metrology and fabrication of large aspheric secondary mirrors. College of Optical Sciences in the University Arizona developed a full fabrication and metrology process with extremely high accuracy and efficiency for manufacturing the large convex secondary mirrors.

This paper presents modern metrology and fabrication process including Swing-Arm Optical Profilometer which is comparable to Interferometry, a Sub-aperture stitching interferometry scalable to a several meters and a Computer Controlled Fabrication Process which produces extremely fine surface figure and finish. Also this most recent development has been applied to the fabrication of the 0.9m secondary mirror of TAO telescope and verified.

9912-27, Session 5

Advanced mirror technology development (AMTD) project: overview and year four accomplishments

H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States)
