Wednesday-Thursday 24-25 August 2011 • Part of Proceedings of SPIE Vol. 8093
Metamaterials: Fundamentals and Applications IV

8093-02, Session 1

Nonlinear waves in metamaterials: state of the art

A. D. Boardman, P. Egan, R. R. C. Mitchell-Thomas, Univ. of Salford (United Kingdom)

Nonlinear waves in optical structures offer the prospect of many applications but are limited for ordinary materials by power limitations and the availability of intrinsic or extrinsic nonlinearity. Many new options, in the context of guided waves, will lead to new forms of computing and light manipulation. A range of planar waveguides will be introduced, in which the nonlinearity originates within a metamaterial component or is supplied through special bounding media. The stopping of light by such structures will be investigated. This will be shown to be a beautiful feature that leads to even more dramatic outcomes as the complexity of the waveguides increases. The trapped rainbow will be taken into a nonlinear regime and overall control using magnetooptics will be developed into forms that could be the basis of many applications. The whole question of soliton formation and propagation will be addressed next and will include both spatial and temporal solitons, and their interactions. The advantages of using couplers will be stressed, and their natural characteristics, through the use of metamaterials, will be connected to the stopping of light. The role of symmetry will be introduced, and the possibility of second-harmonic generation will be admitted, and the extent of metamaterial influence will be quantified. Finally, nonlinear bulk material will be examined using vortices as suitable probes. Many new outcomes will be delivered on this topic, which will emphasize, once again, how a whole range of different metamaterials can be deployed to reveal the fascinating world of nonlinear waves.

8093-03, Session 1

Nonlinear meta-atoms for multi-functional metamaterials

J. F. O'Hara, Los Alamos National Lab. (United States) and Oklahoma State Univ. (United States); M. Reiten, L. M. Earley, D. Roy Chowdhury, J. Zhou, A. J. Taylor, Los Alamos National Lab. (United States)

Nonlinearity adds an unprecedented amount of design flexibility and functionality to technology and is becoming increasingly studied in the context of metamaterials. Nonlinearity is the key to gain, bistability, photon mixing, rectification, and myriad other phenomena. Nonlinear behavior in natural materials begins at the atomic structure. We present a brief survey of some of the fundamentals of nonlinearity in natural materials. Then we present some recent progress in studying analogous behavior in metamaterials and meta-atoms, the fundamental building block of metamaterials. Specifically, we show microwave frequency meta-atoms that support self-sustained oscillations, harmonic generation, chaotic broadband generation, and injection locking and pulling.

In this work, meta-atoms and metamaterials are created using either circuit board milling or microfabrication techniques. Nonlinearity is added through the incorporation of semiconductor inclusions in the meta-atoms, such as varactors and tunnel diodes. Simulations and experiments are performed to determine nonlinear behavior. Meta-atoms are found to respond nonlinearly to both free-space and directly connected electromagnetic stimulation. In addition, nonlinear activity is achieved through either electric or magnetic excitation of the meta-atom. Measured results indicate a strong propensity of nonlinear meta-atoms to achieve numerous and simultaneous nonlinear behaviors, with mixing being the most common. We present our measured or simulated results and discuss their implications in the broader metamaterial perspective. We also discuss the demarcation between basic lumped circuits and effective media.

8093-04, Session 1

Nonlinearity in metatronics

N. Engheta, Univ. of Pennsylvania (United States)

In recent years we have introduced and been developing the concept of "metatronics", i.e. metamaterial-inspired optical nanocircuitry, in which the three fields of "electronics", "photonics" and "magnetic" can be brought together seamlessly under one umbrella - a paradigm which I call the "Unified Paradigm of Metatronics". We have now expanded this paradigm by including and exploring the role of optical nonlinearity in such metatronic circuits. In the present work, we will discuss our theoretical results in combining nonlinearity with the lumped optical circuit elements when accompanied with the ENZ materials for the difference-frequency generation, and the role of optical nanoantennas in enhancing the nonlinearity in metatronics. The enhancement of difference-frequency signal generation using proper design of nanoantennas may lead to composites with unusually strong difference-frequency effects.

8093-05, Session 1

Nonlinear and active metamaterials

A. K. Popov, Univ. of Wisconsin-Stevens Point (United States); I. R. Gabitov, The Univ. of Arizona (United States); N. M. Litchinitser, Univ. at Buffalo (United States); A. V. Kildishev, V. M. Shalaev, Purdue Univ. (United States)

In this talk, recent progress in nonlinear and active metamaterials will be reviewed. The phenomenon of anomalous field enhancement in graded-index metamaterials in the vicinity of zero index transition will be described. Exotic properties of coherent nonlinear-optical energy exchange between the ordinary and backward electromagnetic waves in negative-index materials, such as harmonic generation, frequency-mixing and optical parametric amplification, will be reviewed. Optical properties of active metamaterials with embedded amplifying centers will be described. The possibilities of compensating strong losses inherent to plasmonic metamaterials and for design of optical sensor and unique photonic microdevices will be discussed and numerically simulated.

8093-06, Session 1

Nonlinear spectroscopy on photonic metamaterials

S. Linden, Univ. Bonn (Germany); F. Niesler, N. Feth, M. Wegener, Karlsruher Institut für Technologie (Germany)

So far, research on photonic metamaterials has mostly concentrated on linear optics. However, photonic metamaterials can offer also interesting nonlinear optical properties, e.g., strong second harmonic generation (SHG). Unfortunately, our understanding of the nonlinear properties of photonic metamaterials is not as developed as the corresponding linear theory. In particular, the nonlinear mechanism for SHG from metallic nanostructures is still under debate.

Here, we report on our recent experiments on nonlinear optical spectroscopy of second SHG from split ring resonator (SRR) arrays. In our experiments, the laser frequency is tuned over the fundamental resonance of the SRRs. We find that the SHG process is governed by

the fundamental resonance while the SRR resonance at roughly twice the frequency does not further amplify the SHG but rather leads to reabsorption.

8093-07, Session 2

Nonlinear metamaterials

D. R. Smith, Duke Univ. (United States)

Artificially structured metamaterials have shown enormous promise for their ability to realize unique electromagnetic response that can be used to enable such exotic constructs as negative index or transformation optical media. But, as interesting are the passive materials that have resulted from the metamaterials concept, potentially even more interesting are nonlinear metamaterials, in which the nonlinear susceptibilities of a medium can be designed with considerable freedom simply not available-or not as readily available-in conventional materials. The resulting “metacrystals,” which can be thought of as the analog of conventional nonlinear crystals, can provide new opportunities for managing the propagation of harmonics, and can have the capability to enhance or suppress certain nonlinear processes. We will describe a host of recently developed techniques for the accurate design and characterization of nonlinear metacrystals, showing that artificially structured media can be accurately described in the language of conventional nonlinear optics. Using metamaterial elements containing diodes and other nonlinear inclusions, we show the feasibility of nonlinear metacrystals at microwave frequencies, and demonstrate such phenomena as harmonic generation, three- and four-wave mixing, intensity-dependent resonance tuning, and similar phenomena. In all cases, analytical results, numerical simulations and measurements are all in excellent agreement, and point the way to the development of much more complex and interesting media.

8093-08, Session 2

Powered and nonlinear RF metamaterials

S. A. Cummer, B. Popa, Duke Univ. (United States)

The electromagnetic properties of metamaterials can be engineered to achieve substantially more flexibility and variety than those available from conventional materials. Yet even metamaterials as commonly realized through passive self-resonant metallic inclusions have some limitations. Adding some degree of external control or power to metamaterials can remove some of these limitations and gives metamaterials another level of functionality. We describe our recent efforts to develop an approach for realizing powered and nonlinear metamaterials in which each unit cell contains embedded active or nonlinear elements. Using a directly powered cell architecture, we demonstrate experimentally the effective electromagnetic material properties and the overall behavior that can be achieved with this type of active RF metamaterials. Characteristics such as loss and reciprocity that are dramatically different from passive metamaterials can be realized, potentially increasing the suitability of electromagnetic metamaterials for a variety of applications. We also describe our recent experimental work with active nonlinear metamaterials to create a phase conjugating lens. Varactor diodes are embedded in each metamaterial element and, when parametrically pumped with an external signal, can be made to generate a phase conjugated version of an illuminating source at close to half the pump frequency. We then demonstrate experimentally that an array of these nonlinear metamaterial elements does indeed act as a phase conjugating, and thus time-reversing and negative refracting thin material slab.

8093-09, Session 2

Second harmonic generation in index near zero transmission lines

I. V. Shadrivov, W. R. C. Somerville, D. A. Powell, The Australian National Univ. (Australia)

Nonlinear parametric effects are substantially suppressed in natural materials, because of the so-called phase mismatch. Various techniques, such as quasi phase matching, are used in order to overcome this limitation for achieving, e.g., efficient second harmonic generation. The essence of phase matching is that the indices of refraction for the interacting waves should be equal. This is why it is hard to find in natural materials - which should be dispersionless over the whole octave. In this work we pursue the idea of achieving phase matching between the waves with zero phase velocity. Such waves appear, e.g. in plasma near the plasma frequency, or in the so-called epsilon-near zero metamaterials. Here, using the composite right-left handed (CRLH) transmission line we design the structure which supports zero phase velocity waves at both the fundamental frequency and at the second harmonic. The transmission line has a unit cell structure made of a combination of two regular nonlinear CRLH transmission lines with different parameters in order to achieve the required properties. We analyze the dispersion properties of such a transmission line, and study nonlinear effects experimentally. We observe second harmonic generation, and demonstrate that it is enhanced near the frequency of zero phase velocity. We also measure experimentally the field distribution in the structure in order to experimentally determine its dispersion properties. We expect that similar regimes of the phase matching can be achieved in dual-band index-near-zero metamaterials.

8093-10, Session 2

Magnetoelastic nonlinear metamaterials

M. Lapine, I. V. Shadrivov, Y. S. Kivshar, The Australian National Univ. (Australia)

*(Invited for the Special Session on Nonlinear Metamaterials)

For more than ten years, metamaterials are in a super-lens focus of research attention in electrodynamics and materials science. Rapid progress drives increasing interest in applied fields ranging from microwave engineering to optics. In particular, the possibility of nonlinear phenomena in metamaterials was soon explored [1,2], having established a new research direction with numerous promising ideas on nonlinear, tunable and active metamaterials [3,4].

The initial way to provide strong nonlinearity to metamaterials was found in either employing a nonlinear host medium [1] or engineering the elements of a metamaterial to include a nonlinear component [2]. Both the approaches result in a nonlinear response on the level of single element, which is further enhanced in a metamaterial, offering tools for harmonic generation, parametric amplification, loss compensation, solitons, tunability, etc.

Notably, the very structure of metamaterials remained fixed in such studies. At the same time, we recently reported [5,6] that structural changes in metamaterials offer an excellent means to control their properties, remarkably affecting resonance position and thus providing enhanced tunability of transmission, reflection and absorption.

In this talk, we report a further step forward and analyse a novel type of nonlinearity in metamaterials, which is achieved through specific conformational changes of the structure, analogous to those we employed in structural tuning. This results in exceptionally efficient self-action mechanisms.

For a detailed illustration, we consider an artificial magnetic metamaterial and analyse the nonlinear phenomena resulting from the structural changes, which give rise to unusual patterns of nonlinearity and bistability, providing a road towards interesting nonlinear phenomena.

8093-11, Session 3

Guiding waves with nonlinear metamaterials

N. M. Litchinitser, E. A. Gibson, G. Venugopal, Univ. at Buffalo (United States); Z. Kudyshev, Al-Farabi Kazakh National Univ. (Kazakhstan); A. Pandey, Univ. at Buffalo (United States)

Nonlinear optical metamaterials are likely to enable new reconfigurable, ultra-compact opto-plasmonic devices that would bridge existing gaps in electronic-photonic integration. Some of the major important functionalities to be realized in future opto-electronics chips include: i) buffering of optical signals to allow to avoid congestion of information traffic, ii) bridging the gap between micro-scale photonic waveguides (e.g., optical fibers) and nano-scale optical and electronic devices, and iii) low input power nonlinear optical signal processing. Although several approaches to the realization of such functionalities have been proposed and demonstrated, many of them are not easily scalable to a chip-size footprint.

In this talk we discuss our recent results on linear and nonlinear optics in guided-wave optical metamaterials and their applications for novel nonlinear photonic devices. We present a comprehensive analytical model for light propagation in coupled nonlinear waveguides for the most general case of arbitrary phase mismatch between the waveguides and arbitrary values of nonlinear coefficients and demonstrate that such nonlinear optical guided-wave structures enable a number of new phenomena and degrees of design freedom as compared to conventional nonlinear directional couplers. These unusual properties of metamaterial-based couplers form a basis for the development of ultra-compact all-optical processing applications, including all-optical buffers, flip-flops, and mirrorless lasers. We also discuss nonlinear optical wave propagation and interactions in transition metamaterial structures with various engineered graded refractive index profiles and discuss their potential applications for nonlinear low-intensity optical signal processing and sensing. Practical designs for the proposed structures will also be discussed.

8093-12, Session 3

Nonlinear metamaterial design for enhanced wave mixing.

E. Poutrina, A. Rose, D. Huang, D. R. Smith, Duke Univ. (United States)

For practical applications, the design and optimization of nonlinear metamaterial-based devices requires a quantitative approach, one that relates the particular metamaterial geometry incorporating nonlinear elements to the nonlinear properties of the composite, effective medium. In recent work by Poutrina et. al, an analytical approach was developed allowing the description of a nonlinear metamaterial in terms of effective nonlinear susceptibilities, in analogy with the standard representation common in nonlinear optics. The analytical model employs a perturbative solution to the nonlinear oscillator model that describes a metamaterial inclusion in terms of an effective RLC circuit. In the present work, we use the developed approach to design a metamaterial with the predictably enhanced effective nonlinear characteristics and verify the theory predictions by simulating the three- and four- wave mixing processes in the designed geometries and by performing experiments on a varactor-loaded split ring resonator-based medium. We also demonstrate the capability of designing the symmetry properties of the effective medium for suppressing or enhancing the even-orders nonlinear response. Finally, we illustrate the manner in which the developed nonlinear metamaterial medium could be used to demonstrate nonlinear imaging based on wave-front reversal with four wave mixing.

8093-14, Session 3

Parametric amplification in optical metamaterials

I. R. Gabitov, The Univ. of Arizona (United States) and Southern Methodist Univ. (United States); A. I. Maimistov, National Research Nuclear Univ. MEPhI (Russian Federation); Z. Kudushev, Al-Farabi Kazakh National Univ. (Kazakhstan)

Parametric amplification based on three wave interactions in optical metamaterials is considered. A mathematical model of this phenomenon taking into account both saturation of a pump wave and phase mismatch is derived. Theoretical analysis of parametric amplification in the continuous wave approximation demonstrates a significant difference between the processes of amplification taking place in conventional and negative index materials. We have analyzed the characteristics of amplification depending on system parameters and showed strong dependence on the value of phase mismatch.

8093-39, Session 3

Nonreciprocal transmission and one-way slow light in plasmonic metamaterials

A. B. Khanikaev, C. Wu, S. H. Mousavi, G. Shvets, The Univ. of Texas at Austin (United States)

Nonreciprocity is associated with a special class of systems for which forward and backward propagation behave differently. We propose plasmonic metamaterials endowed with extraordinary nonreciprocal optical properties. The structures considered represent (i) a subwavelength array of holes in an optically thin metal film and (ii) a low-symmetry metamaterial composed of periodically arranged meta-atoms made of plasmonic antennas embedded into magneto-optical medium. We show that both structures behave as one-way photonic mirrors, transmitting light only in one direction while stopping it in the opposite direction. It is found that in the case of the perforated metal the structure supports surface plasmon modes with nonreciprocal dispersion. Coupling of the incident radiation to these modes gives rise to the nonreciprocal response of the metamaterial. In the case of metamaterial made of plasmonic antennas, the nonreciprocal response is stemming from the resonances of individual meta-atoms. This approach allows for more flexibility in the design of the structure; very diverse nonreciprocal effects can be attained with the topologically similar meta-atoms but with slightly different geometrical parameters. As an example we designed the structure exhibiting one-way slow-light behavior, i.e. delaying light propagating in one direction but not in the opposite.

The main advantage of the proposed metamaterials as compared to their contemporary photonic counterparts stems from their plasmonic nature. Plasmonics, thanks to its capability to trap light to subwavelength scales and boost magneto-optical response of the materials, enables the whole one-way mirror or nonreciprocal delay element to be as thin as just one wavelength of the incident light.

8093-15, Session 4

Ultrafast nonlinearities of plasmonic metamaterials

M. Ren, A. Nikolaenko, E. Plum, N. I. Zheludev, Univ. of Southampton (United Kingdom)

We report on extraordinary strong nonlinear properties and ultrafast

transient dynamics of gold-based plasmonic metamaterials and metamaterial nanostructures aggregated with semiconductor nanotubes

8093-16, Session 4

Optical negative refraction by four-wave mixing in thin metallic nanostructures

X. Zhang, Univ. of California, Berkeley (United States)

While all natural materials exhibit refraction in the positive direction, artificially engineered negative index metamaterials (NIM) have been shown capable of bending EM waves negatively. We report the experimentally observed nonlinear negative refraction at optical frequencies using four wave mixing (4WM), wherein the incident and negatively refracted beams are at different frequencies. The nonlinear negative refraction could potentially impact many important applications such as superlens imaging without using actual NIMs which are typically lossy, narrow band, and require complicated fabrication processes.

8093-17, Session 4

Harmonic generation and energy transport in GaP At visible and UV wavelengths

M. Scalora, U.S. Army Aviation and Missile Command (United States); V. Roppo, Univ. Politècnica de Catalunya (Spain); M. A. A. Vincenti, D. de Ceglia, N. Akozbek, The AEgis Technologies Group, Inc. (United States)

We study inhibition of absorption, optical transparency, energy and momentum transport of phase locked harmonic pulses in semiconductors like GaP, at visible and UV wavelengths. In these spectral regions semiconductors are characterized by large absorption, metallic behavior, or a combination of both. This phenomenon is attributed to phase locking between the fundamental and its harmonics that occurs under phase mismatched conditions, irrespective of material parameters, as long as the material is somewhat transparent to the pump. As a result of phase locking the pump impresses its dispersive properties to the generated harmonics which in turn experience no absorption or other de-phasing effects such as group velocity walk-off. The harmonics co-propagate phase- and velocity-locked to the pump, and any energy exchange between the pump and its harmonics ceases away from interfaces. We show experimental and theoretical evidence that phase locking causes the generated harmonics to propagate through GaP at 223nm, where the material displays metallic response, without being absorbed, and that the transport of electromagnetic energy and momentum is quite peculiar and seemingly anomalous. We also show that it is possible to exploit cavity environments to generate and enhance harmonic generation below 200nm in semiconductors like Silicon. These results make it clear that there are new opportunities in ultrafast nonlinear optics and nano-plasmonics in new wavelength ranges.

8093-18, Session 4

Z-scan simulations on metallodielectric stacks with nonlinear absorption

N. C. Katte, J. Haus, P. Powers, J. Gao, A. M. Sarangan, Univ. of Dayton (United States); M. Scalora, U.S. Army Aviation and Missile Command (United States); R. Jakubiak, Air Force Research Lab. (United States)

Experimental investigations reveal significant nonlinear responses from metallodielectric stacks (MDSs) with constituent metal films of silver (Ag), gold (Au) or copper (Cu). In particular, the Cu dielectric MDS exhibited large non-linear absorption. Nevertheless, there is a need to investigate these materials with more faithful numerical techniques in order to account for the underlying physical processes observed in the experiments. We apply a Finite Element Method (FEM) with radial symmetry to numerically solve for the Z-scan experiment of a MDS using the corresponding nonlinear Maxwell equations. The amplitude and the phase of the electromagnetic field at the exit interface of the MDS are used for transforming to the far-field regime.

8093-19, Session 4

Suppression of plasmon losses in metamaterials by means of parametric bichromatic irradiation

A. Kussow, A. Akyurtlu, Univ. of Massachusetts Lowell (United States)

Novel mechanism of suppression losses in plasmonic subsystem in metals and semiconductors is suggested. If two parametrically coupled fields are applied to a metal plasma, a non-linearity of the transport equation affects the electric response, or the permittivity. If the coupling constant between the probe wave and the support wave is small, the permittivity, at the frequency of the probe wave, is still Drude-like, with the re-normalized plasmon frequency. In the case of a strong coupling, unusual response effects are possible (the induced transparency and the considerable suppression of the plasmon losses), with profoundly non-Drude permittivity function.

8093-20, Session 5

Darker than black: the theory of hyperbolic radiation-absorbing metamaterials

E. E. Narimanov, C. Motti, Purdue Univ. (United States)

The broadband super-singularity of the photonic density of states of hyperbolic media leads to a dramatic enhancement of the light scattering from the defects and surface corrugations at the interface of the hyperbolic metamaterial, with nearly all the incident light “sucked” into the propagating modes of the hyperbolic medium. Here, we present the theoretical description of such radiation-absorbing systems.

8093-21, Session 5

Spontaneous emission near hyperbolic metamaterials

Z. Jacob, Univ. of Alberta (Canada); I. I. Smolyaninov, Univ. of Maryland (United States); E. Narimanov, Purdue Univ. (United States)

Engineering the photonic density of states using microcavities or photonic crystals helps to control a plethora of phenomena associated with light. While the unique electromagnetic response of metamaterials and their capabilities have received widepsread attention, the role of the PDOS in nanostructured metamaterials has been unexplored. Here, we unravel how a unique dielectric response can give rise to a divergence in the PDOS for bulk propagating waves within a medium and understand other intriguing properties and advantages of metamaterial based PDOS engineering especially in connection to the Purcell effect.

As opposed to conventional methods for enhanced and directional spontaneous emission based on closed cavity Purcell enhancement of spontaneous emission or open cavity approaches based on photonic crystal waveguides, our design relies on a completely new approach, namely the singularity in the density of states of a hyperbolic dispersion medium. The dielectric response of the medium surrounding the emitter is engineered to provide dramatically increased density of photonic states in a broad bandwidth as well as inherent directionality to the emitted photons. An increased density of photonic states immediately translates

to a larger number of radiative decay channels available for an excited atom ensuring enhanced spontaneous emission, a necessary quality for single photon sources.

We use a green's function approach to calculate the local density of states. In the limit of zero losses, under the effective medium approximation, the LDOS near a hyperbolic dispersion medium is infiinite. We use the semiclassical theory of spontaneous emission to analyze the divergence of the decay rate of an emitter near a metamaterial due to the singularity in the density of states. For a medium which has the dielectric permittivities of opposite signs in perpendicular directions and no losses, the decay rate of a point dipole diverges. This divergent behavior of the decay rate is is counterintuitive to the conventional response of materials where the decay rate and the LDOS goes to a constant value when losses are zero.

8093-22, Session 5

Transition metamaterials in materials with hyperbolic dispersion

A. Pandey, E. A. Gibson, N. M. Litchinitser, Univ. at Buffalo (United States)

Recently, we predicted new phenomena occurring due to the electromagnetic wave propagation in metamaterials with material parameters gradually changing from positive to negative values, transition metamaterials. At oblique incidence, we predicted the phenomenon of anomalous electromagnetic enhancement and resonant absorption in the vicinity of the point where the refractive index changes sign. In all previous studies, we considered an effective isotropic medium with assigned values for dielectric permittivity and magnetic permeability that give rise to an effective gradually changing refractive index. However, the particular mechanism of dissipation and the influence of the microscopic structure of metamaterials on the field enhancement phenomenon would be determined by a physical model of a metamaterial.

In this work, we design and investigate electromagnetic wave propagation in transition metamaterials based on two materials systems: metal/dielectric multilayered structures for optical frequency range and highly doped/undoped semiconductors for mid-infrared frequency range. In the latter case, the level of doping is carefully adjusted such that the effective refractive index gradually changes from positive to negative values. It was shown (Narimanov et al.) that strongly anisotropic materials that possess a negative permittivity component along the direction perpendicular to the interface and positive component along the interface, have hyperbolic dispersion relations. As a result, the component of the Poynting vector along the interface is opposite to the direction of the wavevector component along the interface, leading to the effective negative refractive index. We investigate how the dispersion relation changes when the refractive index gradually changes from positive to negative in these structures.

8093-23, Session 5

Multilayered metamaterials with hyperbolic dispersion

T. U. Tumkur, G. Zhu, P. J. Black, C. E. Bonner, M. A. Noginov, Norfolk State Univ. (United States)

We have developed and studied a family of hyperbolic metamaterials consisting of lamellar metal-dielectric structures which can be fabricated on flat, flexible and curvilinear substrates and functionalized by emitting dye molecules. Hyperbolic materials can accommodate waves with high wavevectors and hence possess broadband singularity in the density of photonic states [1]. Owing to this property, we demonstrate the reduction of radiative lifetimes of emitters. We have also shown that the spontaneous lifetime reduction is much stronger when emitters are placed inside a metamaterial rather than on its surface. Three different types of metal-dielectric lamellar structures, consisting of organic and inorganic dielectric components have been fabricated The first type consisted of 20 alternating layers of silver and IR-140 dye-doped PMMA, which, in agreement with theoretical predictions [1], showed a strong reduction of the fluorescence lifetime, down to 286 ps when the sample was illuminated from the front and 217 ps when it was illuminated from the rear. For comparison, the emission life-times of the same dye deposited onto a glass substrate and silver film were equal 716 ps and 607 ps, respectively. Expectedly, the fluorescence lifetime reduction in films deposited on the top of other undoped metamaterials (including Ag-LiF, Ag-MgF2 and Ag-PMMA lamellar structures), was considerably smaller, as in the case of Ag-LiF which had a fluorescence lifetime equal to 499 ps. Our observation paves the road to many exciting applications including a single photon gun needed for quantum optics and information technology [1].

8093-24, Session 5

Transfer matrix approach to propagation of angular plane wave spectra through metamaterial multilayer structures

P. P. Banerjee, H. Li, R. Aylo, G. T. Nehmetallah, Univ. of Dayton (United States)

The development of electromagnetic (EM) metamaterials for perfect lensing and optical cloaking has given rise to novel multilayer bandgap structures using stacks of positive and negative index materials. Gaussian beam propagation through such structures have been analyzed using transfer matrix method (TMM) with paraxial approximation [1], and unidirectional and bidirectional beam propagation methods (BPMs) [2,3].

Since TMM is naturally a plane wave approach, we use this technique to analyze the non-paraxial propagation of a collection of TE or TM polarized plane waves having an initial Gaussian amplitude profile in 1 transverse dimension (x) through a stack containing layers of positive and negative index materials. The spatial variation of the electric field at any plane (z) during bidirectional propagation through the stack is found from the composite angular plane wave spectrum. Specifically for the TM case, the spatial variations of both the x and z polarization components are calculated. The numerical results from TMM are compared with numerical simulations using FEM and FDTD techniques. The TMM calculations are exact, less computationally demanding, and can be performed for arbitrary angular plane wave spectra. Finally, the TMM based angular plane wave spectrum approach can be readily applied to a wide variety of other cases, such as propagation through induced reflection gratings in nonlinear media.

8093-25, Session 5

Fingerprinting metamaterial behavior in 2D periodic composites: Fundamentals and applications to THz optics.

S. Foteinopoulou, The Univ. of Exeter (United Kingdom); M. Kafesaki, E. N. Economou, Foundation for Research and Technology-Hellas (Greece); C. M. Soukoulis, Iowa State Univ. (United States)

2D periodic composites can behave as uniaxial effective media, with the possibility of extra-ordinary hyperbolic dispersion, not available in natural materials. Such hyperbolic type of dispersion typically occurs when constituents with negative permittivity are present. Accordingly, 2D composites incorporating polar materials can act as uniaxial hyperbolic effective metamaterial. Thus, they become highly attractive structures, since they can enable extra-ordinary beam manipulation in the THz

regime (0.1-10 THz) where traditional visible optics is not suitable. While often the metamaterial composites can be described by traditional effective medium theories, this is not always the case. A mere deviation between actual transmission/reflection and the values predicted by effective medium theory does not necessarily imply effective medium picture breakdown.

Here, we developed a new criterion that establishes an angular fingerprint of effective metamaterial behavior for two-dimensional (2D) periodic composites. We apply such criterion to characterize different candidate polar-polar and polar-dielectric 2D composite structures as effective metamaterials. We found polar-polar metamaterial structures that are highly transmissive in cases where transmission through an identical slab made of either of the constituents would be next to none. In addition, our results suggest that polar-material based metamaterials demonstrate interesting and unusual angular transmission maps for the different polarization channels. We analyze and discuss the underpinning physics of such curious angular polarization-dependent transmission, and how to utilize it for the design of efficient polarization filters and converters.

8093-77, Poster Session

Toward curvilinear metamaterials based on silver filled alumina template

Y. A. Barnakov, P. J. Black, Norfolk State Univ. (United States); N. Kiriy, Cornell Univ. (United States); H. Li, A. V. Yakim, L. Gu, M. A. Noginov, Norfolk State Univ. (United States)

The advent of metamaterials and their continued development over the past decade has revolutionized the fields of electrodynamics and photonics, giving new perspective to the classical interaction of light with matter and enabling scores of unparalleled physical phenomena. Despite of recent tremendous progress in both theory and experiment, the research field is hindered by a lack of inexpensive large-size three-dimensional metamaterials. One way to overcome this problem is to utilize bulk dielectric templates, which nanoporous space can be filled with metals or other dielectrics. Recently, we have demonstrated that an array of silver nanowires embedded into a flat alumina membrane matrix with 35nm-diameter pores behaves as a metamaterial with hyperbolic dispersion, characterized by different signs of the electric permittivity tensor elements. It has been theoretically predicted that a metamaterial with hyperbolic dispersion realized in curvilinear coordinates (with radial or azimuthal anisotropy of metallic inclusions) has a property of a hyperlens - a device allowing for sub-diffraction imaging in the far field. The structure with a similar 'hair brush' morphology but different radial distribution of electric permittivity has been predicted to have a functionality of a non-magnetic optical cloak. In this work, we explore a family of novel curvilinear metamaterials fabricated via inexpensive non-lithographic means. This synthetic route opens a door to design and fabrication of large, three-dimensional bulk metamaterials for a number of practical applications ranging from optical cloaking to broad band sub-wavelength imaging.

Microwave superlens with sloped faces

M. K. Khodzitskiy, A. P. Slobozhanuk, D. S. Filonov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); P. A. Belov, Queen Mary, Univ. of London (Russian Federation)

Over the last ten years, the various designs of superlens have been developed [1-3]. Some of them are based on the concept of canalization of sub-wavelength images [4]. These developments are widely used in the near-field microscopy and magnetic resonance imaging (MRI) [5-6]. In this paper, based on the existing designs of wire medium superlenses, a superlens with sloped faces has been designed. The superlens was developed to increase the resolution and sensitivity of the NMR tomograph with a resonant frequency of 63.86 MHz and magnetic field induction of 1.5 T. The lens has length of 250 cm, the slope of faces is 30 degrees and the size of the working aperture is 40*20 cm2. It consists of a 20x20 array of brass wires with diameter of 2 mm and period of 10 mm. Due to sloped faces, the lens becomes more convenient device for NMR tomography of biological objects. Investigation of near-field transfer by the lens was carried out in the frequency range of 60-68 MHz. A wire antenna in the form of a flag was selected as the source. The flag was located on the distance of 2 mm from the surface of the lens. Numerical simulation in the CST Microwave Studio software package has shown the transmission of the image in the form of a flag with λ/500 resolution to λ /2 distance.

Polarization-insensitive and omnidirectional near perfect broadband metamaterial absorber in the near infrared regime

S. Chen, H. Cheng, J. Tian, Nankai Univ. (China)

We present a near perfect broadband metamaterial absorber in the near infrared regime. The electromagnetic response of mixed-size cut wires combined with thick metal layer is theoretically studied. The broadband absorber is polarization insensitive and the absorption remains high even at large incident angle for both transverse electric (TE) and transverse magnetic (TM) polarizations. By simply adding more loops of the cut wires, the bandwidth of the strong absorption can be effectively enhanced due to the hybridization of surface plasmons in different loops.

Liquid crystal-metal nanorods composites with spatially distorted optic axis for transformation optics

J. Xiang, O. D. Lavrentovich, Kent State Univ. (United States)

Transformation optics uses materials with spatially varying optical properties to control the trajectories of light propagation. The concept is familiar to liquid crystals, in which the optic axis can adopt various configurations in space. For example, a cylindrical nematic LC sample with the optic axis arranged radially would form the light trajectories in such a way that they diverge, leaving a cylindrical wedge behind the axis of the structure un-illuminated, with the angle that depends on the optical anisotropy of the liquid crystal. In this work, we consider a hybrid system, representing a liquid crystal with dispersed metal nanorods, in which the effective refractive index depends on the volume fraction of the metal component. In this hybrid material, one can control not only the orientation of the local optic axis, but also the values of the effective refractive indices. We simulate propagation of light in three basic geometries, filling the composite material in the space between two concentric cylinders, , with the optic axis represented in the cylindrical

coordinates as (a) ; (b,c) where changes from 0 to when increases (b) or decreases (c) in the range . We demonstrate that the geometries (b) produce a non-magnetic optical cloaking effect, while (c) produces a condensing effect on light propagation. This work was supported by AFOSR FA9550-10-1-0527 grant.

Modeling of nonlinear metamaterials

P. L. Colestock, M. Reiten, J. F. O'Hara, Los Alamos National Lab. (United States)

We report the results of a study to model the behavior of nonlinear metamaterials in the microwave frequency range composed of arrays of split-ring resonators combined with nonlinear circuit elements. The overall model consists of an array of coupled damped oscillators whose inter-element coupling is a function of signal amplitude, similar to that which exists in the Fermi-Pasta-Ulam system. [1] We note the potential occurrence of classical nonlinear effects including parametric coupling and FPU recurrence. These in turn lead to nonlinear waves on the array which are a type of soliton particular to the form of nonlinearity that has been incorporated. We have studied, in particular, the nonlinear effects that arise from tunnel diodes embedded in the resonant circuits. Whether or not the aforementioned nonlinear phenomena occur is a function of the details of the nonlinearity and the inherent circuit losses. We derive conditions for stable oscillations and carry out simulations of the resulting circuit frequency response. We shall present these modeling results along with preliminary experimental data from laboratory measurements of prototype nonlinear metamaterials.

Plasmonic toroidal response at optical frequencies

Y. Huang, W. T. Chen, P. C. Wu, National Taiwan Univ. (Taiwan); Y. Chau, Ching Yun Univ. (Taiwan); D. P. Tsai, National Taiwan Univ. (Taiwan) and National Applied Research Labs. (Taiwan) and Academia Sinica (Taiwan); V. A. Fedotov, V. Savinov, N. I. Zheludev, Univ. of Southampton (United Kingdom)

Toroidal dipole is created by currents flowing on a surface of a doughnut-shaped structure along its meridians first considered by Zel'dovich in 1957 [1]. Toroidal metamaterials were first theoretically proposed in 2007 [2]. In 2010, the toroidal metamaterials consisted by four three-dimensional resonant split rings show toroidal response in microwave region [3].

In this paper, we study the optical responses by integrating four U-shaped split-ring resonators (SRRs) together. The resonances of the four U-shaped SRRs array with magnetic field of incident light passing through the resonant rings was numerically investigated by using commercial software COMSOL 3.5a based on finite-element method (FEM). The permittivity of gold was described by the Lorentz-Drude model [4]. The size of a single U-shaped SRR is 110 nm (arms) × 90 nm (bottom) and 30 nm line width wire loop. Simulation results shows toroidal and magnetic dipole resonance at free space wavelength 660 nm and 952 nm respectively. Incident light induced magnetic dipoles point in the same direction produced magnetic resonance. In contrast, four magnetic dipoles form a head-to-tail configuration which concentrates toroidal resonance.

A simple theoretical analysis of the Einstein relation for the DMR (diffusivity-mobility ratio) in Nono compounds on the basis of k.p formalism

S. Singha Roy, JIS College of Engineering (India)

An attempt is made to study the Einstein relation for the diffusivity-mobility ratio (DMR) in nonlinear optical and Optoelectronic compounds on the basis of a newly formulated electron energy spectrum. The results for ternary, III-V and quaternary types of optoelectronic materials form a special case of our generalized investigation. I have also studied the DMR in II-VI, Bi, IV-VI and stressed materials on the basis of various band models as applicable for such focused materials. It has been found taking n-Cd3As2, n-CdGeAs2, n-InAs, n-InSb, n-Hg1-xCdxTe, n-In1-xGaxAsyP1-y lattice matched to InP, CdS, Bi, PbS, PbTe, PbSe and stressed InSb as examples of the aforementioned compounds that the DMR increases with increasing electron concentration in various manners for different band constants of the said materials and the rates of variation are totally band structure dependent. Now the well-known results for non-degenerate wide gap optical and Optoelectronic materials have been obtained as special cases of our generalized theory under definite limiting background.

infrared absorptance of wavelength-selection trapezoid grating

J. Sze, Instrument Technology Research Ctr. (Taiwan); A. Wei, Foxsemicom Integrated Technology Inc. (Taiwan); F. Chen, Instrument Technology Research Ctr. (Taiwan); K. Lee, Chinese Culture Univ. (Taiwan)

A trapezoid grating which improve the contrast of the wavelength-selection infrared absorptance is demonstrated. The absorptance of wavelength-selection trapezoid grating is studied by using the rigorous coupled-wave analysis (RCWA) numerical scheme. The side wall slope of the trapezoid silicon grating plays an inportant role in the infrared absorptance enhancement. According to the calculated spectral absorptance curves of the trapezoid gratings, it is found that the peak is located at the wavelength of 7.0 micrometer, which is equal to the period of the trapezoid grating. The analyzed results show that the maximum contrast absorptance of the trapezoid grating is given at the side wall slope of 18. The modified shape of the grating side walls can be used for further tailoring thermal radiation properties which is useful for enhancing the performance of infrared detectors.

Polarization effects in second harmonic generation from G-shaped nanostructures

E. A. Mamonov, I. A. Kolmychek, A. I. Maydykovskiy, T. V. Murzina, O. A. Aktsipetrov, Lomonosov Moscow State Univ. (Russian Federation); A. V. Silhanek, V. V. Moshchalkov, V. K. Valev, T. Verbiest, Katholieke Univ. Leuven (Belgium)

Planar chiral nanostructures are novel structures that attract attention first of all by their possibility to influence the polarization properties of the transmitted or reflected light by rotating its polarization plane or changing

its ellipticity. In case of the second harmonic generation (SHG) the changes can be more significant. The high sensitivity of the SHG process to the symmetry and shape of the structures can lead to the appearance of new effects such as anisotropy of the rotation of the polarization plane or depolarization of the SHG response. In case of spiral structures one can expect different strength of the nonlinear interaction under the excitation by the left and right circularly polarized pump radiation . In this work polarization properties of optical SHG from arrays of gold G-shaped nanostructures are studied.

Samples were formed as an array of 1x1 microns gold G-shaped nanostructures of 25 nm thickness on the silicon surface. The reflected SHG was studied using an output of the Ti:Sapphire laser at 780 nm. A strong anisotropy of the SHG intensity is observed, induced by the anisotropic amplification of the distribution of the SHG and fundamental fields under the excitation of the structure by linear or circular polarized fundamental beams. Stokes parameters and intensities of polarized and depolarized SHG components were estimated from the experimental data. The intensity of the depolarized SHG component is found to be comparable with the polarized one, both of them being anisotropic and has the symmetry though nor each nanostructure nor the whole array are symmetric. It was found, that one of SHG efficiency is strongly dependent of the type of the circularly polarization of the fundamental radiation.

Second and third harmonic generation at UV and soft x-ray wavelengths from semiconductor gratings

M. A. A. Vincenti, D. de Ceglia, The AEgis Technologies Group, Inc. (United States); M. Scalora, U.S. Army Aviation and Missile Command (United States)

Extraordinary transmission properties are demonstrated in the UV range for GaAs gratings with sub-wavelength apertures under TM-polarization excitation. The metal-like response below 270nm, typical of several semiconductors such as GaAs or GaP, in fact may be used to excite surface waves that lead to enhanced transmission in the linear regime and to novel nonlinear optical phenomena in the UV and soft X-ray ranges. An investigation of the linear transmission as a function of geometrical parameters of the grating reveals the formation of surface waves and relatively high transmission values even in regimes where the nominal absorption is significant. Strong field localization in sub-wavelength cavities and on the surface of the grating can be achieved under proper excitation conditions leading to the enheacement of harmonic generation. Nonlinear contributions to harmonic generation arise from symmetry breaking and the nonlinear magnetic Lorentz force. Preliminary results show promising nonlinear conversion efficiencies at wavelengths below 100nm, and demonstrate cross-coupling of TE and TM polarizations for pump and harmonic signals. A down-conversion process that can re-generate pump photons of polarization orthogonal compared to the incident pump field is also demonstrated.

Enhanced nonlinear optics in resonant GaAs gratings: harmonic generation and optical bistability

D. de Ceglia, G. D'Aguanno, N. Mattiucci, M. A. A. Vincenti, The AEgis Technologies Group, Inc. (United States); M. Bloemer, M. Scalora, U.S. Army Aviation and Missile Command (United States)

We present a study on nonlinear optical processes in GaAs gratings, made by perforating a single layer of GaAs with subwavelength slits. Large enhancement of conversion efficiency, for both second and third harmonic generation, is predicted when a TE-polarized pump field excites the guided mode resonances of the grating. When these modes are excited, the spectrum near the pump wavelength shows abrupt changes of linear transmission and reflection that follow a typical Fano-like shape. At the same time the grating provides dramatic enhancement of local fields and fosters favorable conditions for harmonic generation processes, even in regimes of strong linear absorption at the harmonic wavelengths. In particular, in a GaAs grating pumped at 1064nm, we predict second (532nm) and third (354nm) harmonic conversion efficiencies several orders of magnitude larger than conversion rates achievable in either bulk or etalon structures made of the same material. We demonstrate that these efficiencies are not influenced by linear absorption at the harmonic wavelengths, and they are unrelated to grating thickness or to the order of the guided mode excited. We also analyze the effects of self phase modulation on resonant gratings. In particular we will demonstrate the possibility of triggering optical bistability at relatively low switching intensities by exploiting the strong field localization provided by the grating at the guided mode resonances. Finally, we will discuss the influence of self-phase modulation on the harmonic generation conversion efficiencies.

Nonlinear optical couplers based on strongly anisotropic metamaterial waveguides

G. Venugopal, N. M. Litchinitser, Univ. at Buffalo (United States)

Nonlinear waveguide couplers have attracted a lot of interests in the recent years. Combined with the unique properties of metamaterials, nonlinear directional couplers open fundamentally new opportunities for the development of ultra-compact signal processing functionalities for on-chip applications. Recently, we proposed a novel kind of nonlinear coupler with one channel filled with linear negative index material and another one filled with positive index material one or both of which could be nonlinear. The opposite directionality of phase and velocity in such systems lead to an effective feedback mechanism. We found exact analytical solutions and predicted that such systems can be bi- or multi-stable and support a family of gap solitons. However all previous studies were based on coupled-mode analysis assuming that effective medium parameters for dielectric permittivity and magnetic permeability of metamaterials.

In this work we discuss the design and simulation of nonlinear couplers based on strongly anisotropic metamaterial waveguides. Such waveguides were shown to support negative-index propagating modes (Podolskiy and Narimanov). For these modes, the wave propagation is in a direction opposite to the phase velocity. As a result, the waveguide behaves as a 2-dimensional counterpart of 3-dimensional negative index material. The waveguides in a coupler that we design consists of alternating metal and dielectric subwavelength layers with positive and negative permittivities, respectively. As a nonlinear optical material, we incorporate chalcogenide glass that was demonstrated to have relatively high nonlinear refractive index of ~ 10^(-13) cm2/W. We will report numerical simulations demonstrating novel transmission properties of such couplers, including distributed feedback and bistability.

Optical negative refraction by four-wave mixing in metallic nanostructures

S. Palomba, Univ. of California, Berkeley (United States); S. Zhang, The Univ. of Birmingham (United Kingdom); Y. Park, X. Yin, X. Zhang, Univ. of California, Berkeley (United States); G. Bartal, Technion-Israel Institute of Technology (Israel)

While all natural materials exhibit refraction in the positive direction, artificially engineered materials have been utilized in various ways to bend EM waves negatively. Bulk metamaterials and photonic crystals demonstrated negative refraction of the EM energy flux and wavevectors. A direct way to obtain negative refraction from very thin film has been

theoretically proposed by Tretyakov and Pendry.

Here, we demonstrate nonlinear negative refraction, by using degenerate four-wave mixing (4WM) process to show efficient frequency conversion by a 20nm thick gold film where the newly generated frequency is emerged at a negative angle comparing to the exciting wave. The ratio between the sines of the incident and nonlinearly refracted angles remains a negative constant and depends only on the wavelengths ratio hence rigorously fulfils Snell's law, expanding the phenomenon of negative refraction into the nonlinear regime. Showing the ability for negative refraction by very thin slab, such nanosystems could constitute the building blocks for the implementation of a super lens in the visible region and possible further investigations.

Our approach can operate for all frequencies and polarizations and has no nonlocal effects typically present in metamaterials and it constitutes the first demonstration of negative refraction in ultrathin films.

second order optical susceptibilities of ZnO(0001) and NiO(001) surfaces

A. V. Gavrilenko, V. I. Gavrilenko, Norfolk State Univ. (United States)

Direct fabrication of complex nanostructures with controlled crystalline morphology, orientation and surface architectures remains a significant challenge. Nonlinear optical spectroscopy of the second harmonic generation (SHG) is a tool that is extremely sensitive to a very thin surface layer (up to few atomic monolayers). This technology is therefore a very powerful tool for contact-less monitoring of the nanocrystal growth, as well as surface, and interface structural quality. In this work we study SHG spectra of hexagonal zinc oxide (0001) and nickel oxide (001) surfaces as materials extensively studied for different applications in nanophotonics. Electron energy structure and second order nonlinear optical susceptibilities have been studied from the first principles within the Density Functional Theory (DFT) using ab initio pseudopotentials. Equilibrium geometries of (001) surfaces are obtained by total energy minimization method using the Local Density Approximation (LDA). Optical functions are calculated within the independent particles picture. Analysis of the results is focused on understanding of the physics behind the formation of the second order optical response from the transition metal oxide surfaces, namely contributions of oxygen and metallic d-electron related excitations. Strong contribution to the nonlinear optical susceptibility functions of the high-density d-electrons bellow the Fermi energy in transition metals is demonstrated. Theoretical predictions are compared with available experimental data.

Experimental harmonic generation in the metallic regime of GaP

V. Roppo, Univ. Politècnica de Catalunya (Spain) and Charles M. Bowden Research Ctr. (United States); J. V. Foreman, N. Akozbek, Charles M. Bowden Research Ctr. (United States); M. A. A. Vincenti, AEgis Technologies Group (United States); M. Scalora, Charles M. Bowden Research Ctr. (United States)

When a pump signal traverses an interface into a nonlinear medium it generates SH and/or TH fields, depending on the type of nonlinearity involved. Each harmonic consists in a homogeneous portion that walk-off from the pump field and in an inhomogeneous component phase- and velocity-locked to the pump. The key observation here is that the inhomogeneous component always experiences the same complex index of refraction the pump pulse.

This idea has already been experimentally proved when a pump pulse tuned at 1300nm was launched into a slab of GaAs 500micron thick. Transmitted SH and TH signals were detected far below the material absorption band edge (~900nm). The homogeneous SH and TH signals were quickly absorbed, while the inhomogeneous components continued on through the sample experiencing an effective complex index of refraction identical to the index of the pump, which is tuned in a region of transparency. A detailed investigation of the propagation characteristics of the inhomogeneous component in different circumstances can bring about new interesting scenarios. For example, it has been shown that in a high-Q GaAs cavity the inhomogeneous SH signal (at 612nm) can achieve conversion efficiencies of the order of 1e-3 with pumping field intensities as low as 0.15MW/cm2 inside the cavity.

Following the evolution of this topic, it now comes natural to ask the following question: does this phenomenon hold for harmonic fields tuned at frequencies in the metallic range? That is to say, if the pump field is tuned in the transparency region, will a harmonic field propagate if it happens to be tuned in a region where sign(ε)<0, where one expects no propagating solutions? The short answer to this question is yes and we provide experimental evidence that show how an electromagnetic field is generated and propagates in otherwise forbidden wavelength ranges.

Wave propagation in lossy MTMs surrounded by linear and nonlinear media with arbitrary nonlinearity

Z. I. Al-Sahhar, Al-Aqsa Univ. (Palestinian Territory, Occupied); H. J. El-Khozondar, M. M. Shabat, Islamic Univ. of Gaza (Palestinian Territory, Occupied)

The dispersion relation in a system consists of a lossy metamaterials (MTMs) film surrounded by a linear substrate and a nonlinear cladding with an arbitrary nonlinearity is derived. The surface plasmonic (SP) wave at the interfaces between metamaterials (MTMs) and the nonlinear cover is recovered by taking certain limits. Lossy MTMs have simultaneously complex-negative permeability μ and complex-negative permittivity ε. Results are presented by plotting the SP frequency as a function of the nonlinearity at chosen damping factors. Both the real and imaginary parts are studied. Results also display the wave frequency as a function of plasma frequency. For comparison, the imaginary part is set to zero and curves are reproduced.

Super Talbot effect in anisotropic metamaterial

W. Zhao, Z. Lu, Rochester Institute of Technology (United States)

Advances in metamaterial provide the possibilities to engineer the permittivity of a metamaterial to be almost any arbitrary value (positive, zero, or negative). In particular, if the real part of the permittivity component along the light propagation direction is negative, while the transverse ones positive, the dispersion curve is in hyperbolic form. The anisotropic metamaterial (or hyperbolic metamaterial) can convert the evanescent waves which would normally decay in the conventional materials into propagating waves. The anisotropic metamaterial can be realized by depositing thin, alternating metal-insulator layers.

In this paper, we re-visit the classical optical phenomenon, called Talbot effect and investigate this effect in such an anisotropic metamaterial. From 2D and 3D numerical simulation results, we show that the super Talbot effect can be observed in the metamaterial even the period of the object is much smaller than the incident wavelength. Deep subwavelength resolution of the super Talbot effect can be achieved as long as the attenuation of the metamaterial is small enough. As the incident wavelength is 630nm, the period of the input grating is 94nm and the duty cycle is 50%, for an Ag-SiO2 layered structure (dAg:dSiO2=5nm:5nm), the image size measured at the fourth Talbot imaging plane is about 55nm. The Talbot distance measured is around 152nm. The corresponding effective permittivity is calculated as: -6.46+i0.51 (along propagation direction) and 4.94+i0.05 (along transverse directions).

The super Talbot effect may have the applications in the areas of nanolithography and optical storage.

Numerical optimization for the plasmonic Raman sensor including periodic hole arrays and tapering directions

K. Yamaguchi, Toyohashi Univ. of Technology (Japan); M. Fujii, Toba National College of Maritime Technology (Japan); D. K. Gramotnev, Nanophotonics Pty Ltd. (Australia)

Metal nanostructures are interesting for achieving new types of biosensors because they can work as nanocavities that have high sensitivity when surface plasmons are used. This approach should let us detect the binding reactions of molecules in real time with high sensitivity. However, to achieve this, we must greatly enhance the electromagnetic field and Raman radiation.

Nanofocusing structures for surface plasmons could present a breakthrough in achieving both nanoscale confinement of electromagnetic energy and large, highly controlled local field enhancement required for efficient surface-enhanced Raman scattering.

We previously fabricated a nanofocusing (tapered) hole array in a metal film on a dielectric substrate by using focused ion beam (FIB) lithography and succeeded in observing localized surface plasmon resonances. The results of experiments using this array agreed with most of the calculation results for a tapered hole array obtained using the finite-difference time-domain (FDTD) method. Moreover we numerically determined structural design optimization at the dependences of the expected local field enhancements on Au film thickness, focusing hole diameter, and hole period by the FDTD method in order to take into consideration the plasmonic resonance effects and we concentrated our efforts on periodic nanofocusing hole arrays at the metal-substrate interface.

In this paper, we analysed further structural parameters such as differ from tapered direction and incident direction with the theoretical predictions.

Metamaterials and plasmonics: improved material building blocks

G. V. Naik, J. Kim, P. R. West, A. Boltasseva, Purdue Univ. (United States)

Conventional metals like silver and gold that are used as building blocks for optical metamaterials exhibit excessive losses at optical frequencies. This seriously threats to restrict plasmonic and metamaterial devices in this frequency range to only the proof-of-concept stage. A recent approach that could unlock the technological potential of plasmonics and optical metamaterials is to look for better plasmonic materials (which must have a negative real part of dielectric permittivity). Here we provide an overview of two classes of alternative plasmonic materials - doped semiconductors and intermetallics - that could allow realization of novel transformation optics and metamaterial devices with greatly improved performance operating at near infrared and visible frequencies.

8093-27, Session 6

Understanding and reducing losses in metamaterials

C. M. Soukoulis, Iowa State Univ. (United States)

One of the most serious obstacles when increasing the frequency towards the visible regime is the problem of ohmic losses in the metallic elements and absorption losses in the substrate. By optimizing the overlap of the electromagnetic field and the metal, the metamaterial losses can be reduced by design to some extent. We will present a detailed study of developing the self-consistent calculations of gain with metallic nanostructures in 2D and 3D. The need for self-consistent calculations stems from the fact that by increasing the gain in the metamaterial, the metamaterial properties change, which, in turn, increasing the coupling to the gain medium until a steady state is reached. We will present theoretical and numerical studies has been demonstrated by optical pumping the effective gain coefficient of the combined system can be much higher than its bulk counterpart due to the strong local-field enhancement inside the metamaterials designs. Although optical pumping can compensate losses, it will not materialize to real world applications. We will review how one can reduce the losses with realistic applications; one needs to use semiconductors with gain (quantum dots and quantum wells), which can be pumped by electrical injection. This is compatible with semiconductor industry.

8093-28, Session 6

Effect of losses on nonlocal effects in metal-dielectric multilayered metamaterials

A. A. Orlov, P. M. Voroshilov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); P. A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and Queen Mary Univ. of London (United Kingdom); Y. S. Kivshar, The Australian National Univ. (Australia) and National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

We study the effect of losses on spatial dispersion in metal-dielectric multilayered metamaterials. Previously we discovered that under certain conditions two waves instead of one can be excited in metamaterial under consideration by incident TM-polarized light beam. As was demonstrated earlier, under certain conditions such periodic structures demonstrate strong nonlocal effects manifested, e.g., in the appearance of the second extraordinary wave which can be excited in the metamaterial by an incident TM-polarized light beam and observed through the beam splitting. The existence of an additional light wave is a clear manifestation of the presence of spatial dispersion in the metamaterial, and it validates our earlier observation of strong nonlocal nature of metal-dielectric multilayered metamaterials. Our analysis of such structures with realistic losses demonstrate that losses naturally cause damping of the waves inside of the metamaterial and also reduce the frequency range where birefringence without splitting by polarization is observed. When we employ realistic losses for silver (Ag) as metal, we reveal that the typical losses of silver in the visible range are too high for our purposes. Hence, we consider an active medium with a gain in order to compensate losses.

8093-29, Session 6

Scaling of loss in metamaterials

J. B. Khurgin, The Johns Hopkins Univ. (United States)

It is important to distinguish two separate mechanisms of metamaterial loss increase with frequency: intrinsic material-related loss and purely size-dependent mechanism associated with inability of storing energy outside the metal at high frequencies when electro-static limit is being approached. By highlighting the above we establish the fact that fundamentally losses in the metamaterials with true sub-wavelength features cannot be improved for frequencies higher than 100's of GHz and show that at optical frequencies roughly the same performance is obtained using magnetic (ie.g. split rings) and non-magnetic (e.g. spherical and elliptical nanoparticles) metamaterials.

8093-30, Session 6

Graphene in metamaterials: What makes a material a good conductor?

P. Tassin, T. Koschny, Iowa State Univ. (United States); M. Kafesaki, Foundation for Research and Technology-Hellas (Greece); C. M. Soukoulis, Iowa State Univ. (United States)

Recent developments in the field of metamaterials--or engineered materials with novel electromagnetic properties--have promised a number of exciting applications, in particular at optical frequencies. Most metamaterials consist of carefully designed metallic structures that replace atoms in their role as the basic units of interaction with electromagnetic radiation. Unfortunately, the noble metals are not particularly good conductors at optical frequencies, resulting in significant absorptive loss in photonic metamaterials. Recently, several materials have been proposed to replace metals as the current-carrying elements in metamaterials, such as graphene at optical frequencies and high-Tc superconductors at terahertz frequencies. In this communication, we first address the question of what is a good conductor for use in a metamaterial. We develop a model based on the quasistatic response of metamaterial constituents to an incident electromagnetic field in order to develop a figure of merit for conductors. The results lead to two conclusions: (1) In determining the merits of a certain conducting material, its material properties cannot be uncoupled from certain geometric aspects, such as the layer thickness that can be experimentally obtained. (2) It is the resistivity of the material, rather than the conductivity or permittivity, that gives direct information on the absorptive loss in the metamaterial and on the frequency saturation caused by kinetic inductance. These considerations lead to a figure of merit for conducting materials. Finally, we apply the figure of merit to a number of materials, such as graphene and high-Tc superconductors.

8093-31, Session 7

All kinds of cloaks, all kinds of transformations

M. W. McCall, A. Favaro, P. Kinsler, Imperial College London (United Kingdom); A. D. Boardman, Univ. of Salford (United Kingdom)

Electromagnetic cloaking was the first example of so-called transformation optics where the invariance properties of Maxwell's equations are used to determine how coordinate deformations can be actualized in an electromagnetic medium cite{Pendry2006}. The concept was experimentally realized cite{Schurig2006} and the improvement towards an ideal macroscopic wide-bandwidth cloak continues to be a major goal for the experimentalists. This has included carpet cloaking in 3D cite{Ergin2010}, and the use of polarization selectivity using calcite cite{Chen2011}. Most recently, a significant extension of the concept has been proposed in which the coordinate transformations embrace time as well as space cite{McCall2011}. The electromagnetic medium for realizing spacetime transformations must be dynamic as well as inhomogeneous, and by influencing the local speed of light we showed how it is possible for the light reaching a camera to record an edited version of the events it surveys. Regulating the local speed of light about an average value likely requires that the medium within which the coordinate transformation is carried out be one of uniform refractive index, rather than vacuum. Although this extends the original programme of transformation optics, by using quite abstract methods we have shown how such an extension can be embedded within a general theory of non-birefringent transformations cite{Favaro2011}. However, what if the initial medium is nonlinear or otherwise programmable? Influencing the initial medium will influence the functionality of the final medium in ways that have yet to be explored, with controllable cloaking an obvious goal.

Beyond electromagnetics, transformation theory has been applied now to acoustics to produce a variety of interesting and experimentally realizable schemes cite{Zhang2011,Torrent2007}. Although acoustics is not mathematically equivalent to electromagnetics cite{Cummer2007}, the ideas of actualizing a coordinate transformation do carry over. Therefore, we ask what are the essential ingredients of any transformation theory, and to what other areas of physics can the scheme be applied? We explore the structure and relationship between propagation and constitutive equations towards a general theory.

8093-32, Session 7

3D invisibility cloaks at visible wavelengths

T. Ergin, J. Fischer, Karlsruher Institut für Technologie (Germany); J. C. Halimeh, Ludwig-Maximilians-Univ. München (Germany); N. Stenger, M. Wegener, Karlsruher Institut für Technologie (Germany)

In this contribution, we review our latest work on three-dimensional cloaking utilizing the "carpet cloak" (or "ground-plane cloak") scheme. Here, a bump in a metallic carpet is rendered invisible to an observer by adding a nanostructured metamaterial cloak on top. As a result, the observer again sees a flat metal mirror. In our case, the metamaterial consists of a polymeric woodpile photonic crystal that is used in the long-wave limit. The woodpile is fabricated via stimulated emission depletion-inspired direct laser writing, which allows for a drastic miniaturization of the feature sizes and thus pushes the woodpile's effective medium limit into the visible regime. The filling fraction of the woodpile is changed locally to give rise to a tailored refractive-index distribution. This distribution is derived in the framework of transformation optics using quasi-conformal mapping. We characterize the three-dimensional cloak by optical bright-field and dark-field microscopy using monochromatic circular polarized illumination. A cone of light with a full opening angle of 50 degrees in three dimensions is sampled. Furthermore, we provide numerical ray-tracing calculations which simulate the complete experimental setup within ray optics and the carpet cloak within the effective-medium limit. We find excellent qualitative agreement between experimental results and calculations.

8093-33, Session 7

A transforming device formed by metamaterials creating a visual result of a changed scattering cross section

C. Du, X. Dong, G. Yuan, Q. Deng, C. Liu, Institute of Optics and Electronics (China)

A device for transforming the scattering cross section's shape of perfect electrical conductor (PEC) objects to other arbitrary shapes is presented based on transformation optics. The designed functional device covers the original PEC object with its electromagnetic parameters determined by the transformation expressions. Then, the virtual PEC objects with their definite shape of the scattering cross section will be produced visually. The validation of the device was made by means of finite-element method. Though the designed transformer is anisotropic and inhomogeneous, the development of metamaterials makes it more closely to practice. This device can find applications in many aspects like camouflage some objects from the radar or other target recognition systems.

8093-34, Session 8

Spaser action, loss compensation, and stability in plasmonic systems with gain

M. I. Stockman, Georgia State Univ. (United States)

We demonstrate analytically that the conditions of spaser generation and the full loss compensation in a dense resonant plasmonic-gain medium (metamaterial) are identical. Consequently, attempting the full compensation or overcompensation of losses by gain in such a medium

will lead to an instability and a transition to a spaser state. This will limit (clamp) the inversion and lead to the limitation on the maximum loss compensation achievable. The criterion of the loss overcompensation, leading to the instability and spasing, is given in an analytical and universal (independent from system's geometry) form.

8093-35, Session 8

Design and analysis of metamaterials for the continuous wave terahertz laser

J. Luo, Huazhong Univ. of Science and Technology (China)

The artificially structured electromagnetic materials, which called metamaterials, has led to the realization of phenomena which cannot be obtained with natural materials. We have found many fundamental progress and applications of metamaterials in millimeter wave or microwave, and many usefully potential applications of terahertz as well, but still need considerable efforts to fill this "THz-gap" in future. Therefore, it is especially important to design the metamaterials device in the terahertz frequency regime. For the first, we analyze the split ring resonators(SRRs) model in theory, and many planar SRR arrays with different periodic structures have been designed for later testing, the planar SRR arrays are fabricated using conventional photolithography and electron-beam deposition of gold on n-GaAs substrate, the metal array and n-GaAs together form a Schottky contact. Then the influences of background substrate and the shapes of the SRRs on the terahertz resonance are experimentally investigated at several terahertz frequencies of continuous wave terahertz laser in turn, such as 1.4THz, 2.52THz, 4.25THz, etc., and all the transmission properties are recoded and analyzed, especially, some SRR arrays can obtain about 80 percent absorption of THz amplitude transmission. In addition, computer simulations of the spectral response of the chosen planar metamaterials are performed to analyze the resonance frequency, surface current density and local electric field, which agree well with measured results. These metamaterials may be useful for future applications in the construction of various THz filters, THz antenna, or THz grid structures ideal for constructing THz switching devices.

8093-36, Session 8

Interference enhancement of photoluminescence of ultrathin layer with silicon nanocrystals

S. A. Dyakov, Trinity College Dublin (Ireland); D. M. Zhigunov, Lomonosov Moscow State Univ. (Russian Federation); T. S. Perova, Trinity College Dublin (Ireland); V. Y. Timoshenko, Lomonosov Moscow State Univ. (Russian Federation); A. Hartel, D. Hiller, M. Zacharias, Albert-Ludwigs-Univ. Freiburg (Germany)

Most of prospective applications of silicon nanocrystals (Si-NCs), such as active media for optical waveguides, amplifiers and lasers, or absorbing ultrathin layer for the third generation photovoltaic devices, imply utilization of thin films containing Si-NCs. Therefore, the control of optical properties of such films is of current importance. However, small optical thicknesses of the films and complicated multilayered structure make certain difficulties for the ordinary estimations using standard formulas. We present a model, which enables one to prognosticate the photoluminescence (PL) intensity of multilayered structure. Using theoretical predictions we experimentally observed PL intensity enhancement of 4 nm thick film with Si-NCs for optimally chosen silicon dioxide (SiO2) buffer layer thickness. Moreover, our model enables one to explain nonmonotonic dependence of PL intensity from Si-NCs layer on its thickness.

Alternating layers of stoichiometric SiO2 and silicon rich silicon oxynitride (SRON) were deposited on Si substrates using PECVD system. Subsequently, all samples were annealed for 1 h in high purity N2 atmosphere at 1100oC in order to form Si-NCs in SRON layers. Triple-layered structures consisting of buffer SiO2 layer, emitting SRON layer and capping SiO2 layer were fabricated. For the first set of samples the thickness of buffer layer was varied from 0 to 125 nm, while the thicknesses of emitting and capping layers were fixed. The second set of samples is characterized by variable thickness of emitting SRON layer, the thicknesses of other layers were constant. The PL process is approximated by radiation of chaotically oriented oscillating dipoles.

8093-37, Session 8

Interactions in planar metamaterials: from strong coupling to active tuning

I. Brener, Sandia National Labs. (United States)

The issue of interactions between different types of engineered metamaterial resonances has received considerable attention since it was shown that electromagnetically induced transparency behavior can be mimicked using coupling between metamaterials and/or plasmonic resonators. In this talk I will present some of our recent results on strong coupling between metamaterial resonators and other excitations such as phonons, free carriers and intersubband transitions in semiconductor heterostructures, and ways to exploit these for active tuning of metamaterial properties.

8093-38, Session 8

Octave-wide photonic band gap in three-dimensional plasmonic Bragg metamaterials

H. W. Giessen, R. Taubert, Univ. of Stuttgart (Germany)

Coupling between individual particle plasmon resonances (PPRs) has been a field of extensive research over the past few years. Most of the work was dedicated to near-field coupling with close spacing between the resonant particles. In this limit, retardation is negligible, but also the interesting properties of radiating PPRs are mostly neglected. In contrast, when particles are positioned at distances on the order of their emission wavelength, coupling can be mediated by the radiation fields of the PPRs.

We investigate far-field coupling in three-dimensional stacked plasmonic nanostructures. We show that a superradiant mode forms when particles are stacked at Bragg distance. Increasing the number N of stacked layers leads to the formation of a very broad photonic band gap of about 1 eV.

Ivchenko et al. predicted that the radiative width of the superradiant mode in a structure of Bragg-stacked oscillators is proportional to the number of layers. This can be intuitively understood by the matching of the oscillator phase to their vertical distance, which leads to an increased, "collective" dipole moment of the coupled system.

To demonstrate this, we extracted the FWHM from calculated spectra of Bragg stacked nanowires for one to ten layers. The FWHM of the coupled system increases strongly for increasing number of layers. The dependence of the stop gap width on the plasmonic oscillator strength is investigated by considering different wire geometries: w and h are changed, keeping a constant aspect ratio, in order to compensate for the spectral shift. Therefore the spectral position for the different geometries is constant and only the oscillator strength changes.

For the small wires with low oscillator strength, the width of the mode increases slowly but linearly up to approximately 7 layers and start to saturate for more layers. In contrast, the large wires, which exhibit a big oscillator strength, show a strong increase for the first two layers and almost no further change for higher N. This issue can be understood by taking into account that interaction is only possible within the coherence length of the oscillators. As the large wires couple more efficiently to the radiation field, their decay is on the order of only a few cycles of the light field. Interaction with oscillators beyond this range is not possible. This interpretation is supported by extracting the radiative lifetime for a single oscillator from the linewidth at N=1 and deducing the coherence length of propagation subsequently.

8093-13, Session 9

Linear and nonlinear properties of low spatial symmetry metamaterials

G. Shvets, C. Wu, A. B. Khanikaev, N. Arju, The Univ. of Texas at Austin (United States)

Plasmonic Low Spatial Symmetry Metamaterials (LSPMs) is a novel and exciting recent development in the area of electromagnetic metamaterials because they truly represent building blocks unavailable in Nature. Specifically, while most molecules and atoms possess at least some degree of spatial symmetry (e.g., a finite number of inversion planes), LSPMs can be designed to have none. This opens us exciting opportunities for making new optical devices that are based on both single-layer and multi-layers. For example, LSPM can be used for efficient polarization manipulation.

Three-dimensional LSPM whose properties slowly vary along the direction of light propagation can be used for making slow-light devices.

LSPMs can be used for engineering the radiative lifetimes of metamaterials because they can be designed to support both “bright” (radiant) and “dark” (sub-radiant) resonances. The interference between the two results in the so-called Fano resonance. One attractive feature of LSPMs is that, depending on the light polarization, the same resonance can give rise a Fano-like or Lorentzian line shapes. We will describe the fundamental theory explaining these resonant shapes and present experimental results for the pi-shaped plasmonic antennas. Field enhancement predicted by the simulations will be used to evaluate the potential of LSPM-based devices for nonlinear applications.

8093-40, Session 9

Temporally shaping ultrafast light with metamaterials

D. P. Brown, UES, Inc. (United States); A. M. Urbas, Air Force Research Lab. (United States)

Coherent excitation in optical spectroscopy and control of photo-induced processes like second harmonic generation depend on the temporal properties of ultrafast pulses. In this work, we demonstrate that metamaterials can be fabricated to have very large spectral dispersion properties that can affect both the temporal envelope and phase of each spectral component of an ultrafast pulse in useful ways. Values for the group delay dispersion were found to be as large as plus or minus 4000 fs2. We simulated the effect these materials would have on an ultrafast pulse with a full width half max (FWHM) time duration between 12 and 15fs, and then experimentally tested the pulse shape by transmitting or reflecting off of the metamaterials an ultrafast pulse from an oscillator capable of the same pulse as the simulations. The pulse envelope was determined using fringe resolved autocorrelation (FRAC). Finally, we explored the effects on second harmonic generation and two photon fluorescence both numerically and experimentally, and we examined how the structure orientation of the metamaterial changes these effects.

8093-41, Session 9

Robust optical delay lines via topological protection

M. Hafezi, Joint Quantum Institute (United States); E. A. Demler, M. D. Lukin, Harvard Univ. (United States); J. M. Talyor, Joint Quantum Institute (United States)

Optical signals might be a promising alternative to electronic signals in future circuits. One key requirement is the ability to filter and delay light on-chip over a large bandwidth (several Gbps) for various time-domain processing such as optical buffering and multiplexing. However, disorder in fabrication rapidly degrades performance, leading to effects such as unwanted signal modulation in transmission. Here we show theoretically how exploiting topological properties of optical systems forms a basis for robust optical devices which are immune to disorder.

Our method for realization of topological protected photonic devices makes use of two dimensional arrays of coupled resonator optical waveguides (CROW) to simulate a 2D magnetic tight-binding Hamiltonian with degenerate clockwise and counter-clockwise modes. This approach does not require explicit time-reversal symmetry breaking, but the degenerate modes — time-reversed pairs — behave analogously to spins with spin-orbit coupling in the electronic quantum spin Hall effect (QSHE), and experience a spin-dependent magnetic field. When the clockwise and counter-clockwise modes are decoupled, we can selectively drive each mode and observe quantum Hall behaviors without breaking the time-reversal symmetry in the tight binding Hamiltonian. In a direct analogy to the electronic integer quantum Hall effect, we show that photonic edge states carry light at the perimeter of the system, while being insensitive to disorder, and thereby forms a basis for robust photonic devices. In particular, in comparison to state-of-the-art 1-D CROW systems, our approach can be dramatically more resistant to scattering disorders and fabrication errors.

8093-42, Session 10

Layer-by-layer metamaterials using membrane projection lithography

D. B. Burckel, J. R. Wendt, I. Brener, A. R. Ellis, M. B. Sinclair, Sandia National Labs. (United States)

The lack of a suitable fabrication technique of bulk-like metamaterials containing 3D isotropic unit cells for operation in the IR and optical wavelength ranges continues to present a significant barrier to exploration of potential metamaterial solutions and applications. Recently we have introduced membrane projection lithography (MPL) a fabrication technique capable of creating truly 3D micron-scale metamaterial unit cells. The basic premise behind MPL is creating a patterned membrane suspended over a cavity (the unit cell). Directional evaporation(s) through the patterned membrane results in deposition of a replica of the membrane pattern on the interior face(s) of the cavity.

In this talk we report our recent progress extending MPL to 3D bulk-like materials in a layer-by-layer process. We will present fabrication details addressing complications associated with multi-layer processing as well as optical characterization data showing the impact of moving from a single layer of 3 dimensionally oriented resonators dominated by surface effects to one with resonators embedded in a medium with bulk-like behavior. These micron-scale 3D metamaterials demonstrate that MPL enables exploration into the viability of metamaterial concepts to applications in the thermal IR wavelength range.

Supported by the Laboratory Directed Research and Development program at Sandia National Laboratories. This work was performed, in part, at the Center for Integrated Nanotechnologies, a U.S. Department of Energy, Office of Basic Energy Sciences user facility Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy’s National Nuclear Security Administration under Contract DE-AC04-94AL85000.

8093-43, Session 10

Bottom-up manufacturing methods for application in metamaterials

D. A. Pawlak, K. Bienkowski, M. Gajc, A. Klos, P. Osewski, K. Sadecka, A. Stefanski, Institute of Electronic Materials Technology (Poland)

One of the future ways of obtaining metamaterials or materials with unusual electromagnetic properties most probably will be methods based on self-organization. Novel developments in the bottom-up manufacturing approach towards metamaterials will be discussed. The methods presented are based on eutectic directional solidification as

well as on doping dielectric materials with plasmonic nanoparticles. The investigated methods allow for manufacturing of bulk 2 and 3 D micro and nanostructured materials with various geometries (rodlike, lamellar, spiral) as well as various component materials (oxides, metals, semiconductors). Recently even split-ring resonator geometry has been achieved.

8093-44, Session 10

All dielectric infrared metamaterial

M. B. Sinclair, J. C. Ginn, J. R. Wendt, J. O. Stevens, D. W. Peters, L. I. Basilio, L. K. Warne, I. Brener, P. G. Clem, J. F. Ihlefeld, Sandia National Labs. (United States)

Metamaterials comprising metallic inclusions such as split ring resonators have been utilized for numerous device demonstrations at microwave frequencies. Unfortunately, the increased impact of ohmic losses renders metal-based metamaterials too lossy for devices at optical wavelengths (infrared and shorter). A possible strategy to overcome this fundamental limitation is to replace the metallic inclusions with high permittivity dielectric resonators, thereby replacing lossy conduction currents with displacement currents. A further advantage of the utilization of dielectric resonators is the isotropic metamaterial response that arises due to the high degree of symmetry exhibited by typical resonator shapes (i.e. spheres and cubes). In this presentation, we will describe the design, fabrication, and characterization of all dielectric metamaterials operating in the thermal infrared. The dielectric metamaterials are based on cubic dielectric resonators fabricated from Tellurium and arrayed on a Barium Fluoride substrate. As predicted by analytical and numerical simulation, the metamaterial exhibits a magnetic resonance near 10 um wavelength, as well as an electric resonance at a slightly shorter wavelength. The retrieved effective parameters indicate a negative permeability (permittivity) in the vicinity of the magnetic (electric) resonance. This work represents a first step toward the development of low loss infrared metamaterials suitable for device applications. This work was supported by the Laboratory Directed Research and Development program at Sandia National Laboratories. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

8093-45, Session 10

Nanorod metamaterials as a new plasmonic platform

A. V. Zayats, King's College London (United Kingdom)

Guiding and manipulating light on length scales below the diffraction limit requires structural elements with dimensions much smaller than the wavelength. Recently, novel plasmonic metamaterial has been developed based on arrays of aligned gold nanorods grown in self-assembled anodic aluminium oxide templates. This metamaterial provides a flexible platform with tuneable resonant optical properties across the visible spectral range, that can be specifically designed by changing the length, diameter and separation between the nanorods. Such metamaterials, with a controllable and engineered plasmonic response, can be used instead of conventional plasmonic metals for designing plasmonic waveguides, plasmonic crystals, label-free bio- and chemo-sensors and for development nonlinear plasmonic structures with the enhanced nonlinearities. The high electromagnetic field confinement and hence enhancement makes these systems ideally suited to the creation of active plasmonic devices by hybridization with nonlinear optical materials or sensing applications which benefit from the large effective surface area in such self-assembled, template based materials.

In this talk we will overview applications of plasmonic plasmonic nanorod metamaterial for designing new types of nanoscale waveguides, biosensing platforms and nonlinear optical devices with improved properties.

8093-46, Session 10

Enhanced transmission from a 2-D complementary metallic square array decorated with gold nanoparticles

M. J. Birnkrant, Air Force Research Lab. (United States); D. P. Brown, UES, Inc. (United States) and Air Force Research Lab. (United States); V. P. Tondiglia, SAIC (United States) and Air Force Research Lab. (United States); T. J. Bunning, A. M. Urbas, Air Force Research Lab. (United States)

Enhanced transmission from metallic hole arrays show promise as filters and environmental sensors. Recently, a subset of structures known as Metallic Complementary Arrays (MCA) have been studied. MCA are sandwich type structures that have a metal-insulator-metal (MIM) morphology. The MIM feature of MCA has one metal layer with complementary features to the other metal layer. These materials achieve selective transmission by matching plasmonic modes in the top and bottom layers. Understanding what influences the coupling between the two metal layers is not well understood. In this presentation we explore through simulation and experimentation a method for coupling the two metal complementary layers using nanoparticles. The MCA was fabricated using a modified interference-lithography technique to construct the insulator layer out of photoresist. Subsequently the metal layers were deposited through evaporation of gold. Finally nanoparticles were deposited on top of the MCA. The transmission spectra from a complementary array with nanoparticles showed enhanced transmission of light at wavelengths below the diffraction limit. Enhanced transmission below the diffraction limit is mediated by surface plasmon resonances. In the present case, the nanoparticles may act to impede surfaces plasmons on the MCA allowing for a number of surface plasmon modes to interact between the two metal layers. The influence of the impedance on the coupling between the two metal layers is investigated via nanoparticle coverage and separation distance.

8093-47, Session 10

Planar gradient index photonic metamaterials

Z. Wu, Toyota Technical Ctr., USA (United States)

Metamaterials operating at optical frequencies, referred to as optical or photonic metamaterials, require features fabricated at a subwavelength scale from 50 nm to 1000nm. In this work a planar gradient index metamaterial is designed and demonstrated at optical frequencies by numerical simulation through a finite-difference time domain method in conjunction with an electromagnetic retrieval technique. We confirm the gradient by simulating the deflection of a light beam passing through a multilayer silver (Ag) and magnesium fluoride (MgF2) slab featured with specially designed nano-rectangular holes. The planar gradient index photonic metamaterials we propose can be fabricated by available nano-fabrication technologies. Optical tests can be performed since the designs are also based on the consideration of the frequency range available for evaluation. In this paper, we combined the graded index concept with the fishnet structure for the purpose of extending gradient index metamaterials into optical frequencies. We designed the fishnet unit cell with optimum refractive index range by tuning the unit cell dimensions. A commercial finite-difference time domain software package (CST MICROWAVE STUDIO), was used to calculate transmission and reflection coefficients, also known as S-parameters. A standard material parameter retrieval algorithm was developed to determine effective refractive index from transmission and reflection coefficients. Refractive indices as a function of unit cell geometry were used to the map index profile to the variation of unit cells. The electric field mapping simulations were utilized to show the beam forming mechanism. The light beam deflection was demonstrated by introducing the light passing through planar gradient metamaterial consisting of a multilayer Ag-MgF2-Ag sandwich slab featured with specially designed and arranged fishnet unit cells. Unlike most of previous metamaterial gradient index designs, first, this was designed to operate in positive

index regime away from resonance to minimize losses; second, all of the patterned elements were planar which did not require volumetric unit cell; third, it was for optical frequencies.

8093-48, Session 10

Three-dimensional resonant guided wave networks

S. P. Burgos, E. Feigenbaum, H. A. Atwater, California Institute of Technology (United States)

It has recently been shown that resonant guided wave networks (RGWNs) are an artificial material class where the wave dispersion is controlled through strong coupling of local resonances throughout the waveguide network. In this work, we implement the RGWN concept at λ = 1100–1600 nm in three dimensions with a Cartesian mesh of regularly-spaced cylindrical plasmonic waveguides in a metallic mesh.

The RGWN concept is based on two basic types of elements: isolated waveguides, where the waves accumulate phase, and power-splitting junctions at the waveguide intersections. Due to the simplicity of these two basic network operations, it is possible to comprehensively describe the full network dynamics with a reduced numerical code, which greatly reduces computation time in comparison to full wave simulations and allows for an insightful study of the network dynamics.

The conditions required for designing three-dimensional plasmonic cavities as well as their dependence on wavelength and network layout will be presented. Furthermore, using the Q-factor analysis, we map the eigenmodes of finite-size networks, and we categorize their symmetry and degeneracy based on the steady-state time evolution of the energy density within the network. Lastly, by implementing Bloch boundary conditions instead of PMLs, the numerical code is also used to calculate the bandstructure of infinite 3D network layouts. This method of analysis illustrates the design potential of 3D-RGWNs, which can ultimately be used to program complex network dynamics and functions.

8093-49, Session 11

Optical forces in metamaterials

P. Tassin, R. Zhao, T. Koschny, C. M. Soukoulis, Iowa State Univ. (United States)

Since a few years, it has been proposed to harness optical forces, i.e., the forces that arise when linear momentum is transferred from photons to matter, in micro- and nanophotonic systems. Most attention was focused on optical forces in waveguides, where resonant waveguide modes enable forces on the space scale of the wavelength of light. Recently, we have extended such research to subwavelength structures. We start this communication with a study of optical forces in a prototype of metamaterial constituents--the nanowire pair. We show how the electric and magnetic dipole resonances lead to repulsive and attractive forces, respectively. However, the stacking of nanowire pairs in an array as in metamaterials may dramatically change the nature of optical forces, e.g., changing the forces associated with the electric dipole resonance from repulsive to attractive. In the second part of this communication, we show how the optical force can be exploited for the creation of nonlinear metamaterials. By optimizing a split-ring resonator structure for the enhanced interaction between the elastic and the electromagnetic modes mediated by the optical force, we demonstrate metamaterials with a transmission spectrum that depends on the power of the incident electromagnetic wave. This metamaterial thus allows for the switching of its transmittance by simply changing the incident beam power.

8093-50, Session 11

Electromagnetic forces on parallel plates cavity

J. Ng, Hong Kong Univ. of Science and Technology (Hong Kong, China); H. Liu, Nanjing Univ. (China); Z. Lin, Fudan Univ. (China); Z. Hang, C. Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China); S. Zhu, Nanjing Univ. (China)

Metamaterials are man-made materials which possess unusual optical properties. These materials are often made from sub-wavelength metallic resonators. Most of the studies on these materials are focused on their optical properties, and the effect of optical forces associated with the excitation of resonances in these materials are much less discussed. In this talk, we will study the electromagnetic forces acting on resonating units comprising a simple parallel plate resonator made from gold. This simple system may serve as a prototypical building block of metamaterials. We first understand the physics using a qualitative Lagrangian model, and then full wave numerical simulation (CST microwave studio) is performed.

In microwave scale, gold behaves as perfect electric conductors. The two plates experience a repulsive force due to the leakage of electric fields at the edges. Even with a conventional microwave source (power ~15 mW), it is shown that the microwave force is significantly enhanced at resonance and it can lead to experimentally measurable forces.

In near infrared scale, we need to consider gold as a plasmonic material as the field can penetrate the plates. The two plates attract each others owing to a novel mechanism - the plasmon-induced kinetic energy of the conduction electron reduces the Faraday magnetic energy which induces attraction. We show that the optical forces in near infrared can be enhanced by orders of magnitude write respect to the usual photon pressure and it can be deployed to the manipulation of the cavity itself.

8093-51, Session 11

Electromagnetic radiation pressure on left- and right-handed dissipative media

H. Lezec, A. K. Agrawal, M. Abashin, S. Rajauria, National Institute of Standards and Technology (United States); K. J. Chau, The Univ. of British Columbia (Canada)

We investigate both experimentally and theoretically the radiation pressure exerted by a plane wave of visible-frequency light on a flat slab of dissipative material which is either left handed [1] or right handed (i.e. having electric permittivity and magnetic permeability which are both negative or both positive, respectively). We characterize the radiation-pressure response of an optical-frequency, broadband, left-handed metamaterial based on stacked Ag/Si/Ag plasmonic waveguides, each designed to be left-handed over most of the visible spectrum. A fully-absorbing flat slab of this metamaterial integrated onto a low-stiffness cantilever is shown to experience a pull when illuminated at normal incidence by a plane-wave of free-space wavelength in the range 460 nm to 600 nm. Radiation-induced pull is further confirmed by observation of levitation of free-standing slabs of the metamaterial under illumination at 532nm. An analytic model is proposed which is consistent with the spectral dependence of the measured pressure response. In this model, the real part of the effective refractive index of the metamaterial contributes to a proportionately-large, negative absorption force, which, when it exceeds the positive Lorentz force, yields in a net negative pressure on the object. The origin of the implied momentum-transfer non-equivalence between Lorentz and dissipative forces, related respectively to the wave and particle nature of the photon, is investigated through finite-difference-time-domain simulations of optomechanical pulse-slab interactions, as well as via interferometric measurements of the radiation-pressure response of thin films of high-index, dissipative, right-handed materials on silicon-nitride membranes. [1] V. Veselago, Sov. Phys. Usp. 10, 509-514 (1968).

8093-52, Session 12

Grating-assisted subwavelength far field imaging

V. A. Podolskiy, Univ. of Massachusetts Lowell (United States); S. Thongrattanasiri, N. A. Kuhta, Oregon State Univ. (United States)

High-resolution imaging is of interest for a broad class of applications spanning all parts of the electromagnetic spectrum. Unfortunately, conventional far-field imaging is fundamentally limited by the free-space wavelength. The diffraction limit can be halved with structured illumination microscopy where the spectrum of the incident light is effectively doubled via interference. Alternatively, in the far-field superlens, part of the evanescent radiation emitted by an object is resonantly enhanced via surface plasmon polaritons, and is subsequently converted into propagating waves with a subwavelength diffraction grating, again doubling the resolution. Here we present an approach capable of non-resonant imaging with resolution on the order of 1/20 of the wavelength with far-field measurements.

The spectrum of a subwavelength focal spot is dominated by high-wavenumber components that exponentially decay away from the focal spot. The grating, that plays the role of image-reconstructing structure, located at the image plane, and translates the spectrum of the source by the multiple of inverse grating periods. This way, the diffraction gratings can convert the originally evanescent information into propagating waves which can be measured in the far field. Provided that the far-field measurements of the same object are performed for different values of incident angle, the contributions of different diffraction orders to the final intensity distribution can be separated from each other, and the original field distribution can be calculated.

Here we present a class of algorithms capable of recovering the subwavelength details of the objects and analyze the effect of imaging grating on image recovery

8093-54, Session 12

Gradient index metalenses for extraordinary light focusing

C. Ma, M. A. Escobar, Z. Liu, Univ. of California, San Diego (United States)

The lens is the most commonly used element in optical systems, which however can achieve only diffraction limited resolution at the scale of ~λ/2, with λ being the working wavelength. Because of the versatile and exceptional designability of metamaterials, various superlenses have been proposed and demonstrated with resolving power beyond the conventional diffraction limit in the past decade. However, such superlenses behave remarkably different from their conventional counterpart. For instance, they cannot focus a plane wave due to the lack of phase compensation mechanism. We have recently proposed two types of phase compensated metamaterial lenses, i.e., the metamaterial immersion lens (MIL) and the metalens, which have super resolving power and are able to focus a plane wave to a spot. In this work, we proposed another type of phase compensated metalenses based on planar gradient-index (GRIN) or inhomogeneous permittivity metamaterials, which we refer to as GRIN metalenses. Using a generalized discretization method to analyze both the elliptically and hyperbolically dispersive GRIN metalenses, we investigate all the conditions of anisotropic GRIN material profiles required for both internal and external focusing. Simulation results show that the GRIN metalenses can achieve super resolution focusing and have ordinary or extraordinary Fourier transform functions. The extraordinary focusing behavior may enable exotic imaging applications.

8093-56, Session 12

Studies of plasmonic hot-spot translation by a metal-dielectric layered superlens

M. D. Thoreson, Purdue Univ. (United States) and rlangen Graduate School in Advanced Optical Technologies (Germany); R. B. Nielsen, Technical Univ. of Denmark (Denmark); P. R. West, Purdue Univ. (United States); A. Kriesch, Max-Planck-Institut für die Physik des Lichts (Germany) and Erlangen Graduate School of Advanced Optical Technologies (Germany) and Cluster of Excellence Engineering of Advanced Materials (Germany); Z. Liu, Institute of High Performance Computing (Singapore); J. Fang, Purdue Univ. (United States); U. Peschel, Erlangen Graduate School in Advanced Optical Technologies (Germany) and Cluster of Excellence Engineering of Advanced Materials (Germany); A. Boltasseva, Purdue Univ. (United States) and Erlangen Graduate School of Advanced Optical Technologies (Germany) and Technical Univ. of Denmark (Denmark); V. M. Shalaev, Purdue Univ. (United States)

Single-layer and multilayer superlenses have been studied by a number of researchers in recent years. Most experimental studies have focused on the plasmonic operational regime that is limited to the near-UV range. Numerical studies have also predicted the existence of a canalization regime where superlensing occurs in a layered metal-dielectric system at wavelengths away from the plasmon resonance and into the visible range. This canalization regime has been experimentally observed in the microwave range. In this work, we have experimentally and numerically investigated superlensing in the visible range. By using the resonant hot-spot enhancements from optical nanoantennas as sources, we investigated the translation of these sources to the far side of a layered silver-silica superlens operating in the canalization regime. Using near-field scanning optical microscopy (NSOM), we have observed evidence of superlens-enabled enhanced-field translation at a wavelength of about 680 nm. Specifically, we discuss our recent experimental and simulation results on the translation of hot spots using a silver-silica layered superlens design. In this presentation we will compare experimental results with respective numerical simulations and discuss the perspectives and limitations of our approach.

8093-57, Session 12

Sub-wavelength imaging using stacks of metallic meander structures with different periodicities

P. Schau, K. Frenner, W. Osten, L. Fu, H. C. Schweizer, H. W. Giessen, Univ. Stuttgart (Germany)

Recently it has been questioned if bulk negative index materials (NIM) are really necessary for sub-wavelength imaging since it might not be possible to reduce losses in these materials to an acceptable degree. We suggest an alternative approach, which replaces a bulk NIM with two identical resonant surfaces that allow surface plasmon polariton propagation. The metallic meander structure, which is a thin metal film, corrugated periodically on both sides, acts as such a resonant surface. A direct resonant tunneling transmission of plasmons / photons is observed when two or more meander structures are stacked onto each other [1]. Recently, we have also found that stacks of meander structures with different periodicities show the same resonant tunneling transmission behavior when proper geometry parameters are used for each layer [2]. With respect to physical mechanisms we will explain in detail how changing structural parameters influences the optical properties of resonantly coupled surfaces. Furthermore, we will report on how the variation of the meander periodicity from layer to layer enables sub-wavelength imaging.

8093-58, Session 13

Metamaterial models of exotic spacetimes

I. I. Smolyaninov, BAE Systems (United States)

We demonstrate that optical space in metamaterials may be engineered to mimic physics of various exotic spacetimes.

8093-59, Session 13

Frequency conversion by the transformation-optical analogue of the cosmological redshift

V. Ginis, Vrije Univ. Brussel (Belgium); P. Tassin, Iowa State Univ. (United States) and Vrije Univ. Brussel (Belgium); B. Craps, I. Veretennicoff, Vrije Univ. Brussel (Belgium)

Recently, there has been a lot of interest in electromagnetic analogues of general relativistic effects. Using the techniques of transformation optics, the material parameters of table-top devices have been calculated such that they implement several effects that occur in outer space, e.g., the implementation of an artificial event horizon inside an optical fiber, an inhomogeneous refractive index profile to mimic celestial mechanics, or an omnidirectional absorber based on an equivalence with black holes. In this communication, we show how we have extended the framework of transformation optics to a time-dependent metric-the Robertson-Walker metric, a popular model for our universe describing the cosmological redshift. This redshift occurs due to the expansion of the universe, where a photon of frequency ωem, emitted at instance tem, will be measured at a different frequency ωobs at time tobs. The relation between these two frequencies is given by ωobs a(tobs) = ωem a(tem), where a(t) is the time-dependent scale factor of the expanding universe. Our results show that the transformation-optical analogue of the Robertson-Walker metric is a medium with linear, isotropic, and homogeneous material parameters that evolve as a given function of time. The electromagnetic solutions inside such a medium are frequency shifted according to the cosmological redshift formula. Furthermore, we have demonstrated that a finite slab of such a material allows for the frequency conversion of an optical signal without the creation of unwanted sidebands. Because the medium is linear, the superposition principle remains applicable and arbitrary wavepackets can be converted.

8093-60, Session 13

Geometric-optical studies for metamaterial representations of curved spacetime

T. H. Anderson, T. G. Mackay, The Univ. of Edinburgh (United Kingdom); A. Lakhtakia, The Pennsylvania State Univ. (United States)

Metamaterials offer opportunities to explore curved-spacetime scenarios which would otherwise be impractical or impossible to study. These opportunities arise from the formal analogy that exists between light propagation in vacuous curved spacetime and in a certain nonhomogeneous bianisotropic medium, called a Tamm medium. As the science and technology of nanostructured metamaterials continues its rapid development, the practical realization of Tamm mediums is edging ever closer. We considered two particular curved spacetimes associated with: (a) spinning cosmic strings, and (b) the Alcubierre drive. For both examples, a Tamm medium formulation was developed which is asymptotically identical to vacuum and is therefore amenable to physical realization. A study of ray trajectories for both Tamm mediums was undertaken, within the geometric optics regime. For the spinning cosmic string, it was observed that: (i) rays do not cross the string's boundary; (ii) evanescent waves are supported in regions of phase space that correspond to those regions of the string's spacetime wherein closed timelike curves may arise; and (iii) a non-spinning string is nearly invisible whereas a spinning string may be rather more visible. For the Alcubierre drive, it was observed that: (i) ray trajectories are highly sensitive to the magnitude and direction of the warp bubble's velocity, but less sensitive to the thickness of the transition zone between the warp bubble and its background; and (ii) the warp bubble acts as a focusing lens for rays which travel in the same direction as the bubble, especially at high speeds.

8093-61, Session 14

Collinear meta-acousto-optics and its application to tunable filters

P. P. Banerjee, G. T. Nehmetallah, Univ. of Dayton (United States)

Acousto-optics (AO) or diffraction of light by ultrasound, is used in numerous applications in signal processing, filtering, and image processing. In conventional AO (CAO), the acoustic group velocity has the same direction as the phase velocity, and hence, the acoustic propagation vector. However, in an acoustic metamaterial, dispersion may allow for negative phase velocity but positive group velocity. Therefore, interaction between light and ultrasound wave-vectors is different for noncollinear meta-AO (MAO), implying a new interpretation for upshifted and downshifted interactions [Banerjee, SPIE 7754 (2010)]. In this work, we investigate nominally collinear AO interaction in an acoustic metamaterial. We show that phase matching between the undiffracted and diffracted orders, not normally achievable in collinear CAO, can be satisfied using the dispersive acoustic behavior in MAO. For example, with zero acoustic refractive index, phase-matching between incident and diffracted orders is achievable in optically isotropic materials. Also, using negative acoustic refractive index, phase matching can be achieved using co-propagating incident optical field (e-polarized), diffracted optical (o-polarized) field, and pulsed ultrasound in positive uniaxial media. We develop heuristic theory and detailed model for collinear MAO for CW and multi-frequency (pulsed) ultrasound. Application of collinear MAO to spectroscopy using AO tunable filters is also investigated.

8093-62, Session 14

Plasmonic Bloch-Zener oscillations in metal-dielectric waveguide arrays

Y. Lan, R. Shiu, National Cheng Kung Univ. (Taiwan)

Plasmonic Bloch oscillations, an analog of electron Bloch oscillations in lattice, are periodic oscillations of optical beams that propagate in metal-dielectric waveguide arrays (MDWAs), which is caused by the alternating total internal reflection and Bragg reflection between the two boundaries of the waveguide arrays. When the electric field imposed on the lattice is increased, electron Zener tunneling will occur at the Brillouin zone boundary. However, plasmonic Zener tunneling has been never observed in MDWAs. Neither has the possibility that the optical beam tunneling into the next band will experience another Bloch oscillation been investigated. In this study, plasmonic Zener tunneling and the succeeding plasmonic Bloch oscillation in MDWAs are explored by performing both FDTD simulations and theoretical analyses. The MDWAs consists of alternative silver layers and dielectric layers. The relative permittivities of the dielectric layers have a constant gradient across the waveguide arrays. The plasmonic Zener tunneling is observed at the position of total reflection (Bloch wavevector kx=0), which is caused by that the gap between the first and second equal-kz (longitudinal wavevector) bands is minimum at kx=0, originated from the effectively (transverse) negative refraction index of the MDWAs. The relation between tunneling rate and

permittivity gradient is elucidated. The FDTD-simulated contours of magnetic field intensity correlate well with the predicted ray trajectory using Hamiltonian optics. Furthermore, the tunneling beam is also observed to undergo Bloch oscillation in the FDTD simulation. This Bloch oscillation leads to beam's curling due to change of the direction of the energy flow. Depending on the geometry parameter, the curling beam will move backward, move forward, or even remain unmoved.

8093-63, Session 14

The Goos-Hänchen effect at the non periodic surface of a negative index metamaterial

V. Grünhut, M. A. Cuevas, R. A. Depine, Univ. de Buenos Aires (Argentina)

We present a rigorous analysis about the excitation of surface polaritons at a non periodic, rough interface between a conventional dielectric and a metamaterial with a negative index of refraction. In particular, we study the reflection of a Gaussian beam from a corrugated surface of finite length. We analyze the strong impact that surface polaritons have in the field reflected from this type of metamaterial rough surface and find new features of the well known Goos-Hänchen effect due to the resonant excitation of these surface waves. The dependence of the Goos-Hänchen lateral shift on the incident beam parameters is examined in detail and discussed in different situations among wich is the total reflection case. We compare these characteristics with the limiting case of reflection of a beam from an infinitely periodic grating.

8093-64, Session 14

Anderson localization in one-dimension: quasiperiodic photonic bandgap structures

G. J. Kissel, Univ. of Southern Indiana (United States)

Existing in the "gray area" between perfectly periodic photonic bandgap structures and purely randomized photonic bandgap structures are the so-called "quasiperiodic" structures whose layers are chosen according to some deterministic rule rendering them aperiodic. We consider here a one-dimensional photonic bandgap structure, a quarter-wave stack, with the layer thickness of one of the bilayers subject to being either thin or thick according to various deterministic sequence rules. To produce these "quasiperiodic" structures we examine the following sequences: Fibonacci, Thue-Morse, Double Period, Rudin-Shapiro, as well as the triadic Cantor sequence. To make the approach as rigorous as possible, we model these structures numerically with a long chain (5,000,000 or greater) of transfer matrices, and then use the reliable algorithm of Wolf to calculate the (upper) Lyapunov exponent for the long product of matrices. The Lyapunov exponent is the statistically well-behaved variable used to characterize the Anderson localization effect (exponential confinement) when the layers are randomized, and so should likewise be calculated to ensure a proper characterization of the effect for the "quasiperiodic" systems. This is in contrast to some of the literature which avoids calculation of the Lyapunov exponent, or which calculates the Lyapunov exponent incorrectly. Calculating the Lyapunov exponent allows us to more precisely compare the purely randomized structure with its "quasiperiodic" counterparts. It is found that the "quasiperiodic" photonic systems show much fine structure in their Lyapunov exponents as a function of frequency, and, in a number of cases, the exponents are quite obviously fractal.

8093-65, Session 14

Near-field energy density enhancement in planar metamaterials

J. H. Shi, Harbin Engineering Univ. (China); C. Guan, Harbin Institute of Technology (China)

We theoretically investigate the positive/negative metamaterials with/without substrate built by asymmetrically split rings (ASRs) or asymmetrically split ring apertures (ASRAs) based on a full three-dimensional Maxwell finite element method. The asymmetry provides an easy and practical way to tune the electromagnetic response of metamaterails. The positive metamaterials on quartz glass and freestanding real metallic metamaterials show the quality factor of about 1000 and 1500, respectively. The near-field energy density enhancement 0.1 mm above the ASR metamaterial on glass substrate reaches at the ultra-high value of 150000, 500 times stronger than that of fundamental dipole resonance. The energy density enhanced factor attenuates to be one tenth only increasing the distance above the meta-surface to 0.5mm. The ultrahigh-Q trapped-mode resonances excited by broken structures confine most energy to a very small region of the surface of metamaterials. The freestanding metallic metamaterial will be good candidate to practical applications in microwave and terahertz range while increasing the thickness of quartz and choosing appropriate fabrication may pave to the practical design of the metamaterials on glass substrate. The low-loss trapped-mode metamaterials will be expected further and this tunable trapping of electromagnetic energy is of interest for new non-linear and switchable metamaterials, ultrasensitive media for chemical or biosensing and new types of optical switches.

8093-66, Session 14

Waveguide characteristics for arbitrary permittivity and permeability including for metamaterials

B. R. Lavoie, P. M. Leung, B. C. Sanders, Univ. of Calgary (Canada)

We calculate dispersion, absorption, power flow, and effective width vs input-field frequency for 3-layer slab and circular waveguides wherein the dielectric permittivity and magnetic permeability can both be arbitrary response functions for each of the media. Either permittivity or permeability is also allowed to be identically zero. We study the electromagnetic field behaviour at interfaces between these media and consider, as examples, heterogeneous waveguides based on a dielectric medium enclosed by metal or a metamaterial (including a negative-index metamaterial), i.e. dielectric-metal or dielectric-metamaterial waveguide. Our analysis provides a seamless model that accounts for dielectric-dielectric, dielectric-metal, and dielectric-metamaterial waveguides, and our results highlight that dielectric-metamaterial waveguides show reduced attenuation.

We treat metallic media according to the Drude model and metamaterial media with a modified Drude model that effectively models the magnetic response of the metamaterial. The modified Drude model is appropriate because its predictions are compatible with existing empirical results on metamaterials. Using these models we are then able to model the expected surface modes for metal or metamaterial waveguides; this surface mode is absent in the dielectric-dielectric waveguide. We show that, unlike the lossy surface mode for the dielectric-metal waveguide, which allows only the transverse-electric polarization, the dielectric-metamaterial waveguide can sustain either transverse-electric or transverse-magnetic polarizations with reduced loss.

8093-67, Session 15

Exotic properties of spinning particles metamaterials

A. Asenjo-Garcia, A. Manjavacas, Consejo Superior de Investigaciones Científicas (Spain); J. García de Abajo, Consejo Superior de Investigaciones Científicas (Spain) and Univ. of Southampton (United Kingdom)

We will present exotic electromagnetic properties of assemblies of spinning particles, including light amplification and extreme optical properties.

8093-69, Session 15

density functional study of spin polarization on a carbon material induced by iron atoms

M. M. Rahman, Univ. Putra Malaysia (Malaysia)

We investigate the spin polarization of a non magnetic material, e.g., a carbon material made from ten C atoms forming a hexagonal structure with total spin S=0, induced by a ferromagnetic material, e.g., two Fe atoms with a total spin S=4. Based on the density functional theory, we calculatethe total spin density of the system. Our preliminary results show that the total spin for the ten C atoms changes from S=0 to S=2, while the total spin of the two Fe atoms changes from S=4 to S=0. These results seem to indicate that there is a promising possibility to induce spin polarization on a carbon material by Fe atoms.

8093-70, Session 16

Applied metamaterials

A. M. Urbas, Air Force Research Lab. (United States)

Metamaterials redefine the fundamental properties of systems by creating artificial, meso-scale meta-atoms which dictate the system response to external fields. When assembled into complex, structured materials, these meta-atoms and their mutual interactions can yield effective property sets not found in conventional materials and response tailored to specific application needs. The concept of defining the material properties with structure extends beyond electromagnetics to mechanical and thermal characteristics as well. Significant interest lies in the development of novel metamaterials structures and designs for electromagnetic and mechanical systems that possess properties optimized for selected applications. Key challenges are to develop capabilities to fully analyze the properties of these systems computationally and experimentally, to extract truly representative effective properties, and to understand the effectiveness of materials in an applications context. In the midst of this rapidly evolving field, AFRL is conducting a program to determine the utility of metamaterials in applications, evaluate their technological relevance and identify areas where focused efforts can enable rapid technological insertion. An overview of current research and application potential will be presented.

8093-71, Session 16

Highly sensitive nanostructured SnO2-based sensors for hydrogen sensing

L. A. Patil, Pratap College (India)

Nanostructured SnO2 thin films were prepared by ultrasonic spray pyrolysis technique. Aqueous solution (0.05 M) of SnCl4-5H2O in double distilled water was chosen as the starting solution for the preparation of the films. The stock solution was delivered to nozzle with constant and uniform flow rate of 70 ml/h by Syringe pump SK5001. Sono-tek spray nozzle, driven by ultrasonic frequency of 120 kHz, converts the solution into fine spray. The aerosol produced by nozzle was sprayed on glass substrate heated at 150 oC. The sensing performance of the films was tested for various gases such as LPG, hydrogen, ethanol, carbon dioxide and ammonia. The sensor (30 min) showed high gas response (S = 3040 at 350 oC) on exposure of 1000 ppm of hydrogen and high selectivity against other gases. Its response time was short (2 s) and recovery was also fast (12 s). To understand reasons behind this uncommon gas sensing performance of the films, their structural, microstructural, and optical properties were studied using X-ray diffraction, electron microscopy (SEM and TEM) respectively. The results are interpreted.

8093-72, Session 16

Data transmission performance of CVD grown sub-20 nm indium antimonide nanowires

A. B. Guvenc, M. V. Penchev, J. Zhong, C. S. Ozkan, M. Ozkan, Univ. of California, Riverside (United States)

We investigated the data transmission performance of indium antimonide (InSb) nanowires (NWs) synthesized on InSb (100) substrate using chemical vapor deposition (CVD) having diameters below 20 nm. The data transmission measurements were accomplished on the NW field effect transistors (NWFETs) fabricated on Si/SiO2 substrates. The mobility values of the NWs were calculated from the transconductance, g = dIds/dVgs, in which Ids and Vgs values are acquired from the back gate measurements. Digital data stream is randomly generated and then uploaded to a waveform generator which generates the stream and transmits it repeatedly with the desired frequency. The signal was applied on the sources of the NWFETs and collected from the drains of the same devices. During the data transmission measurements no back gate voltage was applied. Collected data was first filtered with a low pass filter (LPF), to clear the noise and the high frequency parasitic effects then the output of the filter was used to create the eye diagrams of the NWs and by using these eye diagrams, the bit error rates (BERs), attenuation values, quality factor (Q-factor) values and maximum data transmission values are calculated. The results indicate that the data transmission performance of NWs suffer from low mobility values on the order of 10-to-15 cm2V-1s-1 because of their small diameters, crystal defects and oxidation occur during growth and cooling. 20 nm NWs can sustain data rates up to 10 mega bits per second (Mbps) and the data rate is directly proportional to the diameter of the NWs.

8093-73, Session 16

Surface-enhanced infrared absorption and refractive index sensing with highly compliant metamaterials

I. M. Pryce, Y. A. Kelaita, K. Aydin, R. M. Briggs, H. A. Atwater, California Institute of Technology (United States)

Surface enhanced spectroscopic techniques are used widely for chemical detection, and the sensitivity of such sensors depends on the high electric field intensities of nanostructured surfaces. Typically, sensors are limited by their constituent materials at fabrication. Ideally, however, they would be tunable and operate over a broader bandwidth. We propose an approach to designing tunable sensors that exploits the compliance of PDMS. We use split-ring resonator (SRR) based metamaterials as resonantly enhanced sensors and exploit the elastic and plastic deformation properties of PDMS to design tunable metamaterials where greater than linewidth tunability can be achieved. This tunability is used to both enhance absorption from vibrational modes by aligning the resonant frequency of the metamaterial and detect small changes in refractive index.

We fabricate Au SRRs in 100 μm arrays on Si and transfer the patterns to PDMS using a hard/soft nanolithographic pattern transfer technique. The resonators are functionalized with p-mercaptoaniline (pMA). FTIR reflection spectra are measured between 1.5 and 8 μm and we report the change in reflection, ΔR, corresponding to the surface-enhanced absorption of particular vibrational modes. ΔR values of up to 5% are shown and the limit of detection of vibrational modes as a function of strain will be discussed. We also demonstrate the use of these metamaterials as refractive index sensors and measure refractive index sensitivity values as high as 2070 nm/RIU (150 meV/RIU). We will discuss how inducing strain in the PDMS changes the resonator shape and improves the figure of merit for sensitivity.

8093-74, Session 16

Design and fabrication of a chitosan based integrated optical device for humidity sensing

A. Mironenko, Institute of Chemistry (Russian Federation)

Recently, polymers and polymer/inorganic hybrids have become of great interest for development of optical waveguides with tailored optical properties. Due to high availability, relatively low cost and good film-forming properties of some of the natural polymers, their use can be considered as an alternative to molecular design of synthetic polymers for optoelectronic applications. Aminopolysaccharide chitosan is one of the most promising biopolymer-candidates for development of optical waveguides and sensor [1, 2]. Advantages of chitosan are not limited to its easy processability. Refractive index of chitosan film can be tailored via metal ions binding, in-situ reduction and stabilization of metal nanoparticles [3] or incorporation of optically active inorganic nanocrystals into the polymer thin film. Moreover, interactions of chitosan, as a hydrophilic polybase, with organic solvents, water vapor, mineral and organic acids change level of polymer hydration and/or protonation degree, and thus, optical properties of the film that is beneficial for sensing application.

Here we report on preparation of optical waveguides and humidity sensors based on chitosan in different salt forms, chitosan/gold nanoparticles and chitosan/gold nanoparticles/silica hybrides with layered structure. Chitosan-based optical waveguides were obtained on quartz, glass and MgF2 substrates by spin-coating and dip-coating. For investigation of optical properties, the light (wavelength 632 or 532 nm) was coupled into the planar waveguide via the flint glass prism using goniometer. A number of modes, effective refractive index, waveguide propagation losses were determined for all samples in the range of relative humidity 10-99%. It was demonstrated that chitosan-based thin films could be used as humidity sensors with fast response time (0.3-1 s), and highest sensitivity was found for chitosan/gold nanoparticles/silica hybrids with layered structure.

Bridging fiber optics with metamagnetics

X. Wang, G. Venugopal, J. Zeng, D. Lee, N. M. Litchinitser, A. N. Cartwright, Univ. at Buffalo (United States)

A majority of naturally existing optical materials are non-magnetic. In the past few years, it was shown that metamaterials can fundamentally change light-matter interactions by bringing the magnetic component of the field into play. Magnetism at optical frequencies may lead to new fundamental physics and novel applications, including negative index of refraction, super-resolution, and unprecedented opportunities for manipulating light trajectories in space (e.g., cloaking). Recently, Cai et al. demonstrated that coupled nano-strips with varying dimensions enable optical magnetic responses across the whole visible frequency range.

To date, optical metamaterials were primarily demonstrated in a form of thin films with thicknesses on the order of or less than the optical wavelength on a substrate. In order to use them in applications such as photonic integrated circuits or on-chip sensing devices the light in- and out-coupling issue should be solved. Thus, waveguide-coupled metamaterials would be desirable. Fiber optics is a mature technology that enables long-distance, low-loss light delivery. Therefore, merging this mature fiber optics technology with the emerging metamaterials technology would likely enable a plethora of novel applications.

In this talk, we propose and experimentally demonstrate for the first time a fiber-coupled magnetic metamaterial structure. As an example, we demonstrate coupled nano-strip structures developed directly on the face of optical fiber that can serve as building blocks for more complex components such as multi-modality sensors (capable of measuring several properties of the sample at once), sensor arrays, imaging devices, ultra-compact components for photonic integrated circuits, and more.

8093-76, Session 16

Resonant coupling of dielectric waveguides with plasmonic metaatoms

T. Kaiser, C. Helgert, T. Paul, S. B. Hasan, F. Lederer, C. Rockstuhl, T. Pertsch, Friedrich-Schiller-Univ. Jena (Germany)

Metamaterials promise the possibility to tailor the propagation properties of light at the nano-scale. With this contribution we explore the possibility to combine the concept of metamaterials with integrated optics.

We investigate a system consisting of a one-dimensional array of double cut-wires (two very thin gold sheets separated by a dielectric spacer) placed on top of a dielectric slab waveguide, which supports only the fundamental TE and TM mode in the near infrared spectral region around 1550 nm. Strong coupling of the waveguide modes to the plasmonic eigenmodes of the double cut-wire is achieved via the longitudinal component of the electric field, being relatively large for an asymmetric refractive index profile. By tuning the length of the double cut-wires, we can tune the spectral position of the occurring hybrid resonance. We will show by rigorous calculations, that the resonance is anti-symmetric and hence produces artificial magnetism at optical frequencies in this simple scheme.

To further explore the physics of the system, we investigate the dispersion relation of a periodic array of double cut-wires with varying lattice periods. The slab waveguide mode leads to a coupling of the individual plasmonic nanostructures. We find that for short lattice periods the dispersion closely resembles that of the slab waveguide. However when the Bragg frequency approaches the plasmonic resonance frequency, a strong interaction takes place and leads to a back-bending of the dispersion relation with regions of negative group velocity near to the band edge while an avoided crossing of both resonances takes place.

Wednesday-Thursday 24-25 August 2011 • Part of Proceedings of SPIE Vol. 8094
Nanophotonic Materials VIII

8094-01, Session 1

Lu2O3:Eu3+ nanocrystalline powders for nanophotonics materials

D. A. Nadiia, O. M. Vovk, R. P. Yavetskiy, Institute for Single Crystals (Ukraine)

In recent years observed an increasing interest in the scientific community to nanophotonic materials, such as radiation detectors, display device, devices for medical diagnosis, waveguides, modulators. Unique optical properties of such materials can be artificially created and controlled by choice properties of source nanoparticles. Should take into account a number of general requirements to be met by powders, regardless of the application in nanophotonics is a single-phase, compliance stoichiometric composition and low degree of aggregation. The diameter and morphology of nanocrystalline powders are among main critical factors determining their surface activity and possibility to obtain new functional materials. The question of influence phase and chemical composition of precursor on properties of nanocrystalline oxide powders and hence the properties of nanophotonic materials has attracted insufficient attention, thus it became the object of our work.

Lu2O3:Eu3+ nanocrystalline powders are considered as a promising “structural units” for creation of nanophotonics materials, such as optical ceramic, X-ray screens [1,2]. Metastability of the phase composition of precursors, which manifests itself in the coexistence of amorphous and crystalline phases Lu(OH)(CO3)·nH2O, leads to the formation after calcination at T=800°C well dispersed Lu2O3:Eu3+ nanopowders (average size of 25 nm, specific surface 25 m2/g). This nanopowder show excellent sinterability and favorable morphological features for their use in optical ceramic technology for radiation detectors or devices for medical diagnosis.

8094-02, Session 1

Silanization of PECVD-grown silicon quantum dots for optoelectronics applications

I. E. Anderson, R. Shircliff, B. N. Jariwala, S. Agarwal, Colorado School of Mines (United States); P. S. Stradins, National Renewable Energy Lab. (United States); R. T. Collins, Colorado School of Mines (United States)

Semiconductor quantum dots have been the subject of intense research interest due to novel experimentally observed properties, such as tunable bandgap, phonon bottleneck, and a variety of surface effects. The control of these properties makes quantum dots a candidate for revolutionizing a variety of fields, including photovoltaics, optoelectronics, and biological imaging, labeling and sensing. Silicon, a material that is well characterized in its bulk form, may be most relevant to the fields that quantum dot research has aimed to metamorphose. For example, Si is relatively inert and may be an excellent biological sensor; its indirect gap may become more direct as size decreases, allowing for a fine-tuning of the absorption characteristics for photovoltaics and the emission characteristics for light-emitting devices. We present a plasma-based method for Si quantum dot synthesis coupled with a silanization passivation method. Functionalization with silanes enables creation of a stable, colloidal solution of dots, as measured by photoluminescence peak shift, transmission electron microscopy, and light scattering. Silanization requires an oxide shell around the Si core, alleviating concerns about oxidation and processing in an inert atmosphere, and can be performed on free-standing dots created by any synthetic method.

Unpassivated Si quantum dots show vastly different behaviors in photoluminescence and electron paramagnetic resonance than wet-chemically oxidized, silane-functionalized particles. The relative stability, dangling bond density, and relationship to quantum yield for these two populations will be discussed, in addition to their viability as building blocks for solution-processed optoelectronics devices.

8094-03, Session 1

Development of precise tuning method of inter-dot spacing and resonant energy transfer between Au clusters

M. Inada, Y. Yoshihara, H. Kawasaki, Y. Iwasaki, T. Saitoh, Kansai Univ. (Japan); I. Umezu, A. Sugimura, Konan Univ. (Japan)

Nanostructure materials have attracted much attention in recent years for their potential applications. In particular, nanomaterial electronic structures consisting of coupled quantum dots such as in nanocrystal arrays are of considerable interest both fundamentally and technologically, because such electronic structures can be described as Hubbard models due to the competing effects between quantum size and interdot coupling. In addition, ultra-small Au clusters have molecular-like discrete energy structure, which induces distinctive features such as strong photoluminescence(PL) and ferromagnetism, etc. Therefore it is interesting to study a correlation between inter-dot space and collective properties of Au clusters. However it is difficult to control the inter-dot spacing with sub-nanometer resolution. In this study, we report on a development of precise tuning method of quantum-dot spacing and investigate fluorescence resonant energy transfer in Au clusters.

The tuning device consists of a DC motor and capacitance-positioning sensor. After Au nano-clusters, which include Au_5, Au_8 and Au_{13} clusters, were deposited on poly(dimethylsiloxane) film, the film was gently and continuously stretched by the DC motor. The degree of stretching was monitored by the capacitance-positioning sensor. We investigated the PL spectra of Au clusters and we found the blue shift of the PL peak with stretching the film. This peak shift caused by the emission enhancement and quenching from smaller clusters and the larger clusters, respectively. So the stretching the film means an increase the inter-dot spacing, the result can be explained as fluorescence resonant energy transfer from smaller cluster to larger one.

8094-04, Session 1

Si quantum dots and different aspects of applications.

T. V. Torchynska, Instituto Politécnico Nacional (Mexico)

This presentation will discuss the different aspects of the application of Si quantum dots in quantum electronics, such as: light emitting and photonic devices, solar cells and memory structures, one electron transistors and spintronics [1]. The special attention will be paid to the comparison of optical parameters of crystalline and amorphous Si quantum dots embedded in the hydrogenated amorphous silicon (a-Si:H). Nanocrystalline silicon films (nc-Si:H) that are silicon nanocrystals or quantum dots embedded in the hydrogenated amorphous silicon matrix that considered as a promising candidate for the low cost and high efficiency solar cells have been analyzed as well.

8094-05, Session 2

Engineering aperiodic order for optical devices with photonic-plasmonic nanostructures

L. Dal Negro, Boston Univ. (United States)

Deterministic Aperiodic Structures (DAS) are generated by the mathematical rules of L-systems and number theory, manifest unique light localization and transport properties associated with a great structural complexity, and can be fabricated on-chips using conventional nano-lithographic techniques. When combined with metal-dielectric nanostructures, they give rise to large energy gaps like periodic media (i.e. photonic-plasmonic crystals) and highly localized, enhanced field states like disordered random media, including the formation of Anderson-localized modes, forbidden in periodic scattering media. Contrary to random media, DAS possess controllable transport properties from ballistic to anomalous diffusion (slower diffusion than classical random walks) and strongly localized field states with large fluctuations of the photonic mode density - essential attributes to achieve spatio-temporal energy localization and enhanced light-matter coupling, i.e. radiative rates of fluorescent molecules, absorption cross-sections, non-linear optical processes on the nanoscale. In particular, DAS fabricated using metal/dielectric nanoparticles are suitable to engineer efficient nanoplasmonic structures for Surface Enhanced Raman (SERS) sensing, optical detectors, and enhanced light-emitting and nonlinear components.

In this talk, by combining dark-field scattering characterization, micro-photoluminescence and Raman measurements with accurate electrodynamics calculations based on semi-analytical multiple-scattering theories, I will discuss electromagnetic coupling1,2, resonant scattering3, colorimetric biosensing4, light emission5 and surface enhanced Raman sensing6,7 in two-dimensional metal-dielectric photonic-plasmonic arrays based on deterministic aperiodic sequences. In particular, I will survey the optical properties, and assess the device performances, of different aperiodic systems ranging from quasi-periodic crystals to pseudo-random nanoparticle arrays8 fabricated by Electron-Beam Lithography (EBL) on transparent quartz substrates. Finally, I will present novel aperiodic optical nano-antennas structures that can provide strong field localization at multiple frequencies over a broad spectral range9.

8094-06, Session 2

Plasmonic light trapping in nanostructured metal surfaces

A. Polyakov, Lawrence Berkeley National Lab. (United States) and Univ. of California, Berkeley (United States); H. A. Padmore, S. Cabrini, S. D. Dhuey, B. D. Harteneck, X. Liang, P. J. Schuck, Lawrence Berkeley National Lab. (United States)

Metals are commonly used as ultra-fast photoemitters for Free Electron Lasers[1] and as field concentrators for generation of harmonics in a laser-driven plasma. In these applications high optical reflectivity is problematic[1]. This is especially true of gold, silver, and aluminum, which are all efficient reflectors due to their free-electron like behavior. However, by collective excitation of electrons in the form of a plasmon, free-electron metals can completely absorb light[2]. In this work, we demonstrate a practical realization of a new method recently proposed theoretically[2] where light is converted into plasmons, which are trapped in nano-grooves (NGs).

The typical dimensions for the NGs are 10-15nm in width and 30-40nm in depth spaced few hundred nanometers apart. The fabrication steps are: (a) the initial template is made by electron beam lithography from the HSQ resist on the Si substrate (b) gold is evaporated on the template, (c) the template is removed from the gold structure in the KOH bath. The cross section analysis of the resulting gold structure revealed the slanted walls of the NG, which contributed to the reduced sample absorption efficiency (measured absorption is 80% of the theoretical model with perfect NG geometry). Comparison of the experimental data to the Finite Difference Time Domain (FDTD) modeling-based on the profile measurements-is a good agreement.

8094-07, Session 2

All-inorganic quantum-dot light-emitting diodes with metal oxide as charge transport/injection layers

Y. Zheng, L. Qian, R. Zhou, P. H. Holloway, J. Xue, Univ. of Florida (United States)

Light-emitting diodes (LEDs) employing colloidal semiconductor quantum dots (QDs) as emitting layers (EML) have received significant scientific and technological interests. Currently, charge injection/transport layers comprised of conjugated polymers or thermal evaporated small organic molecules are widely used in QD-LEDs in order to achieve high efficiency emission. However, these organic charge transport/injection layers suffer from inferior thermal stability and low charge mobility compared to inorganic materials, and are more susceptible to degradation induced by oxygen and/or water. Here, we have demonstrated two different types of all-inorganic QD-LEDs using metal oxides as charge injection/transport layers. By using thermal evaporated MoO3 as a hole transport layer and ZnO nanoparticles as an electron transport layer, we have demonstrated red, green, and blue light-emitting QD-LEDs with performance approaching those of conventional quantum-dot LEDs with organic charge transport layers. For example, the green QD-LEDs we fabricated show a maximum luminance of 9,000 cd/m2, a peak luminance power efficiency of 1.74 lm/W, and an external quantum efficiency of 1.3. We also demonstrated a novel all-solution processable inorganic QD-LEDs in which the vacuum deposited oxide layer was replaced with a solution deposited oxide nanoparticle layer. Our data show that superior device performance can be achieved by improving hole injection from the oxide layer into the QD EML, which requires engineering of the heterojunction formed between the QDs and the hole transport oxide layer. All-inorganic QD- LEDs have the potential to serve as low-cost, efficient and stable light sources for display and solid-state lighting applications.

8094-08, Session 2

Stability of organic nanowires

F. Balzer, M. Schiek, Univ. of Southern Denmark (Denmark); I. Wallmann, A. Schäfer, A. Lützen, Rheinische Friedrich-Wilhelms-Univ. Bonn (Germany); H. Rubahn, Univ. of Southern Denmark (Denmark)

Organic nanowires from light-emitting conjugated oligomers might become the key ingredient for organics based optoelectronic devices. Different methods for nanowire growth have been pursued in the past such as filling of nanoporous templates, organic molecular beam deposition, and precipitation from solution. The morphological stability of such nanowires with time, in the presence of various gases, and under thermal load is of major importance for their use in any device. In this study the stability of organic nanowires from para-phenylenes, thiophenes, and from naphthyl end-capped thiophenes grown by organic molecular beam epitaxy is investigated via atomic force microscopy and optical spectroscopy. Simple aging experiments under ambient conditions already show substantial changes. Nanoscopic organic clusters, which initially coexist with the nanowires, vanish within hours, whereas wires develop facets and even break up into smaller ones within days. The influence of various gases such as water vapor, oxygen, and nitrogen is investigated to clarify the underlying mechanisms. Thermal annealing of nanowire samples leads to even more pronounced morphology changes, such as a strong decrease in nanowire number density, a strong increase in nanowire height, and the formation of new types of crystallites. This happens even before sublimation of organic material starts. These experiments also shine new light on the formation process of the nanowires.

8094-09, Session 3

Light collimation and resonance in composite negative/positive index photonic crystals

J. Zhang, S. Dhuey, B. D. Harteneck, Y. Wu, D. Olynick, X. Liang, S. Cabrini, Lawrence Berkeley National Lab. (United States)

The negative refraction in photonic crystals (PC) is due to the negatively sloped band folding effect of a strongly modulated PC. However, a negative index PC cannot fulfill some physical functions alone because light diverges after self-focusing. We report two structures composed of super lattice Bragg media of both negative and positive refraction index on SOI wafer for confining light in collimation or resonance. The first structure is composed of positive index air slab (n=1) and negative index PC slab (r =180 nm, a=470 nm, n=-1) periodically. Each PC strip has a length of isolated by an air slab with a length of . The structure shows the zero-average-index condition at the communication wavelength and allows light propagation in collimation. The two termination interfaces of each PC slab assist electromagnetic wave coupling into the waveguide with maximum transmission. Laser at 1.55μm propagates 2 mm long without diffraction as our measurements. The second structure is a periodical arrangement of negative index PC (n=-1) and positive index air (n=1) both in equal-lateral triangle shapes. By choosing of the symmetric equal-lateral triangle shape, light can fold back at the interface of opposite index media and resonant within this structure. The simulation of 1.55 μm wavelength propagation in TM polarization has been done by Rsoft. In conclusion, we are going to report light manipulating by two photonic crystal structures composed of opposite index media. The latest fabrication, simulation and optical measurement results will be presented in the conference.

8094-10, Session 3

Photonic crystal patterning of luminescent sol-gel films for light extraction

A. Revaux, G. Dantelle, Ecole Polytechnique (France); D. Decanini, Ctr. National de la Recherche Scientifique (France); F. Guillemot, Ecole Polytechnique (France); A. Haghiri-Gosnet, Ctr. National de la Recherche Scientifique (France); C. Weisbuch, J. Boilot, T. Gacoin, Ecole Polytechnique (France); H. Benisty, Institut d'Optique Graduate School (France)

For enhanced light extraction, the surface of sol-gel layers containing luminescent centers is patterned by nano-imprint lithography with a square photonic crystal (PhC). Light has to be guided in the slab rather than emitted toward the substrate to be efficiently extracted by the PhC. To increase the light fraction guided in the sol-gel layer, titania sol-gel films (n~1.7) are chosen rather than usual silicones (n~1.5) and a low-index layer of porous latex-templated silica is inserted between the substrate and the TiO2 film (nporous down to 1.16).

To study the effect of the structure of the film itself, we developed model sol-gel waveguides including europium chelates as emitters, which do not induce any microstructure effects (no light scattering). Furthermore, the large Stokes shift and the small absorption cross-section of the chelate at its emission peaks discard reabsorption losses and ensure long propagation distances.

Chelates are spectrally and spatially coupled to the resonant modes of the PhC and the guided light is extracted via leaky modes to free space. We investigate the interaction between the guided mode and the PhC and the role of the porous underlayer with angle-resolved luminescence measurement and complementary simple simulations. This study gives access to the structure and the extraction strength of the guided modes, as well as the cladding influence on them. The role of an underlying porous layer that avoids leakage to the glass substrate has notably been revealed, with critical porous fraction thresholds identified for allowing guided modes to be seen, notably TM modes.

8094-11, Session 3

Controlling polarization anisotropy of site-controlled InAs quantum dots on InP nanopyramids using selective-area epitaxy

J. Yuan, Technische Univ. Eindhoven (Netherlands)

We have studied the shape and polarization control of site-controlled 1.55-μm-region multiple and single InAs QDs on InP (100) pyramids grown by selective- area metalorganic vapor phase epitaxy (MOVPE). The QD size increases with the elevated growth temperature and the QDs strongly elongate which is attributed to increasing As/P exchange. The linear excitation power-dependent PL efficiency reveals negligible nonradiative carrier recombination in single QDs as well as in the InP pyramids. The QDs reveal a distinct degree of linear polarization of the PL in agreement with their shape elongation. Most important the degree of polarization reduces with reduced pyramid base/pyramid top area/QD number due to increasing influence of the symmetric pyramid top on the QD shape, reaching zero for single QDs grown at lower temperature. This is an important finding for the realization of single and entangled photon sources operating in the 1.55-μm telecom wavelength region.

8094-12, Session 3

Structural and vibrational properties of Mg doped ZnO alloy nanostructures

B. Karthikeyan, R. T. Pandiyarajan, National Institute of Technology, Tiruchirappalli (India)

ZnO is II-IV type semiconductor with wide direct band gap of 3.37eV and it has the exciton binding energy of 60meV, which makes high efficiency UV light emitters and exciton related optoelectronic devices. The physical and chemical properties of ZnO nanoparticles can be altered by introducing dopants. Among the dopants Mg2+ doping makes wide range of applications like hydrogen storage material, field effect transistor etc. Owing to the importance of doping in ZnO, we

have prepared Mg doped ZnO alloy nanostructures and studied the structural and vibrational properties. Structural studies are performed through X ray diffraction technique, confirms that the prepared particles are in hexagonal wurtzite structure and the lattice parameters change considerably due to doping. Vibrational properties are done with Fourier Transform Infrared red spectroscopy (FTIR).

All the samples show the IR active optical phonon modes of ZnO show a characteristic broad restrahlen band in the spectral range of 300-600 cm-1. Gaussian fitted band show each band is composition of three different one. These fitted bands are named as B1, B2 and B3. The band centered at 427cm¬1 corresponds to E1(TO) mode. It is observed that the intensity decreases with the increase of Mg concentration, apart from that the surface phonon modes are appeared at 460 and 521cm-1. Compare to the undoped sample all the normal modes show red shift. We completely analysed the structural and phonon properties of mg doped ZnO particles.

8094-13, Session 4

Structural fluorescence in the butterfly Morpho sulkowskyi (Nymphalidae)

E. Van Hooijdonk, Facultes Univ. Notre Dame de la Paix (Belgium) and Univ. Pierre et Marie Curie (France); C. Barthou, Univ. Pierre et Marie Curie (France); J. Vigneron, Facultes Univ. Notre Dame de la Paix (Belgium); S. Berthier, Univ. Pierre et Marie Curie (France)

Evolution and natural selection have generated complexity and efficiency in all living families. Morpho sulkowskyi - a butterfly from Neotropic ecozone (South America) and belonging to the Nymphalidae family - concentrates on its wings distinct but complementary features contributing to its exceptional visual attraction: i) the wings are predominantly white but ii) present a bright blue metallic flash due to a iridescence process; iii) the presence of fluorescent molecules producing a violet-blue coloration when irradiated by ultraviolet light and finally iv) the particular ultrastructure of the scales presenting a three-dimensions natural photonic crystal.

Due to the confinement of the fluorescent sources in a photonic crystal, the emission is preferentially directed in space and its efficiency is enhanced for particular detection angles. Furthermore, a clear correlation is observed between the reflection and the fluorescent processes that control the surface optical response. So, collecting and analyzing data over every emerging direction is shown to be crucial. To quantify these observations and characterize these optical effects, three types of measurements were carried out. First of all, the morphology of the butterfly was examined by means of scanning electron microscopes. In addition, the angular distribution of the reflected light was measured with a high performance viewing angle instrument, providing BRDF data (Bidirectional Reflectance Distribution Function). Finally, an automatic method coupling an ultraviolet source to a gonio-spectrophotometer allows fluorescent emission characterization. This set-up, developed on purpose, is composed of various excitation and analysis modules and provides angular emission maps. Tentative explanation for the measured correlation is presented.

8094-14, Session 4

Photo-induced self-organized dynamic pattern formation in bio-synthesized nanomaterials

N. V. Kukhtarev, T. Kukhtareva, F. Okafor, A. Johnson, Alabama A&M Univ. (United States)

We have observed a dynamic self-organization of laser scattering from the biosynthesized nanofluids with silver and gold nanoparticles.

Various procedures for nanofluid synthesis suitable for different applications are under constant investigation. In our present research the green biosynthesis process has been used for noble nanoparticles production. The aqueous solution of Magnolia Grandiflora leaves has been used as a reductant for silver and gold nanofluids.. We have applied the UV-visible spectroscopy method to control reaction process, fluorescent spectroscopy and nonlinear interferometric imaging experiments for characterization of nanofluids. From the experiments with laser-induced photothermal scattering it is possible to estimate the value of nonlinear refractive index coefficient. The kinetics observed in the pump-probe experiments with blue and red CW laser allowed us to estimate a timescale (~ 1s) of photothermal lens formation and dissipation.

Moreover, we have observed the phenomena of self-organization of the non-linear laser scattering reflected from the fluid's surface. The diverse regular diffraction patterns (hexagons, rolls, squares etc), resembling diffraction of X-rays on crystal structures, were observed in the solutions of biosynthesized nanoparticles.

From the angular size of the observed hexagonal diffraction patterns it was possible to estimate the diameter of diffracting nanoclusters as 18 microns for silver and gold nanofluids and 9 microns for the Magnolia broth. The kinetics of the hexagonal scattering shows a quasiperiodic patterns (resembling heart beats), with a period of about 12 seconds with the slow build-up and sharp disappearance of scattering.

8094-15, Session 4

Multi-color reflection from chiral thin-film stacks

D. J. Brink, Univ. of Pretoria (South Africa)

Iridescence from nano-structured biological materials is fairly well known. Usually the process is based on simple multi-layer interference effects from a thin-film stack typically found in butterfly wings, bird feathers, insects and sea shells. Recently a more interesting and sophisticated nano-structure was found in the exocuticle of scarab beetles, which interacts specifically with circularly polarized light and produces strong resonant reflections of narrow wavelength bands. These structures consist of many hundreds of ultra-thin (~ 5 nm) transparent birefringent layers sandwiched together in such a way that the fast- and slow axes form a (usually left handed) spiral as you look deeper into the material.

In the work presented here we studied the optical reflection from the outer parts of the scarab beetle Proagoderus brucei, which is unusual in the sense that it is one of a very small group of species exhibiting different colors on different parts of its body. The optics of this insect has not been studied before.

Scanning electron microscopy and reflection spectroscopy were used to analyze the structure and optical properties of the exocuticle of this insect. Measurements were compared with a computer model of the optics of the nano structure. In this way observations could be explained, some unknown parameters could be quantified and the properties of similar artificial structures with possible practical applications can be predicted.

8094-16, Session 4

Nanoarchitecture in the black wings of the Troides magellanus: a natural case of absorption enhancement in photonic materials

A. Herman, C. Vandenbem, O. Deparis, P. Simonis, J. Vigneron, Facultes Univ. Notre Dame de la Paix (Belgium)

The birdwings butterfly Troides magellanus possess interesting properties for photonics. The black wings of the male exhibit strong (95%) absorption of the visible light as well as two strong peaks in the infrared (3 µm and 6 µm) both due to melanin. The study of absorption enhancement in this butterfly could be helpful, for instance to realize highly absorbent biomimetic materials. Observations of the wings

using a scanning electron microscope (SEM) revealed that the scales covering them were deeply nanostructured. From these observations, a periodic three-dimensional (3D) model of the scale nanoarchitecture was established and used in numerical simulations in order to calculate the absorption spectrum by means of a 3D transfer matrix electromagnetic method. In order to study separately the effect of the structure on the absorption, the complex refractive index, n+ik, was first taken spectrally constant (n=1.56, k= 0.0358). A broad absorption was observed in the visible range as well as two peaks in the infrared, which were not present for a homogeneous layer. This result clearly demonstrated a structural effect on the absorption. A Lorentz dispersion model was then used to account for the spectral dependence of the complex refractive index. The infrared absorption peaks were enhanced in this case. Therefore a combination of nanostructure and material resonances led to enhancement of the absorption. Finally, in order to quantify this enhancement, a comparison with a planar layer with identical refractive index and identical volume led us to conclude that the absorption was 30% higher with nanostructures.

8094-22, Poster Session

Tuning Surface plasmon absorption in Au-Ag alloy polymer nanocomposite free standing films

B. Karthikeyan, National Institute of Technology, Tiruchirappalli (India)

Nanocomposite polymers gains interest because of its enhanced physical and chemical properties are depends on the nanofillers like noble metallic clusters and semiconducting quantum dots. In situ synthesis is a good way of synthesis for the incorporation of nanofillers in to the polymer host. Noble metal nanoparticles show absorption due to surface plasmon resonance (SPR) in the visible region where the delocalized conduction band electrons oscillate with the frequency of applied optical field. The resonance bandwidth and peak maximum depends on parameters such as nanoparticle size, morphology, concentration and dielectric constant of the host where the nanoparticles are embedded. Alloying is also one of the potential parameter to tune the SPR bad. In the present work we prepared Au-Ag bimetallic and alloy nanoparticles. Particles are synthesized through polyol method where Poly vinyl alcohol is employed as a reducing and capping agent as well. Optical absorption measurements show the strong band at 410 nm and 532 nm is due to SPR of Ag and Au nanoparticles respectively. When the bimetallic structure is formed, there are both the bands in the polymer. Thermal annealing induced the alloy nanostructures makes the absorption band becomes broad and it is between 410 to 532 nm. Increase in annealing time makes more broadened SPR band. Results are discussed based on Mie and Maxwell- Garnet theory.

8094-23, Poster Session

Optical, phonon and structural analysis of Na doped ZnO nanostructures

T. Pandiyarajan, B. Karthikeyan, National Institute of Technology, Tiruchirappalli (India)

Semiconductor nanoparticles gained much attention due to its novel physical and chemical properties, its potential applications in biology and medicine make scientific community to understand the insight of these particles. Doping metal ions in to it will alter its electronic structure and control its band gap. In the present work we report, synthesis, linear optical properties and x ray peak broadening analysis of the Na doped ZnO nanostructure. To prepare Na doped ZnO, simple room temperature wet chemical method was adopted. X ray pattern shows prepared particles are in hexagonal wurtzite structure The individual contributions of small crystallite sizes and lattice strain to the peak broadening in undoped and Na doped ZnO nanoparticles were studied using Williamson-Hall (W-H) analysis. Analysis shows decrease in stress and strain value when sodium is doped in ZnO nanoparticles. Morphological studies were investigated through Scanning Electron Microscopic (SEM). Optical absorption measurements show an exciton absorption peak around ~ 360 nm. When doping concentration increases exciton peak maximum shift towards the higher wavelength. Photoluminescence measurements were done by exciting at 335 nm, when doping concentration increases the intensity of exciton peak maximum is decrease, reveal an exciton peak emission and oxygen vacancy band emissions. All the three bands depend on sodium concentration. Vibrational studies were done by Fourier Transform Infrared Spectroscopy (FTIR), it shows band at 433 cm-1 is attributed to Zn-O bond and in Na doped samples shows red shift. Apart from Zn-O bond surface phonon modes are observed

8094-24, Poster Session

Synthesis of tin oxide, indium oxide and tin-doped indium oxide nanowires by chemical vapor deposition

K. K. Wong, M. K. Fung, Y. C. Sun, X. Y. Chen, A. M. C. Ng, A. B. Djuri?ic, W. K. Chan, The Univ. of Hong Kong (Hong Kong, China)

Nanostructures of tin oxide (SnO2), indium oxide (In2O3) and tin-doped indium oxide (ITO) have attracted researchers' attention due to their unique properties for device applications such as gas sensors, photovoltaic devices and organic light-emitting diodes (OLED). Different forms of the nanostructure such as nanowires, nanobelts and nanoribbons can simply be fabricated by vapor deposition. These wide bandgap metal oxides in the nanostructure forms have the advantages of large surface to volume ratio that make them suitable for device application. For instance, ITO nanowires substrate is a good candidate as conducting electrode for improving the charge collection for photovoltaic devices while SnO2 nanostructures are of interest for gas sensors.

In this study, nanowires of tin oxide, indium oxide and tin-doped indium oxide were fabricated by vapor deposition from a mixture of metal oxide nanoparticles and single-wall carbon nanotubes (SWCNT) placed in the heating zone at 1100 . Nanostructures of different morphologies were found on the Au coated single crystal Si substrates (100) placed at different temperatures downstream from the source. The morphology, growth direction and optical properties were characterized by field emission scanning electron microscopy, transmission electron microscopy and photoluminescence spectroscopy. The influence of source material composition and substrate temperature on morphology and photoluminescence was discussed.

8094-25, Poster Session

Optical and vibrational studies of surface modified ZnO nanostructures

T. Pandiyarajan, R. Nagalakshmi, B. Karthikeyan, National Institute of Technology, Tiruchirappalli (India)

Understanding the optical and electronic properties of semiconductor quantum dots is gaining much interest because of its greater versatility in application, improved performance and new functionalities of the future optoelectronic and bio-sensing devices. Among these semiconductors ZnO attracted much concentration due to their prospective performance in electronics, sensing and imaging related areas. In the present work, we report room temperature synthesis of ZnO nanoparticles. X-Ray diffraction studies confirm the prepared particles are in wurtzite structure. Scanning Electron Microscopy (SEM) studies depict the shape and morphology of the particles. Optical absorption measurements show the presence of exciton peak around ~375 nm. High-energy heavy ion irradiation is relatively a new curiosity in materials science and technology. The nature of modification depends on electrical, thermal and structural properties of target material, the mass of the projectile ion and irradiation parameters. The prepared particles were irradiated at room temperature with 150 MeV Ag3+ ions at the fluences varying

from 1010 to 1012 ions/cm3 using 15 UD Pelletron accelerator. The pristine as well as irradiated ZnO nanostructures were characterized by X-Ray diffraction, Photoluminescence, FTIR and UV-Vis reflectance to study the radiation induced defects on the local structure of materials. Irradiation with the fluence changes the color of the sample from white to orange. Measured phonon modes show variation with fluence. Photoluminescence measurements are done at the excitation wavelength of 335 nm. Measured spectrum show the variation in peak intensity due to irradiation. These results will be discussed in detail in the complete paper.

8094-26, Poster Session

Gd and S sensitizer effect on the upconversion emission of ZrO2:Yb, Er nanocrystals prepared by precipitation method with a hydrothermal process

A. Urbina, E. De La Rosa Cruz, T. López, Ctr. de Investigaciones en Óptica, A.C. (Mexico); P. Salas, Univ. Nacional Autónoma de México (Mexico); C. Angeles, Instituto Mexicano del Petróleo (Mexico); A. Torres, Univ. Autonoma de Nuevo Leon (Mexico)

In this work, it is presented the synthesis of ZrO2:Yb3+, Er3+ nanocrystal by precipitation method with a hydrothermal process and annealing at 1000 oC. All the samples were prepared with 2% mol of Yb3+ and 1% mol of Er3+ and sensitized with different concentration of Gd3+ and S2+. The ceramic powders were characterized with different techniques to determine their chemical composition, crystalline structure, crystalline size, morphology and upconversion emission. All samples present the tetragonal crystalline phase with crystallite size lower than 70 nm with cubic shape. Experimental results suggest the presence of SO4 on the surface of nanocrystals reducing the OHs and then improving the signal emitted. The nanocrystals presented strong upconversion emission enhanced by the presence of both sensitizer, Gd3+ and S2+. A synergistic effect was observed with the combination of both sensitizers, improving the upconverted visible emission. The emission peak centered at 654nm dominates the red band and controlling the dopant composition and sensitizer it is possible to control the red/green intensity ratio.

8094-28, Poster Session

Temperature and frequency dependent admittance of InAs self-assembled quantum dots embedded in GaAs.

A. Sellai, Sultan Qaboos Univ. (Oman)

We have studied using frequency and temperature dependent admittance some electronic properties of InAs QDs embedded in a GaAs structure with emphasis on G-V data which is found to be more sensitive to some aspects of carriers exchange mechanisms. The presence of QDs in our structure is evidenced in the C-V characteristics at all temperatures and frequencies by a plateau-like structure in the bias range -3 V to -2 V that is related to charging and discharging of QDs. Concurrently, the G-V characteristics show a manifest peak in the same bias range at all considered frequencies but only for temperatures below 150K. The peak magnitudes in the concentration profiles, which are directly related to occupancy of charge states, increase as the temperature is decreased with a concomitant reduction of broadening of the profile. Below 40K a second peak, attributed to tunnelling, appears consistently at a slightly higher depletion width. The variations of conductance with both the temperature and applied bias show two regions of maximum G in the range -3V to -2V and for two temperature ranges 50K - 90K and below 40K. The T-dependence of the Gpeak, reveal two different behaviours depending on the T-range. These observations concur for the fact that one of two different mechanisms of carrier escape from the QDs prevails over each temperature range. Moreover, the measured G at any given temperature shows a very significant increase with increasing frequency suggesting that the emission rates are much higher than the frequency of the applied ac signal.

The photoluminescence of CuInS2 nanocrystals: Effect of surface modification

Y. Kim, Y. Cho, K. Chung, C. Choi, Korea Institute of Materials Science (Korea, Republic of)

We have synthesized highly luminescent Cu-In-S(CIS) nanocrystals (NCs) by heating the mixture of metal carboxylates and alkylthiol under inert atmosphere. We modified the surface of CIS NCs with zinc carboxylate and subsequent injection of alkylthiol. As a result of the surface modification, highly luminescent CIS@ZnS core/shell nanocrystals were synthesized. The luminescence quantum yield (QY) of best CIS@ZnS NCs was above 50%, which is 10 times higher than the initial QY of CIS NCs before surface modification (QY=3%). Detailed study on the luminescence mechanism implies that etching of the surface of NCs by dissociated carboxylate group (CH3COO-) and formation of epitaxial shell by Zn with sulfur from alkylthiol efficiently removed the surface defects which are known to be major non-radiative recombination sites in semiconductor nanocrystals. In this study, we developed a novel surface modification route for monodispersed highly luminescent Cu-In-S NCs with less toxic and highly stable precursors. Investigation with the time- and the temperature-dependent photoluminescence showed that the trap related emission was minimized by surface modification and the donor-acceptor pair recombination was enhanced by controlling copper stoichiometry.

8094-18, Session 5

Nearly-total optical extinction in arrays of non-resonant nanorods

P. V. Ghenuche, Ctr. National de la Recherche Scientifique (France) and ONERA (France); G. Vincent, ONERA (France); M. Laroche, Institut d'Optique Graduate School (France); N. Bardou, Ctr. National de la Recherche Scientifique (France); R. Haïdar, ONERA (France); J. Pelouard, S. S. Collin, Ctr. National de la Recherche Scientifique (France)

The interaction of light with non-resonant, dielectric nanostructures can be considerably enhanced by employing the diffraction effect resulting from the multiple scattering of a periodic arrangement of these particles.

In this work we experimentally demonstrate nearly-total optical extinction in arrays of transparent material together with extremely sharp resonances. This phenomenon originates from multiple-scattering in a monolayer of periodical non-resonant scatterers.

Freestanding Si3N4 membranes made of subwavelength square rods (width between $\lambda/5$ – $\lambda/10$) on large surface areas (2.6×2.6 mm2) were fabricated on a Si substrate and drilled by dry etching. Following this procedure, membranes with one-dimensional and two-dimensional patterns were fabricated, both having 500 nm square section bars and 3 µm pitch. High-resolution dispersion diagrams have been measured for the absolute transmission and reflection. Remarkably for a transparent material with a fill factor of only 15%, up to 96% extinction, independent of polarization, is found. The results are quantitatively described by a simple multiple-scattering model.

In addition, when the lossy material is used to fabricate the rods, a considerable absorption enhancement was observed, an indication of the electric field enhancement that occurs in the vicinity of the rods.

A key advantages of such dielectric gratings is the ease of tuning the resonance parameters (frequency, width) by changing the geometrical parameters (period and radius of the rod) without being restricted to the range of frequencies of plasmons. The employment of these geometrical

resonances in dielectric systems may provide new opportunities for applications like stop-band filters, selective mirrors and for applications where florescence quenching must be avoided.

8094-19, Session 5

White light emissions from ZnO quantum dots under 350 nm excitation

J. Oliva, E. De La Rosa Cruz, Ctr. de Investigaciones en Óptica, A.C. (Mexico); A. Torres, Univ. Autonoma de Nuevo Leon (Mexico); O. Meza Espinoza, Ctr. de Investigaciones en Óptica, A.C. (Mexico)

There are many efforts around the world to design new lighting sources, above all for general illumination. Since Zinc Oxide (ZnO) is an innocuous, abundant and inexpensive material which has demonstrated its capacity to produce visible emission by electroluminescence or ultraviolet excitation, it could be an excellent candidate to produce white light. In this work, we synthesized ZnO quantum dots with a wet chemical method. By changing the content of surfactant (Dodecylamine), we were able to control the ratio between the blue and yellow emission bands of ZnO. Luminescence measurements of ZnO nanoparticles dispersed in chloroform under 350 nm excitation and annealing treatments from 70oC to 800oC indicated that blue emission is produced by surface defects due to the interaction of ammines and OH groups with the surface of ZnO quantum dots and yellow emission is originated from oxygen vacancies. FTIR Spectra of as- prepared samples showed that the amount of OH groups, CO2 and bands associated with dodecylamine decreases if the content of this surfactant diminishes, that in turn promotes an increase in luminescence. Also, HRTEM images indicate that the size of spherical nanocrystals increases as the amount of surfactant increases, we obtained nanocrystal sizes ranging from 3 to 10 nm, as consequence, energy band gap values changed from 3.4 eV to 4.3 eV. CIE coordinates were (0.313,0.295), (0.332,0.321) and (0.401,0.406) for the samples which contained 0.17 ml., 0.34 ml., and 0.45 ml. of dodecylamine respectively. All these results point out that our nanoparticles can be used to tune white light emission from cool to warm white light white as well as to use them like “seeds” to growth nanorods with hydrothermal procedures, which would be suitable to fabricate ZnO based LEDs.

8094-20, Session 5

How nanoscale structure determines photoluminescent quantum yield of CdSe/CdS core/shell nanorods

M. A. Pelton, C. She, A. Demortiere, E. Shevchenko, Argonne National Lab. (United States)

Heterostructure nanocrystals consisting of a nearly spherical CdSe core and a larger, rod-shaped CdS shell have attracted considerable attention for their novel optical and optoelectronic properties. They exhibit large absorption cross-sections, good photostability, and strong luminescence, making them attractive for devices such as optically pumped lasers and luminescent solar concentrators. Practical application of the nanocrystals will require optimization of their photoluminescent quantum yield, which in turn requires a fundamental understanding of the processes that limit the yield. We have investigated how optical properties depend on nanoscale structure by measuring quantum yield, time-resolved photoluminescence, and transient absorption on a series of CdSe/CdS core/shell nanorods with different core and shell sizes. We find that the radiative decay rate for all of the samples has a universal dependence on nanoparticle volume, consistent with the conduction-band electron being delocalized throughout the particle and the valence-band hole being confined within the CdSe core. Transient-absorption measurements provide further support for this quasi-type-II band alignment, and also show that trapping of hot carriers is not a significant factor determining luminescence quantum yield. Rather, quantum yields are limited by sample-dependent nonradiative recombination of band-edge carriers; ongoing work is dedicated to determining the microscopic mechanisms responsible for this nonradiative process.

8094-21, Session 5

Photoluminescence from silicon nitride alloys

J. O. Kistner, M. B. Schubert, J. H. Werner, Univ. Stuttgart (Germany)

Silicon nitride alloys emit photoluminescence (PL) all over the visible spectral range. Recent studies (e.g. Ref.[1]) ascribed this luminescence to quantum-size effects within silicon nanocrystals (Si-NC). These quantum dots were either shown or assumed to form inside the matrix of the silicon alloy. Possible luminescence of the alloy itself wasn’t taken into account. We fabricate silicon alloys using plasma enhanced chemical vapor deposition and carefully analyze their optical properties. Similar to the published data, our samples show visible PL, and the PL peak shifts all over the visible range if we tune the composition of the silicon nitride alloy. In contrast to the published data, however, HRTEM analyses prove that our samples don’t contain silicon nanocrystals. Therefore, the Si-NC luminescence model is inadequate to explain the observed luminescence. We found the Band Tail Luminescence model introduced by D.J. Dunstan5 to be in good agreement with our experimental results. This model suggests that the observed luminescence originates from the alloys matrix itself. While the Si-NC luminescence model merely links a predefined crystalline grain size to a luminescence center, the band tail luminescence model explains all aspects of the luminescence. Not only the PL peak position, but also spectral width and relative intensities of the luminescence are described by the band tail luminescence model. We conclude that silicon nitride is an inappropriate matrix for investigating photoluminescence from Si-NC.

Conference 8095: Active Photonic Materials IV

Sunday-Thursday 21-25 August 2011 • Part of Proceedings of SPIE Vol. 8095
Active Photonic Materials IV

8095-01, Session 1

Lasing in photonic nanostructures

C. M. Soukoulis, Iowa State Univ. (United States)

A self-consistent computational scheme is presented for photonic systems with gain incorporated into the nanostructures.The gain is described by a generic four-level system. The loss compensation and the lasing behavior of the photonic nanostructures with gain are studied. A critical pumping rate exists in compensating the losses of the metamaterial. There exists a wide range of input signals where the composite system behaves linearly. When the pumping rate increases, there is a critical pumping rate at which the photonic crystals and or metamaterials systems start lasing.

8095-02, Session 1

Advancing active nanoplasmonics

A. V. Kildishev, V. P. Drachev, S. Xiao, X. Ni, Purdue Univ. (United States); L. Prokopeva, Institute for Computational Technologies (Russian Federation) and Purdue Univ. (United States); J. Trieschmann, J. Fang, V. M. Shalaev, Purdue Univ. (United States)

Loss-free and active metamaterials and nanostructured plasmonic devices can enable new important applications ranging from advanced sensing and imaging devices to nanoscale lasers and optical waveguides. The interaction of light with optical gain materials is of great importance especially in metal-dielectric nanostructures, where the compensation of losses is essential for practical engineering.

In order to design active nanoplasmonic devices, accurate models of this light-matter interaction are required.

A loss-free and active metamaterial in the visible has been recently experimentally demonstrated at the Birk Nanotechnology Center at Purdue; this experiment was supported by FEM-based simulations in frequency domain and the appropriate retrieval of the effective bianisotropic properties.

Our recent progress in this field will be reviewed followed by a brief discussion of the experiment-fitted parameters for (i) gain media - the 4-level system of auxiliary differential equations (ADE), and (ii) noble metals - the general dispersive material (GDM) model, which are imperative for accurate time-domain simulations of active nanoplasmonic devices.

8095-03, Session 1

Dynamics of amplification and gain in nano-plasmonic metamaterials

S. Wuestner, A. Pusch, K. L. Tsakmakidis, J. Hamm, O. Hess, Imperial College London (United Kingdom)

Negative-refractive-index metamaterials can enable a multitude of exciting and useful applications, such as subwavelength focusing, invisibility cloaking, and 'trapped rainbow' stopping of light. The realization of these materials has recently advanced from the microwave to the optical regime. However, at optical wavelengths, metamaterials suffer from high dissipative losses owing to the metallic nature of their constituent meta-molecules. It is therefore not surprising that overcoming loss restrictions is currently one of the most important topics in metamaterials' research [1].

Here we study, based numerical on pump/probe experiments, the nonlinear dynamics of active, negative-refractive-index, double-fishnet metamaterials. We demonstrate that the use of an active medium (laser dyes) embedded into the structure of a double-fishnet NRI metamaterial can lead to complete compensation of optical losses, and even to light amplification [2,3]. Our analysis is based on a full-vectorial time-domain approach that manages to self-consistently couple the evolution of the occupation densities in the gain medium directly to Maxwell's equations in three dimensions [2]. Nonlinearity, saturation of the gain medium and spatiotemporal variations of, both, absorption and emission are all inherent to our model [2,4], avoiding the need for external, pre-calculated inputs. We show that the highly nonlinear character of the pump process for times shorter than ~ 5 ps, as well as the non-instantaneous decay (on a timescale of approximately 100 fs) of, both, the upper absorption state and the lower emission state - both of which, cannot be captured by frequency-domain analyses. Further, we illustrate the importance of a judiciously chosen delay between the pump and the probe pulses in order to maximise the harnessed gain, and probe the system in its linear regime (where the standard effective-parameters retrieval methods apply). Finally we show that the pump-induced population inversion (gain) is found, when properly calculated, to be highly spatially-nonuniform. There are spatial regions where no population inversion occurs, with the probe-pulse being therein absorbed rather than amplified - therefore, particular care should be exercised to avoid using spatially-uniform population/gain distributions, as these could lead to unphysical or optimistic outputs.

Active infrared metamaterials

I. Brener, Sandia National Labs. (United States)

In this talk I will review the current status of electrically tunable metamaterials, both at Terahertz and shorter infrared frequencies. Scaling these active devices to mid and near infrared optical frequencies poses considerable challenges and requires new tuning mechanisms. Some examples include controlling coupling to other dipolar resonances such as phonons and engineered transitions in semiconductor heterostructures.

Infrared detectors with plasmonic cavities

S. Krishna, Ctr. for High Technology Materials (United States)

There is an increased emphasis on obtaining multicolor detectors as a part of the third generation detector development. We have been undertaking research on infrared detectors based on InAs/GaAs quantum dots in a well (DWELL) and InAs/GaSb superlattices. We will discuss approaches to realize multicolor detectors using near field enhancement using surface plasmons coupled to infrared detectors. We will describe our recent work on the development of a plasmonic quantum dot focal plane array.

Manipulating light with photonic metamaterials

B. Ou, J. Zhang, T. S. Kao, K. F. Macdonald, E. Plum, N. I. Zheludev, Univ. of Southampton (United Kingdom)

[invited] We report on a number of new approaches to control the interaction of light with nanostructured photonic metamaterials and new types of metamaterials. This includes nano-mechanical reconfigurable metamaterials for the visible and near-infrared parts of the spectrum; bas-relief and intaglio “full-metal” metamaterials and “loaded plasmon” metamaterials as new types of frequency selective surfaces, perfect absorbers and magnetic walls. We also show how tailoring profile of the excitation optical field can be used to control localization of light in a certain class of plasmonic nanostructures with strongly interacting meta-molecules which has a potential for applications in data storage and imaging

8095-59, Session 2

Miniaturized gas sensors based macroporous silicon

R. B. Wehrspohn, B. Gesemann, D. Pergande, Martin-Luther Univ. Halle-Wittenberg (Germany); S. Schweizer, Martin-Luther-Univ. Halle-Wittenberg (Germany); A. Lambrecht, Fraunhofer-Institut für Physikalische Messtechnik (Germany)

In many fields such as technical, environmental, automotive, and medical applications, miniaturized and mobile gas sensors are indispensable. Moreover, the 9/11 events have led to an increase in the request for sensors and sensor systems that can detect rapidly, efficiently, and at moderate cost trace explosives and a whole range of toxic substances at diverse control points, e.g., at airports and inside air conditioning systems in aircraft and public buildings. Most of the current miniaturized sensing methods are applicable only to certain specific gases that influence the physical properties of the detector materials. We will present two concepts of miniaturized element-specific sensors based on electrochemically-prepared macroporous silicon. Firstly, we will show a miniaturized optical sensor using low-group velocities in a 2D photonic crystals and selective thermal emitters for compact gas sensing in the ppm range [1]. Secondly, a micro-ionization-mobility-spectrometer using needle-like macroporous silicon surfaces is presented that has the potential to measure in the ppt range [2]. The technological limits as well as the physical limits will be discussed.

8095-07, Session 3

On-chip stimulated Brillouin scattering

B. J. Eggleton, R. Pant, The Univ. of Sydney (Australia)

We report the first demonstration of on-chip stimulated Brillouin scattering (SBS) using chalcogenide planar waveguides.

Slotted nanobeam microcavities enabling hybrid photonic devices

J. Schilling, C. Schriever, C. Bohley, Martin-Luther-Univ. Halle-Wittenberg (Germany)

Silicon nanobeam cavities consisting of two lines of equally spaced pores (Bragg mirrors) which enclose a straight section in a silicon strip waveguide gained recently renewed interest when several designs where developed allowing high Q-factors and relatively low mode volumina. With these properties the nanobeam cavities are of special interest for the enhancement of nonlinear optical processes e.g. optical bistability and opto-optical switching. However for efficient nonlinear processes in the near infrared the strong two photon absorption of silicon is a serious obstacle.

We therefore suggest a hybrid approach where a slot is introduced into the silicon nanobeam cavities. This slot can be infiltrated with other nonlinear optical materials (e.g. polymers or chalcogenide glasses) which experience the strong field enhancement within the slot, thus combining the efficient light confinement due to the high refractive index of silicon with the tailored nonlinear optical properties of the infiltrated material.

Here we present first a theoretical investigation of the mode profiles, mode volumina and Q-factors of such infiltrated slot nanobeam cavities. General desing principals are discussed and in particular the impact of a gradual adjustment of the pore distance and pore diameter of the pores closest to the cavity is investigated. Especially the tapering of the pore diameter leads to a smoother transition of the mode profiles from the cavity centre to the adjacent Bragg mirror region resulting in a considerable increase of the Q-factors. Furthermore the influence of the length of the taper is considered and surprisingly a maximum Q-factor of 100 000 can be obtained with a linear taper including only two pores.

Besides these theoretical studies first experimental results demonstrating the described hybrid nanobeam cavity resonances in the near IR will be presented.

8095-09, Session 3

Nanoscale photonics: nonlinear materials and processes

C. Sibilia, Univ. degli Studi di Roma La Sapienza (Italy)

An overview of different nonlinear optical phenomena occurring in nanopatterned materials is presented . In particular a discussion about second order nonlinear effects is reported, including also some nonclassical properties of the interaction with non homogeneous materials

8095-10, Session 3

Enhancement of nonlinear refraction and absorption using cascaded plasmon resonances

S. Toroghi, P. G. Kik, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Metal-dielectric composites exhibit strongly modified linear and nonlinear optical properties due to the existence of localized surface plasmon resonances. We have previously shown that silver nanoparticle arrays can be used to strongly enhance the nonlinear optical refractive and absorptive properties of a composite, and that the spatial arrangement of the particles has a significant effect on the figure of merit for nonlinear absorption. In this talk we discuss an additional enhancement of the nonlinear optical response of such nonlinear metamaterials by making use of cascaded plasmon resonances on coupled silver nanoparticle arrays. The arrays consist of chains of particles with alternating sizes,

i.e. with a binary size distribution. Through numerical simulation, we study plasmon-induced changes in the linear and nonlinear optical properties of these nanoparticle composites as a function of dissimilarity in nanoparticle size within the structure. In successive simulations, the relative size of the particles is varied systematically while maintaining a fixed metal fill fraction. The relative particle volumes were chosen to be 1, 2.3, 4.8, 11 and 30, at a fill fraction of 1%. We find that the introduction of even a small size difference leads to the appearance of new plasmon resonance modes of the coupled nanoparticle chains, which are identified to be an anti-symmetric plasmon resonance (opposite field on neighboring particles), as well as several multipolar modes. It is found that the internal field enhancement in the small particles is four times larger than that found in arrays consisting of particles with a single size, demonstrating the presence of a cascaded resonance effect. We demonstrate that this seemingly moderate additional cascaded enhancement leads to a dramatically enhanced nonlinear optical response of the composites at specific frequencies. Methods for fabrication similar structures using existing nanofabrication tools will be discussed, and the viability of experimentally observing the predicted effects will be addressed.

8095-11, Session 3

Amplification of the nonlinear optical response of metals in induced transmission filters

C. Fuentes-Hernandez, J. Hsu, D. T. Owens, A. R. Ernst, J. M. Hales, J. W. Perry, B. Kippelen, Georgia Institute of Technology (United States)

Metallic nanostructures, such as metal-dielectric photonic bandgaps have been proposed as one class of materials where the large nonlinear optical (NLO) response of metals can be accessed in spectrally broadband passbands that show high transmittance in the visible range. Here, we propose another structure which has been somewhat overlooked in the literature in the context of NLO filters, namely the induced-transmission filter (ITF). In an ITF, a single metal layer, several times thicker than its skin depth, is surrounded by admittance matching layers that allow the opening up of spectrally narrow passbands with high transmittance in the visible range. We present the design and fabrication of Ag-based ITFs having a peak linear transmittance of 63% and we discuss the experimental demonstration of an enhancement in its NLO response by a factor of 30 over an isolated Ag film. We also present a physical model that describes the NLO properties of thin Ag films in the context of ultrafast electron heating and show that its predictions also allow modeling of the NLO response of ITFs. We use this model, to describe how variations in structure impact the strength of the response and demonstrate the possibility of a further enhancement in the nonlinearity by a factor of 2. Finally, we show that a stronger NLO response than Ag can be obtained with the use of Ag/Au bi-metal layers and that these bi-metal layers can be used to fabricate ITFs with more than 80% peak transmittance.

Second harmonic nanoparticles in imaging applications

I. Papadopoulos, C. Hsieh, Y. Pu, J. Choi, D. Psaltis, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Recent developments in nano-science have provided us with a diverse group of nanoparticles capable of second harmonic generation. We review the applications of these particles in imaging. We will focus on how the shape and the size of the particles determine their imaging capabilities.

8095-13, Session 4

Ultrafast switching of semiconductor microcavities

G. Ctistis, W. L. Vos, E. Yüce, Univ. Twente (Netherlands); J. Claudon, J. Gérard, Commissariat à l'Énergie Atomique (France)

Switches are widely applied and necessary ingredients in modulation and computation. Recent progress on photonic integrated circuits [1] promises to overtake boundaries set by conventional switching. Therefore, ultrafast switching of photonic cavities is crucial as it allows the capture or release on demand of tunable photons [2], which is relevant to on-chip communication and to high-speed miniature lasers. Ultrafast switching would also permit the cavity quantum electrodynamical manipulation [3] in real-time.

Switching photonic nanostructures is achieved by changing the refractive index of the constituent materials. To date, the switching speed has been limited by material properties (see [4]), but not by optical considerations. We explore the ultimate fast switching of the cavity resonance in GaAs-AlAs in the telecom range. We exploit the instantaneously fast electronic Kerr effect by the judicious tuning of the pump and probe frequencies relative to the semiconductor bandgap, resulting in a shift of the cavity resonance by nearly one linewidth. The speed of the switching - both on and off - is only limited by the dynamics of the light in our cavity [5].

We explore the not-adiabatic regime of tuning of light in a single-resonance cavity. We observe that the frequency of probe light is changed to a value different from the cavity resonance. The light accumulates a phase shift while it is trapped in the cavity due to a fast change in the refractive index, induced by an earlier pump pulse. Consequently, all light trapped in the cavity obtains a frequency different from the cavity resonance. To our knowledge, such photonic not-adiabatic tuning has not been observed before [6].

Dynamic optical media: ultrafast bandgap photonics application

M. K. Rafailov, RCI Inc. (United States)

It is known that ultra-fast laser is able to change the physical state of solids: to melt, to evaporate, to ionize. It is less known that ultra-fast laser is able to change the optical state of some solids: to bleach it. The effect is most pronounced in semiconductors were the bandgap amplifies the effect in highly non-linear manner. Change in optical state is on the scale of recombination time Such short time changes in semiconductor optical characteristics depend on the bandgap structure, therefore we are introducing the term - Ultrafast Bandgap Photonics. Phenomena of Ultrafast bandgap photonics are time-dependent and bandgap-dependent the optical effects are reversible: ultra-fast laser "bleaches" semiconductor and temporally changes spectral reflectivity, absorptivity, and transmittance as well as polarization characteristics. Applications of Ultra-fast bandgap photonics are remote control of semiconductor characteristics and material properties. Ultrafast Bandgap Photonics

effects may temporally alter photodetector's fundamental characteristics - responsivity and detectivity as well as its response time and spectral bandwidth - all of these may happen with or without changes in photodetector electrical response. While Ultrafast Bandgap Photonics applications are directly depend on pulse dwell time and pulse repetition rate; it is important to say that laser energy per pulse should be carefully managed. In this paper we discuss some foundations of ultra-fast bandgap

photonics - specifically for low pulse energy

Optical response of a slab with time-periodic dielectric function ε(t): Towards a dynamic metamaterial

P. Halevi, J. R. Zurita-Sánchez, U. Algredo-Badillo, Instituto Nacional de Astrofísica, Óptica y Electronica (Mexico)

A dielectric medium with time-periodic permittivity $\varepsilon(t)$ gives rise to a band structure that is periodic in the frequency ω and exhibits wave vector gaps Δk. Light reflected from and transmitted by such a dynamic slab contains harmonics $\omega - n\Omega$ ($n = 0, \pm 1, ...$) where Ω is the modulation frequency. Also, giant resonances are obtained in the response for $\omega = n\Omega/2$ with odd n, provided that a certain condition is satisfied for the slab thickness. Further, we show that a dynamic medium can be realized by means of a low-pass transmission line with varactors whose capacitance is $C(t) = d\varepsilon(t)$ and inductances $L = d\mu 0$, d being the period.

Theoretical modeling of the ultrafast recovery times and low saturation intensities of the intersubband absorption in the InGaAs/AlAs/AlAsSb coupled double quantum wells

P. Ma, Y. Fedoryshyn, H. Jäckel, ETH Zurich (Switzerland)

Nonlinear optical devices, which are capable of performing ultrafast all-optical switching at reasonably low power levels, are required to fulfil the demands of the coming generation of all-optical communication networks. The InGaAs/AlAsSb material system is very promising in this respect due to a number of its specific properties, such as the large optical nonlinearities of the intersubband transitions in quantum wells, the ultra-short relaxation times, and the large conduction band off-set [1].

The all-optical switching mechanism is based on the saturable intersubband absorption in the four-level quantum well system. Our recent pump-probe and absorption saturation experiments revealed ultrafast absorption recovery times with low material absorption saturation intensities in the strained InGaAs/AlAs/AlAsSb symmetric coupled double quantum wells. This article addresses a systematic study of the dynamic nonlinear processes in our quantum well structures by performing theoretical simulations in order to interpret the pump-probe and absorption saturation experimental results. First, the quantum well system is modeled by solving self-consistently the Schrödinger-Poisson equations. Then, modified optical Bloch equations in combination with the density matrix method are employed to simulate the time evolution of the optical nonlinearities under the pulsed excitation. Impact factors related to the dynamic and saturation characteristics of the material, such as the dephasing time, the doping concentration, and the pump pulse duration, are discussed theoretically. Furthermore, a novel switch operation mechanism, where the pump and signal light are resonant to two different intersubband transitions in the four-level quantum well system, are investigated theoretically. Our further experimental and theoretical studies, which are in progress, will provide a deeper understanding of the nonlinear phenomena and the dynamic processes in the coupled double quantum wells embedded into a waveguiding structure for all-optical switches [2].

Electromagnetic unidirectionality in the presence of absorption or gain

A. Figotin, Univ. of California, Irvine (United States); I. Vitebskiy, Air Force Research Lab. (United States)

Magnetic photonic crystals are spatially periodic structures composed of transparent materials, some of which being magnetically polarized. Magnetization, either spontaneous or induced, is always associated with nonreciprocal circular birefringence (magnetic Faraday rotation). It can qualitatively change electrodynamics of the composite medium. In particular, magnetic photonic crystals of certain configuration can display strong spectral asymmetry, implying that electromagnetic waves propagate in one direction much faster or slower than in the opposite direction. This phenomenon is essentially nonreciprocal and unique to magnetic photonic crystals. It can only exist if both time reversal and space inversion symmetries of the composite structure are broken. The spectral asymmetry can result in electromagnetic unidirectionality [1, 2]. In a unidirectional medium, the electromagnetic wave of certain frequency propagating in the forward direction has zero group velocity and greatly enhanced amplitude. Such a wave is referred to as the frozen mode [2, 3]. The wave of the same frequency propagating in the backward direction can have group velocity comparable to speed of light in vacuum.

Consider now forward and backward transmittance of a plane-parallel unidirectional photonic slab. At first sight, the transmittance in the direction of zero group velocity (the forward transmission) should be suppressed, as compared to the backward transmittance, where the light group velocity is large. Our rigorous analysis, though, shows that in the absence of absorption, the forward transmittance averaged over incident light polarization is exactly equal to that of the backward transmittance. But, if we introduce even a modest absorption, the forward transmission reduces dramatically, while the backward transmittance remains almost unchanged. Such a behavior is reminiscent of a nonreciprocal linear isolator. Even more intriguing behavior is expected if a unidirectional photonic crystal includes a gain component. In the latter case, the forward propagating wave can experience a dramatic amplification, while the backward propagating wave is not enhanced at all, or even suppressed. Either effect can be very attractive for practical applications.

PT-synthetic optical materials

T. Kottos, Wesleyan Univ. (United States); D. Christodoulides, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Transport properties of synthetic optical media, with Parity (P) and Time (T) symmetries imposed by a balanced arrangement of gain and loss, are investigated. We find that the temporal behavior of the total power of a propagating beam in linear PT media is insensitive to microscopic details of the system and follows three distinct universal laws which depends only on the magnitude of the gain/loss parameter.

We further show that PT-symmetric Bragg grating structures, at the spontaneous PT-symmetry breaking (exceptional) point, can act as unidirectional invisible media. In this regime the reflection from one end is diminished while it is enhanced from the other. At the same time the transmission coefficient and phase, are indistinguishable from those expected in the absence of a grating. The phenomenon is robust even in

the presence of Kerr non-linearities, and it can also effectively suppress optical bistabilities.

Away from the exceptional point, the interplay of optical nonlinearities with PT-symmetries, allow for diode action. Such PT-synthetic unidirectional optical valves may find promising applications in integrated photonic systems.

8095-19, Session 5

Retooling electromagnetic scattering: one-way photonic chiral edge states and optical manipulation

Z. Wang, Massachusetts Institute of Technology (United States); P. T. Rakich, Sandia National Labs. (United States); J. D. Joannopoulos, M. Soljacic, Massachusetts Institute of Technology (United States)

In ordinary waveguides, photons travel both ways, allowing discontinuities to readily scatter light and induce losses. Photonic chiral edge states, on the other hand, permit electromagnetic waves to propagate only in a single direction. Obstacles and disorder can no longer reflect waves, which exhibit 100% transmission in numerical simulations even across seemingly-impassible perfectly-conducting barriers introduced into the waveguide. I will explain how such phenomena, analogous to quantum-Hall edge states, can arise from magneto-optical photonic crystals. Generalizing earlier predictions by Raghu and Haldane, I show that the key requirement is related to a topological invariant of the bulk bands known as Chern number. I also present our experimental results verifying the existence of these novel phenomena. I will discuss the implications of these novel photonic states in altering the basic physics of momentum transfer. I will also discuss prospects of applying these novel photonic states in optical lattices and optical manipulation.

8095-20, Session 5

Time-reversal and nonlocal effects in PT-symmetric nonlinear lattices with balanced gain and loss

A. A. Sukhorukov, The Australian National Univ. (Australia)

Photonic structures composed of coupled waveguides with loss and gain regions offer new possibilities for shaping optical beams and pulses compared to conservative structures. Such structures can be designed as optical analogues of complex parity-time (or PT) symmetric potentials, which can have a real spectrum corresponding to the conservation of power for optical eigenmodes, for the magnitude of gain/loss below a certain threshold.

PT-symmetric potentials appear in many physical contexts, and one feature actively investigated in the context of quantum theories is the property of nonlocality. We reveal that effective nonlocality of PT-symmetric structures with gain and loss elements can lead to pronounced differences for optical beam dynamics in arrays of coupled waveguides with the same characteristics but different topology.

We also reveal a generic connection between the effect of time-reversals and nonlinear wave dynamics in systems with parity-time (PT) symmetry, considering a symmetric optical coupler with balanced gain and loss where these effects can be readily observed experimentally. We show that for intensities below a threshold level, the amplitudes oscillate between the waveguides, and the effects of gain and loss are exactly compensated after each period due to periodic time-reversals. For intensities above a threshold level, nonlinearity suppresses periodic time-reversals leading to the symmetry breaking and a sharp beam switching to the waveguide with gain. Another nontrivial consequence of linear PT - symmetry is that the threshold intensity remains the same when the input intensities at waveguides with loss and gain are exchanged.

8095-21, Session 6

Spatial coherence of random laser emission

B. Redding, Yale Univ. (United States); M. A. Choma, Yale School of Medicine (United States); H. Cao, Yale Univ. (United States)

Lasing action in disordered media has been studied extensively in recent years and many of its properties are well understood. However, few studies have considered the spatial coherence in these systems, despite initial observations indicating that random lasers exhibit much lower spatial coherence than conventional lasers. We performed a systematic investigation of the spatial coherence of random laser emission as a function of the scattering mean free path and the excitation volume. Our experiments were performed on a series of Rhodamine 640 doped diethylene glycol solutions with varying concentrations of 240 nm diameter polystyrene spheres. Lasing was achieved under optical excitation and spatial coherence was characterized by imaging the emission spot onto a Young's double slit and collecting the interference fringes in the far field. The visibility of these fringes provided a measure of the coherence between two points in the lasing spot separated by the distance of the two slits. We observed dramatic differences in the spatial coherence within our parameter space. Specifically, we found that samples with a shorter mean free path relative to the excitation volume exhibited reduced spatial coherence. We also found that the spatial coherence is strongest across a plane perpendicular to the longest dimension of the excitation volume. A qualitative explanation of the experimental results will be presented. This work provides a means to realize intense, spatially incoherent laser emission for applications in which speckle or spatial cross talk limits performance.

8095-22, Session 6

Classification of light sources and their interaction with active and passive environments

R. El-Dardiry, S. Faez, A. Lagendijk, FOM Institute for Atomic and Molecular Physics (Netherlands)

Emission from a molecular light source depends on its optical and chemical environment. This dependence is different for various sources. We present a general classification in terms of Constant Amplitude and Constant Power Sources. Using this classification, we have described the response to both changes in the LDOS and stimulated emission. To find the correct wave function from a single source or collection of sources becomes much more involved than previously assumed since it requires knowledge of the Green function for both the propagation and the generation of light.

The unforeseen consequences of this classification are illustrated for photonic studies by random laser experiments and are in good agreement with our correspondingly developed theory. In contrast to conventional lasers, random lasers have a statistically isotropic mode selectivity. Their mode selection is solely determined by the spectral shape of the gain curve. In a random laser therefore, measuring the emitted energy into a large enough solid angle corresponds to measuring the total emitted intensity: diffusion mimics an integrating sphere. In our experiments, we utilize this much neglected property of random lasers to study the influence of light source typology on the generation of light in complex media. Our results require a revision of studies on sources in complex media.

8095-23, Session 6

Random lasing in disordered arrays of ZnO nanorods

R. Frank, Karlsruher Institut für Technologie (Germany); A. Lubatsch, Rheinische Friedrich-Wilhelms-Univ. Bonn (Germany);

K. Busch, Karlsruher Institut für Technologie (Germany)

A random laser is in general a strongly disordered, laser-active optical medium. Despite substantial investigations, the physics of homogeneously disordered random lasers bears intriguing, open problems. The conditions for transport and localization and, in particular, the origin of confined spatial regions from which laser radiation is emitted (observed “lasing spots”) as well as the dependence of their size on for instance the pump rate, have remained poorly understood. Here, we consider spatially disordered ZnO nanorod arrays with uniform rod size, as also considered in experiments. These pillars have average diameter of 200 nm and a length of 4.7 μm, with an average rod-to-rod spacing of 500 nm. For such samples, we develop a semianalytical transport theory for random, laser-active systems, including light diffusion, localization, i.e. self-interference effects, and coupling to the semiclassical laser rate equations to account for (coherent) stimulated and (incoherent) spontaneous emission. We solve this laser transport theory with appropriate boundary conditions to obtain the average spatial distributions of the light intensity and of the occupation inversion. The full spatial intensity profile of the lasing spots is obtained numerically in dependence of the pump rate and other parameters such as the average number of nanorods per unitcell (filling fraction), system size and losses, caused by photons escaping out of the disordered array.

Ultrafast active control of optical eigenmodes in a multiple scattering nanowire layer

O. L. Muskens, M. Abb, Univ. of Southampton (United Kingdom); E. P. A. M. Bakkers, Technische Univ. Eindhoven (United Kingdom)

The appearance of an interference pattern after transport of coherent waves through a random medium is the result of coherent summation of thousands of multiple scattering paths with random phases. Although the lack of many-body interactions makes phase coherence generally more robust for optical waves than for electrons, several dephasing processes can influence the transport of light, such as magnetic fields and inelastic scattering from colloids.

Here, we demonstrate a new regime of dephasing in photonic random media on ultrafast time scales. The random medium under study is a layer of strongly scattering nanowires, one of the most strongly scattering materials available today [1]. The nonlinear response of individual pseudomodes is found to be governed by dephasing of multiple scattering light paths on a picosecond time scale. By comparing our results with numerical simulations, we identify absorption and strain deformation as possible mechanisms responsible for the dephasing effects. The new dephasing nonlinearity results in large intensity modulations of around 50%, holding promise for ultrafast control of eigenmodes in nanophotonic switches, random lasers, and cavity quantum electrodynamics [2].

Of considerable importance is also the possibility of achieving nonadiabatic switching, i.e. dephasing of multiple scattering paths during the diffusion time of the light. We will discuss the possibility of controlling phase coherence of correlated paths in mesoscopic transport and, ultimately, the time-reversed light paths involved in photon localization.

Photonic band gap materials: light trapping crystals

S. John, Univ. of Toronto (Canada)

Photonic band gap (PBG) materials [1,2] are artificial periodic dielectric microstructures capable of trapping light in 3D [3] on sub-wavelength scales. This offers new opportunities for efficient solar energy trapping and harvesting in suitably microstructured thin films [4]. It also enables virtually complete control of the flow of light on microscopic scales in a 3D optical chip [5-7] as well as very strong coupling of light to matter where desired. By further engineering the electromagnetic density of states [8-10] within the chip it is possible to realize unprecedented coherent optical control of the quantum state of resonant atoms or quantum dots [11, 12]. This defines a fundamentally new strong-coupling regime for quantum optics. It enables multiple-wavelength channel optical logic to be performed on a chip on picosecond time scales at micro-watt power levels.

I discuss further consequences of light trapping in classical and quantum electrodynamics. I also discuss the challenges and requirements for materials fabrication to realize these remarkable effects.

Strong coupling of plasmons in non-linear waveguides

D. Felbacq, A. Castanie, B. Guizal, Univ. Montpellier 2 (France)

Wave propagation in a planar metal plasmon waveguide is studied. More specifically, the dispersion curve of a metal-insulator-metal waveguide is investigated. Such structures have been investigated in the past in the situation of a thin insulator film. In this work, the situation when the insulator layer supports guided modes is considered. It is shown that, in that case, it is possible to realize the strong coupling of photon modes with plasmons. By means of complex plane analysis, the influence of this coupling on the losses is studied and, for the hybrid plasmon/waveguide photon mode, spatial Rabi oscillations are observed. Finally the introduction of gain is considered as well as some more complicated geometries in view of the practical realization of devices.

8095-27, Session 7

Quantum electrodynamics in photonic crystals

P. Lodahl, Technical Univ. of Denmark (Denmark)

2D photonic crystal membranes fabricated in GaAs containing InGaAs quantum dots have in recent years proven to be a very successful platform for all-solid-state quantum optics experiments [1-4]. In a photonic crystal, the light-matter interaction strength can be tailored, i.e. either enhanced or suppressed by controlling the lattice constant of the structure. We will present experimental results on how highly efficient single-photon sources can be constructed by coupling single quantum dots to a photonic crystal waveguide exploring slow light [3]. The role of disorder in the form of fabrication imperfections is explored and found to lead to Anderson localization of light enabling cavity quantum electrodynamics by exploiting disorder as a way to enhance light-matter interactions [4]. The fundamental limits of using Anderson localization to enhance light-matter interactions are discussed, and the results are compared to the performance of state-of-the-art engineered

nanocavities.

Selective addressing of the resonant modes of a micropillar cavity with white light

G. Ctistis, A. Hartsuiker, E. van der Pol, Univ. Twente (Netherlands); J. Claudon, J. Gérard, Commissariat à l'Énergie Atomique (France); W. L. Vos, Univ. Twente (Netherlands)

There is a tremendous interest in high-quality micropillar resonators because of their potential in cavity-QED experiments such as the demonstration of the Purcell effect [1] or vacuum Rabi splitting [2, 3]. Most experiments are performed with quantum dots as internal light sources. Reflectivity experiments are rare because of symmetry constraints [4].

Here, we present broadband white-light reflectivity experiments on micropillar resonators with diameters ranging between 1 μm and 20 μm. The micropillars consist of a GaAs λ-layer, sandwiched between two Bragg-stacks made of λ/4 GaAs/AlAs layers, and were fabricated by molecular-beam epitaxy. We are able to spectrally resolve distinct transverse modes in the reflectivity experiments and to selectively address single modes by scanning the probe beam along the top facet of the micropillar. The positioning of the focused laser beam turns out to be crucial for pillar diameters exceeding the beam diameter, since at every position the coupling efficiency to different modes changes [5]. By decreasing the pillar diameter, we are able to resolve single modes, since the spacing between the modes increases.

8095-29, Session 7

Diamond photonics and quantum optics

M. Loncar, Harvard Univ. (United States)

Individual color centers in diamond have recently emerged as a promising solid-state platform for quantum communication and quantum information processing systems, as well as sensitive nanoscale magnetometry with optical read-out. Performance of these systems can be significantly improved by engineering optical properties of color centers using nanophotonic approaches. In this work we describe a high-flux, room temperature, source of single photons based on an individual Nitrogen-Vacancy (NV) center embedded in a top-down nanofabricated, single crystal diamond nanowires. Using the nanowire geometry, an order of magnitude brighter single photon source is realized, with an order of magnitude lower pump power, compared to an NV center in a bulk diamond. We also describe fabrication process that combines ion implantation of nitrogen with nanowires fabricated in high-purity diamond crystals. This approach significantly improves single-photon properties of our devices. By embedding nanowires in metals, it is possible to further increase photon production rate (via Purcell effect), as well as improve collection efficiency of emitted photons. Finally, we will describe optical cavities realized in diamond and materials transparent at visible wavelengths (Si3N4 and TiO2) that can enable strong coupling between photons and NV centers.

8095-30, Session 8

Photonic crystal nanolasers with nanoslot structure for sensing applications

T. Baba, S. Kita, H. Abe, S. Hachuda, M. Narimatsu, S. Otsuka, K. Nozaki, Yokohama National Univ. (Japan)

Photonic crystals have achieved ultimately small nanolasers. For example, H0-type devices in GaInAsP semiconductors operate under room temperature cw condition by photopumping with a modal volume of less than 0.2 times the cubic wavelength. The volume is further reduced beyond the diffraction limit by introducing a nanoslot in the cavity. A very narrow nanoslot of 30 nm width is formed by using inductively coupled plasma etching with HI gas. In such a nanoslot, strong mode localization occurs due to large discontinuity of electric field at high-index contrast boundaries. It enhances light-matter interaction in cavity QED and sensitivity of laser wavelength against environmental medium. The nanoslot nanolaser is particularly attractive as a sensor, because the device and optical I/O are much simpler and its performance is, in most cases, much better than passive cavity sensors'. As a sensor of liquid index, it exhibits a high sensitivity of 410 nm/RIU. In addition, it shows low temperature dependence in water, which is attributed to the negative TO effect of water compensating positive one in semiconductors. It suppresses the thermal chirping in laser spectrum to 10 pm order even with the small modal volume, ensuring high resolution sensing. Moreover, remarkable performance is observed when sensing protein; it detects an extremely low concentration of BSA protein in water, i.e. 17 pg/ml. This value implies 200 times higher sensitivity than that of surface plasmon resonance sensors.

8095-31, Session 8

Active semiconductor nanophotonics based on deterministic quantum wire and dot systems

E. Kapon, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Incorporating semiconductor quantum nanostructures such as quantum wires (QWRs) and quantum dots (QDs) into nano-photonic structures provides means for exploring both fundamental quantum photonics phenomena and applications in new photonic devices and systems. Examples include solid-state cavity quantum electrodynamics and quantum information processing and communications [1]. Most work in this field has been done using self-assembled quantum nanostructures, which, however, do not offer the necessary control in terms of optical spectra and positioning of the QWRs/QDs on the photonic chip.

Here, we review recent progress in quantum nano-photonics based on ordered QWR and QD structures grown on patterned substrates [2]. In particular, we discuss V-groove QWRs and pyramidal QDs formed due to growth rate anisotropy and nano-capillarity during metallorganic vapor phase epitaxy on nonplanar, patterned GaAs substrates [3]. This approach yields high quality, site-controlled (In)GaAs/(Al)GaAs QWR and QD systems, e.g., regular arrays of pyramidal QDs with ~1meV inhomogeneous broadening [4]. The confining potential of these wires/dots can be shaped by thickness and/or composition adjustment, producing structures of elaborated potential distributions, e.g., QD molecules and superlattices [5]. The intrinsically high symmetry of the pyramidal QDs yields unique excitonic features such as vanishing fine structure splitting, permitting efficient generation of polarization-entangled photons [6].

Based on these ordered QWR/QD systems, several nano-photonic

devices have been conceived and studied. These include coupled photonic crystal (PhC) cavities showing coupled-mode loss splitting [7], optically pumped, ~1μm long PhC-QWR lasers with sub-μW threshold and coupled-cavity PhC-QWR lasers [8], and single-QDs integrated with PhC membrane cavities [9]. More recently, deterministic coupling of single pyramidal QDs in PhC membrane cavities has allowed the identification of phonon-mediated coupling of the QD exciton and the cavity mode, which persists only for limited (few meV) cavity detuning [10]. This paves the way to the deterministic coupling of several QD-excitons via cavity photons, interesting for exploring many-body quantum photonics phenomena [11]. Implications on the feasibility of realizing "true" QD lasers will also be discussed.

Optical antenna electrodes for modification of QW electroluminescence

K. C. Y. Huang, Stanford Univ. (United States); M. Seo, KAIST (Korea, Republic of); M. L. Brongersma, Stanford Univ. (United States)

We simulated, fabricated and characterized the electroluminescence from InGaAs/ GaAs QW with metal electrodes which function as plasmonic resonator antennas. By patterning the antenna electrodes in the vicinity of a single QW layer with deeply subwavelength lateral width, charge carriers are confined near the antenna and subsequently recombine with enhanced radiative decay rate depending on the electrode/ QW separation and electrode shape. We show that the emission can be efficiently coupled to the antenna resonance which is engineered to reradiate with a specific polarization and unidirectional far-field pattern. The simultaneous control of carriers and photons can be used to improve light extraction and detection from the semiconductor while enabling fast direct modulation of the spontaneous emission.

High aspect ratio nanoscale metallic structures: a platform for photonic devices

P. Kuang, J. Park, W. Y. Leung, K. P. Constant, S. Chaudhary, K. Ho, Iowa State Univ. (United States)

We will report our progress in using high aspect ratio nanoscale metallic patterned structures in a number of optical devices such as light-emitting diodes or solar cells. They have high visible light transmission comparable to indium-tin-oxide electrodes and superior electrical conductivities. They can also provide a platform for switchable optical devices.

8095-35, Session 9

Exceeding the classical light-trapping limit in solar cells

J. N. Munday, D. M. Callahan, H. A. Atwater, California Institute of Technology (United States)

We describe a methodology for designing solar cells that have intensity and absorption enhancements that exceed the ergodic light-trapping limit. From thermodynamic arguments, Yablonovitch determined the maximum absorption enhancement in the ray optics limit for a bulk material to be 4n^2, where n is the index of refraction of the absorbing layer. We extend this treatment by considering the local density of optical states (LDOS), which shows that absorption enhancements can exceed 4n^2 under specific design criteria. Using a combination of analytical and numerical methods, we show how structures can be designed to beat the ergodic limit over an arbitrarily large wavelength range using frequency sum rules. For thin film solar cells, incorporating a plasmonic back reflector can result in spatially averaged LDOS enhancements of 1 to 3, and a metal-insulator-metal (MIM) structure can result in enhancements of over 200 near the bandedge of Si. We also find that placing the active material within a localized metallic resonator can lead to a nearly spatially uniform LDOS with enhancements above 1000. Purely dielectric structures can also lead to intensity enhancements exceeding the ergodic limit. For a low index active layer (n=1.5) clad by a high index layer (n=3), the LDOS enhancement is greater than 10. Finally, we show that for thin film solar cells with dispersive dielectric structures such as photonic crystals the ergodic light-trapping limit can be exceeded with LDOS enhancements of 2 to 5 by placing a planar solar cell in close proximaty to a photonic crystal.

8095-36, Session 9

Multiexciton effects in semiconductor nanocrystals from the perspective of lasing and solar energy conversion

V. I. Klimov, Los Alamos National Lab. (United States)

Using semiconductor nanocrystals one can produce extremely strong spatial confinement of electronic wave functions not accessible with other types of nanostructures. One consequence of this effect is a significant enhancement in carrier-carrier interactions that lead to a number of novel physical phenomena including ultrafast mutiexciton decay due to Auger recombination and efficient generation of multiple electron-hole pairs by single photons via carrier multiplication. In this talk, I will discuss the implications of ultrafast Auger decay for lasing applications of nanocrystals and several recent approaches developed in our group for resolving this problem by engineering carrier-carrier interactions in various types of heterostructured nanocrystals. I will also review the current status of carrier-multiplication research including experimental challenges in studies of this phenomenon, the role of extraneous effects, the competing energy relaxation channels such as hot-electron transfer, and implications of carrier multiplication in solar photovoltaics.

8095-37, Session 10

Explorations of photonic nanostructures for thermal and quantum applications

S. Fan, Stanford Univ. (United States)

I will review some of our recent progresses in understanding photonic nanostructures. Examples including modified photon-photon interactions in one-dimensional nanophotonic systems, and new understandings of near-field thermal transfer.

8095-38, Session 10

Near-unity collection efficiency of single photons using a planar dielectric antenna

K. Lee, X. Chen, Max-Planck-Institut für die Physik des Lichts (Germany); H. Eghlidi, A. Renn, ETH Zurich (Switzerland); S. J. Goetzinger, V. Sandoghdar, Max-Planck-Institut für die Physik des Lichts (Germany)

Single-photon sources have been discussed as the building blocks of quantum cryptography, optical quantum computation, spectroscopy, and metrology. However, the feasibility of these proposals depends on the availability of single photons with a high fidelity. For sources based on single emitters, this implies near-unity collection efficiency into well-defined modes. Some of the current state-of-the-art efforts aimed at achieving these criteria have been demonstrated, but despite an impressive progress the results still fall short. Here we report on a broad-band room-temperature scheme, which uses a layered dielectric structure for tailoring the angular emission of a single oriented molecule such that more than 96% of the emitted photons are collected with a commercially available microscope objective, leading to recorded photon count rates of about 50 MHz. Furthermore by adjusting the antenna parameters we could make an output mode to be very close to the radially polarized doughnut mode which can be converted into other modes such as the fundamental mode of an optical fibre with high fidelity. Our approach is wavelength insensitive and also compatible with cryogenic experiments. We will discuss various details of the design, fabrication and characterization of our dielectric planar antenna and its various applications to other types of single emitters - semiconductor quantum dots, diamond color centers, or solid-state ions.

8095-39, Session 10

Integrated quantum photonics

K. Aungskunsiri, D. Bonneau, E. Engin, D. Fry, J. P. Hadden, P. Kalasuwan, J. Kennard, T. Lawson, L. Marseglia, E. Martin-Lopez, J. C. F. Matthews, J. Meinecke, A. Peruzzo, K. Poulios, P. Shadbolt, A. Stanley-Clark, M. Halder, J. Harrison, D. Ho, P. Jiang, A. Laing, M. Lobino, A. Politi, B. R. Patton, M. Rodas Verde, X. Zhou, M. J. Cryan, J. G. Rarity, M. G. Thompson, S. Yu, J. L. O'Brien, Univ. of Bristol (United Kingdom)

Quantum information science aims to harness uniquely quantum mechanical properties to enhance measurement and information technologies, and to explore fundamental aspects of quantum physics. Of the various approaches to quantum computing [1], photons are particularly appealing for their low-noise properties and ease of manipulation at the single qubit level [2]. Encoding quantum information in photons is also an appealing approach to quantum communication, metrology (eg. [3]), measurement (eg. [4]) and other quantum technologies [5]. However, the implementation of optical quantum circuits with bulk optics has reached practical limits. We have developed an integrated waveguide approach to photonic quantum circuits for high performance, miniaturisation and scalability [6]. Here we report high-fidelity silica-on-silicon integrated optical realisations of key quantum photonic circuits, including two-photon quantum interference and a controlled-NOT logic gate [7]. We have demonstrated controlled manipulation of up to four photons on-chip, including high-fidelity single qubit operations, using a lithographically patterned resistive phase shifter [8]. We have used this architecture to implement a small-scale compiled version of Shor's quantum factoring algorithm [9] and demonstrated heralded generation of tuneable four photon entangled states from a six photon input [10]. We have combined waveguide photonic circuits with superconducting single photon detectors [11]. We describe complex quantum interference behaviour in multi-mode interference devices with up to eight inputs and outputs [12], and quantum walks of correlated particles in arrays of coupled waveguides [13]. Finally, we give an overview of our recent work on fundamental aspects of quantum measurement [14,15] and single photon sources [16,17].

8095-40, Session 10

Nonlinear optics near the single photon level with quantum dots coupled to photonic crystals

E. Waks, D. Sridharan, R. Bose, H. Kim, T. Shen, Univ. of Maryland, College Park (United States); G. S. Solomon, National Institute of Standards and Technology (United States)

Quantum dots (QDs) are stable, bright, semiconductor based light emitters that exhibit a quantized energy spectrum. For these reasons

they are excellent candidates for development of lasers, nonlinear optoelectronic components, and basic building blocks for future quantum information technology. Such applications critically depend on the ability to create strong interactions between QDs and photon fields. One method to engineer these strong interactions is to use photonic crystal structures. Photonic crystals are materials with a periodic index of refraction that can guide and confine light on the size scale of an optical wavelength, resulting in extremely strong atom-photon interactions. In this talk we will discuss our work to engineer strong nonlinear optical effects near the single photon level using a single quantum dot coupled to a photonic crystal cavity. We show that these interactions can be used to create all-optical switching with 8 GHz switching speeds using as few as two photons for the switching pulse. This device is approaching the fundamental limit where a single control photon can nonlinearly interact with a single target photon via cavity reflectivity modification. We then describe our effort to extend the device to a planar geometry that enables large scale integration on a chip. In addition,we show that by exploiting QD spin under high magnetic field we can attain improved switching performance, and also engineer entanglement between a photon and a single quantum dot, providing the potential for compact quantum devices that can be integrated on a semiconductor chip for future quantum information applications.

8095-52, Poster Session

The importance of nonlinear reflectance and transmittance measurements on the characterization of the nonlinear optical properties of metallic nanomaterials

C. Fuentes-Hernandez, Georgia Institute of Technology (United States); H. Hu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); A. R. Ernst, Georgia Institute of Technology (United States); D. A. Fishman, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); J. Hsu, Georgia Institute of Technology (United States); S. Webster, D. J. Hagan, E. W. Van Stryland, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); B. Kippelen, Georgia Institute of Technology (United States)

Z-scan is one of the most commonly used techniques to characterize the nonlinear optical (NLO) properties of many optical materials, including metallic nanomaterials such as ultrathin metal layers, metal nanoparticle doped glasses, and many others. To date, Z-scan data has been analyzed using the original formalism proposed by Sheik-Bahae M., et.al. (IEEE Journal of Quantum Electronics, 26, 760, 1990). In this formalism, the NLO changes in the sample's reflectance, $\Delta R(I(z))$, are neglected. This implies that the NLO changes in transmittance, $\Delta T(I(z))$, measured in open-aperture Z-scan experiments can be directly correlated with the NLO changes in absorptance,$\Delta A(I(z))$, such that $\Delta A = -\Delta T$. However, this approximation of the original Z-scan formalism, valid for most dielectrics and semiconductors, both organic and inorganic, is no longer valid in metallic nanostructures where the NLO changes in reflectance (R) and transmittance (T) can be of the same order of magnitude, hence making $\Delta A = - \Delta T - \Delta R$. Here, we discuss the implications of having strong changes in the reflectance by characterizing the NLO properties of a 20 nm Au film using a combination of T and R pump-probe and Z-scan experiments implemented with 500 fs pulses at 560 nm. We use spectroscopic ellipsometry to measure the linear refractive index of Au and use a physical model of the metal's permittivity to describe the linear and NLO properties measured by pump-probe experiments. Furthermore, we show that Z-scan traces can be recovered from these experiments and how neglecting ΔR in the analysis of transmittance Z-scan data leads to misleading estimations of the magnitude, and even the sign, of the NLO changes observed.

8095-53, Poster Session

thermal tuning of a silicon photonic crystal cavity infilled with an elastomer

A. K. Erdamar, M. van Leest, S. J. Picken, J. Caro, Technische Univ. Delft (Netherlands)

Thermal tuning of the transmission of a cavity in silicon photonic crystal (PhC) slab globally infilled with an elastomer was investigated. In contrast to liquids used for infiltration, elastomers are more stable and durable. In addition, elastomers have a high coefficient of thermal expansion and as a result exhibit a relatively strong decrease of the refractive index upon heating. This appreciable thermo-optic property (-3.5 x 10-4/K) can counteract the positive thermo-optic coefficient of the host material silicon (1.85 x 10-4/K), and thus enables a measurable blue shift of the cavity transmission. Here, we use the elastomer Kraton SEBS G 1657 using global infilling and global heating of the PhC. The triangular hole-type PhCs are fabricated in silicon-on-insulator (SOI) material, using electron-beam lithography and cryogenic inductively coupled plasma etching in an SF6-based plasma. Membrane PhC devices are obtained by underetching the silicon layer in buffered HF. The infilling is done by applying a drop of the elastomer dissolved in cyclohexane (2% by weight) to the PhC membrane. The cavity we use is a hole-type cavity with modified surrounding holes. Transmission measurements are performed with the end-fire technique, using a white light source and an optical spectrum analyzer. The infill effect on the band gap and on the cavity resonance is clearly observed, the shift in either case being about 135 nm. Temperature-dependent measurements of the cavity resonance at eight temperatures in the range 293-333 K show a linear blue shift of 2.64 nm, large enough for tuning the transmission of modest Q cavities.

Mode of propagation of optical radiation with self-similar pulse shape in layered medium with nonlinear absorption

V. A. Trofimov, O. V. Matusevich, D. A. Smotrov, Lomonosov Moscow State Univ. (Russian Federation)

We investigate the possibility of propagation of laser pulse which has self-similar shape at its propagation in a medium with two-photon absorption. The consideration is based on the solution of problem as nonlinear eigenfunction problem for the Schrödinger equation with periodic nonlinear coefficients which describe the nonlinear absorption and dielectric permittivity. Under certain conditions this eigenfunction gives us the pulse shape with requiring properties. We investigate the realization of mode of the laser pulse propagation with self-similar its shape in layered medium with two-photon absorption. In the case of homogeneous absorption medium the shape of pulse is similar to the soliton shape taking place for a propagation of laser radiation in a medium with Kerr nonlinearity.

Photopolymer films doped with zeolite nanocrystals

M. Moothanchery, I. Naydenova, Dublin Institute of Technology (Ireland); S. Mintova, Ecole Nationale Supérieure d'Ingenieurs de Caen et Ctr. de Recherche (France); V. Toal, Dublin Institute of Technology (Ireland)

The effect of zeolites nanocrystals (pure silicate, aluminosilicates and aluminophosphate) incorporated in acrylamide based photopolymer layers for holographic applications is investigated. The presence of the zeolite nanocrystals improved the refractive index modulation and also resulted in substantial suppression of polymerization shrinkage. The

higher refractive index modulation achieved is beneficial for applications such as holographic data storage as it provides higher storage capacities. Besides, the high refractive index modulation is advantageous for the fabrication of spectroscopic devices and holographic optical elements. The holograms recorded in the acrylamide photopolymer films doped with the zeolite nanoparticles are identified for further sensor application.

Coherent optical imaging through opaque photonic media

G. Ctistis, E. G. van Putten, D. Akbulut, J. Bertolotti, Univ. Twente (Netherlands); A. Lagendijk, FOM Institute for Atomic and Molecular Physics (Netherlands); W. L. Vos, A. P. Mosk, Univ. Twente (Netherlands)

Scattering of light is usually seen as a nuisance in microscopy. Scattering limits the penetration depth and strongly deteriorates the achievable resolution. However, by gaining active spatial control over the optical wave front it is possible to manipulate the propagation of scattered light even far in the multiple scattering regime [1]. It was recently shown that in this way scattered light can even be exploited for perfect optical focusing [2]. These wave front shaping techniques pave the way for new microscopy methods based on strong light scattering [3-6].

We use fluorescent beads to demonstrate concentration of scattered light into a focus much smaller than the wavelength. Exploiting such a small focus, we demonstrate imaging of gold nanostructures through an opaque scattering layer. We obtained a very high resolution proving that scattering can significantly improve the image quality in microscopy.

The effects similar to quantum teleportation and superluminality at propagating of laser pulse in medium with combined nonlinear response

V. A. Trofimov, O. V. Matusevich, Lomonosov Moscow State Univ. (Russian Federation)

The effect of laser pulse propagation with group velocity, which is faster than light velocity at given conditions, is widely investigated at present, in particular for photonic crystals. We have found out the similar effect under the interaction of two laser pulse in medium with combined nonlinear response for 2D or 3D cases and for propagation of femtosecond pulse in nonlinear medium under the condition of temporal dispersion of nonlinear response.

The physical reason of such laser pulse propagation concludes in self-induced optical grating due to nonlinear interaction of laser radiation with matter. The grating acts on laser pulse in similar way as photonic crystal acts on velocity of laser light passed through the one.

We predict and investigate the increasing of group velocity of some sub-pulses, which appear under the dual-waves interaction in nonlinear medium.

We shown the distortion, introduced in one of pulses, acts on the other pulse immediately despite on time interval between the pulses. In this case we can say about the effect that is like to teleportation effect in quantum mechanics

8095-58, Poster Session

Tunable subradiant lattice plasmons by out-of-plane dipolar interactions

W. Zhou, T. W. Odom, Northwestern Univ. (United States)

Plasmonic nanostructures can concentrate optical fields into nanoscale volumes, which is useful for plasmonic nanolasers, surface enhanced Raman spectroscopy, and white-light generation. However, the short lifetimes of the emissive plasmons correspond to a rapid depletion of the plasmon energy, preventing further enhancement of local optical fields. Dark (subradiant) plasmons have longer lifetimes, but their resonant wavelengths cannot be tuned over a broad wavelength range without changing the overall geometry of the nanostructures. Also, fabrication cannot be readily scaled because their complex shapes have subwavelength dimensions. Here we report a new type of subradiant plasmon with a narrow (~5 nm) resonant wavelength that can be easily tuned by changing either the height of large (> 100 nm) gold nanoparticles arranged in a two-dimensional array or the incident excitation angle. At resonance, strong coupling between out-of-plane nanoparticle dipolar moments suppresses radiative decay, trapping light in the plane of the array and strongly localizing the optical field onto each nanoparticle. This new mechanism can lead to new applications for subradiant plasmons because height-controlled nanoparticle arrays can be manufactured over wafer-scale areas on a variety of substrates.

8095-41, Session 11

High-performance Ge quantum well modulators for optical interconnects

S. A. Claussen, E. H. Edwards, S. Ren, R. K. Schaevitz, R. M. Audet, E. Tasyurek, E. Fei, T. I. Kamins, J. S. Harris, D. A. B. Miller, Stanford Univ. (United States)

Electrical interconnects are rapidly nearing fundamental limitations related to their density-scaling a wire down in size does not allow it to carry more information-and the environmentally-significant amount of power they consume. Optical interconnects provide a promising solution, but require CMOS-compatible, low-energy optical components in order to be a feasible alternative. Ge/SiGe quantum wells (QWs) exhibit the quantum-confined Stark effect, a strong electroabsorption mechanism that enables compact optical modulators for use in future optical interconnect systems.

To design and optimize high-performance modulators, we have experimentally investigated the ultrafast carrier dynamics and transport properties of Ge/SiGe QWs. We have also developed a simple model for the electroabsorption spectrum of this material, which allows us to account for both absorption from our QW design and the less-desirable background absorption that limits device performance.

We have demonstrated Ge/SiGe QW modulators in both a surface-normal, asymmetric Fabry-Perot geometry and a waveguide geometry. The asymmetric Fabry-Perot design allows for high contrast ratios with small changes in absolute absorption. We have recently achieved contrast ratios of 4.8 dB over a 1 V swing. Better understanding of the background absorption in the QWs and resonator cavity will enable future contrast ratios of more than 10 dB with a greatly reduced insertion loss. The waveguide modulators are enabled by selective-area epitaxial growth of the QWs and provide easy integration with other interconnect components. We have demonstrated a waveguide modulator with an active area of 5μm2, an extinction ratio of 3.2 dB and a speed of 3.5 Gb/s.

8095-42, Session 11

Engineering aperiodic order for optical devices with photonic-plasmonic nanostructures

L. Dal Negro, Boston Univ. (United States)

Deterministic Aperiodic Structures (DAS) are generated by the mathematical rules of L-systems and number theory, manifest unique light localization and transport properties associated with a great structural complexity, and can be fabricated on-chips using conventional nano-lithographic techniques. When combined with metal-dielectric nanostructures, they give rise to large energy gaps like periodic media (i.e. photonic-plasmonic crystals) and highly localized, enhanced field states like disordered random media, including the formation of Anderson-localized modes, forbidden in periodic scattering media. Contrary to random media, DAS possess controllable transport properties from ballistic to anomalous diffusion (slower diffusion than classical random walks) and strongly localized field states with large fluctuations of the photonic mode density - essential attributes to achieve spatio-temporal energy localization and enhanced light-matter coupling, i.e. radiative rates of fluorescent molecules, absorption cross-sections, non-linear optical processes on the nanoscale. In particular, DAS fabricated using metal/dielectric nanoparticles are suitable to engineer efficient nanoplasmonic structures for Surface Enhanced Raman (SERS) sensing, optical detectors, and enhanced light-emitting and nonlinear components.

In this talk, by combining dark-field scattering characterization, micro-photoluminescence and Raman measurements with accurate electrodynamics calculations based on semi-analytical multiple-scattering theories, I will discuss electromagnetic coupling1,2, resonant scattering3, colorimetric biosensing4, light emission5 and surface enhanced Raman sensing6,7 in two-dimensional metal-dielectric photonic-plasmonic arrays based on deterministic aperiodic sequences. In particular, I will survey the optical properties, and assess the device performances, of different aperiodic systems ranging from quasi-periodic crystals to pseudo-random nanoparticle arrays8 fabricated by Electron-Beam Lithography (EBL) on transparent quartz substrates. Finally, I will present novel aperiodic optical nano-antennas structures that can provide strong field localization at multiple frequencies over a broad spectral range9.

fJ/bit photonic platform based on photonic crystals

M. Notomi, NTT Basic Research Labs. (Japan)

Currently, demands for low-power integratable nano-photonic components are increasing for next-generation chips where the introduction of a large number of photonic components is discussed in order to resolve the energy consumption and heat generation problems of present CMOS chips. However, this is challenging because conventional photonic components are too large, too energy-consuming, and hard to integrate. In this talk, we argue that a photonic crystal is one of the promising candidates for this purpose. For the last several years, a number of sophisticated designs for high Q nanocavities based on photonic crystals have been developed. Recently, we have applied these nanocavities for various photonic devices, and achieved ultra-low energy consumption operation. First example is an all-optical switch. We applied a so-called H0 cavity which is the smallest dielectric-core cavity, composed from composition-optimized InGaAsP. By this design, we achieved fast all-optical switching operation with an optical pulse of less than 1 fJ and 10-25 ps length. Second example is a laser. We adopted a novel buried-heterostructure photonic-crystal cavity design to realize strong photon/electron confinement and small thermal resistance. We achieved room-temperature optically-pumped CW lasing with the threshold power of 1.5 micro-watts. Furthermore, we achieved 20GHz direct modulation, corresponding to 8.76fJ/bit energy consumption. These energy/bit numbers are about two orders of magnitude lower than previous results. They indicate that it is now possible to realize nanpphotonic devices with fJ/bit energy consumption. I will also discuss other low-power nanophotonic devices based on photonic crystals and possible impacts for future ICT.

8095-44, Session 11

Ultra-low threshold lasers and modulators based on optical nanocavities

J. Vuckovic, B. Ellis, G. Shambat, A. Majumdar, A. Faraon, Stanford Univ. (United States)

Achieving the operation of semiconductor optoelectronic devices (lasers and modulators) at sub-10fJ control with speeds exceeding 10GHz, as is required by the ITRS roadmap [1], remains a big challenge and requires radical approaches. Nanophotonic devices could operate at such a low-energy and high-speed limit. A strong localization of light inside of optical nanocavities (such as photonic crystals) increases the strength of light-matter interaction, which in turn reduces thresholds for various optical effects, including lasing and modulation. We have employed such a platform to demonstrate the lowest threshold electrically injected semiconductor laser, operating at only 150nA threshold current - an order of magnitude lower than any electrically injected semiconductor laser so far. In addition, we have demonstrated ultra-fast electro-optic modulation with only ~0.6fJ control energy per bit. In both of these cases, we have developed practical, scalable structures employing lateral current injection into a photonic crystal nanocavity [2]. In addition to being fast and energy efficient, the small size of these devices is also important for achieving high density of integration; moreover, such operation can be achieved with moderate values of the resonator quality factors, which also alleviates the energy consumption of thermal stabilization circuit.

We have also demonstrated a proof of concept electro-optic modulator based on a single quantum dot strongly coupled to a photonic crystal nanocavity that enables operation at the ultimate limit of control energy - sub-aJ per bit [3]. Finally, to make these devices silicon CMOS compatible, we are investigating a platform based on a combination of silicon and germanium [4].

Financial support was provided by IFC, AFOSR, Office of Naval research, and DARPA.

Integrated metaphotonics

A. D. Boardman, P. Egan, R. R. C. Mitchell-Thomas, Univ. of Salford (United Kingdom)

Building up a range of integrated metamaterial waveguide devices is not only attractive from a fundamental point of view, but it is going to be possible to create a number of beautiful down-stream applications. It is in this sense that the presentation is developed under the general integrated metaphotonics heading. In the first instance, the propagation of waveguide modes in double negative material and materials characterised by other combinations of relative dielectric permittivity and relative permeability, together with some degree of geometrical complexity will be considered. The general properties of linear metamaterial guides will be exposed, and the extent to which nonlinearity and magnetooptic influence can be used as control agents will be investigated. The degree of control obtained by manipulating planar waveguide interfaces is shown to be another fascinating outcome from the use of special metamaterials and this will be highlighted for certain frequency windows. Certain systems lead to the possibility of not only slowing light down, but to the concept of actually stopping light, heralding new types of all-optical computer chips. Tapered, and discontinuous guides will be investigated, with this in mind, leading to new ideas about switches and X-junctions and the famous trapped rainbows. All of these will be shown to emerge from the use of modern metamaterials, and that there are certain novel features that always emerge from them. In addition to this and soliton propagation, transformation optics will be invoked by reaching out for a dramatic use of the spacetime cloak, or the history editor

8095-46, Session 12

Active plasmonic devices enhanced by waveguide dispersion engineering

C. Min, G. Veronis, Louisiana State Univ. (United States)

Plasmonic devices, based on surface plasmons propagating at metal-dielectric interfaces, have shown the potential to manipulate light at deep subwavelength scales. One of the main challenges in plasmonics is achieving active control of optical signals. In this paper, we introduce active plasmonic devices enhanced by waveguide dispersion engineering. We consider plasmonic waveguide systems consisting of a metal-dielectric-metal waveguide (MDM) side-coupled to arrays of MDM stub resonators. The MDM waveguide and stubs are filled with an active material whose absorption coefficient can be modified with an external control beam. Such plasmonic waveguide systems can be engineered to support slow-light modes. We find that, as the slowdown factor increases, the sensitivity of the effective index of the mode to variations of the refractive index of the active material increases. Such slow-light enhancements of the sensitivity to refractive index variations lead to enhanced performance of active plasmonic devices such as switches. To demonstrate this, we consider absorption switches based on Fabry-Perot cavity structures, consisting of slow-light plasmonic waveguide systems sandwiched between two conventional MDM waveguides. We find that increased slowdown factor leads to increased induced change of the propagation length of the slow-light mode for a given refractive index variation, and therefore to increased modulation depth. Compared to conventional MDM absorption switches, slow-light enhanced switches achieve significantly higher modulation depth with moderate insertion loss. We use a scattering matrix theory to account for the behavior of the devices which is in excellent agreement with numerical results obtained with the finite-difference frequency-domain method.

8095-47, Session 12

Slow light using negative metamaterials

S. Sridhar, W. Lu, Y. Huang, D. Casse, S. Savo, Northeastern Univ. (United States)

Controlling the speed of light is a fundamental challenge that can lead to new physical phenomena and applications. We show that a nonresonant planar waveguide consisting of conventional dielectric cladded with single-negative materials supports degenerate propagating modes for which the group velocity and total energy flow can be zero if the media are lossless.

We have carried out the first experimental observation of slow light utilizing the mechanism of the degeneracy of forward and backward waves, in the GHz microwave regime in a planar waveguide consisting of a dielectric core cladded by single-negative metamaterial. The metamaterial cladding consisted of periodic arrays of metallic split-ring resonators (SRRs), exhibiting an effective negative permeability. Group delay dispersions obtained from pulsed measurements are in complete agreement with that obtained from a theory of slowing light.

Absorptive losses severely limit the velocity reduction, and will even destroy the zero-group velocity condition for real frequency/complex wave vector modes. We show that by incorporating gain G into the core dielectric, there exists a critical gain value Gc at which we can recover the condition of zero group velocity, so that light pulses can be stopped and stored. This structure is simpler to achieve than double-negative metamaterials, has small footprint, and can be incorporated into ultracompact on-chip optoelectronics.

These nanoscale metamaterial waveguides offer the prospect of on-chip slow light devices where light speeds are reduced by orders of magnitude, enabling ultra-compact optical delay lines and buffers.

8095-48, Session 13

Electrically active 3D photonic and plasmonic crystals

P. V. Braun, Univ. of Illinois at Urbana-Champaign (United States)

Photonic and plasmonic crystals provide unprecedented control over light emission, absorption and propagation, which has led to the proposal of a large variety of optoelectronic devices. Three-dimensional devices with electronic functionality have however remained elusive, as fabrication of three-dimensional, electrically active nanostructured materials remains complex. Numerous techniques have been demonstrated to fabricate 3D photonic and plasmonic crystals, including colloidal crystallization, phase mask and multibeam interference lithography, direct laser writing, photolithography, and wafer bonding, but, most of these techniques result in amorphous or polycrystalline material which does not possess the required electronic properties for application in optoelectronics. There are a number of elegant techniques which make use of single crystal semiconductor substrates, however they tend to require elaborate, slow processing, are limited in what photonic crystal structures may be created, and have not demonstrated electrical functionality. In this work we demonstrate a method of forming 3D photonic and plasmonic crystals from single crystal III-V semiconductors by metal-organic vapor phase epitaxy (MOVPE). We employ a template-based fabrication method and grow semiconductor material to fill the structure using a form of selective area epitaxy.

The epitaxial growth process (originating at the substrate, in contrast to conformal growth) is much the same as the growth of planar III-V devices in that light emitting layers (e.g. quantum wells), cladding layers, electrically doped layers, etc may all be grown in a single process. Thus the layers of an optoelectronic device may be defined by the MOVPE growth parameters while the photonic crystal structure is simultaneously imparted to the material using the 3D template. To demonstrate the potential of this technique we have fabricated vertically emitting LED's with embedded InGaAs QW's. The fundamental behaviors of this growth technique will be discussed, including prevention of polycrystalline nucleation, doping and fabrication of light-emitting heterostructures.

8095-49, Session 13

'Giant' nanocrystal quantum dots: a new class of active emitters for photonics applications

J. Hollingsworth, Y. Ghosh, A. M. Dennis, J. Kundu, B. N. Pal, Y. Park, S. Brovelli, Los Alamos National Lab. (United States); A. V. Malko, The Univ. of Texas at Dallas (United States); V. I. Klimov, H. Htoon, Los Alamos National Lab. (United States)

Nanocrystal quantum dots (NQDs) are nearly ideal candidates for light-emission applications due to high quantum efficiencies, and narrow-band and particle-size-tunable photoluminescence. However, they suffer from important deficiencies, including intermittency in fluorescence intensity, or "blinking", at the single-NQD level and chemical-environment-dependent photo-instability at the ensemble level. We recently reported the first demonstration of an inorganic shell approach to address these outstanding issues; namely, the suppression of blinking and ensemble-level instabilities.[1,2] Here, I will review these results, as well as key findings establishing the new "giant" NQDs (g-NQDs) as a functionally new class of colloidal quantum dot: significant suppression of nonradiative Auger recombination,[3] highly emissive multiexcitons [4] and near-unity biexciton emission, and a shell-thickness-dependent transition from NQDs characterized by a continuous distribution of emission states (thin-shell systems) to NQDs characterized by a single emission state (thick-shell systems). Beyond a summary of these fundamental studies, I will focus on the fabrication of new g-NQD compositional systems and the ability to tune g-NQD emission wavelength by control of the core/shell electronic structure. Lastly, I will describe the integration of g-NQDs into light emitting devices, as (1) robust, "passive" phosphors and (2) active layers in electrically pumped light emitting diodes, where the thick-shell NQDs provide significant advantages compared to their thin-shell counterparts in terms of device efficiencies, self-reabsorption, and/or stabilities.

8095-50, Session 13

Tunable mesoporous Bragg reflectors based on block-copolymer self-assembly

S. Guldin, Univ. of Cambridge (United Kingdom); M. Kolle, Univ. of Cambridge (United Kingdom) and School of Engineering and Applied Sciences, Harvard University (United States); M. Stefik, Cornell Univ. (United States) and Ecole Polytechnique Federal de Lausanne (Switzerland); U. B. Wiesner, Cornell Univ. (United States); U. Steiner, Univ. of Cambridge (United Kingdom)

Mesoporous distributed Bragg reflectors (MDBRs) are an emerging class of photonic materials with unique properties due their porosity on the sub-optical length scale.[1] MDBRs have great potential as sensing materials, as adsorption and desorption of gas phase molecules lead to reversible changes in the refractive index of the stack. MDBR based "photonic noses" have been proposed that mimic the olfactory system. [2] In optoelectronic applications, MDBRs can be used to manipulate the flow of light. Examples include light harvesting elements in dye sensitised solar cells and resonance cavities for hybrid lasers.

We present a new route for the fabrication of MDBRs which relies on the self-assembling properties of the block copolymer PI-b-PEO in combination with sol-gel chemistry. This allows unprecedented control to finely tune porosity and pore size in the outcome inorganic material, which is exploited to manipulate the refractive index of the building blocks. Stacking-up multiple layers of alternating refractive index results in a fast and reliable assembly of a continuous network with well-defined interfaces. The outcome are MDBRs of high quality optical properties even when made of the same type of material. The effects of these unique characteristics on the photonic functioning will be discussed in detail.

Fabrication of three-dimensional gyroid photonic microstructures

M. Gu, M. Turner, Swinburne Univ. of Technology (Australia)

Three-dimensional (3D) photonic microstructures are an important platform for 3D photonic bandgap materials. If their feature size becomes smaller than the operating wavelength, they physically behave as metamaterials providing new properties that do not exit in nature. More importantly, the 3D photonic microstructures are necessary platforms to produce chiral geometries. It has been shown that chiral microstructures have important nanophotonic functionalities including their ability to enhance and control the chirality of light, which leads to applications such as negative index metamaterials, compact broadband circular polarisation filters, ultrasensitive biosensing and nanoscale plasmonic motors. However, the lack of symmetry and uniaxial chirality within typical chiral microstructures is not suitable for certain applications. In this talk, we will present our recent progress on fabrication, characterisation and metallisation of 3D microstructures based on the chiral, cubic networks found within the gyroid minimal surface inspired by a recent finding in butterfly wings.

Conference 8096: Plasmonics: Metallic Nanostructures and Their Optical Properties IX

Sunday-Thursday 21-25 August 2011 • Part of Proceedings of SPIE Vol. 8096
Plasmonics: Metallic Nanostructures and Their Optical Properties IX

8096-01, Session 1

Recent progress in plasmonics (Keynote Presentation)

X. Zhang, Univ. of California, Berkeley (United States)

Plasmonics takes advantage of the properties of surface plasmon polaritons in which photons are coupled to the quasi-free electron oscillations on metal surface. Recent advances of plasmonic applications include nano photonics, sub-diffraction-limit imaging, and plasmonic nano-laser etc.

Motivated by transformation optics - an approach to controlling the propagation of light by spatially varying material optical properties - various plasmonic lens designs will be demonstrated that can focus or bend surface plasmon polaritons with significantly reduced scattering loss in comparison to previously reported plasmonic elements. A technique that uses Brownian motion of single molecules for two-dimensional imaging of the enhancement profile of single hotspots on the surfaces of metallic thin films and nanoparticle clusters will also be introduced. Additionally I will show a nanoscale plasmonic motor directly driven by light and its rotation velocity and direction are controlled by tuning the wavelength of the incident wave to excite different plasmonic modes. I will also present the experimental demonstration of nanometer-scale plasmonic lasers, generating optical modes a hundred times smaller than the diffraction limit. Direct measurements of the emission lifetime reveal a broad-band enhancement of exciton spontaneous emission rate and the signature of apparently threshold-less lasing.

The abilities of advanced plasmonic techniques to transform surface plasmon polaritons, to image nanometer-sized hotspots, to generate significant optical torques at the nanoscale, and to create coherent light source at truly nano scale will benefit applications such as energy conversion, in vivo biological detection and manipulation, mechanical transducers and actuators, and active photonic circuits.

8096-02, Session 1

Plasmonics with gain (Keynote Presentation)

A. V. Zayats, King's College London (United Kingdom)

We will consider strategies for amplification of surface plasmon polariton waves propagating on the interface of metal and gain dielectric. Various amplifying configurations including hybrid plasmonic crystals will be considered. The applications of gain-effects in all-optical nanophotonics will be dis-cussed.

Resonant interaction of surface plasmon polaritons (SPP) with molecules, ions and semiconductor quantum dots near a metal interface attracts considerable attention since its understanding may lead to new nanophotonic technologies for sensing, optical data processing and quantum information. One of the most significant applications may be the amplification of the SPP waves or lasing into SPP modes.

In this talk we will discuss various experimental realisations of SPP amplification in dielectric-loaded plasmonic waveguides as well as plasmonic crystals hybridised with gain medium. We will report on the observation of amplified spontaneous emission of surface plasmon polaritons excited at the inter-face with a resonant amplifying medium. Generally, amplified spontaneous emission occurs during light propagation in the gain medium with inverse population and is sometimes called, travelling wave lasing or superfluorescence. Significant spectral narrowing of the SPP emission line is observed with the very low ASE threshold. We will also report on SPP Bloch mode amplification in plasmonic crystals were this effect leads to the increase in the enhanced transmission.

The amplification of SPPs and associated Ohmic loss compensation during their propagation on a metal-dielectric interface have profound implications in design of plasmonic interconnects and all-optical signal processing devices based on plasmonic components.

8096-03, Session 2

Superconducting plasmonics

A. Tsiatmas, R. Buckingham, V. A. Fedotov, N. I. Zheludev, Univ. of Southampton (United Kingdom)

[Invited] Superconductors due to their vanishing ohmic resistance and dominant kinetic inductance have the ability to support propagating plasmonic excitations from low frequencies up to the THz regime. These modes can be confined on the scale of few tens of nanometres and propagate up to hundreds of times their wavelength. This reveals a significant potential for applications of superconducting plasmonic structures that originates from the easy incorporation of active control in these devices

8096-04, Session 2

Near-field imaging of terahertz plasmon waves with a subwavelength aperture probe

O. Mitrofanov, R. Mueckstein, Univ. College London (United Kingdom)

Visualization of Terahertz (THz) plasmons with THz local near-field probes allows studying ultra-fast plasmonic phenomena in the time domain, with access to the electric field of plasmonic waves rather than the intensity. We demonstrate that the integrated sub-wavelength aperture near-field probe can be used to map THz surface plasmon waves in space and time with high resolution. The precise knowledge of the probe structure, which incorporates a photoconductive detector in the near-field zone of the sub-wavelength aperture, allows to identify the coupling mechanism and to explain the nature of the observed phenomena. Using this probe, we mapped (in space and time) THz plasmon waves formed on a metallic surface by tightly focused 2.0THz pulses (Ref. 1) and the formation of standing plasmon waves in THz antennas. Using several experimental near-field observations we show that this probe detects the spatial derivative of the electric field of surface plasmons rather than the field itself. The coupling mechanism results in an apparent spatial phase shift of the detected surface plasmon wave.

The understanding of the coupling mechanism provides a framework for analysis and interpretation of THz near-field images, where surface plasmon effects may be present. We will discuss how this microscopy method can be applied to track surface plasmon propagation and formation of plasmonic resonances. The method can provide a vital insight into the role of THz surface plasmons in basic physical phenomena and in THz devices.

8096-05, Session 2

From vacuum Rabi splitting towards stimulated emission with surface plasmon polaritons.

R. J. Moerland, A. Väkeväinen, A. Eskelinen, G. Sharma, P. Törmä, Aalto Univ. School of Science and Technology (Finland)

Coherent phenomena in Surface Plasmon Polariton (SPP)/emitter systems, where strong coupling dominates, are an intensly studied

subject for lasing and coherent energy transfer applications. Also a coherent phenomenon is vacuum Rabi splitting; we have reported on strong coupling between SPP and Rhodamine 6G (R6G) molecules, showing double vacuum Rabi splitting energies up to 230 and 110 meV [1]. The system in Ref. 1 consisted of a 50 nm layer of silver on top of a SiO2 substrate. A layer of R6G molecules, embedded in PMMA, is deposited on top by spincoating. The same system is also interesting for studying enhancements in spontaneous emission, and for obtaining stimulated emission. The R6G molecules in the system are pumped by a 532 nm laser, while the emission spectrum of the hybrid SPP/emitter system is recorded. As the laser pump intensity is increased, the recorded spectrum reflects the change from spontaneous emission towards stimulated emission. We will show our latest results in this area of research.

J., Kuzyk, A., Pettersson, M., Tikkanen, H., Kunttu, H., and Törmä, P., Vacuum Rabi splitting and strong coupling dynamics for surface plasmon polaritons and Rhodamine 6G molecules, Physical Review Letters 103, 053602 (2009). http://link.aps.org/doi/10.1103/PhysRevLett.103.053602

8096-06, Session 2

Transformation plasmonics and gradient index plasmonics

Y. Liu, T. Zentgraf, M. H. Mikkelsen, Univ. of California, Berkeley (United States); J. G. Valentine, Vanderbilt Univ. (United States); X. Zhang, Univ. of California, Berkeley (United States)

Taking advantage of transformation optics, we demonstrate that the confinement as well as propagation of surface plasmon polaritons (SPPs) can be managed in a prescribed manner by carefully controlling the dielectric material properties adjacent to a metal. Since the metal properties are completely unchanged and the transformed dielectric materials can be isotropic and non-magnetic, it provides a straightforward way for practical realizations. We show that our approach can assist to tightly bound SPPs over a broad wavelength range at uneven and curved surfaces, where SPPs would normally suffer from significant scattering losses. In addition, a 180-degree plasmonic bend with almost perfect transmission is designed.

We further propose to slowly change the thickness of an isotropic dielectric cladding layer and hence the local effective index of SPPs, instead of directly modifying the permittivity of the dielectric medium. As the local effective index of SPPs is varied gradually in a truely continuous manner we term our approach gradient index (GRIN) plasmonics, in analogy to the well-known GRIN optics. Applying this method, we design and demonstrate two different devices: a plasmonic Luneburg lens to focus SPPs and a plasmonic Eaton lens to bend SPPs. In comparison with previously reported plasmonic elements, the scattering loss of SPPs in our designs can be significantly reduced since the optical properties are adiabatically changed. Fluorescence imaging and leakage radiation microscopy are applied to characterize the performance of the fabricated GRIN plasmonic devices based on gray scale lithography, showing a good agreement with the numerical simulation.

8096-07, Session 2

Controlling the motion of metallic nanoparticles with fast electron beams

J. Aizpurua, Centro de Fisica de Materiales (Spain) and Donostia International Physics Ctr. (Spain); A. Reyes Coronado, Univ. Nacional Autónoma de México (Mexico); P. E. Batson, Rutgers, The State Univ. of New Jersey (United States); R. G. Barrera, Univ. Nacional Autónoma de México (Mexico); A. Rivacoba, Univ. del País Vasco (Spain) and Donostia International Physics Ctr. (Spain); P. M. Echenique, Donostia International Physics Ctr. (Spain) and Univ. del País Vasco (Spain)

We analyze the total momentum transfer from fast electron beams, like those employed in scanning transmission electron microscopy (STEM), to plasmonic nanoparticles. The calculation of the momentum transfer is obtained by integrating the electromagnetic forces acting on the particles over time. Numerical results for single and dimer metallic nanoparticles are presented, for nanoparticle sizes ranging between 2 and 10 nm. Our calculations show that depending on the specific values of impact parameter and separation distance, the total momentum transfer yields a force that can be either attractive or repulsive. We corroborate these findings with experimental results that confirm the theoretical predictions. The time-average forces calculated for electron beams commonly employed in STEM are on the order of piconewtons, comparable in magnitude to optical forces and are thus capable of producing movement in the nanoparticles. This effect can be exploited in mechanical control of nanoparticle induced motion, as demonstrated experimentally.

8096-08, Session 3

Quantum plasmonics and plexcitonics

P. J. Nordlander, Rice Univ. (United States)

A recently developed fully quantum mechanical approach for the description of plasmonic and excitonic nanoparticles is discussed.[1] It is shown that quantum effects can have a pronounced influence on the electric field enhancements near the nanoparticle surfaces and on the optical properties strongly coupled nanoparticles. For closely spaced metallic nanoparticles, electron transfer and nonlocal screening can drastically reduce the electric field enhancements across the gap and result in a Charge Transfer Plasmon (CTP) where an oscillatory electric current is induced between the different particles.[2] The energy of the CTP is found to depend strongly on the electronic structure of the junction and the presence of molecules inside the gap.[3] For the coupled plasmonic-excitonic system where bonding and antibonding hybrid plexciton states are formed,[4] quantum effects can lead to a drastic enhancement of the excitation cross section of the excitons.

Theoretical modeling of relaxation dynamics in gold nanorod-dye assemblies for fluorescence enhancement

J. Vella, Jr., Air Force Research Lab. (United States) and General Dynamics Information Technology (United States); A. Urbas, Air Force Research Lab. (United States)

Using metal nanostructures to concentrate optical-frequency electric fields has garnered significant interest in the literature. For example, by combining an organic dye with a nanorod whose plasmon resonance frequency is similar to the absorption maximum of the dye, a significant enhancement in the fluorescence quantum yield can be observed. The prevalent theory for describing such an enhancement is kinetic and ascribed to an increase in the intrinsic rate of fluorescence, while the rate of non-radiative decay remains constant. Analysis of the literature will reveal that systems exhibiting fluorescence enhancement also show an alteration of the Stokes shift. The traditional kinetic description of plasmon-enhanced fluorescence cannot explain the origin of this shift. Using well-known theories developed by Onsager and Debye, it will be shown that it is possible to model plasmon-enhanced fluorescence not as an increase in the intrinsic rate of fluorescence, but by a perturbation of the equilibrium, photoexcited dipole moment of an emitter situated between two gold nanorods. This theory not only offers an explanation

of the altered Stokes shift in plasmon-enhanced fluorescence systems, but also offers the possibility of the direct and absolute calculation of the electric field that is concentrated between two gold nanorods.

8096-10, Session 3

Quantum plasmonics

V. Zwiller, R. Heeres, S. Dorenbos, Technische Univ. Delft (Netherlands)

Our work centers on the demonstration of quantum plasmonics, where single plasmons are created, propagated and detected.

A crucial part is played by Superconducting Single-Photon Detectors, which have some very useful properties such as short dead-time, low dark counts, wide operating wavelength range (UV - IR) and straight-forward operation. The sensitivity in the >1μm range is Especially interesting to ensure low losses for plasmons and for telecom applications. We have recently demonstrated that these detectors are also suitable for integrated quantum optics experiments by showing on-chip detection of single plasmons. In this experiment, a single quantum dot was used as a single photon source and the stream of single photons was coupled through free-space to a plasmonic waveguide made of a narrow gold stripe making its way to the superconducting detector. This on-chip detection of single plasmons enables the development of complex optics circuits at a small length scales. In the future, a single emitter could also be integrated in the near-field, resulting in more efficient excitation of plasmons and a potential enhanced emission rate due to the Purcell effect.

We are currently building more advanced systems where plasmonic beam splitters and pairs of detectors are combined to form an interferometer. An experiment that is now within reach is the observation of Hong-Ou-Mandel interference with plasmons.

8096-11, Session 3

Room temperature semiconductor plasmon laser

R. Ma, R. F. Oulton, V. J. Sorger, G. Bartal, Ctr. for Scalable and Integrated Nanomanufacturing (SINAM) (United States); X. Zhang, Ctr. for Scalable and Integrated Nanomanufacturing (SINAM) (United States) and Lawrence Berkeley National Lab. (United States)

Plasmon lasers are a new class of coherent optical amplifiers that generate and sustain light well below its diffraction limit. Their intense, coherent and confined optical fields can enhance significantly light-matter interactions and bring fundamentally new capabilities to bio-sensing, data storage, photolithography and optical communications. However, metallic plasmon laser cavities generally exhibit both high metal and radiation losses, limiting the operation of plasmon lasers to cryogenic temperatures, where sufficient gain can be attained. Here, we present room temperature semiconductor sub-diffraction limited laser by adopting total internal reflection of surface plasmons to mitigate the radiation loss, while utilizing hybrid semiconductor-insulator-metal nano-squares for strong confinement with low metal loss. High cavity quality factors, approaching 100, along with strong lambda/20 mode confinement lead to enhancements of spontaneous emission rate by up to 18 times. By controlling the structural geometry we reduce the number of cavity modes to achieve single mode lasing.

8096-12, Session 4

Using chiral metamaterials for the ultrasensitive characterisation of biomacromolecular structure

M. Kadodwala, Univ. of Glasgow (United Kingdom)

Spectroscopic techniques based on circular dichroism, the differential interaction of circularly polarised electromagnetic (EM) radiation with matter, are powerful tools for studying bio-materials, liquid crystals, polymers, and magnetic materials. The inherent weakness of the underlying dichroic phenomena require relatively large amounts of material for spectroscopic measurements, typically for biomaterials ≥ microgram are necessary. We have created a new type of light, which is generated in the vicinity of plasmonic chiral metamaterials, that has a greater level of chirality than circularly polarised light, this new property is referred to as superchirality. Our discovery transforms circular dichroic measurements, because the superchiral light magnifies the asymmetries displayed in dichroic measurements by at least six orders of magnitudes. This new form of spectroscopy, could presage new powerful biosensing array technologies, which would allow for the first time both the ultrasensitive detection and structural characterisation of a biomaterial.

8096-13, Session 4

Importance of magnetic polarization in the absorption of metallic nanoparticles

A. Asenjo-Garcia, A. Manjavacas, V. Myroshnychenko, J. García de Abajo, Consejo Superior de Investigaciones Científicas (Spain)

We study the dipolar magnetic polarizability of common metallic nanoparticles. Remarkably, particles of size and morphology commonly encountered in colloidal synthesis can exhibit a strong imaginary part in the magnetic polarizability, which is comparable in magnitude to or even larger than the electric polarizability. This means that the absorption of a particle can be dominated by its magnetic response.

However, this contribution is routinely overlooked. Our results demonstrate that this is not correct in many situations. We study the magnetic polarization of common metallic nanoparticles of different materials, sizes, shapes, and show that the magnetic contribution will dominate the absorption in many cases.

Various particle shapes, such as spheres, rods, ellipsoids, or disks, are numerically analyzed and compared to analytical solutions when available. In the case of spheres, analytical solutions are provided based upon the Mie formalism [1]. For non-spherical particles, we produce numerical calculations using the boundary element method [2]. It is found that this behavior is highly dependent on the particle geometry. For instance, the contribution of magnetic polarization to light absorption is largely enhanced in disk-shaped particles of large aspect ratio. The opposite behavior is found for metallic rods.

Our work provides a clear demonstration of the unexpected large effect of magnetic polarization in the absorption properties of commonly encountered metal nanoparticles extensively used in plasmonics.

8096-14, Session 4

Dipole limit and resonance-domain effects in second-harmonic generation from arrays of metal nanoparticles

M. Kauranen, G. Genty, R. Czaplicki, H. Pietarinen, H. Husu, M. Zdanowicz, K. O. Koskinen, R. Siikanen, Tampere Univ. of

Technology (Finland); J. Lehtolahti, J. Laukkanen, M. Kuittinen, Univ. of Eastern Finland (Finland)

The optical properties of metal nanoparticles are dominated by their plasmon resonances, which depend on the particle size and shape. The resonances give rise to strong local fields near the particles, which can enhance nonlinear interactions. However, localized surface defects can also support their own plasmonic modes and thereby lead to highly local nonlinear responses.

We have earlier shown that localized nonlinear sources that are retarded with respect to each other can lead to effective quadrupole effects in second-harmonic generation (SHG) from arrays of metal nanoparticles. Such effects significantly complicate the analysis of the nonlinear response. In this paper, we show that such effects are suppressed essentially completely by the improved sample quality made possible by state-of-the-art lithographic techniques. This opens the possibility of designing nonlinear metamaterials with truly engineered properties.

To demonstrate tunable nonlinear responses, we order anisotropic, L-shaped nanoparticles in a lattice with sub-wavelength period for their resonant wavelengths. By varying the mutual orientation of the particles, we modify the symmetry and dichroic properties of the structures. More importantly, the SHG responses of two samples that have similar orientational particle distribution are found to vary by more than an order of magnitude depending on the detailed particle ordering. The results are explained by long-range coupling between the particles, which becomes possible because the changes in particle ordering double the structural period and thus open diffraction orders. Such resonance-domain effects provide new approaches for optimizing the optical responses of metamaterials.

8096-15, Session 4

Directional light scattering of Au nanoshells and nanocups at a dielectric interface

N. S. King, Y. Li, Y. Zhang, P. J. Nordlander, N. J. Halas, Rice Univ. (United States)

The fields of plasmonic solar cell enhancement and remote sensing require a strong understanding of the effects of an inhomogeneous medium on the plasmonic response and resulting scattering profile. In this presentation, we show how the refractive index of a supporting substrate modifies the far-field radiation pattern of symmetric and asymmetric nanoparticles. Asymmetric nanoparticles, such as nanocups, are of particular interest because the reduction in symmetry produces two orthogonal dipole modes that align with the structure of the nanoparticle and are independent of the direction of the incident illumination. Controlling the orientation of these particles requires a supporting substrate or encapsulating medium, but offers the ability to selectively excite a specific plasmonic mode, determining the scattering properties of the system. Angular radiometric measurements confirm the predicted $\cos(\theta)2$ dipole scattering of nanoshells and the unique scattering properties of oriented nanocups on simple glass substrates. High refractive index substrates, such as silicon, lift the degeneracy of the dipole plasmon modes and allow for hybridization with higher order modes. The resulting scattering profile for both nanoshells and nanocups differ greatly in both intensity and localization of the scattered light. Finite element method (FEM) simulations of the nanoparticle system with substrates varying in refractive index from glass to silicon confirm experimental results and show the progressive change in scattering profile.

8096-16, Session 4

Multi-band scattering and enhancement in a reduced symmetry cross nanoantenna

R. Adato, A. A. Yanik, H. Altug, Boston Univ. (United States)

Metal nanoparticles function as optical frequency antennas, providing a means with which to impedance match nanoscale emitters, absorbers or scattering objects to far-field radiation. This antenna functionality, however, results from the particles' structural resonances, and is typically narrowband. Single element antenna geometries that extend the bandwidth, or offer tunable resonances at multiple frequencies would open new opportunities in surface enhanced spectroscopies, ultra fast / small detector elements and nonlinear process enhancement. To this end we propose a cross shaped nanoparticle antenna which provides multiple resonances that are independently tunable over a wide range of frequencies. By adjusting the polarization of the incident light, the dimensions and symmetry of the structure we experimentally demonstrate the ability to tune several addressable resonant modes over a spectral range of greater than 4-5 μm in the mid-infrared. Numerical simulations indicate strong near-field enhancements similar to those of the dipolar resonances of rod shaped antennas. Finally, we show that the behavior of the nanoparticle can be predicted via classical antenna / circuit theory. The particle design can therefore be systematically engineered in an intuitive manner and easily fabricated in a repeatable manner that is suitable to high-throughput methods. This is essential for practical implementation and in contrast to geometries that rely on near-field coupling effects and therefore the presence of nanoscale, difficult to control gaps.

8096-17, Session 5

Nonlinear photothermal and photoacoustic plasmonics beyond the spectral limits (Keynote Presentation)

V. P. Zharov, Univ. of Arkansas for Medical Sciences (United States)

Advanced plasmonic nanostructures with enhanced absorption, fluorescence, and scattering properties enable progress in microscopy, spectroscopy, diagnostics, and cancer therapy. However, because of their relatively broad plasmonic bands of 100 to 200 nm, multicolor capacity of these structures is limited.

To resolve this fundamental problem of conventional spectral microscopy we introduce a platform which comprises three interrelated steps1-2 : 1) the development of nanostructures with relatively narrow conventional plasmonic bands (e.g., multilayer nanotubes); 2) laser-induced nonlinear signal amplification accompanied by spectral narrowing phenomena due to synergy of nonlinear effects (e.g., optical, thermal, acoustic, or nanobubbles; and 3) spectral reading of narrow plasmon resonances without broadening effects. Using nonlinear photothermal and photoacousic spectroscopy with advanced tunable pulse lasers, we demonstrated ultrasharp resonances up to a few nanometers wide in relatively broad plasmonic spectra of various nanostructures, including golden carbon nanotubes and multilayer gold nanorods.

The described approaches can use various detection schematics (e.g., thermal-lens, photoacoustic, radiometry, phase-contrast, and heterodyne methods) for study of laser-nanoparticle interactions with resolution beyond the spectral limits, measurements of tiny red and blue plasmon resonance shifts in nanoplasmonic sensors , and multispectral imaging and multicolor cytometry.

8096-19, Session 5

Antenna-assisted hydrogen sensing in a single plasmonic nanofocus

N. Liu, M. Tang, Univ. of California, Berkeley (United States);

M. Hentschel, H. W. Giessen, Univ. Stuttgart (Germany); A. P. Alivisatos, Univ. of California, Berkeley (United States)

We present a plasmonic hydrogen sensor which consists of a single Pd dot and a plasmonic gold nanoantenna. The Pd dot is brought into the nanofocus of the gold nanoantenna, which is resonantly excited by light. Upon exposure to hydrogen, the Pd dot changes its dielectric properties. Hence, the resonance of the gold nanoantenna is shifted and can be easily detected.

We record several series of experiments, using different amounts of hydrogen as well as different shapes of nanoantennas and different separations between the Pd dot and the antenna. It turns out that the triangular nanoantenna with a distance of 10 to 20 nm yield the best results, giving a spectral shift of around 5 nm for a hydrogen concentration of 1% in nitrogen.

Our work will open a pathway for extremely sensitive detection of molecules and atoms down to the single particle level.

8096-20, Session 5

Engineering light scattering and field concentration in nano-plasmonic necklaces for multi-parametric sensing

A. J. Pasquale, B. M. Reinhard, L. Dal Negro, Boston Univ. (United States)

Particle clusters with different degrees of rotational symmetry consisting of circular loops of gold nanoparticles, dubbed “Nano-Plasmonic Necklaces,” are proposed as a novel, reproducible platform for elastic and inelastic (SERS) optical sensors with polarization insensitive behavior. The engineering of nano-plasmonic necklaces allows for full control of the plasmonic hot-spot locations and optimization of near-field strength by photonic cavity coupling with gap plasmons, making them a promising candidate for inelastic surface-enhanced molecular Raman sensing. The polarization insensitivity of plasmonic necklaces guarantees that the plasmonic hot-spots remain excited within the necklaces irrespective of the incident polarization of the excitation field, which is a significant advantage compared to hot-spots in the usual plasmonic dimer configurations. Moreover, the necklace configuration enables photonic-plasmonic coupling effects where the incident radiation gets resonantly trapped into circular resonator modes which strongly enhance the hot-spot intensity. Plasmonic necklaces of different rotational axes were fabricated using electron-beam lithography and electron-beam deposition of gold films. Engineering design rules are determined for hot-spot formation, polarization insensitivity, and intensity distribution in nano-plasmonic necklaces and the results are confirmed by experimental Surface Enhanced Raman Scattering (SERS) data obtained using a molecular monolayer of p-mercaptoaniline as the analyte.

8096-150, Session 5

Electrically controlled nonlinear generation of light with plasmonics

W. Cai, A. Vasudev, M. L. Brongersma, Stanford Univ. (United States)

Plasmonics enables a unique opportunity to develop ultra-compact optical devices at a subwavelength scale by utilizing two of its most important strengths: extreme concentration light intensity to far below the diffraction limit and an ability to support simultaneous electrical and optical functions. These features also make plasmonics an ideal candidate for electrically manipulating nonlinear optical interactions at the nanoscale, an area that has remained largely unexplored. Here we experimentally demonstrate electrically controlled harmonic generation of light from a plasmonic nanocavity filled with a nonlinear medium. The metals that define the nano-resonator also serve as electrodes that can facilitate high electric fields across the nonlinear material. We tune the frequency-doubling of a 1.56 μm fundamental wave by applying a control voltage to the electrodes, yielding a nonlinear modulation of ~7% per volt and ~140% at a bias of 20 volts.

8096-21, Session 6

Interacting with light at the nanoscale (Keynote Presentation)

L. K. Kuipers, FOM Institute for Atomic and Molecular Physics (United States)

As we perfect our ability to engineer the optical properties of nanostructures, we obtain a handle on light-matter interactions. We can enhance them and even induce new ones, such as the effective light-matter interaction mediated by the magnetic component of light rather than the electric component. Here, we present our latest results on local investigations of light-matter interactions. We use the fact that our near-field nanoprobe is actually metallo-dielectric nanostructure to gain access to light-matter interactions on a sub-wavelength scale. The symmetry of the probe allows, on the one hand, different vector components of the light to be distinguished and, on the other hand, diamagnetic light-matter interactions to be induced.

8096-22, Session 6

Close interactions in gap nanoantennas

J. Aizpurua, R. Esteban Llorente, P. Albella, Centro de Fisica de Materiales (Spain); N. Large, Centro de Fisica de Materiales (Spain) and Ctr. d’Elaboration de Matériaux et d’Etudes Structurales (France); A. Garcia Etxarri, Centro de Fisica de Materiales (Spain) and Stanford Univ. (United States); M. Schnell, P. Alonso-Gonzalez, CIC nanoGUNE Consolider (Spain); R. Hillenbrand, CIC nanoGUNE Consolider (Spain) and IKERBASQUE, Basque Foundation for Science, Bilbao (Spain)

Many concepts from the electromagnetic response in radiowave technology can be transferred to the optical and infrared range of the spectrum. In particular, metallic gap antennas offer the possibility to tune the spectral response by simple modification of the material properties within the gap. Particularly interesting is a situation where the gap surfaces forming the gap are in close proximity. Under these conditions, aspects such as non-locality of the response or the dimension of the gap modify drastically the near-field properties of the antenna. Furthermore, the presence of free-carriers within the gap can modify the optical response of the antenna within a very short time, showing the potential to act as an ultrafast optical switcher. We study theoretically the spectral response of these antennas and identify the surface modes that interfere to produce distinct spectral features. These modes are experimentally identified with use of scanning-near-field optical microscopy both in amplitude and phase. The characterization and understanding of the amplitude and phase of the local fields in gap antennas is of utmost importance in sensing and for design of optical nanodevices.

8096-23, Session 6

Seeing magnetic light-matter interactions: quantifying and enhancing magnetic dipole emission

R. Zia, Brown Univ. (United States)

Although it is often assumed that light-matter interactions are dominated by electric dipole transitions, strong optical frequency magnetic dipoles do exist. In fact, we see magnetic dipole emission everyday from the Lanthanide ions that help to illuminate everything from fluorescent lighting to solid-state lasers. Nevertheless, most applications have

overlooked the device implications of these magnetic dipole transitions throughout the visible and near-infrared regime. Moreover, the magnetic dipole contributions of many important transitions (such as the 1550nm line of Erbium) have not been fully characterized. In this talk, we will illustrate how the naturally occurring magnetic dipole transitions of Lanthanide ions provide a new degree of design freedom for photonic and plasmonic devices. Specifically, we will demonstrate how the different symmetries of electric and magnetic dipoles can be exploited to identify, enhance, and control light emission.

8096-24, Session 6

Coupling mechanisms for nano-U-dimers

N. Gneiding, E. Krutkova, Erlangen Graduate School in Advanced Optical Technologies (Germany); E. Tatartschuk, Erlangen Graduate School in Advanced Optical Technologies (Germany) and Clemson Univ. (United States); E. Shamonina, Imperial College London (United Kingdom) and Erlangen Graduate School in Advanced Optical Technologies (Germany)

Properties of split-ring metamaterials are governed by inter-element interactions. These interactions lead to slow eigenmodes of coupling, which, due to their short wavelengths, are ideal candidates for the design of near-field manipulating devices. In this paper we explore the electric and magnetic coupling mechanisms in nano-U dimers comprising two identical nano-U elements per unit cell arranged axially and twisted relative to each other by an arbitrary angle. We study theoretically coupling in a periodic chain of nano-dimers in the frequency range 100-300 THz. In our analytical model, the electric and magnetic coupling can be expressed through the self and mutual terms for magnetic and electric field energy, considering the continuity equation between the current and charge distributions within each U-element. In addition, we incorporate the effect of kinetic inductance due to the inertia of the electrons (noticeable as element dimensions become as small as 100 nm). The resulting dependence of the electric, magnetic and the total coupling constant on the twist angle within the dimer obtained analytically is shown to agree with numerical simulations (CST Microwave Studio). Our approach should enable an effective design of metamaterial structures with desired properties and would be a useful tool in developing THz range manipulating devices based on propagation of slow waves propagating by virtue of coupling.

8096-25, Session 6

Plasmonic enhancement of ultrafast all-optical magnetization reversal

V. Kochergin, L. A. Neely, MicroXact Inc. (United States); I. N. Krivorotov, Univ. of California, Irvine (United States); E. V. Kochergin, Donetsk National Technical Univ. (Ukraine); K. L. Wang, Univ. of California, Los Angeles (United States)

Ultrafast all optical magnetization switching in GdFeCo layers on the basis of Inverse Faraday Effect (IFE) was demonstrated recently and suggested as a possible path toward next generation magnetic data storage medium with much faster writing time. However, to date, the demonstrations of ultrafast all-optical magnetization switching require powerful femtosecond lasers and are not yet compatible with the size, cost, and power consumption requirements of data storage and data processing applications. In this contribution we show that utilization of IFE enhancement in plasmonic nanostructures may provide the way to achieve fast all-optical magnetization switching with smaller/cheaper laser sources with longer pulse durations. Our modeling results predict that significant enhancement of IFE around all major types of plasmonic nanostructures for a circularly polarized incident light. Unlike the IFE in uniform bulk materials, nonzero value of IFE is predicted in plasmonic nanostructures even with a linearly polarized excitation, which is the highest for the intrinsically chiral (non-rotationally symmetric) plasmonic nanostructures. The DC magnetic fields around plasmonic nanostructures in most cases are highly nonuniform even on the nanoscale. However, we will show the plasmonic geometries at which the uniform on the nanoscale ExE* product is predicted to exceed ~10^4 IFE enhancement. Experimentally, all-optical remagnetization at 20 times lower laser fluence and roughly 100 times lower value of laser fluence/pulse duration ratio was achieved in plasmon-enhanced samples to verify the model predictions. The path to achieve higher levels of enhancement experimentally will be discussed.

8096-26, Session 7

Strongly driven electron emission from nanoparticles in few-cycle laser fields (Keynote Presentation)

S. Zherebtsov, F. Süßmann, Max-Planck-Institut für Quantenoptik (Germany); J. Plenge, Freie Univ. Berlin (Germany); J. Passig, Univ. Rostock (Germany); C. Graf, V. Mondes, Freie Univ. Berlin (Germany); M. I. Stockman, Georgia State Univ. (United States); E. Rühl, Freie Univ. Berlin (Germany); T. Fennel, Univ. Rostock (Germany); M. F. Kling, Max-Planck-Institut für Quantenoptik (Germany)

The acceleration of electrons in local near-fields of nanoparticles driven by few-cycle laser pulses is studied and provides insight into the electron dynamics and surface charging of the particle. Liberated electrons are accelerated / decelerated in the local field at the surface and affected in their attosecond dynamics by the build-up of a surface trapping potential and electron-electron interactions. By using isolated nanoparticles we can explore the regime near, at and beyond the material damage threshold. The extremely short pulse duration of only a few cycles in our studies ensures that the electron dynamics responsible for the observed phenomena occurs before any nuclear dynamics. At high intensities, a higher effective dielectric constant is predicted for dielectric nanoparticles. Experiments to observe such non-linearities are currently underway. They may allow insight into non-linear effects in bulk materials, which cannot be easily studied at these intensities. The approach holds promise that the regime of non-linear plasmonics may be reached and examined for the first time. Experimental results and calculations on the strongly driven electron emission from isolated nanoparticles in few-cycle laser fields will be presented.

8096-27, Session 7

Plasmonic field enhancement for generating ultrafast extreme-ultraviolet light pulses

I. Park, S. Kim, J. Choi, S. Kim, KAIST (Korea, Republic of)

Ultrafast extreme-ultraviolet (EUV) light pulses are a key tool for time-resolved spectroscopy to investigate atomic motion in molecules and electronic motion inside and between atoms. High-harmonic generation by focusing near-infrared (NIR) pulses on noble gases is a well-known method of generating such ultrashort EUV pulses. In this report, we show a 3-dimensional metallic waveguide that enables plasmonic generation of ultrashort EUV pulses through field enhancement by means of surface-plasmon polaritons. Compared with bow-ties previously used for field enhancement by stationary resonance of localized surface plasmons, the net volume of more than 20 dB intensity enhancement turns out to be three orders of magnitude larger. The intensity of incident NIR pulses is enhanced by a factor of ~350, being strong enough to produce EUV harmonics up to the 43rd order in interaction with Xe gas directly from a modest input of ~1011 Wcm-2. This plasmonic method maintains pulse repetition rate as high as 75 MHz in our experiment without use of extra cavities. No phase-matching is needed since EUV pulses are generated within a sub-wavelength spot near an exit aperture of 100 nm diameter whereby driving NIR pulses are mostly blocked. Furthermore, ultrafast DUV pulses with a center wavelength of 266 nm can also be produced by means of surface third-harmonic generation with deposition of a SiO2

layer at the exit aperture. The plasmonic waveguide is fabricated on a cantilever nanostructure, with immunity to thermal damage and optical breakdown, to be suited for near-field spectroscopy with atomic-scale lateral selectivity.

8096-28, Session 7

Adiabatic and nonadiabatic metallization of dielectric nanofilms by strong optical fields

M. I. Stockman, M. Durach, A. Rusina, Georgia State Univ. (United States); M. F. Kling, Max-Planck-Institut für Quantenoptik (Germany)

We consider a 1-10 nm-thin nanofilm of an insulator subjected to a strong oscillating electric field normal to it. The frequency of this field may be in the range from microwave to optical, depending on the film thickness (in the near-ir to visible range for a ~1-2 nm thickness). The strength of this field is considered to be in the range ~1-10 V/nm. When this field is slow, adiabatic, it induces a reversible phase transition in the film to a state reminding metal. The electron population can be transferred from one surface of this nanofilm to another. For fast, nonadiabatic fields, using quantum-mechanical treatment we demonstrate that a femtosecond pulse causes nonlinear polarization and ultrafast formation of plasmonic band in the high-frequency response of a nanostructure. This ultrashort pulse creates a non-equilibrium excitation of the nanostructure, which can be controlled using adiabatic phase accumulation effect. The demonstrated possibility of ultrafast switching between insulator and plasmonic metal phases can be employed for creation of active plasmonic elements for ultrafast nanocircuits

8096-29, Session 7

Attosecond control of electrons emitted from a nanometric metal tip

P. Hommelhoff, Max-Planck-Institut für Quantenoptik (Germany)

It is well know that plasmonic effects can lead to greatly enhanced field strengths near surfaces. In this contribution we discuss the interaction of few-cycle femtosecond laser pulses with a sharp tungsten tip. We measure the electron emission current and record electron energy spectra. We observe above-threshold photoemission (ATP), i.e., electrons promoted in energy to states higher than needed to leave the metal. When we increase the laser intensity, the electronic spectral peaks start to shift, indicating the onset of strong-field effects [1].

Further, we show measurements with carrier-envelope-phase (CEP) stable pulses. We observe strong CEP effects (spectral interference). We show that electrons are detected originating from either one or two sub-cycle emission points in time. We observe that plateau electrons re-collide with the tip elastically and coherently, well known from high harmonic generation and above-threshold ionization in the gas phase. Because of field-enhancement, a simple laser oscillator suffices to reach the required peak field strengths.

With different tip materials, we believe that this work will enable probing of plasmonic near-fields on the (sub-)nanometer-attosecond scale.

8096-30, Session 8

Plasmonic nanoantennas: new properties and functions (Keynote Presentation)

N. J. Halas, Rice Univ. (United States)

Nanostructures designed to harvest light can have many functions: energy and/or charge transfer and storage, light scattering or refraction, for example. We will describe two families of nanoantennas with unique properties: nanoscale hemispheres, and nanoantenna-diodes. Nanoscale hemispheres possess both electric and magnetic plasmon modes, each with their own unique light-refractive properties. Nanoscale hemispheres can also give rise to strong nonlinear optical effects, dependent upon their orientation with respect to incident excitation. These properties will be discussed. The integration of nanoantennas into electronics, where an optical structure can simultaneously provide an electrical response, is a new functionality better known in electrochemical than in electronic device contexts. We will describe how an optical antenna can also function as a photodetector, with a device response that is a hybrid combination of these two distinct types of devices.

8096-31, Session 8

Resonant properties of transmitting and receiving plasmonic resonator antennas

E. S. Barnard, Geballe Lab. for Advanced Materials (GLAM) (United States); M. L. Brongersma, Stanford Univ. (United States)

A combined theoretical and experimental study of wavelength-scale plasmonic resonator antennas is presented. Using full-field electromagnetic simulations and analytical optical antenna models, we are able to derive simple and intuitive design rules to achieve antennas with a desired set of optical properties (field enhancement, scattering cross section, absorption cross section, and resonant frequency) based on their geometric properties. As part of these design rules we are able to quantify reflection phase and understand this quantity in terms of the end-face near-field. With these design rules, we have constructed resonance maps that allow a designer to choose an antenna structure that provides desired resonant properties for a specific application. We then apply these design rules to create antennas that resonantly enhance absorption on thin silicon detectors as well as enhance emission of cathodoluminescence (CL). Through spatial and spectral mapping of both photocurrent and CL we clearly show the fundamental and higher-order resonant modes of these antennas. With CL we are also able to map the spatial distribution of these resonant modes with 10 nm resolution. In addition to these specific demonstrated applications, the results of this study enable optical engineers to more easily design a myriad of plasmonic devices that employ optical antenna structures, including nanoscale photodetectors, light sources, sensors, and modulators. Additionally the understanding of phase may be critical to designing resonant elements for metamaterials.

8096-32, Session 8

High resolution structural and optical characterization of top-down and bottom-up engineered plasmonic nanostructures

D. T. Schoen, M. L. Brongersma, Stanford Univ. (United States)

The use of electron energy loss spectroscopy (EELs) in the scanning transmission electron microscope (STEM) has been recently demonstrated to be a powerful tool for the high resolution mapping of plasmonic mode density in small metallic structures. To date, the majority of these studies have focused on small particles or the inverse structure, holes in a thin metallic film, either singly or in small clusters. One area largely unexplored so far by these techniques is the influence of material processing and quality on more complicated engineered nanostructures like would be used in integrated nanoplasmonic circuitry. Results of STEM EELs plasmon mode mapping of a variety of engineered metallic nanostructures will be presented. A comparison will be made between structures fabricated with top-down techniques, including electron beam lithography and focused ion beam milling, with structures fabricated by bottom up techniques, including chemically synthesized silver nanowires. Results of structural characterization by atomic force microscopy and high resolution TEM will also be presented and correlated with the optical property measurements.

8096-33, Session 8

High resolution fluorescence microscopy using nanoplasmonic antennas

K. Kim, Y. Oh, W. Lee, D. Kim, Yonsei Univ. (Korea, Republic of)

High resolution imaging below the diffraction limit has been widely investigated since precise molecular tracking and nanoscaled scanning are needed to understand various phenomena in sub-cellular environments. STED microscopy, field optical superlens imaging, and photo-activated light microscopy have been notably come into the spotlight as new approaches for sub-diffraction imaging.

In this paper, we introduce a concept for high resolution imaging based on the excitation of surface plasmons. It is commonly known that electromagnetic fields are localized to small spots, which is called hot spots, by nanoplasmonic antenna structures. Hot spots that are smaller than the diffraction limit can in principle excite molecular fluorescence. If a hot spot is formed in an extremely small size on a molecular scale by an optimum design of nanoplasmonic antenna, fluorescence excitation can be post-processed to produce highly localized images.

The concept was experimentally confirmed by imaging nanosized fluorescent beads, tracking dynamics of rhodamine tagged microtubule, and visualizing endocytotic internalization of GFP-tagged adenoviruses in live cells. Various nanoplasmonic antennas were fabricated by electron beam lithography and chemical annealing method. The imaging results confirm the enhancement of resolution after appropriate post processing methods.

8096-34, Session 9

Metamaterials from plasmonic nanoantenna arrays

M. Orenstein, Technion-Israel Institute of Technology (Israel)

Nano antennas are an exciting new addition to the field of photonics. The nanoantenna element exhibits two desirable characteristics - first it collects light from much larger effective area than its actual size and the second - it can concentrate the collected energy in an effective light capacitor (stopped light) with dimensions in the nano regime - much smaller than the actual antenna size. Using these unique features we constructed arrays of such nanoantennas to generate metamaterials - the latter was employed for the enhancement of light-matter interactions. In the process of construction of these metamaterials we would discuss parameters such as the inter-antenna spacing to avoid cells interactions (especially because such nanoantenna may have effective cross-section dimension of 1 wavelength - which contradicts the subwavelength requirements of metamaterials), and the separate optimization of the antenna efficiency and light field enhancement. We'll discuss robust ways to fabricate the antenna with predetermined resonance(s) and discuss in details nanoantenna configurations yielding either spectral broad-band or multi-harmonic responses.

In the second part of the talk, several applications of nanoantenna based metamaterials - that we experimentally realized, will be discussed, including high efficiency organic solar cells, enhanced emission rate communications wavelength LEDs - breaking the bottle neck for faster data modulation of such devices, and finally manipulating nonlinearly the vacuum field.

8096-35, Session 9

Diode-coupled Ag nanoantennas for nanorectenna energy conversion

R. M. Osgood, S. Giardini, M. Kinnan, P. Stenhouse, M. Hoey, J. Carlson, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); G. Fernandes, J. H. Kim, J. Xu, Brown Univ. (United States); W. R. Buchwald, Air Force Research Lab. (United States); M. Chin, B. Nichols, U.S. Army Research Lab. (United States)

Arrays of "nanorectennas" consist of diode-coupled nanoantennas with plasmonic resonances in the visible/near-infrared (vis/nir) regime, and are expected to convert vis/nir radiative power into useful direct current [1,2]. We study plasmonic resonances in large format (~ 1 mm^2 area) arrays, consisting of electron beam-patterned horizontal (e.g., parallel to the substrate) Ag lines patterned on, and Ag nanoparticles dispersed atop, ultrathin (< 20 nm) tunneling barriers (NiO, Al2O3, and other oxides) [3]. These tunneling barriers, located on a metallic ground plane, rectify the alternating current generated in the nanoantenna at resonance. We measure the plasmonic resonances in these Ag nanoantennas, and find good agreement with modeling, which also predicts that the electric field driving the electrons into the ground plane (and therefore the rectification efficiency) is considerably enhanced at resonance. Various metal-insulator-metal tunneling diodes, incorporating the afore-mentioned barrier layers and different metals for the ground plane, are experimentally characterized and compared to our conduction model. We present experimental data on and analysis of nanorectenna power generation vs. wavelength and power of incident vis/nir radiation. Our e-beam fabrication technique is scalable to large dimensions [4], and allows us to easily probe different antenna dimensions.

8096-36, Session 9

Addressing quantum emitters with optical antennas

A. G. Curto, G. Volpe, T. H. Taminiau, M. P. Kreuzer, R. Quidant, N. F. van Hulst, ICFO - Instituto de Ciencias Fotónicas (Spain)

Optical antennas offer the promise of complete electromagnetic control over single photon emission and absorption at the nanoscale. They can efficiently address quantum emitters by modifying their interaction with light in polarization, angular radiation pattern and transition rates. Here, we report unidirectional and multipolar emission of quantum dots by near-field coupling to nano-antennas. The emitters are locally deposited at the end of metal nanowires. Yagi-Uda antennas are shown to direct and polarize quantum dot luminescence. Nanowire linear antennas supporting resonances of increasing order convert an otherwise purely dipolar emission into multipolar radiation. Finally, we quantify emitter-antenna coupling.

8096-37, Session 10

Toward low-loss plasmonics without metals

M. A. Noginov, L. Gu, J. E. Livenere, G. Zhu, A. K. Pradhan, R. Munde, M. J. Bahoura, Norfolk State Univ. (United States); A. Urbas, J. Vella, Jr., Air Force Research Lab. (United States); V. A. Podolskiy, Univ. of Massachusetts Lowell (United States); E. Narimanov, Purdue Univ. (United States)

In this presentation, we will review our recent efforts aimed at the development of low-loss plasmonics that does not use metallic components. In particular, we will focus on two types of systems (i) highly concentrated dyes, in which the negative value of electric permittivity is sought in the vicinity of a very strong absorption line, and (ii) transparent conductive oxides - heavily doped degenerate semiconductors - in which plasma frequency corresponds to a near infrared range.

8096-38, Session 10

Nanoplasmonics in direct band-gap semiconductors

N. Dietz, M. I. Stockman, Georgia State Univ. (United States)

We explore nanoplasmonics concepts on selected group of III-Nitride compound semiconductor nanostructures, e.g., indium-rich InGaN alloys, that can be tuned over a large transmission range and fabricated with almost metal-like free-carrier concentrations of up to ~10^{21} cm^{-3}. We have experimentally shown that for the highly doped InN the permittivity is negative (metal-like) and plasmonic quality factor is Q=5-6 for ir frequency 0.4-0.7 eV, or wavelength 1.5-3 micron, which is in the same range as for gold in the visible region. Thus, the heavily doped InN is a very promising plasmonic material in the near-ir. Theoretically, we have shown that an adiabatic cone compressor built on InN is able to enhance the optical intensity by a factor of ~500 with a high throughput. We also develop theory of a spaser built on a highly-doped InN plasmonic core surrounded by moderately-doped GaN gain medium.

8096-39, Session 10

All-optical control of single plasmonic nanoantenna-ITO hybrids

O. L. Muskens, Univ. of Southampton (United Kingdom); M. Abb, Univ. of Southampton (United States); N. Large, J. Aizpurua, Centro de Física de Materiales (Spain) and Donostia International Physics Ctr. (Spain)

Nanoscale plasmonic components are of enormous interest for their capabilities of locally enhancing electromagnetic fields and controlling emission. Active control of such components will enable a new generation of tunable devices. We present theoretical and experimental work exploring different routes toward achieving all-solid state modulation of nanoantenna resonances.

A new approach to antenna switching has been introduced recently where we make use of a photoconductive bridge between the two arms of a dimer antenna [1]. In order to experimentally achieve nonlinear control of nanoantennas on ultrafast time scale in a solid-state configuration, we are exploring hybrid nonlinear antenna systems. As a first important candidate, we have investigated Indium Tin Oxide (ITO) as a nonlinear optical material for plasmonic applications.

We have investigated the nonlinear response of nanoantenna-ITO hybrids under picosecond pulsed laser excitation using a combination of linear and ultrafast single-antenna spectroscopy [2]. We find that the modulation of the nanoantenna-ITO hybrid is distinct from that of a pure gold nanoantenna in absence of ITO, and from ITO in absence of the antenna. We will discuss possible mechanisms of enhanced antenna-ITO nonlinearity. Our results hold promise for new types of nonlinear antenna devices which could enable active control of local optical fields for use in nanophotonic modulators, nonlinear optics, sensing, and emission control.

Coupling of plasmon with semiconductor nanoresonators: from modeling to device design

P. Fan, J. Liu, R. Pala, L. Cao, M. L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

As both metallic and semiconductor nanostructures have the unique abilities to control the flow of light within a deep subwavelength volume, they are promising candidates as building blocks for compact photonic and optoelectronic devices and circuitry. Hereby, we theoretically and experimentally studied the light coupling of a propagating surface plasmon wave supported by a metal surface to the optical resonances of a semiconductor nanowire. We examined the structure as a side-coupled-cavity system and demonstrated efficient excitation of optical resonances in the nanowire by a propagating surface plasmon. Strong light coupling leads to a sharp suppression of plasmon transmission as well as efficient absorption in nanowire. These optical properties provide guidelines for incorporating multiple optical components and engineering complex optoelectronic functionalities within compact device systems, such as nanowire plasmonic photodetection and surface plasmon modulation.

8096-41, Session 10

Plasmonically enhanced emission from an inverted III-nitride light emitting diode

M. A. Mastro, U.S. Naval Research Lab. (United States)

Silver thin film and nanoparticles deposited on the surface of InGaN quantum well structures have been shown by several groups to plasmonically enhance the optically pumped emission. The necessity of placing the active region of the device within approximately 30 nm of the plasmonic metal is a subtle dilemma for GaN-based LEDs. Hence, nearly all reports of exciton to surface plasmon coupling have been based on quantum well structures that are not designed for electroluminescence.

The final grown layer in a traditional GaN-based LED structure is a p-type GaN:Mg contact layer. The magnesium dopant has a high activation energy in GaN, which limits the conductivity of the p-type contact layer. This necessitates a thick (100 to 300 nm) current-spreading p-type layer in commercial LEDs, which places the active region beyond the plasmon fringing field thickness, making exterior plasmonic enhancements impractical.

A new inverted LED approach was developed with the key layer for enabling plasmonic enhancement being a thin n++ (Al)GaN top contact, which brings the quantum well into the fringing field of the silver nanoparticles. This proximity allowed the excitons induced within the quantum well to couple to the surface plasmons, thereby increasing the emission by approximately a factor of four in a functional LED. Furthermore, the inverted LED allows flexibility in the alloy composition of the top contact layer, which alters the dielectric environment and plasmonic response of the metal.

8096-42, Session 10

Silicon plasmonics

U. Levy, B. Desiatov, I. Goykhman, The Hebrew Univ. of Jerusalem (Israel)

In the past two decades we are witnessing a rapid progress in towards the realization of CMOS compatible, silicon nanophotonic devices for monolithic on-chip integration of optical devices and systems. In parallel, the field of plasmonic is blooming, offering substantial advantages in the confinement of electromagnetic energy at the nanoscale. Thus, the combination of silicon nanophotonics with plasmonics seems to be a natural choice. In this work we review our work in the field of silicon plasmonics. Specifically, we demonstrate nanoscale confinement of light by the use of silicon plasmonic nanotapers on a chip. In addition, we report on our silicon plasmonic hybrid waveguide showing sub 100 nm confinement together with a propagation length of ~ 100 microns. Finally, we demonstrate a silicon plasmonic Schottky detector that allows the detection of signals at telecom wavelengths. The device is based on a self aligned process and combined LOCOS waveguide interfaced with a metal strip.

8096-43, Session 11

Surpassing conventional light-trapping and efficiency limits for solar energy conversion with plasmonic structures (Keynote Presentation)

H. A. Atwater, California Institute of Technology (United States)

Light-trapping and enhanced absorption is an important avenue for improved photovoltaic efficiency and cost reduction. We describe plasmonic thin film photovoltaic designs for light absorption and conversion efficiency that exceed what is achievable in conventional solar cell designs, and we report on experiments illustrating enhanced light absorption and conversion efficiency in thin film Si and GaAs and polymeric photovoltaic structures[1].

Thermodynamic arguments predict the maximum absorption enhancement in the ray optics limit for bulk dielectric materials to be 4n^2, where n is the index of refraction of the absorbing layer [2]] and a similar analysis for thin waveguide structures found a maximum absorption enhancement of <4n^2 [3]. Using a combination of analytical and numerical methods, we describe why these structures do not surpass the conventional light trapping limit, and show how to design structures that can. The conventional limit can be exceeded in waveguide-like structures with elevated local density of optical states (LDOS) compared to that of the bulk, homogeneous material. To achieve this, modes of the structure must also be populated via an appropriate incoupling mechanism. We find using full wave simulations that ultrathin solar cells incorporating a plasmonic back reflector can achieve spatially averaged LDOS enhancements of 1 to 3, and a metal-insulator-metal (MIM) structure can achieve enhancements over 50 at a wavelength of 1100 nm, the band edge of Si. We also report in detail on plasmon-enhanced light trapping in thin film amorphous silicon solar cells that achieve near-record photovoltaic conversion efficiency.

8096-44, Session 11

Nonlinear optical responses of aperiodic plasmonic arrays for on chip applications

G. F. Walsh, Boston Univ. (United States) and U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); S. Minissale, Boston Univ. (United States); B. R. Kimball, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); L. Dal Negro, Boston Univ. (United States)

Symmetry breaking in deterministic aperiodic plasmonic nano structures produces significant spatial field localization distributed over broad frequency spectra. These characteristics are ideally suited to enhance second and third order nonlinear processes for on-chip nanoplasmonic device applications. In this paper, we experimentally investigate the nonlinear optical properties of non-centrosymmetric aperiodic arrays of gold nanoparticles, with a controlled degree of disorder, fabricated by electron beam lithography. Two nonlinear optical phenomena, second harmonic generation (SHG) and the optical Kerr effect are investigated. Arrays are pumped with femto-second optical pulses at near infrared wavelengths and surface SHG is measured by angularly resolved scattering measurements. Experimental results are also reported for additional arrays coated with thin polymer films exhibiting strong optical Kerr effects. Localized enhancements of the nonlinear index are characterized by z-scan measurements and by a novel Fourier space measurement technique that we have developed to investigate optical nonlinearities in aperiodic structures ranging from quasi-crystals to pseudo-random media. These studies are important to the engineering of the next generation of plasmonic switches with controlled nonlinear index and frequency generation on a single chip.

8096-46, Session 11

Applications of plasmonic oligomers, metamaterials, and nanoantennas (Keynote Presentation)

H. W. Giessen, Univ. Stuttgart (Germany)

We present an overview of 2D and 3D plasmonic oligomers [1], metamaterials, and nanoantennas which are utilized for different purposes. Stacked 3D metamaterials can be used as perfect absorbers, which give angle and polarization independent absorption beyond 90% in the visible and near-infrared region [2]. Utilizing transition metals as well as plasmonic induced transparency schemes [3], the application of sensors for liquids and gases becomes feasible [4]. Cavity enhancement allows for tailoring the spectral resonances of plasmonic systems and results in very high figures of merit for the sensor schemes [5,6]. Arranging plasmonic substructures in 3D geometries, chirality can result as optical property. Using this method allows for the construction of novel broadband circular polarizers with large angle acceptance angles. Nanoantennas can aid the sensing and nonlinear properties of plasmonic nanostructures as well. We are going to discuss applications in this area as well.

Nonlinear plasmonics with nanocavity gratings

F. Capasso, Harvard Univ. (United States); P. Genevet, Univ. de Nice Sophia Antipolis (France)

Here we report on a novel approach based on plasmonic nanocavity gratings to enhance surface nonlinear processes.1 We have designed plasmonic nanocavities, made of nanogrooves in a gold film and arranged them periodically. A single narrow groove (tens of nanometers wide) defined on a metal surface can be viewed as a portion of a metal-insulator-metal waveguide terminated by a metallic mirror on one side and a dielectric mirror (air) on the other. It therefore forms a cavity that sustains Fabry-Perot modes. Because the cavity mode is confined in a sub-wavelength volume, large fields are established both in the metal and in the dielectric under resonant excitation. In addition to these localized surface plasmons a grating of nanogrooves enables the coupling of free space light to surface waves propagating on the corrugated surface.

We apply this concept of coupled resonances to four-wave-mixing in gold and demonstrate an enhancement of the generated signal of up to 2000 compared with an un-patterned surface, two orders of magnitude higher than previously reported.1 This result shows that

plasmonic nanocavity gratings are a promising route to enhancing optical nonlinearities in the metal and also in any material filling the cavities, with potential applications to nanoscale frequency conversion and highly sensitive vibrational spectroscopy and microscopy.

Attosecond measurement of petahertz plasmonic near-fields

F. Süßmann, S. Zherebtsov, Max-Planck-Institut für Quantenoptik (Germany); T. Fennel, Univ. Rostock (Germany); E. Rühl, Freie Univ. Berlin (Germany); M. F. Kling, Max-Planck-Institut für Quantenoptik (Germany)

As compared to conventional electronics, plasmonic systems can operate at lightwave (petahertz) frequencies and have enormous potential to push the frontiers in electronics in both size and speed. The development of lightwave electronics would mark a major breakthrough and enable among other applications up to 6 orders of magnitude faster computation and communication technology. Attosecond metrology enables access to petahertz optical phenomena . We aim to control and measure nanoplasmonic fields on attosecond timescales and extend the attosecond streaking spectroscopy technique to measurements of enhanced plasmonic near-fields of isolated metal spheres. Temporal resolution is achieved by limiting the emission of high energetic, direct photoelectrons to a sub-cycle time window using attosecond XUV pulses that are phase-locked to the driving NIR field. These direct photoelectrons integrate the force exerted by the optical fields on their way to the detector, leading to a change in their kinetic energy. TOF spectra recorded for different time delays between the NIR and XUV pulses will give insight into the evolution of the local electric field and surface charge dynamics. Unlike in traditional streaking experiments, both the temporal and the spatial decay of the near-field cause the energetic shift of the electrons. This has to be considered during the reconstruction of the local field.

First experimental results and simulations will be presented, showing the feasibility of such an approach and the influence of laser intensity, particle size and composition on the obtained waveforms.

8096-49, Session 12

Optical response and ultrafast spectroscopy of metal-based hybrid nanoobjects

F. Vallee, D. Mongin, A. Lombardi, P. Maioli, A. Crut, N. Del Fatti, Univ. Claude Bernard Lyon 1 (France)

The size, shape and structure dependencies of the properties of nanoobjects, and the concomitant possibilities opened to control them, lead to considerable activities in the academic and industrial domains. Confinement effects in nanoobjects formed by a single material, e.g., a metal or a semiconductor, have now been extensively studied. Less interest has been devoted to complex systems, combining multiple material components in the same nanoparticle, e.g., bimetallic or hybrid metal-semiconductor particles. However, combining the nanoscale response of their components offer wide ranges of possibilities for developing novel plasmonic systems, and also raise fundamental questions on plasmon-plasmon or plasmon-exciton coupling and on energy and charge transfer mechanisms between the forming materials.

We report on investigation of the linear optical response (extinction) of hybrid hammer-like shape nanoparticles formed by a metal (Au sphere) and a semiconductor (CdS or ZnO rod). The results on ensemble and a single particle are interpreted in terms of dielectric coupling of the two-materials, yielding a good reproduction of the experiments in the non-resonant exciton-plasmon regime. The ultrafast nonlinear response of these nanohybrids has also been investigated using a two-color wavelength-tunable femtosecond pump-probe technique. When carriers are injected in the semiconductor part, a spectral shift of the gold surface plasmon resonance is observed yielding evidence for ultrafast electron transfer between the two-materials. Measurements performed in CdS-Au hybrids probing the carrier population in the semiconductor part with 50 fs pulses suggest an upper limit for the electron transfer time of about 10 fs.

Light-field control of electronic motion at nanoscaled condensed matter interfaces

A. Schiffrin, Max-Planck-Institut für Quantenoptik (Germany); T. Paasch-Colberg, Max-Planck-Institut für Quantenoptik (Germany) and Technische Univ. München (Germany); D. Gerster, Technische Univ. München (Germany); N. Karpowicz, Max-Planck-Institut für Quantenoptik (Germany); S. Mühlbrandt, Max-Planck-Institut für Quantenoptik (Germany) and Technische Univ. München (Germany); J. Reichert, J. V. Barth, Technische Univ. München (Germany); R. Kienberger, Technische Univ. München (Germany) and Max-Planck-Institut für Quantenoptik (Germany); R. Ernstorfer, Fritz-Haber-Institut der Max-Planck-Gesellschaft (Germany) and Max-Planck-Institut für Quantenoptik (Germany) and Technische Univ. München (Germany); F. Krausz, Max-Planck-Institut für Quantenoptik (Germany) and Ludwig-Maximilians-Univ. München (Germany)

The advent of intense few-cycle near infrared (NIR) laser pulses with stable and tunable carrier envelope phase (CEP) has enabled the control of electromagnetic fields with attosecond time precision [1]. Here we aim at exploiting these few-cycle NIR optical fields with well-defined CEP to generate and control the motion of charge carriers within heterogeneous nanoscaled solid state interfaces. We demonstrate the generation of directly measurable photocurrents in unbiased gold-coated SiO2 nanogaps, whose magnitude and directionality can be tuned with the laser CEP. This effect vanishes with the increase of the laser pulse duration. We claim that such phenomenon is the signature of optically induced electron tunneling at the metal-dielectric interface with subsequent acceleration of the charge carrier in the ultrashort laser field. This ultrafast current injection at a nanoscaled condensed matter system represents a first step towards femtosecond lightwave electronics.

Resonance energy transfer near metal nanostructures mediated by surface plasmons

T. V. Shahbazyan, Jackson State Univ. (United States); V. Pustovit, Ctr. de Recherche Paul-Pascal (France)

A theory of resonance energy transfer (RET) between donor and acceptor molecules (or quantum dots) situated near a plasmonic nanostructure is presented that incorporates nonradiative and radiative transfer channels while maintaining energy balance between transfer, dissipation and radiation. It is shown that plasmon-enhanced radiative transfer (PERT) is the dominant RET mechanism in a wide range of parameters. Numerical calculations performed for molecules near spherical Ag nanoparticle indicate that RET is determined by competition between plasmon enhancement and metal quenching and its magnitude is highly sensitive to molecules positions. There are regions in parameter space where plasmon-mediated RET can be either enhanced or reduced relative to Foerster transfer, consistent with experiment. A comparison between our theory and previous models is performed.

Theory of energy transfer interactions near sphere and nanoshell based plasmonic nanostructures

M. S. Shishodia, Tel Aviv Univ. (Israel) and Holon Institute of Technology (Israel); B. D. Fainberg, Holon Institute of Technology (Israel) and Tel Aviv Univ. (Israel); A. Nitzan, Tel Aviv Univ. (Israel); G. Li, Northwestern Univ. (United States)

Molecular exciton-metallic nanoparticle complexes are the subject of intensive study. Metallic nanostructure mediated electric-field enhancement, and the proximity of a metal interface can greatly alter dipole-dipole interactions in excitonic and energy transfer donor-acceptor systems. In addition, excitonic (energy transfer) interactions accompanied by plasmonic response of metallic contacts can have substantial effects on the electronic transport properties of molecular nanojunctions [1]. In this paper, we present a theoretical model for energy transfer near sphere and nanoshell particle/particle-pair based metal nanostructures. The model is based on multipole spectral expansion and uses the surface plasmon-dressed Coulomb interaction [2]. We study also the energy transfer in a molecular wire between two metallic contacts representing a nanoparticle dimer in the presence of plasmonic hybridization. It is worthy to note that nanoshell exhibits superior plasmonic properties by virtue of geometry controlled spectral tuning of resonances arising from the hybridization of cavity and sphere plasmons. Exploiting tunability feature of nanoshells, wavelength specific designs for optimal energy transfer, and the possible effects on molecular junctions will be presented.

Fluorescence lifetime measurements of single molecules in DNA templated gold nanoparticle dimers

M. Busson, L'Institut Langevin (France); B. Rolly, B. Stout, N. Bonod, Institut Fresnel (France); S. Bidault, L'Institut Langevin (France)

Gold nanoparticle groupings can act as optical antennas: they couple efficiently in the near field to photon emitters to enhance their interaction with the far field. A typical way to design nanoantennas is to couple the plasmonic modes of gold nanoparticles positioned a few nanometers apart. We demonstrate here how efficient optical antennas can be synthesized by the programmed assembly of DNA functionalized gold nanoparticles. This bottom up strategy allows us to tune particle sizes and spacings while fully controlling the chemical environment of the antenna.

In practice, a known number of thiolated DNA single strands are grafted on the surface of polyethylene glycol stabilized gold particles with diameters ranging from 5 to 40 nm. Hybridization of complementary DNA sequences drives the assembly of well defined nanoparticle groupings with spacings ranging between 6 and 30 nm.

The optical properties of single groupings are studied by confocal scattering spectroscopy. Shortening the DNA linker induces a clear red shift of the plasmon resonance wavelength. Experimental data from scattering spectroscopy are correlated with electron microscopy images and theoretical calculations.

The interaction of the antenna with a single chromophore added to the DNA scaffold is studied using fluorescence lifetime measurements. Experiments are performed on single molecules using time-correlated single photon counting in a confocal geometry. The increased local density of optical states in the antenna enhances the de-excitation rate of the fluorescent molecule. The influence of the dimer interparticle spacing on single molecule fluorescence lifetime is being investigated.

8096-54, Session 14

Hybrid semiconductor/plasmonic devices for nanophotonics (Keynote Presentation)

M. L. Brongersma, Stanford Univ. (United States)

Metamaterials and nanophotonic devices are most commonly constructed from metallic (i.e. plasmonic) nanostructures. However, recent research has begun to also exploit the optical resonances of high-permittivity semiconductor and dielectric nanostructures to realize similar optical functionalities. In this talk, I will illustrate the use of plasmonic, semiconductor, and dielectric nanostructures in a variety of applications (nanoscale sources, high-speed modulators, and detectors) and discuss their relative strengths and weaknesses. I will also discuss several exciting new hybrid semiconductor/plasmonic devices that capitalize the relative strengths of each of the constituent materials to obtain new functionalities.

8096-55, Session 14

Controlling electroluminescence from QW using plasmonic resonator antenna electrodes

K. C. Y. Huang, Stanford Univ. (United States); M. Seo, KAIST (Korea, Republic of); M. L. Brongersma, Stanford Univ. (United States)

We simulated, fabricated and characterized the electroluminescence from InGaAs/ GaAs QW with metal electrodes which function as plasmonic resonator antennas. By patterning the antenna electrodes in the vicinity of a single QW layer with deeply subwavelength lateral width, charge carriers are confined near the antenna and subsequently recombine with enhanced radiative decay rate depending on the electrode/ QW separation and electrode shape. We show that the emission can be efficiently coupled to the antenna resonance which is engineered to reradiate in a specific polarization and unidirectional far-field pattern. The simultaneous control of carriers and photons can be used to improve light extraction and detection from the semiconductor while enabling fast direct modulation of the spontaneous emission.

8096-56, Session 14

Enhancing photonic-plasmonic interactions on active devices using circular scattering in aperiodic spirals

J. Trevino, S. Yerci, L. Dal Negro, Boston Univ. (United States)

Deterministic arrays of Au nanoparticles arranged in aperiodic spiral geometries (Vogel's spirals) have been engineered and fabricated onto planar optical devices in order to enhance photonic-plasmonic coupling and increase light-matter interactions over broad frequency spectra. Vogel's spirals lack both translational and orientational symmetry in real space, while displaying continuous circular symmetry (i.e., rotational symmetry of infinite order) in reciprocal Fourier space. We investigate the novel regime of "circular multiple light scattering" in finite-size deterministic structures and we experimentally and theoretically show that circular symmetry in diffused reciprocal space gives rise to polarization-insensitive planar diffraction over a large and controllable range of wavelengths. The multi-band/broadband polarization-insensitive planar diffraction observed in aperiodic spirals is a highly desirable property for the engineering of a variety of device applications that require enhancing photonic-plasmonic coupling over planar optical

chips. In this work, we will present fabrication and characterization of both plasmon-enhanced Schottky solar cells and plasmon-enhanced electroluminescence from Er-doped silicon-rich silicon nitride (Er:SiNx) LEDs coupled to deterministic aperiodic Au nanoparticle arrays were fabricated using electron beam lithography on Si wafers. Arrays with different morphologies and nanoparticles sizes were systematically investigated in a large range of geometrical parameters. Our results demonstrate reproducible absorption and extraction enhancement from lithographically defined deterministic aperiodic arrays with optimized broadband scattering suitable for the engineering of reproducible Si-based devices.

8096-57, Session 14

Coupling of nanoparticle plasmons with molecular linkers

N. Zabala, Univ. del País Vasco (Spain) and Centro de Fisica de Materiales (Spain) and Donostia International Physics Ctr. (Spain); O. Pérez-González, Univ. del País Vasco (Spain) and Donostia International Physics Ctr. (Spain); P. J. Nordlander, Rice Univ. (United States); J. Aizpurua, Centro de Fisica de Materiales (Spain) and Donostia International Physics Ctr. (Spain)

Following the emerging interest in connecting molecular electronics and plasmonics, we study the spectral signatures of molecular linkers in plasmonic cavities of gold nanoparticle dimers. Different dielectric models and sizes for the linker are considered to envisage the relation between the spectral changes observed in the extintion spectra and the electronic transport through the molecules.

For thin junctions a BDP (Bonding Dimer Plasmon) mode, arising from the coupling of dipolar modes of the individual particles, is excited and blue-shifted as the radius is increased. When wider junctions are involved another mode, which corresponds to a real charge transfer between the nanoparticles and is known as CTP (Charge Transfer Plamon), emerges at longer wavelengths. The characteristics of these modes are observed with a simple pure conductor, but when an excitonic bridge is considered, more features appear in the extinction spectra as a consequence of the plasmon-exciton coupling, as revealed from the dispersion curves obtained for different sizes and characteristic resonant frequencies of the molecules.

The electromagnetic field is obtained by solving Maxwell's equations numerically with the Boundary Element Method (BEM).

We believe that the understanding of the spectral changes in plasmonic cavities with molecular linkers may help to the control the switch of different plasmon modes.

8096-58, Session 14

Tayloring the optical properties of LEDs by using surface plasmon polariton gratings

J. Moosburger, OSRAM Opto Semiconductors GmbH (Germany)

The enhancement of light extraction and tailoring the emission characteristics are two of the major challenges for state of the art LED chips. Beside conventional approaches like surface roughening, metal gratings and metal nano particles can be used as an alternative approach.

Looking at the extraction efficiency of LED chips, SPP gratings on one side can be used to avoid the limitations of total internal reflection (TIR) at planar surfaces, where light should be coupled out. At a flat surface, light beyond the critical angle is reflected back and hence the probability of absorption within the chip increases. With SPP gratings, light beyond TIR can couple into extraction modes via SPP states.

On the other side, SPP gratings can be used to make unavoidable absorbers 'translucent'. The main focus here are metal contacts at the emitting surface that normally contribute to internal losses.

In addition, the emission characteristic of a LED chip can be shaped by defining SPP gratings on top. Due to the periodicity of the grating, the SPP's can couple to discrete extraction modes. Hence by changing periodicity, filling factor and over all pattern of the grating, the extraction profile can be altered.

The presentation will summarize theoretical calculations, experimental results and fabrication issues of plasmonic structures on inorganic LEDs. Furthermore a benchmark with state of the art LEDs and an outlook for future potentials of SPP gratings for LEDs will be given. This work was done within the EU funded project PLEAS.

8096-59, Session 14

Thermo-induced electromagnetic coupling in gold/polymer hybrid plasmonic structures probed by surface enhanced Raman scattering

N. Félidj, L. Dos Santos, H. Gehan, G. Charron, J. Grand, J. Aubard, C. Mangeney, Univ. Paris 7-Denis Diderot (France)

Since its discovery four decades ago, surface enhanced Raman scattering (SERS) has been considered as one of the most sensitive tools for the chemical analysis of very few amount of molecules adsorbed onto metallic nano-particles (NPs), especially gold and silver.

One challenging aspect in SERS concentrates on the demonstration that a single molecule or very few molecules could be detected under specific conditions. It requires very huge electric field enhancements occurring within the gap between two NPs or between NPs and a gold film. Of particular interest is the possibility to control this latter interaction in order to optimize the Raman enhancement factor. In this work, we propose to address this issue by designing a stimulable device made of gold colloidal nanoparticles connected to a gold flat film through an active thermosensitive polymer brush layer, capable to externally modulate the distance between the NPs and the substrate. As a linker, we used Poly (N-isopropylacrylamide) that undergoes a reversible, inverse phase transition at a lower critical solution temperature (LCST) of about 32°C in pure water. Below the LCST, the polymer chains are in an extended conformational state. Above the LCST, it is in a hydrophobically collapsed conformational state. These conformational changes of the linker between the gold nanoparticle assemblies and the surface induce dramatic modifications of the optical properties of the substrate. In particular, above the LCST, the proximity of the colloidal particles to the gold film leads to a strong interaction regime with higher SERS spectra than below the LCST.

Origin of localized surface plasmon resonances in thin silver film over nanosphere patterns

S. K. Cushing, L. A. Hornak, J. Lankford, Y. Liu, N. Wu, West Virginia Univ. (United States)

Film over nanosphere (FON) patterns are formed by depositing a silver film on top of a close-packed polystyrene (PS) sphere template. Multiple localized surface plasmon resonance (LSPR) peaks are experimentally measured by transmission UV-Vis spectroscopy in the three dimensional FON pattern for thin silver films. Increasing the sphere size in the close-packed template or increasing the deposited silver film thickness redshifts the LSPR peaks to varying degrees. A finite difference time domain (FDTD) analysis reveals that the main LSPR peaks originate from a quadrupole and a dipole coupling mode near the triangle gap

surrounded by three adjacent PS spheres. The physical location and the electromagnetic enhancement of the two resonant modes are determined for different thickness of deposited silver films. It is found that the resonance modes do not change with varying film thickness.

8096-75, Poster Session

Semi analytical numerical analysis of plasmonic structures in layered geometries

A. Alparslan, C. Hafner, ETH Zurich (Switzerland)

Following the advancements in the fabrication process of photonic structures, various nano devices became quite popular, including photonic crystals, chemical and bio sensors, optical antennas and waveguides. Usually, these devices are fabricated in a multilayered structure. In the numerical analysis of such structures, the multilayered geometry is often ignored for sake of simplicity, which can cause inaccuracies in the results. Especially for structures that support Surface Plasmon Polariton (SPP) or guided wave modes, the errors become so high that the computations become useless. In order to analyze such structures, it is crucial to use a numerical tool that deals with layered geometries in an efficient and robust way.

The Multiple Multipole Program (MMP) is one of the most accurate simulation tools for the analysis of plasmonic structures. It uses a superposition of analytical solutions of Maxwell's equations (point sources, plane waves, Bessel functions, etc., so called expansions), to fulfill the boundary conditions on the boundaries or interfaces of structures. In the case of structures involving layered geometries, the boundary matching procedure becomes expensive, if not impossible, since the number expansions and matching points increases dramatically. In order to tackle this problem, layered media Green's functions (LMGF), which are the analytical responses of the layered geometry in presence of a point source, are introduced as a new expansion set for MMP. By using the advantages of MMP and LMGF, a robust, efficient and user-friendly simulation tool is obtained. In this talk, the derivation of the method together with some results from OpenMaX, the open-source program that includes the latest MMP version, will be presented.

8096-76, Poster Session

Site selective surface enhanced Raman scattering on nanostructured cavity arrays

F. Lordan, J. H. Rice, Univ. College Dublin (Ireland); B. Jose, R. J. Forster, T. E. Keyes, Dublin City Univ. (Ireland)

Raman spectroscopy is an extremely powerful analytical tool. Surface enhanced Raman spectroscopy (SERS) enables sample sensitivity to extend down to the single molecule level. There is presently great interest in using uniform nanostructured surfaces to give reproducible and strong SERS signal. The nanocavities studied here have spherical cap architecture and are arranged uniformly in an Au array. These structures support both localised and delocalised plasmons. Localised surface plasmon polaritons exist inside the nanocavities (Mie plasmons) and delocalised or propagating surface plasmon polaritons exist on the flat surface of the sample (Bragg plasmons). The angle dependence property of surface enhanced Raman is used in the present work to enable comparison between SERS caused by localised plasmons and SERS caused by delocalised plasmons. The samples used here were modified to enable separate investigations of the two plasmon types. The externally modified array had dye placed only on the flat top surface of the array. The internally modified array had dye placed only on the internal walls of the cavities. Results show that the changes in Raman intensities with respect to the incident angle depend on the location of dye on the array.

8096-77, Poster Session

Enhanced polarization anisotropy of metal nanoparticles and their spectral characteristics in the surface plasmon resonance band

N. Ghosh, J. Soni, Indian Institute of Science Education and Research (India)

The spectral and angular polarization behavior of light scattered from metal nanoparticles were investigated using polar decomposition of the scattering matrices. The scattering matrices [S(theta, lambda), theta is the scattering angle, lambda the wavelength] for both preferentially and randomly oriented spheroidal (prolate and oblate) silver nanoparticles were generated in their surface plasmon resonance spectral region (380 - 600 nm) using the T-matrix approach. S(theta, lambda) were generated for silver nanoparticles having varying sizes and aspect ratios and for dielectric particles having identical size and shape. These were analyzed using the polar matrix decomposition approach, to derive quantitative individual polarization properties, namely, retardance, diattenuation and depolarization. The decomposition-derived linear retardance (delta, phase difference between orthogonal linear polarizations) from preferentially oriented silver nanoparticles showed distinct spectral features, the values for delta peaking around the spectral overlap region (400 - 450 nm) of the longitudinal and the transverse plasmons. Further, the magnitude of delta and its spectral behavior was observed to undergo systematic changes with varying aspect ratio and the size of the nanoparticles. In contrary, for similar dielectric nanoparticles, the scattering-induced delta was considerably weaker and did not show any appreciable spectral variation. The decomposition-derived value for diattenuation (d, differential attenuation of two orthogonal polarization states) for the silver nanoparticles also showed interesting spectral characteristics, which were again absent for the dielectric particles. The enhanced linear retardance (and its distinct spectral characteristics) for the metal nanoparticles was attributed to the additional phase differences between the longitudinal and the transverse plasmon polarizabilities, which was confirmed further by studying the angular variation of delta (theta) for these nanoparticles. The analysis also revealed that when averaged over all possible orientation of the particles (for randomly oriented spheroids), addition of the retardance and diattenuation matrices having random orientation of axes manifests as stronger depolarization (D) of light in spheroidal metal nanoparticles as compared to their dielectric counterparts. The details of the studied dependence of delta, d and D on size parameter and aspect ratio of the nanoparticles will be presented. Initial results of complementary experimental studies and their implications for spectral, polarimetric biomedical imaging will also be discussed.

Manipulation of multi-dimensional plasmonic spectra for information storage

K. Yang, W. T. Chen, P. C. Wu, C. J. Chen, National Taiwan Univ. (Taiwan); C. Weng, Instrument Technology Research Ctr. (Taiwan); C. Kuan, National Taiwan Univ. (Taiwan); M. Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States); D. P. Tsai, National Taiwan Univ. (Taiwan) and Instrument Technology Research Ctr. (Taiwan) and Research Ctr. for Applied Sciences (Taiwan)

We demonstrate a concept of optical data storage through plasmonic resonances of metallic nano-structures. Metallic nano-structures exhibit strong variations in their reflectance and/or transmittance spectra due to surface plasmon polariton resonances. We study the variations of spectra through 50x50 arrays of repeated unit cells covering a total area of ~50x50μm2. Each cell contains 10 different nano-features, such as an ellipse, a ring, a circle, a triangle, a square, etc. The size of each unit cell is 500x500nm2, and the periodicity is 1.0μm. The variations of spectra is

obvious enough to be distinguished, so that it should be possible to store and then retrieve data from different spectra. This paper presents the results of a study aimed at proving the feasibility of the concept.

Controlling the fluorescence dynamics of a single emitter by coupled metallic nanostructures

C. Vandenbem, Facultes Univ. Notre Dame de la Paix (Belgium); L. S. Froufe-Pérez, Instituto de Ciencia de Materiales de Madrid (Spain); R. Carminati, Ecole Supérieure de Physique et de Chimie Industrielles (France)

A key issue in photonics is the controlled modification of spontaneous emission. Changes of the spontaneous decay rate are induced by changes in the local density of electromagnetic modes, and are quantitatively described by the classical electrodynamic response of the surface. In consequence, the development of nano-optics techniques has stimulated the use of metallic nanostructures to act on the spontaneous decay rate but also on the fluorescence intensity, and on the radiation pattern of isolated emitters, leading to the concept of optical nanoantenna.

In addition, control of plasmon-resonance frequencies can be achieved either by playing with the shape of metallic nanostructures either by coupling different plasmonic modes of nanostructures. The latter case has the adavantage that these hybrid plasmonic modes can lead to either radiative or non-radiative coupling depending on their coupling to free space.

In the present work, we study theoretically and numerically the possibility of controlling the fluorescence features with systems involving coupled plasmon modes. Depending if the emitter is coupled to the radiative mode or the non-radiative mode (dark mode), the apparent quantum yield and the fluorescence lifetime exhibit different behaviors. The concept is general and can be illustrated on several geometries such as the dimer of two nanoparticles, a thin metallic film or a hybrid system coupling a metallic film and a single metallic nanoparticle.

Optical properties of silver nanoparticle dispersed in polymer matrix

A. Ziaeemehr, Imam Khomeini International Univ. (Iran, Islamic Republic of); R. Poursalehi, Shahed Univ. (Iran, Islamic Republic of)

We studied the effects of nanofiller size on the refractive index and optical transparency of nanoparticle polymer nanocomposite. The size of nanofillers has been considered from 3 up to 30 nm. In a precise calculation of absorption and scattering of polymer matrix, the modified size dependent refractive index is used. In addition, this quantity obtained with considering size dependent surface effects.

The calculated results indicated the particles refractive index depends strongly on the diameter of particles, especially for smaller particles at long wavelengths. Also it was found that optical extinction intensity increases for larger nanoparticle and the wavelength of maximum of optical exhibited a red shift. Inconsistency between refractive index of nanofiller and polymer matrix increases the scattering, and in some application, light scattering and any other type of wastage are extremely important.

The results of this study can be applied for optimization of size and loading fraction of nanoparticle filler for preparation of modified nanocomposites with lower light scattering and lower refractive index mismatch.

hp-FEM applied to scattering problems in plasmonics

M. Wang, C. Engström, ETH Zurich (Switzerland); K. Schmidt, Technische Univ. Berlin (Germany); H. Brandsmeier, C. Hafner, ETH Zurich (Switzerland)

The simulation of plasmonic structures is numerically difficult mainly because of the rapid field variation at the metallic surface. Standard low-order finite element and finite difference methods are inefficient for this class of problems. Therefore, it is highly desirable to develop efficient finite element methods able to simulate plasmonic structures.

In this paper, we use high-order curvilinear finite elements for scattering problems with both Absorbing Boundary Conditions (ABCs) and radial Perfectly Matched Layers (PMLs). For ABCs, we develop adaptive strategies, which are implemented in the hp- finite element code CONCEPTS. CONCEPTS uses blending technique for high-order boundary approximation, which is mandatory for curved boundaries.

We study the plasmonic behavior of two nearby nano particles with smooth interfaces and use solutions obtained with the Multiple Multipole Program (MMP) as reference solutions. The hp-FEM simulations with ABC and PML show a very good agreement with MMP. Of central importance is the use of quadrilateral curvilinear finite elements, which accurately describe the geometry of the problem. Together with high-order basis functions and an adaptive strategy, these elements significantly enhance the performance of FEM.

near-field mapping by laser ablation of PMMA coatings

J. Fiutowski, C. Maibohm, J. Kjelstrup-Hansen, H. Rubahn, Univ. of Southern Denmark (Denmark)

Near-Field optics has attracted much attention in various fields of science due to its prospect for spatially resolving optical fields at length scales far below the diffraction limit. Though several applications for local field enhancement have been successfully demonstrated, spatial mapping and direct measurement of the optical near-field surrounding nanostructures of noble metals is still important both for basic and applied studies of exploitation of localized surface plasmons (LSP). Spatial mapping and direct measurement of the optical near-field surrounding noble metal nanostructures are often done with optical scanning techniques such as scanning near-field optical microscopy (SNOM) or photon scanning tunneling microscopy (PSTM). Here we report sub-diffraction spatially resolved mapping of strong localized field intensity enhancement on gold nanostructures based on local laser ablation of an “imaging” polymer layer. We take advantage of the transparency and well known ablation threshold of poly (methyl methacrylate) PMMA thin films, spin coated onto regular arrays of elevated gold nanostructures on a gold substrate. Sub-ablation threshold illumination is obtained via Laser Scanning Microscope with a femtosecond laser system tuned to excited Localised Surface Plasmons (LSP) on the nanostructures. The accompanying field enhancement on the nanostructures together with sub-threshold excitation exceeds the PMMA ablation threshold creating arrays of local ablations and corresponding topographic modifications of the polymer film. Such modifications can be quantified straightforwardly via, e.g., scanning electron or atomic force microscopy.

Study of the morphology and optical properties of nanoparticle-polymer conjugates

R. C. Wadams, L. Fabris, Rutgers, The State Univ. of New Jersey

(United States)

Organic-based bulk heterojunction solar cells (BHJSCs) consist of phase-separated blends of conducting polymers and fullerene derivatives. The polymer active layer donates electrons to the n-type fullerene phase upon absorption of solar radiation. Ideally, electrons diffuse into the heterojunction before recombination, and are dissociated at the polymer-fullerene interface. BHJSC quantum efficiency is limited by the polymer and fullerene morphology, and by the polymer's narrow absorption spectrum.1 It has been proposed that nanoparticle incorporation into the active layer can enhance light absorption.

Noble metal nanoparticles exhibit localized surface plasmon resonances (LSPRs) upon absorption of electromagnetic radiation. The absorption spectrum is size, shape, and material dependent. Spherical nanoparticles exhibit one LSPR. Once symmetry is broken, such as with rods, multiple absorption bands are possible. Additionally, pairing nanoparticles in dimers creates intense electromagnetic field enhancements within the intermetallic junction due to plasmonic coupling. The introduction of nanoparticles in BHSCs can potentially increase the absorption spectrum of the active polymer layer.

Recently, nanoparticles have been covalently bonded to polymeric chains allowing investigation of polymer-nanoparticle interactions, and 1-dimensional nanoparticle assemblies.2 Our expectation is that binding nanoparticle dimers onto polymer backbones will affect the morphology and optical properties of the conjugate. It is anticipated that ordering of the polymer-based active layer can be induced by the presence of anisotropic nanoparticles with elongated shape, such as nanorods.

Herein we describe our approach for the synthesis of covalent nanoparticle dimer-polymer conjugates. Gold and silver nanoparticles, of various morphology (e.g. spheres, rods, bones), and their dimers are synthesized, and conjugated to polymer chains. The effects on the morphology and optical properties induced by the coexistence of the nanoparticle dimers and polymers are analyzed, and the potential benefit brought about by these hybrid nanostructures is evaluated.

Optical characterization of nanopillar black silicon for plasmonic and Solar cell application

M. R. Gartia, Y. Chen, Y. C. Bordain, Z. Xu, J. Eichorst, J. C. Mabon, J. A. N. d. T. Soares, R. M. Clegg, G. L. Liu, Univ. of Illinois at Urbana-Champaign (United States)

With the goal of improving photo-absorption of photovoltaic device and for plasmonic application we have fabricated nanopillar black silicon devices through etching-passivation technique which does not require any photomask and whole wafer scale uniformity is achieved at room temperature in a short time. We have also performed a thorough optical characterization of the device. We have carried out cathodoluminescence (CL) and current dependent CL spectroscopy study for our device. Further we present the photoluminescence characteristics of our device both at room temperature and at low temperature (77 K) with different excitation sources. The characterization done using Raman spectroscopy showed the possible phonon broadening effects. We performed a reflectance and absorption measurement using Varian Cary-5 instrument to measure the effect of nano structuring the silicon wafer. In order to render the device for plasmonic property, we have applied a thin layer of silver (80 nm) using e-beam evaporation. Then we performed a series of different optical characterization to probe the plasmonic effect of our device such as surface plasmon enhanced fluorescence, angle dependent reflectance measurements to show the different surface plasmon modes, high resolution cathodoluminescence (CL) experiment, surface enhanced Raman spectroscopy (SERS) measurement , Fluorescence Lifetime Imaging Microscopy (FLIM) experiment to show the lifetime modification on nanoplasmonic device. Finally, we have made both organic and inorganic solar cell using our device to demonstrate the utility of the current device. The results for the I-V measurement for the devices is provided in the paper.

Surface-plasmon-enhanced visible light emission of ZnO/Ag grating structures

M. Gwon, E. Lee, Ewha Womans Univ. (Korea, Republic of); K. Yee, Chungnam National Univ. (Korea, Republic of); D. Kim, Ewha Womans Univ. (Korea, Republic of)

Surface plasmon polaritons (SPP) are resonant interactions between the surface charge oscillations and the electromagnetic waves at the metal/dielectric interface. Periodic nanostructures can bridge the SPP-photon momentum gap and modify the optical properties of the dielectric layers. ZnO/Ag thin films can be used as back reflectors in silicon thin film solar cells. It is interesting to investigate how the grating structures can influence SPP-photon coupling and resulting optical properties of ZnO/Ag layers.

ZnO/Ag thin films were deposited on one-dimensional periodic structures, with the periodicity of 1000 and 1400 nm, fabricated by nanoimprint lithography. The ZnO/Ag grating structures exhibited multiple peak features in visible-range photoluminescence (PL). Whereas a ZnO/Ag planar thin film showed two major PL peaks in UV and visible region. Moreover the PL intensity of the periodic structures was 100 times larger than that of the planar counterpart. These results could be understood as a result of SPP-exciton interaction. The grating structures also exhibited quite distinctive features in reflectance from the planar samples. There were several reflectance dips, which were caused by photon-induced SPP excitation via the grating coupling. Thus, the PL peaks, well matched with the reflectance dips, represent the excited SPP energies, determined by the grating periodicity. Finite-difference time-domain simulations supported all the experimental results.

Two dimensional standing wave surface plasmon fluorescence imaging by subwavelength slit arrays

W. Qian, Nanyang Technological Univ. (Singapore); J. Bu, Nankai Univ. (China); P. S. Tan, Sr., Nanyang Technological Univ. (Singapore); X. C. Yuan, Sr., Nankai Univ. (China)

Four counter-perpendicular sub-wavelength slit arrays embedded on the silver film are proposed to convert free-space light to surface plasmon (SP) waves. The excited counter-propagating SP waves interfere each other to form two dimensional standing wave patterns in the region of the structure center area. Since the SP wavelength is shorter than free space propagating electromagnetic waves, this constructive interference pattern contains an attenuation of the high spatial frequency $kSP=4\pi/\lambda SP$. This standing wave profile can served as the virtual probing mechanism to excite fluorescence near the metal surface. Then a linear inversion scheme is utilized to recover the fluorescence density from a serial of images obtained by conventional microscopy by using phase shifting method. The simulation results show that the resolution can reach to $\lambda SP/4$ which is clearly beyond diffraction limit. The main advantages of these promising new paths are that they do not require any scanning of the sample and do not require one to mount an interference setup in the microscope. This designed sub-wavelength slit arrays structure is one of the potential methodologies to realize the real time, wide field, on-chip, and high-spatial resolution fluorescence imaging.

Numerical study of optical and EELS response of coupled metallic nanoparticles

S. Guillaume, L. Henrard, Facultes Univ. Notre Dame de la Paix (Belgium)

Localized surface plasmon resonances (LSPR) govern the optical properties of metallic nanoparticles at the nanoscale level and depend strongly on their shape, size and environment. Futhermore, for particles close to one another, coupling occurs and gives rise to new plasmon modes that can be described in terms of hybrization of the plasmon modes of the individual nanoparticles. For given geometries, such as a dolmen-like structure made of 3 gold nanorods, a transmission window appears in the optical spectrum due to Fano resonances. Because, dark modes are invisible in optics, one has to probe locally the response of the nanoparticles to get insight on the origin of these Fano resonances. This is why we investigate numerically the energy electron loss (EELS) response of coupled metallic nanoparticles, together with their optical properties. To achieve this, calculations are performed in the frame of the discrete dipole approximation both for optical and EELS excitations.

In the case of a gold dolmen-like structure, the bright mode of the monomer and the dark mode of the dimer are found to have a similar energy. Moreover, the dark mode is narrow compared to the broad dipolar mode of the monomer. These observations explain the origin of the transmission window and the Fano resonances of the spectrum. However, it also appears that the “optical Fano mode” is unexpectedly very active in EELS at a lower energy than in the optical spectra. Influence of the system configuration on EELS excitability is then questioned for other geometries.

Design and analysis of subwavelength plasmonic waveguide array

V. Dillu, S. Singh, R. K. Sinha, Delhi Technological Univ. (India)

We examine the propagation of plasmonic TM (Transverse Modes) modes generated in the designed periodic array of silicon (Si) and silver (Ag) on Si substrate. The properties of surface plasmons are tailored by altering the size of Ag nano rods and its periodicity. Conventional waveguides cannot guide electromagnetic energy below the diffraction limit of light, which can be overcome by texturing the metal or dielectric surface. In this design we have textured by placing metallic, Ag nanorods on Si substrate. This provides the missing momentum needed, since SPP modes always lay beyond the light line. Ag nanorods are structured at nano dimensions to control and manipulate Surface Plasmon Polariton (SPP) propagation and thus open new possibilities in light matter interaction.

Here, we report the design and analysis of subwavelength plasmonic photonic crystal structure for the purpose of generation and propagation of SPP. TM polarized SPP propagating through the linear defect created in the periodic array of Ag (Silver) and Si (Silicon) nano rods on Si substrate have been theoretically analyzed using Finite Difference Time Domain (FDTD) computational calculations. The band gap and transmission spectra for the full structure are studied and further the structure with linear defect is designed for propagating plasmonic radiations. The structure shows high confinement below the diffraction limit and helps in scaling down the size of the proposed device. These investigations validate the use of nano structures for SPP propagation and hence miniaturize the optical and electronic devices for specific applications.

Plasmonic cavity made of defect in an array of asymmetric T-shaped structures

Y. Chang, M. N. Abbas, M. Shih, Academia Sinica (Taiwan)

Plasmonic cavities that strongly confine light are finding applications in many areas of physics and engineering, including coherent electron-photon interactions. Here, we introduce a defect in a 1D array of asymmetric T-shaped structures to form an optical cavity to confine the light in small area, and we obtained a relatively high quality factor (≈200) with very small effective mode area [0.0375(λ/n)2] which is far below the diffraction limit. Furthermore, we showed that abrupt change at defect edge will increase the radiation losses and will suppress the quality factor to 64.

Properties of nano-ridge surface plasmon mode

J. Guo, The Univ. of Alabama in Huntsville (United States); R. A. Soref, W. R. Buchwald, Air Force Research Lab. (United States); G. Sun, Univ. of Massachusetts Boston (United States)

We investigate the surface plasmon-polariton mode guided by nanometer scale metal ridges embedded in dielectric materials. We calculate the mode confinement, attenuation, and figure-of-merit for a variety of metal ridge structures in the 1.5 to 4.5 um infra-red wavelength range. We compare the properties of the surface plasmon nano-ridge mode and the nano-strip surface plasmon mode. Although the trade-off between the confinement and the propagation length always holds, we find the properties of the nano-ridge surface plasmon mode are quite different from the nano-strip mode. The nano-ridge surface plasmon waveguide can provide a more strongly confined mode within the surrounding dielectric. This mode property enables potentially a variety of integrated sensor applications in the infra-red wavelength regime.

Mapping localized plasmon modes in metal nanoparticles via electron energy loss spectroscopy and cathodoluminescence

V. Myroshnychenko, J. García de Abajo, Consejo Superior de Investigaciones Científicas (Spain); G. Boudarham, J. Nelayah, O. Stéphan, M. Kociak, C. Colliex, Univ. Paris-Sud 11 (France); A. I. Denisyuk, G. Adamo, K. F. MacDonald, N. I. Zheludev, Univ. of Southampton (United Kingdom); J. Rodríguez-Fernandez, Univ. de Vigo (Spain) and Ludwig-Maximilians-Univ. München (Germany); E. Carbó-Argibay, L. M. Liz-Marzan, Univ. de Vigo (Spain)

Localized surface plasmon (SP) modes can be tailored by controlling the size and morphology of metal nanoparticles. This finds exciting applications in photonic devices and optical sensing. The development of these applications requires knowledge of the spatial variation of the near fields associated to SPs.

In this work, the rich structure of SP modes localized in individual noble-metal nanoparticles prepared via lithography or colloidal chemistry is explored by optical spectroscopy [1], spatially resolved electron energy-loss spectroscopy (EELS) performed in a scanning transmission electron microscope (STEM) [2,3], and by electron beam-induced radiation emission performed in a scanning electron microscope (SEM) [4]. Spectral features and spatially-resolved maps of SP modes collected for individual nanoparticles of different morphologies (rods, decahedra, prisms, and split-ring resonators) are shown to be in good agreement

with theoretical STEM-EELS and optical excitation calculations obtained using the boundary element method based upon rigorous solution of Maxwell's equations [5]. Our results show the unmatched capability of electron beams for spectrally and spatially probing SP modes in nanoparticles with a wide variety of morphologies.

Role of silver nanoparticles in the laser-induced reversible colour-marking and controlled crystallization of mesoporous titania films

N. Crespo-Monteiro, Univ. Claude Bernard Lyon 1 (France) and Univ. Jean Monnet (France) and Lab. Hubert Curien (France); N. Destouches-Castagna, Univ. Claude Bernard Lyon 1 (France) and Lab. Hubert Curien (France) and Univ. Jean Monnet (France); L. Bois, F. Chassagneux, Univ. Claude Bernard Lyon 1 (France); E. Gamet, Lab. Hubert Curien (France)

Due to their surface plasmon resonance silver nanoparticles are known to absorb visible light and give glasses various colors. Grown in mesoporous titania films, they give the material a photochromic behaviour that can be used to produce rewritable data carriers.1 On the one hand, UV light forms silver nanoparticles thanks to the photo-induced generation of electrons by titania matrix. On the other hand, visible light oxidizes the silver nanoparticles via the photoexcitation of electrons on Ag and their stabilization by oxygen molecules. The well controlled porosity of the mesoporous films allows to tune the nanoparticles size and to obtain, under UV illumination, homogenous distributions of small nanoparticles embedded within the titania matrix, which color the films. As all nanoparticles absorb light similarly, the film can then be completely bleached under exposure to a visible laser beam whose wavelength falls in the SPR band of the particles. Therefore, CW UV and visible focused-laser radiations, respectively, can repeatedly print and completely erase colored micropatterns within TiO2/Ag films. The paper shows patterns printed under different conditions, deals with the reproducibility of the process and the inscription stability, and explains the nanoscale mechanisms, including silver migration during exposures, leading to the reversible color changes on the basis of TEM, SEM, absorption spectroscopy and Raman micro-spectroscopy characterizations. The paper also evidences that CW laser illuminations at higher intensity locally crystallize the titania matrix and investigates the influence of the absorption-induced heating around nanoparticles.

Three-dimensionally arranged metal-nanoparticles based on phase separation of block-copolymers

H. Yabu, T. Higuchi, M. Shimomura, Tohoku Univ. (Japan)

Metal-dielectric hybrid nanostructures are received grate interests due to their potentials for novel photonic materials including left-handed metamaterials. Recently, we found a simple method for preparing block-copolymer and polymer blend particles by evaporation of good solvent from their solution containing poor solvent (Self-ORganized Precipitation (SORP) method). Moreover, lamellae and other phase-separation structures are formed in block-copolymer nanoparticles. In this paper, we show the preparation of nano-structured metal-polymer hybrid particles by combination of the SORP method and electroless plating. Their optical properties will be discussed.

Metal-dielectric hybrid nanostructures are received grate interests due to their potentials for novel photonic materials including left-handed metamaterials. However, few effort has been done for developing nanoparticles having well-controlled metal-dielectric hybrid nanostructures. Recently, we found a simple method for preparing block-copolymer and polymer blend particles by evaporation of good solvent from their solution containing poor solvent (Self-ORganized Precipitation (SORP) method). Moreover, lamellae and other phase-separation structures are formed in block-copolymer nanoparticles.

In this paper, nanoparticles of metals stabilized with block-copolymer micelles are also embedded i n the phase-separated block-copolymer nanoparticles. Au nanoparticles were prepared in the block-copolymer micelles of poly(styrene-block-2-vinylpyridine) (PS-b-P2VP). PS-b-P2VP micelles were formed in toluene, and then, Au ions are complexed with pyridine moieties of PS-b-P2VP. After reduction of Au ion to Au, Au nanoparticles embedded in PS-b-P2VP micelles (AuNP@PS-b-P2VP) were prepared. The tetrahydrofran (THF) solution of AuNP@PS-b-P2VP was mixed with THF solution of poly(styrene-block-isoprene) (PS-b-PI), water was added into the mixed solution. After evaporation of the THF, the polymer-metal composite particles were prepared. Their internal structures were observed by using a transmission electron microscope (TEM), the particles with phase separation structures were formed. Furthermore, Au nanoparticles were included into the phase-separated particles. Their optical properties will be discussed.

Experimental demonstration of long range surface plasmon devices based on metallic subwavelength gratings

Z. Wu, Q. Zhan, Univ. of Dayton (United States)

The electron density oscillations along metallic surfaces, or on metallic films can cause electromagnetic surface waves propagation, which is known as surface plasmon polaritons (SPPs). When the incident light couples into SPPs, a sharp decrease in reflectivity of the incident light will occur. This sharp decrease in reflectivity is known as surface plasmon resonance (SPR). Devices such as electro-optic (EO) modulators, spectral notch filters, and refractive index and biochemical sensors have been designed using attenuated total reflection type arrangement based on SPR. The performance of the SPR in these applications is largely determined by the width as well as the depth of the dip in the reflectance curve. Recently, long range surface plasmon (LRSP) device design that replaces the metallic thin film with a metallic subwavelength grating to support the propagation of LRSP and offer much narrower SPR has been proposed and studied. In this paper, we experimentally demonstrate the SPR of LRSP propagating along metallic gratings is indeed narrower than that propagating along metallic films. An ultra-high resolution rotational stage with a resolution of 5.5×10-5 rad is used to resolve the ultra-narrow SPR curves.

The experiment measurement of the SPR curves of LRSP devices with a gold film and a gold grating are shown, which clearly demonstrates that the device with a gold grating yields a much narrower SPR curve. The experiment result confirms our numerical prediction that LRSP devices with metal gratings give better device performance than those with metal films.

A plasmonic phase plate using nanoslits

E. H. Khoo, A*STAR Institute of High Performance Computing (Singapore); K. Crozier, Harvard Univ. (United States)

Today's demand for sensing and imaging application are greatly satisfied by nano-plasmonics devices. One interesting property of plasmonics is their polarization sensitivity in nanoslits. Lightwave with polarization

perpendicular to the nanoslit is transmitted with amplitude greater than unity. This is termed as “extraordinary optical transmission” [1]. When the polarization is parallel to the nanoslits, no light is transmitted. The phase of lightwave transmitting through the nanoslits can be altered. It is done by altering the geometrical dimension and/or filling the nanoslits with high index materials.

We propose a phase plate using nanoslits. The nanoslits are placed in perpendicular on a gold film with thickness 200 nm. Incident lightwave with linear polarization 45 degree from x and y axis are transmitted through the corresponding nanoslits Ny and Nx. The nanoslit, Nx is altered to have phase delay for electric field polarization in y direction (Ey).

Nanoslit Nx is filled up with SiO2 so as to create a 0.5 pi phase delay. It is observed that the transmitted amplitude of Ey through Nx is twice of Ex through Ny. Hence to equalize the amplitude, two Ny nanoslits are required.

The field distribution amplitude is obtained by using FDTD with Lorentz-Drude model of gold film. Hence a linear polarization lightwaves at 45 degree from x and y axis is converted to a right-hand circular (RHC) polarization. If RHC polarized light is incidence onto the phase plate, then linear polarized light at 45 degree from x and y axis is obtained.

Distance-dependent fluorescence intensity on PMMA structures on a metallic film

Y. Hung, National Sun Yat-sen Univ. (Taiwan); J. Tai, National Sun Yat-Sen Univ. (Taiwan) and Academia Sinica (Taiwan); C. Yuan, M. Shih, J. Tang, Academia Sinica (Taiwan)

Fluorescence intensity on PMMA gratings and plain PMMA mesa on Au film was investigated. The intact Au film thickness is 50nm on a cover glass and PMMA thickness on top of Au ranges from 50nm to 320nm. A layer of fluorophore material was spun on top of PMMA grating structures which are patterned by using E-beam lithography system. It is found that the fluorescence intensity changes rapidly by varying the PMMA thickness. The fluorescence intensity performs quite the opposite on PMMA grating area and plain PMMA mesa. Both are on Au film. Detailed surface plasmon mode calculations on the different PMMA thickness will be performed and analyzed. The lifetime of fluorophore material on the PMMA mesa and PMMA grating structures has been measured. This is to distinguish how the optical mode distribution of the pumping light affects the fluorescence intensity and how the different dielectric environment (optical mode density) affects the emission cycles which result in the emission intensity difference. Spatially-precise lifetime measurement and fluorescence intensity on grating valley and hill are performed by using a confocal microscope. The fluorescence emission shows different intensity performance on grating valley and hill when different PMMA thickness is coated. The measurement and observation is quite different from what people think about the quenching effect on a direct metal film. The optical field distribution will be analyzed by simulations.

Localized surface plasmon lithography for Nanopatterning fabrication

X. Dong, Y. Zhang, Institute of Optics and Electronics (China); J. Du, Sichuan Univ. (China); L. Shi, C. Du, Institute of Optics and Electronics (China); F. Gao, Sichuan Univ. (China)

A method is reported for manufacturing nanostructures by employing localized surface plasmon (LSP) lithography. At the first, the mechanism for realizing LSP lithography by using different kind of masks for exciting LSPs and accumulating a large amount of localized energy from the incident light field are described, where the masks can be selected with formals of nano-tip array, nano-pattern with the fine tapers and a structure formed by a soft mould on a thin metal film; then, the masks as the important part for fulfilling the nanolithography are characterized in design and fabrication under the available lab environment; finally, the typical experiments by using the mask formed of a soft mould on a thin metal film are carried out for fabricating nanopatterns with the minimum feature size from 100 nm ~ 30 nm in both regular and arbitrary arrangement and the dependence of the resolution (pattern periodicity) and stability of lithography on the geometrical parameters of the soft mould, such as ridge width, mould periodicity, ridge depth and slope, have been systematically studied and analyzed by Finite-Difference Time-Domain. In conclusion, the optimal minimum feature size can reach 17 nm by the proposed method.

Measurement of spontaneous emission enhancement in subwavelength metallo-dielectric lasers using phase-resolved spectroscopy

Q. Gu, M. Nezhad, B. Slutsky, O. Bondarenko, Y. Fainman, Univ. of California, San Diego (United States)

Subwavelength scale laser devices are of great interest as potential components for integrated photonic circuits. We previously reported room temperature lasing operation of subwavelength scale metallo-dielectric cavity lasers with InGaAsP MQW in the 1.5μm region [1]. In this paper, we investigate the Purcell effect, which describes the enhancement of spontaneous emission (SE) in a small volume and/or highly resonant cavity. Using phase-resolved spectroscopy, we measure carrier lifetimes of bulk InGaAsP MQW wafer as well as optically pumped metallo-dielectric lasers with cavity size ranging from 300nm to 1μm. After extracting the SE lifetime from carrier lifetime through numerical models, we are able to obtain the SE enhancement rate of various sizes of lasers with respect to their bulk counterpart. Through rate equation modeling and fitting to experimental light-light (LL) curves, we study the SE enhancement’s effect in lasing characteristics, especially in the sub-threshold region. In addition, by using cavity quantum electrodynamics (CQED) theory, we investigate SE enhancement’s dependence on various parameters including homogenous broadening linewidth of emitters, density of emitter states, quality factor Q and effective mode volume Veff. With this knowledge, we can further optimize the design of our laser cavity structure. Due to shortened SE lifetime and potentially low lasing thresholds, these lasers can find applications in high-speed optical communications, information processing, and on-chip optical interconnects.

Scattering readout at detuned surface plasmon resonance of gold nanorods for continuous-wave multi-dimensional optical storage

A. B. Taylor, J. W. M. Chon, Swinburne Univ. of Technology (Australia)

Exciting progress has been made in the field of gold-nanorod based five-dimensional optical storage, utilizing surface Plasmon resonance (SPR) mediated photothermal melting and two-photon luminescence (TPL) from gold nanorods as the recording and read-out mechanisms [1]. However the requirement of femtosecond pulses limits the applicability to consumer electronics. To address this, we propose the use of a continuous wave (CW) readout mechanism. CW readout is however hampered by exponential signal extinction in multi-layer setting.

For multilayered gold nanorod films, readout is achieved by strong scattering under SPR condition. Due to the magnitude of this scattering decreasing away from the peak SPR wavelength, detuning the readout wavelength can reduce the level of signal extinction through the layers, yielding more efficient readout at deeper layers in the sample matrix. Detuning from SPR however results in reduced scattering from the nanorods. We show that balancing these two factors results in an optimal readout wavelength that is specific to each layer.

Continuous wave laser operation provides a viable alternative to TPL based readout, and should be studied rigorously for its successful device application. We have already demonstrated that the continuous wave recording is possible [1]. Here, we demonstrate the viability CW readout in a 16-layer gold nanorod sample matrix.

Hybrid photonic-plasmonic crystal nano-cavities

X. Yang, Ctr. for Scalable and Integrated Nanomanufacturing (SINAM) (United States); A. Ishikawa, Univ. of California, Berkeley (United States); X. Yin, Ctr. for Scalable and Integrated Nanomanufacturing (SINAM) (United States); X. Zhang, Univ. of California, Berkeley (United States)

Optical cavities with both high quality factor Q and small modal volume Vm are of great importance in the enhancement of light-matter interaction. Although conventional dielectric cavities can be designed to have ultrahigh Q factors, such as microspheres, microtoroids and photonic crystal cavities, the physical sizes of these cavities cannot be smaller than the wavelength scale in order to confine photon effectively. Therefore, the mode volumes for these dielectric cavities are diffraction limited. Surface plasmon polaritons (SPPs) provide a new way to confine electromagnetic waves beyond the diffraction limit. The unique dispersion relation of SPPs supports high wave vectors with ultrashort wavelengths, resulting in different kinds of plasmonic nanocavities with subwavelength mode volumes and metal-loss-limited Q factors. Here, we propose a novel hybrid photonic-plasmonic crystal nanocavity consisting of photonic crystal structures coupled to a metal surface with a nanoscale air gap in between. Based on the periodic variation in the effective index of hybrid mode, a unique hybrid photonic-plasmonic crystal with a transverse magnetic (TM) band gap is formed at the wavelength of 1,550 nm. One-dimensional hybrid crystal nanocavities having parabolic variation of lattice constant are then designed with high quality factor Qtot of 330 and deep subwavelength mode volume Vm of 0.0056 3. The calculated Purcell factor is as high as 4,560 with an extremely large Qtot/Vm of 60,000 -3. This new type of high-Q/Vm broadband nanocavity will be of great importance in the enhancement of light-matter interactions, such as cavity QED, nonlinear optics, low-threshold nanoscale lasers, and optomechanics.

Optimizing of the surface plasmon induced strengthening of PV efficiency

W. A. Jacak, Wroclaw Univ. of Technology (Poland); J. Krasnyj, Odessa International Univ. (Ukraine); L. Jacak, Wroclaw Univ. of Technology (Poland)

The experimentally observed significant increase of photo-voltaic efficiency due to surface plasmons mediating the energy transfer in solar cells with metallic nanoparticles deposited on a photo-active layer of semiconductor (i.e. Si or III-V type and also of conjugated organic polymer semiconductor) is explained as the result of strengthening of inter-band transition probability induced by electrons coupling to plasmons in the near-field regime. We identify and analyze two competitive mechanisms which contribute to the overall PV efficiency increase which can be optimized with respect to the dimension of metallic nano-components. The first effect resolves itself to strengthening of the dipole plasmon oscillation amplitude with the nanoparticle radius growth, which favors larger nanoparticles sizes in regard to PV efficiency increase. The second one, oppositely, favors lower radii of particles, as it is related to partial departure from the momentum conservation principle in a translation non-invariant nano-system with coupling in the near-field. The atomic scale limit of the latter effect gives pronounced enhancement of the interband transition probability due to allowing all indirect (with nonconserved momentum) transitions [1]. The effect is, however, strongly reduced with the growth of metallic nano-particle radius. Particularities of this dependence are analyzed, including various types of nanoparticles depositions on the photo-active layer. The other effect of plasmon radiation efficiency size dependence is analyzed also for larger metallic nanospheres (with radii beyond 50 nm for Au and Ag nanoparticles) when saturation of Lorentz friction is predicted and experimentally confirmed.

Au/TiO2 and Ag/TiO2 nanocomposites with high concentrated “hot spots” under near IR femtosecond pulsed excitation

A. Aiboushev, A. Astafiev, N.N. Semenov Institute of Chemical Physics (Russian Federation); Y. Lozovik, Institute of Spectroscopy (Russian Federation); O. M. Sarkisov, N.N. Semenov Institute of Chemical Physics (Russian Federation); V. Nadtochenko, N.N. Semenov Institute of Chemical Physics (Russian Federation) and Institute of Problems of Chemical Physics (Russian Federation)

Luminescence of gold and silver nanoparticles photodeposited on titanium dioxide mesoporous films was studied by multi-photon and near-field apertureless microscopy. Luminescence was registered under the multi-photon excitation by femtosecond pulses of Ti:sapphire laser. It was observed that Me/TiO2 (Me=Au, Ag) nanocomposites have high concentration (~10^5) of bright luminescence spots (“hot spots”) which reveal stability to degradation under long illumination. Moreover the most intense “hot spots” have luminescence enhancement of order of 10^5. Application of Me/TiO2 mesoporous films for Raman scattering spectroscopy was demonstrated for Rhodamine B molecules. Me nanoparticles configuration of “hot spot” was established by polarized multi-photon experiments and FDTD analysis. “Hot spots” luminescence enhancement analyzed by FDTD in terms of Me nanoparticles near-field enhancement coefficient at wavelength of excitation. It was shown that the highest enhancement coefficients are in near IR wavelengths for Me/TiO2 nanocomposites. Thus Me/TiO2 nanocomposites can be effectively used for near IR single molecule spectroscopy and biological objects visualization. Additionally various Me/substrate (Me=Au, Ag; substrate permittivity range: from 1 to 10) systems were analysed by FDTD to get the “best” substrate in terms of near-field enhancement coefficient for each wavelength of excitation.

Silver core-pectin shell nanoparticles on metal enhanced singlet oxygen generation

L. S. A. de Melo, A. S. L. Gomes, R. E. de Araujo, Univ. Federal de Pernambuco (Brazil)

The photosensitized production of singlet oxygen can induce cell death, and therefore be explored in several areas, such as Photodynamic Therapy (PDT). PDT is a photochemical process that has been use on cancer treatment, photorejuvenation, wrinkles, discoloration, fungal and bacterial infections. Photosensitizer molecules, as Riboflavin, can activate singlet oxygen generation by a triplet interaction with ground-state molecular oxygen. We demonstrate the potential application of

new monodispersive core-shell (Silver core-Pectin shell) nanoparticles on PDT. Here, localized Plasmon Resonance was explored improving PDT photosensitizer excitation process. Metal-enhanced singlet oxygen generation in Riboflavin-Silver colloid was observed. The developed Silver-Pectin nanoparticles consist of 13 nm Silver nanospheres involved by a 11 nm thicker monolayer of Pectin. Pectin, a complex carbohydrate found in plants primary cell walls, isolates the Silver nanosphere increasing the biocompatibility of the colloid. The nanoparticle-photosensitizer distance is an important parameter for the enhancement of singlet oxygen production. Therefore, the Riboflavin interaction with Silver nanospheres without Pectin shell was also analyzed. Both Riboflavin photosensitizer and Silver Localized Plasmon can be excited with a blue light. Blue LEDs were used to excite the colloid with Riboflavin. The singlet oxygen fluorescent sensor Green Reagent was used to monitor the singlet oxygen production in the colloid. We report a 1.8-fold increase in the Riboflavin emission and a 1.7-fold enhancement in singlet oxygen production.

Complete three-dimensional optical characterization of single gold nanorods

F. Wackenhut, Eberhard Karls Univ. Tübingen (Germany); A. V. Failla, Max-Planck-Institut für Entwicklungsbiologie (Germany) and Eberhard Karls Univ. Tübingen (Germany); T. Züchner, A. J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

We will show a powerful technique to fully characterize individual gold nanorods by using confocal microscopy in combination with higher order laser modes. We obtain topological information far beyond the optical diffraction limit. This achievement extends and completes what was previously shown using a 2D system. We demonstrate that it is possible to determine the orientation of gold nanorods by looking at their elastic and inelastic scattering patterns. This extents the results achieved already in [1] with high precision (i.e less than 1 degree for the in plane and about 5 degree for the out of plane angle) to a 3D system. On the other hand, we clearly show that this improved technique permits to detect local changes of the refractive index of the dielectric medium surrounding the particles. In order to extend the results already shown in [2] we applied this technique to a 3D system. More over the elastic scattering pattern is strongly dependent on the phase relation of the scattered and reflected light, while the inelastic scattering pattern does not depend on this phase relation. Thus, by measuring in-situ the elastic and inelastic scattering patterns, it is possible to gain additional information while measuring the 3D orientation. For example, when the distance of a particle to an interface changes, the phase relation changes and therefore the elastic scattering pattern is strongly influenced. This phase relationship can be also influenced by the aspect ratio of the particle. Thus by comparing elastic and inelastic scattering, one can determine either the distance from the interface or the aspect ratio of a single gold nanorod.

Controlling inter-nanoparticle coupling: Highly uniform SERS substrates of plasmonic colloids

N. Pazos-Perez, Univ. Bayreuth (Germany) and Univ. de Vigo (Spain); A. Schweikart, Univ. Bayreuth (Germany); R. A. Alvarez-Puebla, L. M. Liz-Marzan, Univ. de Vigo (Spain); A. Fery, Univ. Bayreuth (Germany)

Metallic nanoparticles and especially gold, are in the focus of interest because of their highly depend electric and optical properties on the specific particle size, shape, and surrounding environment. Therefore, they are ideal candidates for their potential use in microelectronic, optical, and biomedical applications. Thus, a big effort has been put in developing new methods which allow a fine control over the particle shape and size. These achievements allow us to fine tune the materials properties in order to use them for a desired application. However, the lack of capability to form organized structures is still a very important challenge in order to use these materials in many applications. In this work we report a novel method to structure, in a macroscale range, arrays of organized gold colloids into 1 and 2D linear parallel arrays which are highly uniform substrates for Surface Enhanced Raman Scattering (SERS). These structures were fabricated through self-assembly of gold nanoparticles upon solution-drying in a periodic confining structure. The technique leads to uniform, parallel linear nanoparticle arrays with the precise arrangement defined through the dimensions of the particles and the grooves. Moreover, the good reproducibility of these structures among big areas, make them perfect candidates as ultrasensitive substrates for SERS due to the controlled formation of arrays of hot spots. Which provide high and uniform SERS enhancement over extended areas. Furthermore, this method, is completely lithography-free so, low cost processing and allows tuneability of the width and spacing of the channels and consequently of the particle patterns between fractions of a micron and many micrometers. Characterization was done by means of transmission electron microscopy (TEM), scanning electron microscopy (SEM), atomic force microscopy (AFM), UV-vis, dark field, and SERS spectroscopy.

Selective plasmonic excitation of rotation-symmetric nanostructures

S. Jäger, M. Fleischer, K. Braun, D. P. Kern, A. J. Meixner, D. Zhang, Eberhard Karls Univ. Tübingen (Germany)

The plasmonic properties of nanostructures depend strongly on their size, shape and environment [1]. We investigated the plasmonic excitation of rotation-symmetric gold nano-post arrays fabricated on a Si wafer under different laser wavelengths and polarization conditions. Confocal optical microscopy and spectroscopy were performed by confocal optical microscopes using either parabolic mirror or an air-objective-lens for laser focusing and signal collection. Instead of using linearly polarized Gaussian beams, we used cylindrical vector beams to distinguish between different plasmonic modes. Our experiments demonstrated that radially polarized beam focusing by parabolic mirror excited the plasmonic modes along the z-direction of the nano-posts more effectively than by the objective-lens due to a dominant out-of-the-plane electric field. Azimuthally polarized beam focusing by either parabolic mirror or objective lens was effective to excite the circular plasmonic modes of the rotation-symmetric nanostructures. Spectroscopic investigations revealed that the two-photon photoluminescence intensity was an excellent indicator of the resonance excitation of the nano-structures [2]. In addition, a short excitation wavelength such as 514 nm was found to selectively excite the plasmonic modes along the circular rim of the posts, whilst the 633 nm excitation was more effective to excite the plasmonic modes along the z-direction of the posts. The capability of selective excitation of different plasmonic modes is important for optical sensor design based on metallic nanostructures.

Spectral dependence of the amplification factor in surface enhanced Raman scattering

A. Irrera, C. D'Andrea, B. Fazio, Istituto per i Processi Chimico-Fisici (Italy); P. Artoni, Univ. degli Studi di Catania (Italy); O. M. Maragò, M. A. Iatì, G. Calogero, P. G. Gucciardi, Istituto per i

Processi Chimico-Fisici (Italy)

Surface Enhanced Raman Scattering (SERS) is characterized by a strong signal amplification (up to 108-10) when both the excitation and the Raman photons frequencies match the localized plasmon resonances (LSPR) of the nanoparticles (NPs). In order to understand if the effective LSPR profile refers to the bare NPs or to the resonance of NPs "dressed" with the probe molecules, we perform multiwavelength (514nm, 633nm and 785nm) SERS experiments using evaporate gold NPs as SERS-active substrate on which we deposited Methylene Blue molecules (MB) that yields a resonance energy red-shift and a broadening of LSPR profile.

The SERS spectra at the investigated excitation wavelengths display a different intensity ratio of the characteristic MB band (peaks at 450 cm-1 and 1620 cm-1) with respect to the Raman counterpart. While at 515nm the 1620 cm-1 mode is more enhanced with respect to the peak at 450 cm-1, at 785 nm the opposite is observed. At 633 nm the two modes experience the same enhancement factor. This behavior is compatible with the hypothesis that the re-radiation enhancement factor is proportional to the LSPR of "dressed" NPs.

The results are, also, compared with experiments carried out on Mercaptopyridine and L-Tyrosine molecules that not affect the LSPR profile.

Laser induced photothermal aggregation of gold nanorods for SERS detection of biomolecules in liquid environment

A. Irrera, B. Fazio, C. D'andrea, V. Villari, N. Micali, O. M. Maragò, M. A. Iatì, M. G. Donato, G. Calogero, P. G. Gucciardi, Istituto per i Processi Chimico-Fisici (Italy)

Surface-Enhanced Raman Scattering (SERS) from isolated metal nanoparticles is usually much weaker compared to what is observed on aggregates due to the strong field enhancement occurring in the gap regions (hot spots) between adjacent nanoparticles [1]. The controlled creation of highly efficient hot spots in liquid (the natural habitat of biomolecules) is a challenge in which optical forces can play an important role by promoting the aggregation of metal nanoparticles in the focus of a laser beam (optical trapping) or their accumulation on a surface (by radiation pressure). Here we show that laser induced aggregation of gold nanorods in a buffered solution of Bovine Serum Albumin (BSA) leads to the formation of SERS-active agglomerates. Indeed, due to the blue shifted excitation (632.8 nm line of a He-Ne laser) with respect to their localized surface plasmon resonance (λ_{LSP} = 687 nm [2]) the gold nanorods are pushed by the radiation forces. Approaching the laser focus towards the bottom of the glass cell containing the solution, the optical forces and the involved thermal effects, make to aggregate such rods into highly efficient "hot spots" regions. This occurrence enables us to observe a strong SERS signal of BSA molecules staying in their proximity, with an enhancement factor of 105 allowing the detection of protein at concentrations as low as 10-7 M in its natural habitat.

Optical properties of metal coated nanoscrew Si

H. Jin, G. L. Liu, Univ. of Illinois at Urbana-Champaign (United States)

Optical properties of random nanoscale features provide applications such as light scattering in photovoltaics or surface enhanced Raman scattering (SERS) substrates for biosensing. Randomized nanostructures reduces the specular reflectance and in turn increases diffusive reflectance. Nanowire growth, chemical etching or RIE based random etch has been demonstrated to form such surfaces. Previously demonstrated work have produced nanoscale features that resemble nanowhiskers, porous surface, cones or straight pillars.

In this paper, a unique nanoscrew Si structure is presented. The nanoscrew surface is made by anodized aluminum oxide (AAO) mask formation followed by extended deep reactive ionic etching (DRIE). Dense random zig-zag pillar structures that represent screw shapes are formed, with 1 um in height and the bottom base width ranging from 100 nm to 250 nm. The tip of the nanoscrews have radius of curvature even lower than 10 nm. The apparent naked-eye view of the nanoscrew surface, which only consists of nanopatterned N-type single crystalline Si is diffusively green. The optical properties of nanoscrew Si with and without metal deposition is presented as discussion in applications for SERS.

Reshaping the fluorescence spectrum with random metal dielectric films

K. Seal, The Univ. of Tennessee (United States); X. Xu, Oak Ridge National Lab. (United States); Z. Zhang, Q. Li, The Univ. of Tennessee (United States); B. Gu, Y. Li, Oak Ridge National Lab. (United States); D. A. Genov, Louisiana Tech Univ. (United States)

The effects of metallic nanostructures on the emission of fluorophores result in a number of important effects, including increased photostability, fluorescence resonance energy transfer and directional emission. The complexity of fluorophore-metal interactions is influenced by the structure of the metal nanostructures, which governs their optical response. In disordered metallic nanostructures illuminated at visible and near-infrared frequencies, the optical response can involve localized and propagating surface plasmon modes which interact individually with the fluorophores. Specifically, semicontinuous metal films are characterized by broad absorption across the visible and near-infrared frequencies. This absorption spectrum can be controllably altered by effecting structural changes via a process called photomodification, wherein sufficiently intense coherent light at a specific frequency and polarization can be used to induce "holes" in the absorption spectrum. This tailoring of the optical response can in turn be used to alter the fluorescence spectrum in a controllable manner, with applications including bio-markers and sensing. In this study, semicontinuous films were photomodified to alter the absorption spectrum. Consequently, changes in the peak position and width were observed in the resulting emission from fluorophores placed in proximity to the metal films. The changes were sensitive to the polarization, incident angle and excitation frequency. Directionality was also observed in the fluorescent emission, indicative of surface plasmon coupled emission due to the effective dielectric response of the films. Theoretical calculations based on the finite difference frequency domain method show good correspondence with experimental data and provide a direction toward optimizing the photomodification process to effect sensitive changes to the fluorescence spectrum.

Subwavelength directional SPP couplers

A. Kriesch, Max Planck Institute for the Science of Light (Germany) and Erlangen Graduate School in Advanced Optical Technologies (Germany) and Friedrich-Alexander-Univ. of Erlangen-Nuernberg (Germany); J. Wen, Max Planck Institute for the Science of Light (Germany) and Friedrich-Alexander-Univ. of Erlangen-Nuernberg (Germany); D. Ploss, Max Planck Institute for the Science of Light (Germany) and Erlangen Graduate School in Advanced Optical Technologies (Germany) and Friedrich-Alexander-Univ. of Erlangen-Nuernberg (Germany); P.

Banzer, Max Planck Institute for the Science of Light (Germany) and Friedrich-Alexander-Univ. of Erlangen-Nuernberg (Germany); U. Peschel, Friedrich-Alexander-Univ. of Erlangen-Nuernberg (Germany)

Plasmonic gap-waveguides open up new dimensions for the manipulation of light on a subwavelength scale. Based on recent progress in fabrication technologies, the interest in highly integrated SPP components has grown substantially. A lot of attention has been attracted by subwavelength directional SPP couplers and waveguide loaded optical antennas; the first of which allow for connecting individual SPP transmission lines, the latter of which are used for probing sub wavelength circuitry from the far field.

Here we report on experiments, in which we investigated directional coupling between highly integrated adjacent SPP gap waveguides (~80nm gap width, ~15µm long, ~130nm pitch), in a broad wavelength range. Gap-waveguides are well known to allow for a further miniaturization compared to SPP stripe waveguides, due to their higher field confinement. Waveguides and connected plasmonic antennas were etched into plane silver films (~100 nm thickness) on a silica substrate using focused ion beam milling (FIB). For exciting the SPP waveguide, we optimized a plasmonic antenna for the NIR wavelength range of 1400 nm≤λ≤1700 nm, where losses are expected to be small.

In the presentation, we compare experimentally measured wavelength dependent coupling parameters with those, obtained from rigorous finite element method (FEM) and finite difference time domain (FDTD) calculations. We demonstrate that the concept of directional couplers, known from integrated optics, can be transferred to the nanoscale, thus enabling future nanoplasmonic circuitry. At the same time control of plasmonic coupling is a first step towards subwavelength discrete diffraction in larger arrays.

Cooperative infrared to visible upconversion and visible to near-infrared quantum cutting in Tb and Yb co-doped glass containing Ag nanoparticles

Z. Pan, G. Sekar, R. Akrobetu, R. Mu, S. H. Morgan, Fisk Univ. (United States)

Tb, Yb, and Ag co-doped glass nano-composites were synthesized in a glass matrix Li2O-LaF3-Al2O3-SiO2 (LLAS) by a melt-quench technique. Ag nanoparticles (NPs) were formed in the glass matrix and confirmed by optical absorption. Plasmon enhanced luminescence was observed. Cooperative infrared to visible upconversion and visible to near-infrared quantum cutting were studied for glass samples with different thermal annealing times. Because the Yb3+ emission at 940 - 1020 nm is matched well with the band gap of crystalline Si, the phosphors studied may be potentially applied for silicon-based solar cells.

Plasmon-based light enhancement from a hybrid copper-gold planar structure

M. S. Nawrocka, S. Shrestha, Adelphi Univ. (United States); R. R. Panepucci, Ctr. de Tecnologia da Informacao Renato Archer (Brazil)

For Raman and fluorescence spectroscopy, the ability to fabricate plasmonic nanostructures using readily available materials and processes offers remarkable advantage in the development of methods to characterize trace amounts of physical, chemical and biological substances. We report a novel configuration and an optical characterization of a copper-gold planar structure resulting in strong plasmonic enhancement of the electromagnetic field in the red region of the spectrum. The structure consists of aggregates of gold nanospheres (20 +/- 2) nm in diameter (dropped and dried from a colloidal solution) on a thin continuous copper film (50 +/- 20) nm thick (deposited on a silicon substrate using sputter deposition). We observed enhanced plasmon resonances with a peak at 665 nm and FWHM of 150 nm, measured from a light scattered from the structure using a dark-field reflection-mode microspectroscope. We attribute the strong field enhancement to the coupling of interparticle plasmon resonances from gold nanospheres to the surface plasmons induced in the copper film. Additionally, the high reflectivity of the copper layer reflects the portion of light that would otherwise be transmitted, thus increasing the collection efficiency of the scattered light. We achieved the homogeneity and planarity of the copper-gold structure through the electrostatic attraction between the negative surface charge of gold nanospheres and a lattice of positive ions of copper oxide, formed by ionic bonds during the exposure of copper to air. Such homogeneity and planarity cannot be achieved using gold and silver films that do not possess the lattice of ions and where the deposited nanospheres move towards the edge of the drop. We foresee that when integrated with easily available lasers emitting red wavelengths, the proposed copper-based nanostructure is a cost-effective step towards the development of lab-on-chips with applicability in public safety, global health-care, homeland security and defense.

Emission control with metallic hole arrays

R. J. Moerland, Aalto Univ. School of Science and Technology (Finland); L. K. Kuipers, FOM Institute for Atomic and Molecular Physics (Netherlands) and Univ. Twente (Netherlands); M. Kaivola, Aalto Univ. School of Science and Technology (Finland)

Adding holes in a periodic arrangement to metallic thin films greatly affects the optical properties of the metal film. The compound structure can exert a large influence on electromagnetic fields that interact with the hole array. Many parameters affect the actual response of the hole array, such as the periodicity, the size of the holes and their shape. We will show that, for a fixed periodicity and hole area, a change in aspect ratio of rectangular holes over a narrow range is sufficient to significantly alter the lifetime and far-field radiation patterns of a single emitter, e.g., a molecule, embedded in the central hole of a hole array. Due to the complexity of the geometry, analytical results are hard - if not impossible - to obtain. Therefore, an FDTD simulation scheme is used to obtain the evolution in time of the radiated fields by a single dipole, which models the emitter. By recording the electric field and current at the location of the dipole, the relative local density of states can be obtained after Fourier-transforming the fields. From the spatially Fourier-transformed time-harmonic near fields, far-field angular emission spectra are calculated, showing a strong dependence on the aspect ratio of the holes: the directionality of the emission is radically altered with increasing aspect ratio.

Growth of ultra thin silver films monitored by in situ spectroscopic ellipsometry during high power impulse magnetron sputtering

L. Sun, N. R. Murphy, Air Force Research Lab. (United States) and General Dynamics Information Technology (United States); A. R. Waite, Air Force Research Lab. (United States) and Universal Technology Corp. (United States); J. G. Jones, R. Jakubiak, Air Force Research Lab. (United States)

High precision in both film thickness and optical constant of ultra thin Ag films is crucial for their application in optical coatings and plasmonic metamaterials. For such applications, very thin layers of Ag must be used to minimize optical losses; however, it is difficult to make continuous Ag films that are less than 20 nm thick. Deposition of noble metals on oxides follows the Volmer-Weber island growth process with island formation

occurring at the initial stages followed by nucleation and coalescence. Below the coalescence threshold the optical dispersion does not follow that of bulk Ag, with both the index of refraction and extinction coefficient deviated in the visible wavelength region. Since island formation results from an imbalance in cohesive energies between adatoms within the film and atoms with the substrate, one way to decrease the adatom-adatom interaction is to use highly energetic deposition techniques such as high power impulse magnetron sputtering (HiPIMS). Coalescence thresholds of thin Ag films grown by DC magnetron sputtering and HiPIMS were determined using in situ spectroscopic ellipsometry (SE) during growth. With SE, the coalescence threshold was reached when the optical dispersion of the film matched that of the bulk Ag. The high degree of ionization and low deposition rate offered by HiPIMS resulted in increased film densities, refractive indices, lower coalescence thresholds and smoother film surfaces compared to those grown with DC magnetron sputtering.

Subradiant plasmonic fano resonances For ultrasensitive biomolecular detection

A. A. Yanik, A. E. Cetin, M. Huang, A. A. Artar, Boston Univ. (United States); S. H. Mousavi, A. B. Khanikaev, G. Shvets, The Univ. of Texas at Austin (United States); H. Altug, Boston Univ. (United States)

We introduce an ultrasensitive label free detection technique based on asymmetric Fano resonances in plasmonic band-gap devices with far reaching implications for real time biosensing and point-of-care diagnostics. By exploiting high quality factor (Qsolution~200) sub-radiant dark modes, we experimentally demonstrate record high figures of merits (FOM~162) for intrinsic detection limits. Our experimental record high sensitivities are attributed to the nearly complete suppression of the radiative losses that are made possible by the high structural quality of the fabricated devices as well as the sub-radiant nature of the resonances. To fabricate high optical quality sensors, we introduce a novel high-throughput nanofabrication technique with extremely uniform and precisely controlled nano-features. The demonstrated label free sensing platform offers unique opportunities for point-of-care diagnostics in resource poor settings by eliminating the need for labeling as well as mechanical and light isolation.

(United States)

Plasmon resonances in metal nanostructures depend strongly on the size, shape, composition, orientation and dielectric environment of the metal nanostructure. However, most metal nanostructures have been restricted to passive templates, with little dynamic tunability in the optical response. In the current experiment study, we demonstrate active control of the plasmonic response from Au nanostructures by the use of a novel multiferroic substrate -LuFe2O4 (LFO) - to tune the surface enhanced Raman scattering (SERS) response in real time. From both experiments and numerical simulations based on the finite-difference time-domain method, a threshold field is observed, above which the optical response of the metal nanostructure can be strongly altered through changes in the dielectric properties of LFO. This offers the potential of optimizing the SERS detection sensitivity in real-time as well as the unique functionality of detecting multiple species of Raman active molecules with the same template. We also observe evidence of interaction between the plasmon modes and polaron excitations that are inherent in multiferroic LFO. Our results indicate that the plasmons have a strong screening effect on the polarons which can be mediated by altering the dielectric response of LFO via external applied fields.

Tunability of plasmonic fano resonances in nanoparticle clusters

H. Sobhani, P. J. Nordlander, Rice Univ. (United States)

Fano resonances in strongly coupled metallic nanostructures such as Heterodimers,[1] Ring/Disk cavities,[2] Fanoshells, [3] Heptamer and Octamer clusters [4] enable highly efficient LSPR sensing due to their narrow linewidths. They are also of significant importance in plasmonic waveguiding and light harvesting applications such as photodiodes. In this talk, we describe how plasmonic Fano resonances can be moldeled using a combination of fully retarded electromagnetic simulation methods such as FDTD and FEM. We also discuss Fano resonance modeling using a simple intuitive harmonic oscillator model which expose the underlying physics, the interference between superradiant and subradiant collective plasmon modes.

Enhanced and suppressed transmission through metal gratings at the plasmonic band edges

M. Bloemer, U.S. Army Aviation and Missile Command (United States); D. de Ceglia, M. A. A. Vincenti, The AEgis Technologies Group, Inc. (United States); M. Scalora, U.S. Army Aviation and Missile Command (United States); N. Akozbek, The AEgis Technologies Group, Inc. (United States)

Extraordinary optical transmission through metallic gratings is mediated by Fabry-Perot cavity modes inside the apertures and surface waves propagating along the grating. Anomalous features arise in the grating transmission spectrum when the optical period for the surface wave is equal to the grating pitch. The surface waves can be plasmonic in nature or due to diffracted orders propagating parallel to the surface. At optical frequencies, plasmonic effects are well separated from Wood-Rayleigh anomalies. The plasmonic band gap properties were determined with COMSOL by propagating a plasmon on a smooth Ag surface followed with a section containing a series of air gaps. The reflection spectrum for the plasmons shows a well defined frequency gap for plasmon propagation. The COMSOL simulations for light transmitted through the grating reveal anomalies in the vicinity of the plasmonic band gap. At the center frequency of the gap where surface waves are forbidden, the transmission through the grating is very low and the reflection is 98%. Standing waves are formed at the band edges and the fields become localized. At the high energy band edge the electric field localizes in the low index medium and the magnetic field in the high index medium. The

field localization reverses at the low energy band edge. As a result of the localization at the band edges, the surface plasmons couple strongly to the Fabry-Perot cavity modes at the high energy band edge leading to enhanced transmission through the grating with the opposite properties for the low energy band edge.

Numerical investigation of the plasmonic properties of bare and cysteine-functionalized silver nanoparticles

M. Csete, A. Sipos, A. Szalai, E. Csapo, V. Hornok, I. Dekany, Univ. of Szeged (Hungary)

Theoretical and experimental studies were performed to develop silver nanoparticles (Ag NPs) based Localized Surface Plasmon Resonance sensor which can be used to determine the dependence of aggregation on pH and bio-molecule concentration, and to follow the aggregation kinetics based on spectral monitoring. The absorption spectra of different Ag NPs containing aqueous dispersions were numerically computed by Finite Element Method (FEM) applying the RF module of COMSOL software package, and compared to spectra determined by UV-Visible spectroscopy between 300 and 650 nm. This comparative study proved that the spectrum measured on citrate-stabilized bare Ag NPs aqueous dispersion with absorbance maximum at λmeas = 385 nm corresponds to the characteristic surface plasmon band of spherical Ag NPs with 8.25+/-1.5 nm diameter. The presence of aggregates in aqueous dispersions resulted in splitting on the spectrum, when the surface of the Ag NPs having a concentration of c_Ag = 2×10-4 M was functionalized with L-cysteine (Cys) having a concentration of c_Cys = 5.7×10-6 M. The FEM computation proved that the maximum at λmeas_1 = 390 nm corresponds to quadrupolar resonance, while the second maximum red-shifted to λmeas_2 = 574 nm and λmeas_2'= 625 nm originates from coupled dipolar plasmon resonances on extended aggregates at pH=2.98 and pH=4.92, respectively. The most simple aggregate-type that exhibits resonance at the measured absorptance maxima was determined by varying the number of Ag NPs, the thickness of the Cys shell, and the inter-particle distance in linear chains aligned along the E-field oscillation direction.

Resonance behaviour of gold nanoparticles: coupled plasmonic modes

A. Mahdavi, Erlangen Graduate School in Advanced Optical Technologies (Germany); E. Tatartschuk, Erlangen Graduate School in Advanced Optical Technologies (Germany) and Clemson Univ. (United States); E. Shamonina, Imperial College London (United Kingdom) and Erlangen Graduate School in Advanced Optical Technologies (SAOT) (Germany)

Metamaterials acquire their functionality from the structuring of the small building blocks, "artificial atoms". Understanding the nature of the resonance behaviour of unit cells is crucial for designing a structure with desired properties. In this paper we study the resonant behaviour of a variety of metallic nanoparticles in the region of hundreds of THz, including square-cross-section nanorods, nanoparticles of L, U and O shapes, and split rings with a variable gap size.

The split ring, the most prominent subwavelength resonator, can be described as an LC circuit. However, if it is miniaturized to be as small as several hundreds of nanometers, its resonant behavior does not just simply scale with the size. The resonance frequency saturates and the field modes change significantly. The effects that need to be incorporated here are those of kinetic inductance due to the inertia of the electrons and of plasmon-polaritons at the metal/dielectric interface noticeable as the surface plasma frequency is being approached.

For a better understanding of the resonant behavior of plasmonic nanoparticles we investigated standing wave patterns of surface plasmon polaritons on nanoparticles of different shapes. Our numerical results (CST Microwave Studio) suggest that the resonant behavior of each of these particles is similar to that of periodic arrays of nanorods with specific lengths and periodicities. For the first time to our knowledge, the interaction of the gap edges of a split ring, previously described in terms of the self-capacitance, has been interpreted in terms of coupled plasmonic modes.

Effective permittivity of concentrated random multiple component linear plasmonic composites

S. Wani, T. Cong, A. Sangani, R. Sureshkumar, Syracuse Univ. (United States)

Electromagnetic wave propagation in plasmonic media is of fundamental and practical interest. We present a new technique for calculating the effective medium properties of concentrated linear plasmonic composites containing multiple metallic (Ag, Au, Al and Cu) monodisperse spherical inclusions in a homogeneous absorbing matrix. The underlying physical motif was the separation of the space surrounding any inclusion into two regions, one immediately surrounding the particle with the properties of the matrix (the size of this region depends on the static structure factor) and an outer effective medium. Ensemble averaged Maxwell equations were derived for the system. Self consistent closure relations were found for the conditionally averaged fields by solving the vector Helmholtz equations for a layered sphere in an infinite matrix. In the quasi-static limit, predicted values of effective permittivity were in excellent agreement with those of Maxwell-Garnett theory. However, for large particle sizes and relatively high volumetric concentrations (~ 1%), the relationship between the concentration and the attenuation constant becomes nonlinear as evidenced by experimental measurements on Ag nanoparticle suspensions in ethylene glycol. Further, the resonance peak red shifted and broadened with increasing concentration.

Broad band, tunable super-lenses in the visible region of electromagnetic spectrum with metallodielectric stacks (MDS)

N. C. Katte, J. Haus, A. M. Sarangan, J. Gao, Univ. of Dayton (United States); R. Jakubiak, Air Force Research Lab. (United States); M. Scalora, U.S. Army Aviation and Missile Command (United States)

We compare the two main designs based upon combinations of Ag/GaP and Au/GaP, and calculate the super-resolving band widths. The super-resolving bandwidth of the Ag/GaP design is (520nm-560nm), while that of the Au/GaP design is (630nm-660nm). We evaluate these two designs in their ability to resolve two 20nm wide apertures separated by a center-to-center distance of 80nm. We also compare two numerical techniques, used to study these systems, namely the transfer matrix method (TMM) and the finite element method (FEM). The TMM is simple and provides a first evaluation of the samples' expected performance. The FEM technique is numerically more demanding, but it is more robust for determining super-resolution. Finally we discuss the practical limitations of our super-resolving imaging devices in resolving objects that are much smaller than the incident wavelength.

Tunable surface plasmon polaritons in Ag composite films by adding dielectrics or semiconductors

D. Lu, J. Kan, E. E. Fullerton, Z. Liu, Univ. of California, San Diego (United States)

Surface plasmon polaritons (SPPs) in metal films concentrate electromagnetic energy into subwavelength scale in the optical regime. Its unique properties enable light guiding and manipulation at the nanoscale, sub-diffraction-limited optical imaging, highly-sensitive biomolecular detection, highly efficient semiconductor light emissions, and enhanced solar energy utilization, etc. However, all these useful applications rely on the fixed SPP properties associated with existing materials, which on the other hand limit their capabilities to specific conditions. By adding a small percentage of SiO_2 or Si into pure Ag films, we recently demonstrate SPP properties of metal films can be well tuned. Those composite films are characterized by an oil-immersion optical microscope to obtain their angular resolved reflection spectra in the Fourier space for different wavelengths. The resonance position and bandwidth of SPPs in the composite films can be well predicted by an adopted phenomenological model after taking into account both the volumetric average of the permittivities of the mixed components and the size and interface effects. Their dispersion relations deviate from those of pure Ag films and have advantages to provide a larger SPP wave vector at longer wavelengthes. This type of tunable composite films serves as a promising alternative to current metals for broader working frequencies.

Metallic nanoshells with semiconductor cores: optical characteristics modified by core medium properties

N. K. Grady, Institute of Physics (China) and Rice Univ. (United States); R. Bardhan, Rice Univ. (United States); T. A. Ali, Institute of Physics (China); H. Xu, N. J. Halas, Rice Univ. (United States)

It is well-known that the geometry of a nanoshell controls the resonance frequencies of its plasmon modes; however, the properties of the core material also strongly influence its optical properties. Here we report the synthesis of Au nanoshells with semiconductor cores of cuprous oxide (Cu2O) and examine their optical characteristics. This material system allows us to systematically examine the role of core material on nanoshell optical properties, comparing Cu2O core nanoshells ($\varepsilon c = 7$) to lower core dielectric constant SiO2 core nanoshells ($\varepsilon c = 2$) and higher dielectric constant mixed valency iron oxide nanoshells ($\varepsilon c = 12$). Increasing the core dielectric constant increases nanoparticle absorption efficiency, reduces plasmon line width, modifies plasmon energies and changes which mode is “bright.” We show that these effects arise from realignment of the cavity and sphere plasmon energies, changing the composition of the hybridized nanoshell plasmons. Modifying the core medium provides an additional means of tailoring both the near- and far-field optical properties in this unique nanoparticle system.

Engineering dispersion in omnidirectional single-layer plasmonic metamaterials at visible frequencies

S. P. Burgos, R. M. Briggs, H. A. Atwater, California Institute of Technology (United States)

It has recently been shown that an array of coupled coaxial metal-dielectric-metal plasmonic waveguides can serve as a wide-angle polarization insensitive metamaterial with a tunable effective index response at visible frequencies. The metamaterial index is set by the antisymmetric mode index of the constituent plasmonic waveguides, which ranges from positive to negative values in the visible frequency spectrum as set by the surface plasmon resonance of the metal-dielectric material combination and the thickness of the dielectric channel slot.

Full-wave simulations and three-dimensional dispersion calculations are used to engineer the metamaterial dispersion. In-plane dispersion curves $\omega(kx,ky)$ show that the metamaterial has an isotropic response in the x-y plane as characterized by a hyperbolic band diagram. By matching this with the mode index dispersion of the coupled waveguide array $\omega(kz)$, we show that it is possible to access omnidirectional refractive indices ranging from negative ($neff = -2$) to positive values ($neff = 1$) in the $\lambda = 400–600nm$ freespace wavelength range. Further simulations investigate the structure’s imaging capabilities, and confirm the metamaterial omnidirectional response over the visible spectrum.

The metamaterial refractive index response is verified through Snell-Descartes refraction experiments conducted on a metamaterial slab composed of a close-packed hexagonal array of 25-nm thick Si annular apertures embedded in a 200-nm Ag film and cut at a 3º angle using focused ion-beam milling. The metamaterial effective index is measured for both s- and p-polarized waves at incident angles ranging from $\theta = 0–50º$, and the results verify the functionality of the design as a wide-angle polarization insensitive metamaterial at visible frequencies.

Plasmonic and photonic realizations of resonant guided wave networks

E. Feigenbaum, S. P. Burgos, R. M. Briggs, H. A. Atwater, California Institute of Technology (United States)

In the last two decades, plasmonics has become an important tool for designing the optical properties of complex media due to its ability to manipulate nanoscale light-matter interactions. Recently, we reported a new class of artificial photonic materials, called resonant guided wave networks (RGWNs), which define new directions in optical dispersion control. In a RGWN, localized waves resonate in closed paths throughout a network of waveguides connected by power splitting junctions, enabling wave dispersion that is dependent on the waveguide network layout. Control of the local wave interference allows for “programming” the network to achieve a desired photonic function.

Here we describe realizations of resonant guided wave networks: a two dimensional network of intersecting 200nm-wide plasmonic air channel waveguides in a Au matrix and a mesh of Si-based 500nm-wide photonic waveguides with careful designed power splitting elements introduced into their intersection junctions. In both cases, we couple λ=1500nm light using a grating into a Si-on-insulator ridge waveguide that is in turn end-coupled to the network inputs. We will present concept designs of waveguides profiles, power splitting elements, and waveguide terminations. We also compare and verify NSOM measurements of near-field interference patterns of various network designs with analytical network representations and FDTD numerical simulations. These results highlight the viability of the RGWN concept, and once again the powerful design capabilities facilitated by plasmonics.

Multiple fano resonances with hybridized metamaterials

A. A. Artar, A. A. Yanik, H. Altug, Boston Univ. (United States)

We experimentally and theoretically demonstrate a physical phenomenon that is used to obtain Fano resonances at multiple spectral positions by constructing a scalable metamaterial medium. This metamaterial system is formed by multiple layers of coupled meta-atoms, where each layer possesses radiant and subradiant modes. A strong near field coupling between the layers results in hybridized modes of the total structure, which are pulled to different resonant frequencies. These hybridized

modes of different decay characters interact through the structural asymmetry, giving rise to multiple Fano resonances. An analogy to the atomic physics concept of electromagnetically induced transparency is drawn, where the eigenstates of the three-dimensional metamaterial system can be modeled as multiple three-level systems. A theoretical perturbative model taking into account both the plasmon hybridization and subradiant-radiant mode coupling is presented to provide further insight to the behavior of the multi-layered metamaterial. For experimental demonstration of this novel phenomenon, we propose a lift-off free fabrication technique, which utilizes dielectric membranes as the building blocks. This fabrication scheme allows simultaneous patterning of multi-layered structures that are automatically registered in the third-dimension. Excellent agreement between simulated and experimental results is observed. The proposed multi-layered metamaterial can be used to enhance non-linear processes at multiple frequency domains opening up new possibilities in optical information processing.

PEDOT:PSS light sensor enhanced by localized surface plasomon of gold nano-partcles

S. Zeng, National Taiwan Univ. (Taiwan)

In this paper, we used PEDOT:PSS(Poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate)) as light sensing material with enhanced sensitivity by localized surface Plasmon resonance generated by gold nanoparticles. PEDOT:PSS was spin coated on ITO glass substrate and 120 nm of Al were evaporated above the PEDOT:PSS. The electrical properties of PEDOT:PSS was then enhanced after adding the gold nanoparticles between the ITO glass substrate and the film of PEDOT:PSS . We observed that the sample with gold nanoparticles has lower resistance when the samples were lighted. Compared with no illumination, the sample resistance (with naonparticles) decreased about 30%. This is not observed in the sample without gold nanoparticles. And when the density of the gold nanoparticles was increased, the total resistance of the sample was further decreased. When the sample with naonparticles was illuminated at different wavelengths , the total resistance of the sample was distinct. We measured the current intensity at 0.5 voltage at various wavelengths , and we can obtain that the current intensity correlate with the surface Plasmon resonance frequency of gold nanoparticles .

Size and periodicity effects of tuned extrordinary transmissinon through hole arrays in a Ag-Al2O3 metamaterial thin film

E. A. Ray, R. Lopez, The Univ. of North Carolina at Chapel Hill (United States)

We show the effects of hole shape, size, and periodicity variation on extraordinary transmission through a tuned metamaterial of 4 pairs of alternating layers of Ag-Al2O3 with 20 nm thicknesses. Transmission through cross or rectangular holes is shifted to the red by 200 nm from transmission through circular or square arrays with square arrays exhibiting a strong enhancement in the blue end of the spectrum. The advantage of a metamaterial over a Ag film of similar thickness is the tunability of the surface plasmons coupling k-vector. For the metamaterial, we are able to tune it to support surface plasmons from periodicities ranging from 130 nm to 215 nm, which effectively shifts the transmission peaks from the blue end of the spectrum in Ag films across the visible and into the red. With this adaptation, we can selectively tune the metamaterial or periodicity to exhibit enhanced transmission over a wide range of wavelengths in the visible. In a parallel vein, when the hole arrays are replaced by pillar arrays, we see the red shift more pronounced from the Ag film to the metamaterial in all shapes, and an asymmetric hole shape exhibits a 100 % increase in transmission from hole to pillar. For all shaped pillars, transmission is highest in the red end of the spectrum and exhibits a relatively small shift in transmission despite a 20 % increase in periodicity.

Mapping near-field coupling effects in infrared gap antennas

P. Alonso-Gonzalez, P. Albella, L. Arzubiaga, M. Schnell, J. Chen, F. Huth, F. Golmar, F. Casanova, L. Hueso, CIC nanoGUNE Consolider (Spain); J. Aizpurua, Centro de Fisica de Materiales (Spain); R. Hillenbrand, CIC nanoGUNE Consolider (Spain)

The vector near-field distribution of infrared gap antennas (linear dipole antennas coupled via a nanometric gap) is mapped by scattering-type scanning near-field microscopy (s-SNOM). The images provide direct experimental evidence of strong in-plane near-field localization inside a gap as small as 50 nm. By measuring the gap fields as a function of the total antenna length (near-field spectroscopy), we observe a clear resonance shift compared to uncoupled linear dipole antennas, thus verifying strong near-field coupling via the gap. We also find significant differences between near-field and far-field spectra of the antennas and discuss their implications.

Vector near-field imaging of the infrared antennas [1, 2] was carried out with s-SNOM where s-polarized laser light is used for antenna excitation. A dielectric Si tip scatters the local near fields of the antennas. Interferometric and polarization-resolved detection of the tip-scattered light yields amplitude E and phase ϕ of the in- (x) and out-of-plane (z) near-field components (Ex, ϕx) and (Ez, ϕz).

Fig. 1 shows the near-field patterns obtained for a single gap antenna with a gap width of about 50 nm. The out-of-plane near-field component (Ez, ϕz) shows large near-field amplitudes at both sides of the gap, while a phase jump of about 180° occurs at the gap center [3]. The in-plane near-field component (Ex, ϕx), in contrast, is strongly enhanced exactly inside the gap and directly verifies field concentration inside the gap.

To provide experimental evidence of near-field coupling in the infrared gap antennas, we perform near-field spectroscopy. We fabricate gap antennas of different total length (but constant gap size) and measure the in-plane gap field as a function of the antenna length. A comparison with near-field spectra of single dipole antennas (continuous nanorods) shows a pronounced resonance shift, which clearly verifies near-field coupling across the antenna gap.

Our results show that vector near-field mapping is a powerful tool for measuring spectral resonance shifts in the near field of infrared antennas, in both amplitude and phase. This enables detailed studies of near-field coupling signatures, including the mapping of strongly localized field enhancement (“hot spots”) and resonance shifts of near-field spectra, which are not accessible by far-field spectroscopy.

Generalized surface plasmon modes partially coherent

J. C. Juarez-Morales, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Elementary long-range plasmon modes are described assuming an exponential dependence of the refractive index in the neighbourhood of a conductive thin film. The study is performed using coupling mode theory. The interference between long-range plasmon modes allows the synthesis of surface sinusoidal plasmon modes which can be considered as generalized plasmon modes completely coherent. These sinusoidal plasmon modes are used for the synthesis of new surface plasmon modes partially coherent, which are obtained by means of an incoherent superposition of sinusoidal plasmon modes where each period is considered as a random variable. The kinds of surface modes generated have a profile easily tuneable which is controlled by means of

the probability density function associated to the period. The numerical simulation for sinusoidal, Bessel, Gaussian and dark hollow plasmon modes are presented.

Multipoles on crescent silver nanorod excited by light with different frequencies

S. Chen, C. Yue, W. Lin, Far East Univ. (Taiwan)

In this study, we numerically analyze the interaction of a crescent silver nanorod with polarized visible light, and some specific optical properties are demonstrated. Crescent nanorod is constructed from a cylinder by removing a smaller eccentric cylinder from it, thus, the thickness of the shell has a continuous variation. In comparison with a tube-like nanorod, crescent nanorod could provide a wider freedom to electromagnetic modes. For single frequency, the electric multipoles are different with frequency expectedly. And a strong intensity of surface plasmon polariton could stay inside the chamber of the nanorod only at the resonant frequencies. For continuous wave, the types of multipoles are important evidences in understanding the optical characteristics, though it is hard to be predicted. We are studying the possibility of Fano-like resonance in a crescent nanorod if the incident light includes two or more frequencies. Due to the gradual variation of the wall thickness, a Fano-like extinction spectrum might be obtained under some specific conditions.

Nanogap-engineerable Raman-active nanodumbbells for single-molecule detection

Y. D. Suh, Korea Research Institute of Chemical Technology (Korea, Republic of)

Surface-enhanced Raman scattering (SERS)-based signal amplification and detection methods using plasmonic nanostructures have been widely investigated for imaging and sensing applications. However, SERS-based molecule detection strategies have not been practically useful because there is no straightforward method to synthesize and characterize highly sensitive SERS-active nanostructures with sufficiently high yield and efficiency, which results in an extremely low cross-section area

in Raman sensing. Here, we report a high-yield synthetic method for SERS-active gold-silver core-shell nanodumbbells, where the gap between two nanoparticles and the Raman-dye position and environment can be engineered on the nanoscale.

Atomic-force-microscope-correlated nano-Raman measurements of individual dumbbell structures demonstrate that Raman signals can be repeatedly detected from single-DNA-tethered nanodumbbells. These programmed nanostructure fabrication and single-DNA detection strategies open avenues for the high-yield synthesis of optically active smart nanoparticles and structurally reproducible nanostructure-based single-molecule detection and bioassays.

Optical and electrical characterization of carbon nanotubes by terahertz spectroscopy: comparison between modeling and experimental results

E. Dadrasnia, H. Lamela, Univ. Carlos III de Madrid (Spain)

Electromagnetic terahertz (THz) radiation in frequency range of 0.3 to 10 THz is the next border in science and technology. The first THz-wave time-domain spectroscopy (THZ-TDS) was shown in the late 1990s (Ugawa, et al.,Physical Review B,60,1999, Kang, et al.,Physical Review B,75,2007, Parrott, et al.,Advanced Materials,21,2009). Following then, carbon nanotubes have been widely investigated to find their unique properties and structure in electronic and mechanic fields. Their structures and properties have been applied for enormous applications in photonic emission, scanning, microscopy and tuning fields (Dresselhaus, et al.,2001). The study of the plasma frequency of carbon nanotube films in high frequency range of THz-TDS is increasingly interested topic since the THz-TDS uses coherent electromagnetic pulse and does need the complicated numerical solution compared to Fourier transformation infrared (FTIR) (Kim, et al.,Journal of the Korean Physical Society,50,2007).

This paper studies about the optical and electrical properties of carbon nanotubes by utilizing THz electromagnetic wave spectroscopy. Absorption and dispersion of single-walled carbon nanotubes (SWNT) films are investigated by Terahertz time-domain spectroscopy (THz-TDS) in order to recognize the electrical and optical characteristics of carbon nanotubes of pure and F-doped single-walled carbon nanotubes in the frequency range of 0.2-3 THz. To fit well results based on the Jeon et al. (Journal of Applied Physics,98,2005) experimental setup, this study combines the Maxwell-Garnett with Drude models. It allows us to better understand a sequence numerical modelling of carbon nanotubes for different devices based on the experimental data.

This work is supported by MITEPHO project (http://www.uc3m.es/portal/page/portal/grupos_ investigacion/optoelectronics/european_projects/mitepho) which is coordinated by GOTL research group in Carlos III de Madrid University with foundation grant agreement number 238393 (EU-FP7) in order to develop compact tunable dual-mode diode lasers and terahertz spectroscopy in sensing and biomedical applications.

New laser optoacoustic spectroscopy (LOS) system to quantify gold nanoparticles in a liquid tissue phantom for biomedical applications

H. Lamela, V. Cunningham, D. C. Gallego, Univ. Carlos III de Madrid (Spain)

The increasing demand for new techniques to enhance the spectroscopic characterisation and optical contrast of in-vivo unhealthy tissue is at the forefront of new innovations in nanomedicine. Such novel optical based medical techniques can provide physiological definition, enhanced therapeutic efficiency and aid in early and effective diagnostic decisions. Targeted gold nanostructures are forming an integral part in solving current demands for biomedical applications, already providing numerous advances in fields of high sensitive diagnostic imaging (Eghtedari, et al.,Nano Letters,7,2007, Eghtedari, et al.,Nano Letters,9,2009), optical enhanced targeted drug delivery (Yih, et al.,Journal of Cellular Biochemistry,97,2006, Han, et al.,Angewandte Chemie-International Edition,45,2006) and localized cancer cell destruction by means of phototherapy (Rozanova, et al.,Science in China Series B-Chemistry,52,2009, Huang, et al.,Nanomedicine,2,2007). Knowledge of the optical properties of such nanostructures is vital for efficient medical procedures.

In this paper, a novel real-time Laser Optoacoustic Spectrometer (LOS) prototype which demonstrates the potential of the photon to ultrasound conversion, via optoacoustics, is presented and proven to be a valuable technique for characterisation of gold nanorod solutions within turbid media that mimics the optical properties of healthy soft tissue. This analysis has been motivated by the authors previous work in the field of nanoparticle concentration characterization at a single wavelength (532 nm) (Cunningham, et al.,Optics and Laser Technology,42,2010) and spectroscopic characterisation of spherical nanoparticles within the visible range from 410 to 650 nm (Lamela, et al.,Optics and Laser Technology,2010). In this paper real-time results from the LOS on an embedded gold nanorod colloidal solution are presented for the complete wavelength range from 410 nm to 1000. The optical source used is a Q-switched Nd:YAG pumped Optical Parametric Oscillator (OPO) controlled by specifically designed software. A comparative analysis of results obtained from a parallel reference measurement scheme,

based on standard collimated optical transmission and standard UV-VIS spectrophotometry will be provided.

Analyzing symmetry in photonic band structure of gyro-magnetic photonic crystals

S. Khorasani, A. Najafi, Sharif Univ. of Technology (Iran, Islamic Republic of)

In the band structure analysis of photonic crystals it is normally assumed that the full photonic gaps could be found by scanning high-symmetry paths along the edges of Irreducible Brillouin Zones (IBZ). We have recently shown [1] that this assumption is wrong in general for sufficiently symmetry breaking geometries, so that the IBZ is exactly half of the complete BZ. That minimal required symmetry arises from the requirement on time-reversal symmetry. In this paper we show that even that requirement might be broken by using gyro-magnetic materials in the compostion of photonic structures, under which the time-reversal symmetry no longer holds. As a result, for sufficiently asymmetric structures we can observe that the IBZ extends fully to the boundaries of the complete BZ, that is IBZ must be taken to be as the same as the BZ.

Surface enhanced coherent anti-Stokes Raman scattering on nanostructured gold surfaces

C. Steuwe, J. J. Baumberg, S. Mahajan, Univ. of Cambridge (United Kingdom)

In this paper, we demonstrate a novel method for combining plasmonic surface enhancement with Coherent anti-Stokes Raman Scattering (CARS) on gold sphere segment void substrates. We show that Surface-Enhanced CARS (SECARS) allows for a 10^5 enhancement within our nanostructures, which is a key approach towards reliable single molecule Raman spectroscopy.

Plasmonic enhancement of Raman scattering and fluorescence on surfaces has been a topic of strong interest over the last three decades. However, so far only a few attempts of plasmonic-enhanced nonlinear Raman scattering have been reported, on colloidal spheres [1]. Here colloidal-crystal templated electrodeposition is used to fabricate sphere segment void (SSV) substrates that show large, reproducible enhancements in surface-enhanced Raman spectroscopy (SERS) [2]. Since the plasmonic properties of nanostructures are extremely sensitive to geometry, it is possible to optimize the substrates for SERS by fine tuning the structural architecture. With these substrates, enhancement factors exceeding 10^6 in SERS have been shown [3]. Since CARS is a third-order effect, it overcomes the weak scattering cross section of spontaneous Raman scattering by coherently converting three photons of two different frequencies into an anti-Stokes photon. Hence, combining plasmonic enhancement and CARS gives rise to strong Raman scattering in SECARS.

Here we demonstrate SECARS of a monolayer of benzenethiol molecules on a plasmonic SSV substrate using a single laser approach (in combination with nonlinear wavelength conversion). SECARS spectra in presence of Raman active bonds coincide with spontaneous Raman spectra of the same sample.

We compare the SECARS enhancement to SERS and CARS on a variety of structures and show that the enhancement is strongly dependent on the structural geometry of the sample.

Broadband optical antenna with a disk structure

I. Wang, The Hong Kong Polytechnic Univ. (Hong Kong, China)

Broadband optical antennas are of interest as they can transmit more information like traditional microwave UWB antennas. This paper presents a design of broadband optical antennas with a concentric disk structure. An equivalent circuit for the optical antenna with a disk structure is introduced. The broadband radiation at optical frequencies was demonstrated via the computer simulation.

Investigation of cross-dipole metallic infrared frequency selective surfaces

J. Zhou, L. Wang, W. Zeng, Y. Y. Wang, Wuhan Univ. of Technology (China)

In this paper, we investigate cross-dipole infrared frequency selective surfaces using the finite element method (FEM). The Lorentz-Drude model is used to model the metallic film plasmonic effect at near infrared frequencies (1 -5 um). The transmission spectrum is obtained and compared to those without considering the plasmonic effect. The filter transmittivity and ohmic loss as a function of metallic film thickness are also studied. The results show that the plasmonic effect of metallic film reduces the filter transmittivity and shifts the resonant frequency to longer wavelength while the increased metal film thickness reduces both amplitude and bandwidth of the transmitted signal at infrared frequency.

Key words: cross-dipole, infrared frequency selective surfaces, finite element method, Lorentz-Drude model

Surface plasmon propagation and coupling in silver nanowires

Y. Peng, K. Kempa, Boston College (United States)

Nanowire plasmonics have attracted a lot of research attention recently [Takahara et al, 1997; Liu et al, 2008; Ma et al, 2010]. In our study, we simulate surface plasmons in nanowires using the FDTD method. We investigate the details of the surface plasmon propagation, including the dispersion, field profiles, and the material and radiative dumping. We also investigate the radiative emission from plasmons at nanowire ends, as well as the coupling of plasmons between nanowires. These results are compared with experiments, and are used to validate the idea of employing these nanowires as transmission lines in the discretely guided electromagnetic effective medium [Kempa et al, 2008]. These results could also be important to the nanocircuit design [Assefa et al, 2010], and in the field of the nanostructure fabrication [Nah et al, 2010].

Fabrication and test of an optical magnetic mirror

J. G. Hagopian, P. A. Roman, S. Shiri, E. J. Wollack, NASA Goddard Space Flight Ctr. (United States); M. Roy, U.S. Army Research Lab. (United States)

Traditional mirrors at optical wavelengths use thin metallized or dielectric layers of uniform thickness to approximate a perfect electric field boundary condition. The electron gas in such a mirror configuration oscillates in response to the incident photons and subsequently re-emit fields where the propagation and electric field vectors have been inverted and the phase of the incident magnetic field is preserved. The author suggested fabrication of sub-wavelength-scale conductive structures that could be used to interact with light at a nano-scale and enable synthesis of the desired perfect magnetic-field boundary condition. In a magnetic mirror, the interaction of light with the nanowires, dielectric layer and ground plate, inverts the magnetic field vector resulting in a 0 degree phase shift upon reflection. Geometries such as split ring resonators and sinusoidal conductive strips were subsequently shown to demonstrate magnetic mirror behavior in the microwave [1] and then in the visible [2]. Work to design, fabricate and test a magnetic mirror began in 2007 at the NASA Goddard Space Flight Center under an Internal Research and Development (IRAD) award. Our initial nanowire geometry was sinusoidal but orthogonally asymmetric in spatial frequency, which allowed clear indications of its behavior by polarization. We report on the fabrication steps and testing of magnetic mirrors using a phase shifting interferometer and optical imaging techniques.

Plasmons in nanoscale, metal junctions: optical rectification and thermometry (Keynote Presentation)

D. Natelson, D. R. Ward, Rice Univ. (United States); F. Heuser, F. Pauly, Karlsruher Institut für Technologie (Germany); J. C. Cuevas, Univ. Autónoma de Madrid (Spain); D. A. Corley, J. M. Tour, Rice Univ. (United States)

For more than 15 years, physicists (and chemists) have been able to perform experimental studies of electronic transport through single molecules in nanoscale junctions, looking at current as a function of voltage. These studies have revealed rich physics, including evidence for quantum entanglement (the Kondo effect) and inelastic processes involving vibrations. However, there are limits to how much one can learn from dc conduction. Fortunately, we have found that some of the same nanoscale metal structures used to perform the electronic measurements have tremendous utility in optical studies. Thanks to plasmons, the collective modes of the electronic fluid, these metal structures act like an optical antenna, channeling optical energy into and out of precisely the region of interest. We use simultaneous electronic transport and optical characterization measurements to reveal new information about electronic and optical processes in nanoscale junctions fabricated by electromigration. Comparing electronic tunneling and photocurrents allows us to infer the optical frequency potential difference produced by the plasmon response of the junction. Together with the measured tunneling conductance, we can then determine the locally enhanced electric field within the junction. In similar structures containing molecules, anti-Stokes and Stokes Raman emission allow us to infer the effective local vibrational and electronic temperatures as a function of DC current. This permits new fundamental studies of heating and dissipation at the nanometer scale.

Magnetic and fano resonance engineering with nanoscale plasmonic clusters

J. Fan, Harvard School of Engineering and Applied Sciences (United States); K. Bao, Rice Univ. (United States); C. Wu, Univ. of Texas (United States); J. Bao, Univ. of Houston (United States); V. Manoharan, Harvard School of Engineering and Applied Sciences (United States); N. J. Halas, P. J. Nordlander, Rice Univ. (United States); G. Shvets, Univ. of Texas at Austin (United States); F. Capasso, Harvard School of Engineering and Applied Sciences (United States)

Subwavelength metallic structures enable the broad manipulation of electromagnetic fields at the nanoscale due to their ability to support surface plasmons, which are oscillations of free electrons in metal that couple with the electromagnetic field. We show that clusters of strongly interacting metallic particles support a hierarchy of tunable plasmonic structures that exhibit strong electric, magnetic and Fano-like resonances. Two materials systems are discussed: lithographically defined metallic disk clusters and the self-assembled metal-dielectric colloidal clusters.

Magnetic dipole resonances are the basis for many types of metamaterials. We show that they are supported in close-packed arrangements of three nanoparticles, which can be characterized as closed loops of nanoinductors and nanocapacitors. Furthermore, magnetic resonators that are isotropic in three dimensions can be constructed with tetrahedral clusters, which can be viewed as a cluster of four trimers with varying spatial orientations. We experimentally verify magnetic resonances in trimer clusters and propose routes to the assembly of tetrahedral clusters.

Fano-like resonances result from the coherent coupling between a superradiant and subradiant plasmon mode, and they are characterized by a narrow minimum in the scattering spectra. We show that clusters of four and seven spheres exhibit strong Fano resonances that are, respectively, anisotropic and isotropic in the plane of the nanostructure. We also show that the Fano resonance can be broadly tailored by fabricating clusters comprising disks of varying size. Finally, we demonstrate that these structures are the basis for highly sensitive nanoscale localized surface plasmon resonance (LSPR) detection.

8096-63, Session 15

Ab initio engineering of fano resonances

B. Gallinet, O. J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Under certain conditions, the coupling between a bright (radiative) and a dark (non radiative) mode leads to the formation of asymmetric Fano resonances. Although Fano resonances are widely used in plasmonic nanostructures and metamaterials, how their shape is affected by the individual modes and their coupling is not yet well known. In this work, we pave the route towards the engineering of strong and spectrally sharp Fano resonances by building a link between the two classical oscillators' model, electrodynamics and the quantum theories of autoionization of Fano and Feshbach to describe the asymmetric resonance in terms of electromagnetic field configuration in plasmonic nanostructures. General conclusions for the determination of the resonance parameters are drawn, in particular on its width and asymmetry. Using a surface integral simulation technique for electromagnetic scattering on three-dimensional individual and periodic nanostructures, we investigate the resonance properties of each building block separately, in the near-field

and the far-field zones, to induce the properties of the coupled system. We numerically validate our model for structures that are currently under extensive investigation in the plasmonic and metamaterial communities. The insights into the physical comprehension of Fano resonances gained this way will be of great interest for the design of plasmonic sensing platforms and metamaterials.

8096-64, Session 15

Wide-angle spectrally selective plasmonic metamaterials for energy applications

G. Shvets, B. Neuner III, C. Wu, The Univ. of Texas at Austin (United States); S. Savoy, J. John, A. Milder, Nanohmics, Inc. (United States)

The infrared part of the spectrum is of particular interest for a broad range of applications, including thermal photovoltaics, thermal signature camouflage, and solar thermal applications. It is also a very appealing optical spectral range for plasmonic metamaterials because metallic losses are significantly lower in the infrared than in the visible part of the optical spectrum. I will describe the concept and the first experimental demonstration of a large-area spectrally-selective wide-angle infrared absorber based on a single-layer plasmonic metamaterial. This large-area structure is fabricated using the Nano Imprint Lithography (NIL) and tested using angle-resolved spectroscopy. By changing the dimensions and material composition of this metamaterial, we demonstrate the ability to control its spectral properties.

Angle-resolved spectroscopy of these structures reveals a wide-angle response, including complete absorption at the resonant frequency due to the excitation of the short-range plasmon. The short propagation length of the plasmon is used for engineering a more sophisticated (broadband) spectral response by designing sub-wavelength macro-cells consisting of several base unit cells.

We will also describe a simple design paradigm of engineering the spectral response of the macro-cell by analytically expressing its characteristic impedance in terms of the impedances of the base unit cells. Applications to thermal photovoltaics will be addressed by designing a plasmonic structure that compresses the broad solar spectrum into a spectrally-narrow infrared photons which are emitted with the peak emissivity approaching that of the black body.

8096-65, Session 16

Optical spin-Hall effects in plasmonics (Keynote Presentation)

E. Hasman, Technion-Israel Institute of Technology (Israel)

Spin-Hall effect is a basic phenomenon arising from the spin-orbit coupling of electrons. In particular, the spatial trajectory of the moving electrons is affected by their intrinsic angular momentum. The optical spin-Hall effect (OSHE) - beam deflection due to the optical spin (polarization helicity) - was recently presented. The effect was attributed to the optical spin-orbit interaction occurring when the light passes through an anisotropic and inhomogeneous medium. Here, we present and experimentally observe the OSHE in coupled localized plasmonic chains. The OSHE is due to the interaction between the optical spin and the path of the plasmonic chain with an isotropic plasmonic mode. In addition, OSHE was observed due to the interaction between the optical spin and the local anisotropy plasmonic mode, which is independent on the chain path. A spin-dependent orbital angular momentum was observed in a circular path. Moreover, a wavefront phase dislocation due to the scattering of surface plasmons from a topological defect is directly measured in the near-field by means of interference. The dislocation strength is shown to be equal to the incident optical spin and with analogy to the magnetic flux parameter in the Aharonov-Bohm effect. OSHE in spontaneous emission was also obtained in a structure consisting of a coupled thermal antenna array. The effect is due to a spin-orbit interaction resulting from the dynamics of the surface waves propagating along the structure whose local anisotropy axis is rotated in space. The OSHE in the nanoscale provides an additional degree of freedom in spin-based optics.

Plasmon propagation in gold and silver nanowires

M. A. Pelton, Argonne National Lab. (United States); B. Wild, L. Cao, Univ. of Chicago (United States); B. Khanal, Los Alamos National Lab. (United States); Y. Sun, Argonne National Lab. (United States); E. Zubarev, Rice Univ. (United States); S. Gray, Argonne National Lab. (United States); N. F. Scherer, Univ. of Chicago (United States)

Noble-metal nanowires can serve as plasmonic waveguides, efficiently transporting optical energy along the wire while confining electromagnetic fields laterally on dimensions much smaller than the diffraction limit. Nanoplasmonic waveguides fabricated using top-down lithographic methods suffer from significant losses due to scattering from edge roughness and grain boundaries. Chemically synthesized silver nanowires have been demonstrated to overcome this limitation. However, these structures have limited chemical and physical stability: they degrade in ambient environments, and they are easily damaged by intense radiation. We therefore investigate plasmon propagation in individual chemically synthesized gold nanowires and compare to propagation in silver nanowires. Propagation length is measured as a function of wavelength using a fluorescence-imaging technique, and group-velocity dispersion is measured using an interferometric spectroscopic technique. By comparing measurement results to electromagnetic simulations based on the finite-difference time-domain method, we find that plasmon propagation is determined by the intrinsic properties of the metal for both gold and silver wires. Although inherent absorption means that propagation lengths in gold are shorter than in silver, the greater stability of the gold wires opens up new scientific and technical possibilities, including detailed structural characterization using x-ray diffraction and nonlinear-optical effects at high field strengths.

Reversed diffraction laws and anomalous scaling properties in plasmonic systems.

G. Bartal, Technion-Israel Institute of Technology (Israel)

Periodic nanostructures made of metals and dielectrics have shown the ability to guide and transmit optical information much smaller than the wavelength of the carrier wave, overriding the fundamentals limits of diffraction. Owing to the plasma-like nature of the metallic constituents, manifested as negative dielectric function, these nano-structures enable the formation of surface plasmons on the metal-dielectric interfaces and exhibit strong mode confinement and anomalous propagation characteristics, such as negative refraction, anomalous diffraction and enhanced transmission through hole arrays. The strong metal dispersion, along with the loss inherent in such systems, also results in unique scaling of the diffraction and resolution properties with the wavelength which can even be opposite to those found in conventional dielectrics. We study those anomalous scaling phenomena in both resonant and non-resonant plasmonic nano-structures. We show how the resolution and diffraction in periodic metal-dielectric systems scale anomalously with the wavelengths, where longer wavelengths exhibit better resolution power and weaker diffraction - opposite to those found in conventional dielectrics. Likewise, resonant plasmonic systems like silver superlens also show interesting scaling properties where the angular frequency spectrum of a thin silver slab sandwiched between dielectric layers scales in a super-linear manner with the refractive index of the dielectrics, comparing to linear scaling of the dielectric media alone.

Plasmonic logic gates and devices in silver nanowire networks (Keynote Presentation)

H. Xu, Institute of Physics (China)

Here we show that the local electric field distribution of propagating SPs along Ag NWs can be imaged by coating the NWs with a layer of quantum dots. In Ag NW networks of simple geometries, plasmons launched along a NW can be controllably routed to a specific NW output. The underlying physical mechanism, interference between SPs launched at different positions along a primary NW, is clearly observable, as is the detailed evolution of the plasmon field along the device. The addition of a second plasmon input makes it possible to turn on or off emission paths, resulting in combinations of optical signals that execute specific interferometric Boolean logic operations. This primary NW can thus be viewed as the plasmonic equivalent of a bus in a central processing unit. By loading the primary NW with plasmons launched with specific input properties at the secondary input NWs, the resulting plasmonic interference enables routing and out-coupling to specific output NWs. We believe this concept can be further generalized and expanded to more complex structures that can combine optical signals in various ways, and that a multiple-input, multiple-output plasmonic bus may serve as an efficient splitter, router, switcher and/or multiplexer in future complex plasmonic networks designed for computation and information processing functions. These findings shed new light onto both fundamental understanding of propagating plasmons in complex networks and may advance the development of integrated plasmonic devices for new generation information technologies.

8096-70, Session 16

Localized field enhancements in two-dimensional V-groove metal arrays

J. Beermann, S. M. Novikov, Univ. of Southern Denmark (Denmark); T. Søndergaard, J. Rafaelsen, K. Pedersen, Aalborg Univ. (Denmark); S. I. Bozhevolnyi, Univ. of Southern Denmark (Denmark)

We investigate field enhancements in two-dimensional 800-nm-periodic arrays of (108 - 121 nm deep) V-grooves (opening angles 38 -75 degrees) fabricated using focused ion beam milling in a 190 nm thick gold film on top of a fused silica substrate. Simulated and experimental reflection spectra, high-resolution two-photon luminescence (TPL) images, and microscopy of surface enhanced Raman scattering (SERS) obtained from the V-groove metal arrays are compared revealing good correspondence in the spectral dependences of reflection and local TPL as well as SERS measured at the groove bottom. We relate the obtained field intensity enhancements reaching 85 with nanofocusing and resonant interference of counter-propagating plasmons by the periodic closed tapered groove gaps. We discuss the complementarities of the TPL and SERS techniques used for estimating the relative field intensity enhancement in the nanostructures, i.e., TPL signals originating from inside the metal compared to SERS originating from Raman active molecules adsorbed at the metal surface. The achieved reflection spectra and enhancements depend on the geometry of the V-groove arrays and can actually be tuned in the wavelength range from visible to infrared, making this configuration promising for a wide range of practical applications, e.g., within surface-enhanced spectroscopies.

8096-71, Session 17

Biosensing based on plasmon resonance energy transfer (PRET)

S. Dutta Gupta, G. Suarez, C. Santschi, O. J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

In 2009, Choi et al. introduced the concept of plasmon resonance energy transfer (PRET, Nano Letters vol. 9, p. 85, 2009) to enhance the absorption of cytochrome c for measuring oxidative stress in living cells. In this contribution, we study in detail both theoretically and experimentally the conditions under which strong coupling can exist between cytochrome c and plasmon nanoparticles. By monitoring the optical absorption of cytochrome c, we introduce a non-invasive way of monitoring the release of oxidative stress, which plays a complex and multifaceted role in cell physiology. Such oxidative stress occurs for example when cells are exposed to toxic agents. The technique is extremely sensitive and enables measuring hydrogen peroxide released by micro-organisms with an unprecedented sensitivity. The versatility of this approach is illustrated by two series of experiments on aquatic micro-organisms and on cancerous cells. For aquatic micro-organism, the ability to monitor PRET over long periods provides insights into the relation between toxicity and photosynthesis. The proposed scheme is not limited to cytochrome c and detection of reactive oxygen species, but can also find a broad range of applications in strongly coupled bio-plasmonic system, such as for example oxygen sensing using hemoglobin.

8096-72, Session 17

Design of hybrid plasmonic materials for SERS direct and indirect sensing

R. A. Alvarez-Puebla, Univ. de Vigo (Spain)

Surface-enhanced Raman scattering (SERS) is gaining prominence as an ultrasensitive and ultrarapid detection technique. In the recent years many applications involving both direct and indirect sensing has been developed in biomedicine, biolabelling, medical imaging, multiplex high-throughput screening, pollutant monitoring or molecular and material characterization. Notwithstanding, several aspects such as colloidal stability, plasmon tunability, detection of molecular species with low affinity for gold or silver surfaces, low SERS cross-sections of aliphatic molecules or transition metals detection are still challenging. Here we demonstrate how the rational design in materials from controlling shape, size and composition of the initial colloidal nanoparticles, that will act as optical enhancers, to their integration into hybrid materials for advanced sensing, may resolve most of those SERS shortcomings.1-5 Furthermore we disuse the advantages or disadvantages of the different SERS approaches (direct sensing with single particles, generation of hot spots and indirect sensing with biological interfaces and encoded nanoparticles) to the different analytical and bioanalytical problems.

Experimental demonstration of n=0 in metal-insulator-metal waveguides at cutoff

E. J. R. Vesseur, T. Coenen, FOM Institute for Atomic and Molecular Physics (Netherlands); N. Engheta, Univ. of Pennsylvania (United States); A. Polman, FOM Institute for Atomic and Molecular Physics (Netherlands)

The spatial advance of the phase of light is controlled by the refractive index, essential to many if not all optical applications. Surface plasmons enable a strong modification of the dispersion of light, allowing to taylor effective refractive indices that are very large or even negative. A special case occurs when the refractive index reaches a value close to 0. This condition can be met in waveguides near cutoff, which was experimentally demonstrated in the microwave regime and was also predicted for plasmonic waveguides. So far, it was impossible to reach this condition at visible wavelengths due to limitations in nanofabrication and the difficulty of probing the n = 0 condition in a buried waveguide.

Here, we present a metal-insulator-metal plasmon waveguide that shows an effective n = 0 at cutoff. Waveguides with accurately controlled dimensions were fabricated using a sequence of steps including focused ion beam milling. Modes of the waveguides were excited using a 30 keV electron beam penetrating through the layer stack. By collecting the emitted radiation as a function of electron beam position we directly observe the spatial mode profiles and determine the dispersion relation of plasmon modes near cutoff. At cutoff, the enhanced density of optical states is directly observed from a peak in the electron-beam induced emission spectrum.

Conference 8097: Optical Trapping and Optical Micromanipulation VIII

Sunday-Thursday 21-25 August 2011 • Part of Proceedings of SPIE Vol. 8097
Optical Trapping and Optical Micromanipulation VIII

8097-01, Session 1

iTweezers: from toy to tool

R. W. Bowman, G. M. Gibson, Univ. of Glasgow (United Kingdom); D. M. Carberry, L. Picco, M. J. Miles, Univ. of Bristol (United Kingdom); M. J. Padgett, Univ. of Glasgow (United Kingdom)

Holographic optical tweezers are fast becoming an established tool in micro- and nano-science. We present developments in both the interface and the underlying technology as used in our lab, along with some of the uses we have put them to. Real time particle tracking from stereoscopic video images enables us to determine position to nanometre precision in 3D. This can be performed in real time at several kHz, allowing us to position-clamp trapped objects in 3D and measure positions and forces with optically controlled tools. Our multi-touch iPad interface gives interactive control over multiple traps at the same time, which opens new possibilities for controlling tools, structures and other dynamic processes.

8097-02, Session 1

Profile measurement using standing wave trapping

T. Washitani, M. Michihata, T. Hayashi, Y. Takaya, Osaka Univ. (Japan)

We proposed a new measurement technique for surface profile using the standing wave trapping in air condition. The high-accuracy scale and the high-sensitive sensor are required in the profile measurement. In our measurement system, the optical trapping particle is used as the sensor. The standing wave pattern is used as the measurement scale, which has wavelength-determined interference pitch (λ/2). Therefore, this measurement technique is expected to perform the high-accuracy measurement. It was experimentally found that the vertical measurement range is about 250 μm. The uncertainly of the sensor is ±λ/100. Thus, this technique is capable of measuring large objects in height. When measuring the continuous surface, the sensor particle is scanned in the horizontal direction above the measured surface. The trapped sensor particle in the standing wave field axially moves to follow the measured surface topography. The particle jumps when the surface profile exceeds the pitch of the standing wave pattern. Therefore, the surface profile can be calculated based on the measurement of the particle motional variation. At first, we realized to measure the smooth surface profile such as micro-lens. As pre-measurement, the dependency of the scale pitch on measured surface angles was investigated. A micro-lens was measured with the angle dependency correction. This shows the improvement of the measurement accuracy. When measuring the discontinuous surface, the sensor particle is scanned in the vertical direction on the measured surface. Cross-correlation of sensor signals reveals the step height distance of the discontinuous surface.

8097-03, Session 1

Surface imaging of biological samples using holographic optical tweezers

D. B. Phillips, J. A. Grieve, S. Olof, S. Kocher, Univ. of Bristol (United Kingdom); R. W. Bowman, M. J. Padgett, Univ. of Glasgow (United Kingdom); M. J. Miles, D. M. Carberry, Univ. of Bristol (United Kingdom)

We present an imaging technique using an optically trapped cigar-shaped probe controlled using holographic optical tweezers. The probe is raster scanned over a surface, allowing an image to be taken in a manner analogous to scanning probe microscopy (SPM), with automatic feedback control provided by analysis of the probe position recorded using a high speed CMOS camera. The probe is held using two optical traps centred at least 10μm from the ends, minimising laser illumination of the tip, so lowering the chance of optical damage to delicate samples. The technique imparts less force on samples than contact SPM techniques, and allows highly curved and strongly scattering sample to be imaged, which present difficulties for imaging using photonic force microscopy. To calibrate our technique, we first image a known sample - the interface between two 8μm diameter polystyrene beads. We then demonstrate the advantages of this technique by imaging the surface of the soft algae Pseudopediastrum. The scattering force of our laser applied directly onto this sample is enough to remove it from the surface, however we can use our technique to image the algae surface with minimal disruption while it is alive, un-adhered and in physiological conditions. The resolution is currently equivalent to confocal microscopy, but as our technique is not diffraction limited, there is scope for significant improvement by reducing the tip diameter and limiting the thermal motion of the probe.

8097-05, Session 1

Back-focal-plane interferometry: position or force detection?

A. Farré, M. Montes-Usategui, Univ. de Barcelona (Spain)

After an intense development of optical tweezers as a biophysical tool during the last decades, quantitative experiments in living cells have not found in this technique its best ally, mainly due to the lack of a reliable method to measure forces in complex environments. The detection of forces is usually carried out in an indirect manner, through the measurement of the sample position in the trap. However, this method depends critically on the experimental conditions. The attempts to overcome this problem either require complicated in situ calibrations, which make their use impossible in the study of dynamic processes, or they are inaccurate. Using a different approach, Smith et al. developed a method based on the direct measurement of the momentum change of the trapping beam, but its diffusion has been modest mainly because it requires a counter-propagating optical trapping system, which is difficult to implement and combine with other techniques. Although it has not been used for this purpose yet, it seems a more suitable method for in vivo experiments since the measurement depends only on some properties of the sensor apparatus but not on the experiment itself. Recently, we showed that this method can also be used in single-beam traps. Here, we provide further evidence of this and, more importantly, we show that this method is essentially equivalent to back-focal-plane interferometry with some specific restrictions on the force sensor system. An important implication is, as we will show with some examples, that the signal recorded with back-focal-plane interferometry can be used to directly track forces inside living cells.

Three dimensional force and torque transduction with holographic optical tweezers: calibration techniques and experimental realisation

J. A. Grieve, S. H. Simpson, D. B. Phillips, S. Hanna, Univ. of Bristol (United Kingdom); R. W. Bowman, G. M. Gibson, M. J. Padgett, Univ. of Glasgow (United Kingdom); M. J. Miles, D. M.

Carberry, Univ. of Bristol (United Kingdom)

Mechanical microtools that are actuated with holographic optical tweezers exhibit many differences to traditional microspheres. Calibration of these tools can prove to be a challenge, and the often used power spectral density technique cannot be fit accurately due to the presence of six corner frequencies. In this talk we explain the intricacies of calibrating any rigid 3D structure, demonstrate three dimensional control of them, and the measurement of all six degrees of freedom. This is achieved by utilising a stereoscopic imaging system to produce precise, three dimensional CCD tracking of the tools, leading to the calibration of the full 6x6 stiffness matrix. In an experimental setting we further demonstrate concurrent force and torque curves obtained by interacting samples with our microtools, along with discussion on the sensitivity and accuracy which may be obtained.

8097-07, Session 2

Hydrodynamic synchronization of light driven propellers

R. Di Leonardo, Univ. degli Studi di Roma La Sapienza (Italy); A. Buzas, L. Kelemen, G. Vizsnyiczai, L. Oroszi, P. Ormos, Biological Research Ctr. (Hungary)

Hydrodynamic interactions are believed to be responsible for the coordinated motion of cilia and flagella in motile microorganisms. Very recently numerical simulations and macroscopic experiments have began to provide insights in this phenomenon of hydrodynamic synchronization. We investigate a simple microscopic system of independently light driven propellers coupled by hydrodynamic interactions. Microscopic propellers are fabricated by using two photon polymerization while holographic optical tweezers are used to trap and drive them by radiation pressure. Hydrodynamic synchronization is clearly observed when the applied optical torques are finely tuned and disappears progressively as the two propellers are brought far apart. Due to the unavoidable presence of noise in any micron sized system, we discuss hydrodynamic synchronization as a stochastic phenomenon.

8097-08, Session 2

A microsyringe contolled using a triple beam optical trap

W. T. Ramsay, M. Bechu, L. Paterson, Heriot-Watt Univ. (United Kingdom)

A limited range of instruments are available which allow the controlled injection of sub-picoliter volumes; cumbersome, commercially produced mechanical microinjection systems and microfluidic, lab-on-a-chip devices account for the majority. We present an optically controlled microsyringe capable of dispensing femtolitres of liquid. Triple beam optical tweezers are used to manipulate hollow glass microneedles and also polymer microspheres which were used as ‘handles’ to assist the manipulation of microneedles and ‘plungers’ to dispense liquid from the microneedle.

Standard optical tweezers were used with the addition of a Ronchi ruling (250 lines per inch) mounted in the image relay telescope. The diffraction pattern generated by the Ronchi ruling produced three optical traps in the sample chamber. Trap spacing was controlled by translating the ruling along the axis of beam propagation within the image relay telescope.

Utilizing the three-beam trap, it was possible to manipulate pulled, borosilicate capillaries (5-50µm in length, 1-5µm in diameter) both perpendicular and parallel to the axis of the capillary. Rolled SO/SO2 microtubes (4µm diameter, 50µm long) were also manipulated, however in this case polymer microspheres were used as ‘handles’. In both cases the microneedles did not align vertically along the propagation axis; an advantage over using a single beam optical trap. Tweezing a microsphere within a microneedle dispenses femtolitres of liquid from the needle. The force exerted on microneedles is calculated to be in the order of picoNewtons so may have applications where femtolitre volumes must be controllably delivered beyond a barrier, such as single cell microinjection.

8097-09, Session 2

Fast optical force based cell sorter assisted with CUDA and computer vision techniques

G. Xu, W. Qin, N. L. Johnson, Z. Ma, Clemson Univ. (United States); X. Peng, Shenzhen Univ. (China); B. Z. Gao, Clemson Univ. (United States)

Optical force and microfludics based cell sorting is a newly developed cell manipulation technique. It is non-invasive and easy to control comparing with conventional flow cytometry methods. We investigate a novel high speed, computer vision assisted cell sorting device that utilizes the optical force generated by a weakly focused laser beam to move individual cells and direct cell separation in a microfludics system. This paper focus on the computer vision based detecting cell, tracking cell position, and estimating moving speed, which are the core of the cell sorting components. In order to distinguish cells by their size and moving speed that indicates cells’ physiological characteristics, high speed computer-vision techniques are first introduced. We use sobel edge detector to find potential edges of moving objects (cells or other noises) in each video frame captured by a high speed camera first. Then Hough transform (HT) is used to calculate parameters (center and radius) of the real moving cell’s contour. Finally particle filter (PF) is selected to realize cell tracking and its speed measurement. Because HT and PF are all time consuming, in our study we use CUDA compatible GPU-Tesla 1060 and Quadro FX 1800 and program on it to implement real-time processing. The experimental results show that this method can track five to nine cells at approximately 130 to 170 frames per second. The signals from the imaging system are used to trigger a laser beam to laterally move the cells in the microfluidic channel to achieve cell separation.

8097-10, Session 2

Active matter on asymmetric substrates

C. J. Olson Reichhardt, J. Drocco, T. Mai, C. M. Reichhardt, Los Alamos National Lab. (United States)

We investigate the dynamics of self-driven particles on symmetric and asymmetric substrates. This system could be realized using self-driven colloids on optical traps or swimming microorganisms such as bacteria in microstructures. In an asymmetric array of funnel-shaped barriers, particles that undergo only Brownian motion experience no net flow; however, if the particles are undergoing run and tumble type dynamics we find a net flow of particles or a ratchet effect. We investigate the effect of different particle dynamics on the ratchet effect. For example, if the particles reorient to follow the barrier walls they encounter, we observe a ratchet effect; however, if the particles reflect or scatter off the barrier walls, the rectification is reversed or destroyed. We also consider particle-particle interactions which can either promote or decrease the ratchet effect in accordance with different rules. In certain swarming moddles the ratchet effect can even be reduced.

8097-11, Session 3

Direct force and ionic-current measurements on DNA in a nanocapillary

O. Otto, L. J. Steinbock, R. Skarstam, J. L. Gornall, U. F. Keyser, Univ. of Cambridge (United Kingdom)

We demonstrate for the first time combined optical tweezers and ionic-current measurements in which the nanopore is located perpendicular to the trapping laser. Traditionally, quadrant photo-detectors are used to measure the displacement of a trapped colloid while the attached DNA is

pulled into a silicon nitride nanopore [1,2]. High-speed video cameras in combination with glass nanocapillaries offer an alternative [3,4]. We apply novel optical fiber illumination for real-time tracking of optically trapped colloids on a microsecond time scale. Using a cross-correlation based algorithm after image acquisition from a CMOS camera we are able to measure the position of a colloid at rates up to 10,000 frames per second over hours [5].

A complete understanding of polyelectrolyte kinetics in strongly confined environments like nanopores or nanocapillaries is still elusive. In order to gain new insight we perform electrophoretic force and ionic-current measurements on single and multiple DNA molecules inside the orifice of a nanocapillary and attached to an optically trapped colloid [6]. We quantitatively model our findings with a combined Poisson-Boltzmann and Stokes-Equation approach and show that our results are in good agreement with data obtained for Si3N4 nanopores [2].

8097-12, Session 3

Sequence dependent effect on DNA elasticity

K. Raghunathan, J. Milstein, Univ. of Michigan (United States); Y. Chen, Cornell Univ. (United States); J. D. Meiners, Univ. of Michigan (United States)

We have used constant force axial optical tweezers to understand the subtle effects of DNA sequence variations on its mechanical properties. Sequence variations in the DNA can affect two fundamental properties, namely the intrinsic curvature and the elasticity of the molecule. To delineate the effects of curvature from elasticity, we have designed sequences of DNA which have nearly identical curvatures but varied AT content and measured their elasticity. We have verified the similarity of curvatures of these sequences computationally and using polyacrylamide gels. Our experiments have shown that the persistence length is highly dependent on the elasticity of DNA; in fact it varied almost two fold between sequences containing 67% AT and 40% AT content region. Thus, the cost of bending a GC rich region of the DNA is energetically much costly compared to an AT rich sequence. The biological implications of this may be substantial, as the need to bend DNA is involved in a host of regulatory schemes, ranging from nucleosome positioning to the formation of protein-mediated repressor and enhancer loops.

8097-13, Session 3

Laser microbeam - kinetic studies combined with molecule - structures reveal mechanisms of DNA repair

B. Altenberg, European Molecular Biology Lab. (Germany); P. Grigaravicius, Deutsches Krebsforschungszentrum DKFZ (Germany); K. O. Greulich, Fritz Lipmann Institute (Germany)

Kinetic studies on double strand DNA damages induced by a laser microbeam have allowed a precise definition of the temporal order of recruitment of repair molecules. The order is Ku70/80 - XRCC4 --- NBS1 --- Rad 51. Ku70/80 and XRCC4 molecules represent the inaccurate NHEJ pathway, NBS1 a switch and Rad51 the almost error free HRR pathway, These kinetic studies are now complemented by studies on molecular structures of the repair proteins, using the program YASARA which does not only give molecular structures but also physicochemical details on forces involved in binding processes. It turns out that the earliest of these repair proteins, the Ku70/80 dimer, has a hole with high DNA affinity. The next molecule, XRCC4, has a body with two arms, the latter wth extremely high DNA affinity at their ends and a binding site for Ligase 4. Together with the laser microbeam results this provides a detailed view on the early steps of DNA double strand break repair.The sequence of DNA repair events is presented as a movie.

8097-14, Session 3

Ultrafast Imaging of Microbubble Cavitation using Integrated Optical Trapping for Spatial Control: Progress and Prospects

P. A. Campbell, Univ. of Dundee (United Kingdom)

Cavitation, which involves the formation and dynamic evolution of bubbles, is a ubiquitous phenomenon in fluids.

Recently, the area has received heightened interest in medical contexts due to the utility of [shelled] bubbles for exploitation both as contrast agents for clinical diagnostic ultrasound imaging, and increasingly, for their emerging potential as microscopic drug delivery systems. Micrometer-sized bubbles [microbubbles (μBs)] are most clinically relevant as their small size allows them to flow easily within even the smallest vessels of the vascular system. This size constraint results in bubble resonant frequencies lying in the MHz range, and in turn, requires [ultrasonic] driving frequencies in a comparable range. Accurate monitoring of μB response at sampling rates greater than the Nyquist limit thus requires the use of ultra-high speed microphotography. Moreover, in order to develop a fundamental understanding of bubble behavior over a range of clinically relevant scenarios, it is imperative that spatial control be exercised over their whereabouts relative to any proximal surfaces, and indeed, to other bubbles, so that the effects of any boundary constraints and acoustic cross-talk can be discriminated. Only one technique can be applied readily to this situation, that neither interferes with the incident ultrasound wave, nor perturbs any resultant hydrodynamical response in the surrounding fluid: that technique is optical trapping.

Interestingly, the first demonstration of such optical trapping for low-index μBs occurred in 1988 [1], however it was not until 2005, when the first fully integrated study incorporating high speed imaging sequences of optically trapped μBs activated by ultrasound was published [2]. This was followed in 2007 by an independent study, using an alternative architecture, and which demonstrated the explicit role of proximal walls on the dynamic of shelled μB for the first time [3]. Both of these latter studies underscored the flexibility and power of combining optical trapping and high speed imaging as an innovative new approach to cavitation studies.In this review paper, the lead authors and architects of those latter two studies [2,3] bring their collective experience together for the first time, assessing the process of how their respective integrative solutions converged, and moreover how emerging technologies such as the use of spatial light modulators can be exploited fully in this context. A full reference list, including all conference papers in this area, is included, so that this review represents a completely up-to-date snapshot of the state of the art, as well as a sober assessment of where the most fruitful future directions may lie, given the rapidly evolving CCD industry that underpins modern high speed imaging systems.

8097-15, Session 4

Characterization of oil-producing microalgae using Raman tweezers

O. Samek, P. Zemánek, Z. Pilát, M. ?er?, S. Bernatová, J. Je?ek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

In order to utilize algae for efficient fuel production, the optimal cultivation

parameters have to be determined which, in turn lead to high production of oil in the selected cell line. Therefore, rapid techniques allowing for the characterisation/identification of algal species, and consequently for the determination of the unsaturation degree of the constituent fatty acids in the algal lipid bodies are required. Thus, Raman spectroscopy can offer an attractive alternative for lipid characterization that has not yet been sufficiently exploited in algae investigations.

We present that Raman spectroscopy can be combined with optical tweezers and with microfluidic chips so that this instrument is capable to measure algal nutrient dynamics and metabolism in vivo, in real-time, and label free, making it possible to detect population variability as a biosensor. Moreover, employing an active sorting switch, cells can be sorted depending on input parameters obtained from Raman spectra.

8097-16, Session 4

High speed tracking of intracellular structures: understanding the transport mechanisms in living plant cells

C. López-Quesada, Univ. de Barcelona (Spain); M. Joseph, Consejo Superior de Investigaciones Científicas (Spain); J. Selva, A. Farré, G. Egea, Univ. de Barcelona (Spain); M. D. Ludevid, Consejo Superior de Investigaciones Científicas (Spain); E. Martín-Badosa, M. Montes-Usategui, Univ. de Barcelona (Spain)

Intracellular transport in plant cells is governed by an internal flux, known as cytoplasmatic streaming, which facilitates the exchange of materials between organelles and between the cell and its surroundings. Recent studies have shown that this directed flow of the cytosol is dependent on the actin filament integrity and requires the proper action of myosin XI molecular motors. However, the role that myosins play in the movement of particular intracellular organelles remains unclear. These may be directly pulled by myosin motors or carried away by the flux in the cytosol produced by the active movement of another organelle. In order to elucidate the underlying mechanism by which cytoplasmatic streaming is generated, we analysed the motion both protein bodies, which are membranous structures that are artificially induced in transgenic tobacco leaves. In addition, these synthetic organelles can be used as a handle to exert large forces by means of optical tweezers, which may be important for the study of the mechanics of the cell transport system in living cells.

In vitro myosin XI motors move processively along actin filaments with a fixed step size of 35 nm. These transporters, which are the fastest known molecular motors, stride along the actin tracks at velocities up to 7 μm/s. In order to determine whether a particular transported cargo moves in a stepwise mode, a high-speed, highly accurate tracking method is required, such as FIONA. Large temporal resolution is guaranteed by using a fast back-illuminated EM-CCD camera (Ixon-860, Andor Technologies), which is characterized by its high frame rate and sensitivity. Our results reveal that cargos move in a stepwise mode, suggesting that myosin XI directly pulls these structures throught cell's cytosol.

8097-17, Session 4

The viscoelastic properties of the vitreous humour measured using an optically trapped local probe

F. Watts, L. E. Tan, Univ. of Strathclyde (United Kingdom); M. Tassieri, Univ. of Glasgow (United Kingdom); C. G. Wilson, Univ. of Strathclyde (United Kingdom); J. M. Girkin, Durham Univ. (United Kingdom); A. J. Wright, Univ. of Strathclyde (United Kingdom)

We present results demonstrating for the first time that optical tweezers can be used as a local probe to measure the variation in the viscoelastic properties of the vitreous humour of a rabbit eye. The beads were injected into a dissected vitreous and optically trapped using a 532nm wavelength laser beam and an inverted microscope. The quasi-Brownian motion of the optically trapped bead was monitored on a fast CCD camera on the millisecond timescale. Analysis of the bead trajectory provides local information about the viscoelastic properties of the medium surrounding the particle [1]. The linear viscoelastic properties of a material can be represented by the frequency-dependent dynamic complex modulus , where G' (ω) is the storage (elastic) modulus and G" (ω) the loss (viscous) modulus. Previous methods for measuring the viscoelastic properties of the vitreous destroy the sample and allow only a single averaged measurement to be taken per eye, whereas, with our approach, we were able to observe the variation in G' (ω) and G" (ω) across the sample and the inhomogeneous nature of the vitreous. The motivation behind these measurements is to gain a better understanding of the structure of the vitreous humour in order to design effective drug delivery techniques. In particular, we are interested in methods for delivering drug to the retina of the eye in order to treat sight threatening diseases such as age related macular degeneration.

8097-18, Session 4

Investigating the interaction forces between T-cells and antigen-presenting cells using an optical trapping system

A. J. Wright, Univ. of Strathclyde (United Kingdom); R. Benson, R. W. Bowman, G. M. Gibson, M. J. Padgett, Univ. of Glasgow (United Kingdom); J. M. Girkin, Durham Univ. (United Kingdom); J. M. Brewer, P. Garside, Univ. of Glasgow (United Kingdom)

The interactions between T-cells and antigen-presenting cells (APCs) are crucial in triggering a successful antigen-specific, adaptive immune response leading to protection against a particular pathogen or disease. At present very little is known about the magnitudes of the forces involved in these interactions. We present results showing for the first time that optical tweezers can be used to measure these cell-cell interaction forces. We were able to see a clear difference in the interaction force depending on the presence or absence of specific antigen. The optical trapping system incorporated a fast camera to provide sensitive position detection and was developed to be stable and vibration free, allowing interaction forces to be measured on a time scale of several minutes. We combined two Laguerre -Gaussian beams, with equal but opposite handedness, to create a trapping beam with a 'petal pattern' intensity profile that had no net orbital angular momentum and therefore did not cause the trapped object to rotate. The T cell of interest was trapped directly with this beam and no exogenous beads were added to the sample. Interaction forces between T cells and APCs in the presence of specific antigen ranged from 0-6.5pN, whereas, when the specific antigen was absent the interaction forces ranged from 0-1.5pN. The accuracy of the system will be discussed in terms of how accurately we can track the position of the optically trapped cell and the methods we used for limiting cell roll.

8097-19, Session 4

Viability studies of optically trapped T-cells

N. McAlinden, D. Glass, O. Millington, A. J. Wright, Univ. of Strathclyde (United Kingdom)

We present a viability study of optically trapped live T cells and T cell hybridomas. T cells form an important part of the adaptive immune response system which is responsible for fighting particular pathogens or diseases. The cells of interest were directly trapped by a laser operating at a wavelength of 1064 nm and their viability was measured as a function of time. Cell death was monitored using an inverted fluorescent microscope to observe the uptake by the cell of the fluorescent dyes propidium iodide and trypan blue. Studies were undertaken at various laser powers and beam profiles and the data compared to results taken

using a laser beam with a wavelength of 532nm to optical trap the cells. There is a growing interest in optically trapping immune cells and this is the first study that investigates the viability of a T cell when trapped using a conventional optical trapping system. In such experiments it is crucial that the T cell remains viable and trapping the cell directly means that any artefacts due to a cell-bead interface are removed. Our motivation behind this experiment is to use optical tweezers to gain a greater understanding of the interaction forces between T cells and antigen presenting cells. Measuring these interactions has become important due to recent theories which indicate that the strength of this interaction may underlie the activation of the T-cell and subsequent immune response.

8097-20, Session 4

Elastic light scattering measurements from multiple red blood cells in line tweezers

A. Kauppila, M. Kinnunen, Univ. of Oulu (Finland); A. Karmenyan, National Yang-Ming Univ. (Taiwan); R. Myllylä, Univ. of Oulu (Finland)

Different theoretical models have been developed to understand light scattering processes in biological medium and for helping in analysis of experimental data, both at a cellular level and in bulk tissues. Experimental verification of the simulation models is difficult at a cellular level. Optical tweezers, combined with a light scattering measurement facility, has enabled the measurement of elastic light scattering distributions from single particles and cells. The aim of this paper is to present elastic light scattering measurement results from several red blood cells (RBC) and compare the results with the theoretical ones found in literature. Elliptical optical tweezers is used to keep one, two and three RBCs next to each other and stable in place during the measurements. Face-on and rim-on incidences of He-Ne laser light (vertical polarization) in relation to the RBCs are used. In the face-on case, light scattering intensity is larger from two RBCs than from one RBC, but no difference was found when using 3 RBCs instead of two RBCs. In the rim-on case, clear changes in the shape of scattering light intensity field were found when the number of RBCs was increased from one to two. Those results are in agreement with modelling, where it was found that scattering patterns are almost independent of the lateral distance of the RBCs in the face-on case, and, the multiple scattering effect needs to be taken into account when several RBCs are along the direction of the incident wave.

8097-21, Session 5

Plasmonic nanogels with robustly tunable optical properties

T. Cong, S. Wani, R. Sureshkumar, Syracuse Univ. (United States)

Metal nanoparticles (e.g. Ag and Au) are widely investigated as attractive candidates for inorganic-organic assemblies because of their unique optical and electronic properties. Fluids with metal nanoparticles can be used to manufacture thin films and interfaces for applications such as light trapping in photovoltaic devices, microelectric devices and biosensor technology. In this study, plasmonic nanogels were produced by self-assembly of wormlike surfactant micelle and metal nanoparticles in an aqueous solution at room temperature. The structure of the nanogel was studied by cryogenic transmission electron microscopy and rheological measurements. The optical absorbance of the gels could be robustly tuned by varying the nanoparticle type (Au or Ag), size, shape and/or concentration. Specifically, multicomponent nanogels capable of broadband absorption of the solar radiation were synthesized. These gels had relatively low viscosity (~ 1), long shelf-life (~ weeks), thermal stability up to 80 degree C and are thermoreversible. Hence, they can be easily processed to make thin films and interfaces with tunable optical properties. Structure, rheology and optical properties of these plasmonic nanogels as well as their potential application to high efficiency photovoltaics design will be discussed.

8097-22, Session 5

Femtosecond laser structured surfaces for opto-fluidics and sensing

R. Buividas, D. J. Day, S. Juodkazis, Swinburne Univ. of Technology (Australia)

Surface patterning by ripples, the self-organized quasi-periodic sub-wavelength relief structures, is demonstrated on large areas with sub-millimeter cross section using femtosecond laser pulses. The period of ripples, L, is determined by the wavelength of irradiation, w, and the refractive index of materials, n, as L = w/2n in (semi)transparent materials and is close to L = w on the metallic and absorbing surfaces for normal incidence. We choose high refractive index materials such as Si, TiO2, GaP, GaAs, Al2O3 ITO for creating patterns where the width of a groove/ridge is between 100 - 200 nm. Such patterns are prospective for surface enhanced Raman shattering (SERS) after coating them by plasmonic metals. The orientation of the ripples, their wavevector, is determined by the orientation of the linearly polarized light. In the case of elliptical and circular polarization, patterns of a more complex geometry but with similar feature sizes are obtained. SERS activity of samples has been confirmed. Such directly written SERS sensors do not require multi-processing lithographic fabrication steps which are not practical or expensive for the large sub-1mm regions. The complex sub-wavelength roughening of the surface by ripples is found to change wetting conditions as revealed by video monitoring water droplet put in touch with the rippled regions. Application potential of ripples in applications of electrowetting on ITO substrates is discussed.

8097-23, Session 5

Electrowetting-controlled bio-inspired artificial iridophores

S. Manakasettharn, J. A. Taylor, T. Krupenkin, Univ. of Wisconsin-Madison (United States)

Many marine organisms have evolved complex optical mechanisms of dynamic skin color control that allow them to drastically change their visual appearance. In particular, cephalopods have developed especially effective dynamic color control mechanism based on the mechanical actuation of the micro-scale optical structures, which produce either variable degrees of area coverage by a given color (chromatophores) or variations in spatial orientation of the reflective and diffractive surfaces (iridophores). In this work we describe the design, fabrication and characterization of electrowetting-controlled bio-inspired artificial iridophores. The developed iridophores geometrically resemble microflowers with the flexible reflective petals. The microflowers are fabricated on a silicon substrate using surface micromachining techniques. After fabrication a small droplet of conductive liquid is deposited at the center of each microflower. This causes the flower petals to partially wrap around the droplet forming a capillary origami structure. The dynamic control over the degree of wrapping is achieved by applying a voltage differential between the conductive core of the petals and the droplet. The applied voltage causes dynamic contact angle change between the droplet and each of the petals due to the electrowetting effect. We have characterized mechanical and optical properties of the microstructures and discuss their electrowetting-based actuation. These experimental results are in good agreement with a simple theoretical model based on electrocapillarity and elasticity theory. This work forms the basis for a broad range of novel optical devices.

8097-25, Session 5

Femtosecond laser structuring of waveguides for sensing applications

D. J. Day, R. Buividas, G. Gervinskas, S. Juodkazis, Swinburne Univ. of Technology (Australia); M. Mikutis, G. Slekys, ALTECHNA

Co. Ltd. (Lithuania)

Tightly focused femtosecond laser pulses were used to open cavities and drill-throughout holes in the optical single and multi-mode fibers. The cross section of the holes and cavities ranging from 10 to 50 micrometers. This direct laser writing approach makes it possible to minimize the amount of waveguide material which should be removed for uncompromised mechanical performance. The proof-of-the-principle demonstration of incorporating fibers into a microfluidic chip is demonstrated. We show that fabricated open cavities and holes in the waveguides can be used for direct monitoring of absorption changes. Simple design and integration possibility of laser-fabricated waveguide sensors is prospective for optofluidic applications.

8097-79, Session 5

A thiol-ene/methacrylate-based polymer for creating integrated optofluidic devices

M. Baylor, Carleton College (United States); R. R. McLeod, R. Boyne, N. Cramer, C. N. Bowman, Univ. of Colorado at Boulder (United States)

We present a new photopolymer that allows the creation of physical features (e.g. micro-fluidic channels) and optical index features (e.g. waveguides) as coplanar components in an optofluidic device using standard photolithography techniques. The polymer consists of two monomer species that polymerize at different rates. The methacrylate gels rapidly to create a scaffolding structure. The thiol-ene is a high-index polymer that cures more slowly. An initial exposure of the fluidic-structure mask brings the polymer to a rubbery gel point. Any unexposed monomer is a liquid and can by removed using a solvent wash leaving physical structures in the polymer. A second short exposure of the waveguide mask initiates the creation of index structures resulting from diffusion of high-index monomer into the exposed region. A final flood-cure permanently fixes the optical structures.

Using the above process we create an integrated refractometer that includes a polymer waveguide crossed by a micro-fluidic channel, a butt-coupled fiber source and a detector attached to a single base. Waveguide loss for a 12 mm x 60 micron x 60 micron waveguide-only sample was 0.28 dB which includes material absorption, scattering losses, and coupling losses. When the 160.5 micron fluid channel was introduced in a waveguide plus channel device, the total loss of the waveguide plus the channel was 4.2 dB decreasing to 1.8 dB when filled with water due to improved index-matching between the channel and the waveguide. Using direct-write and contact liquid photopolymerization techniques, we believe this work can be extended to make 3D optofluidic structures.

8097-26, Session 6

Hydrodynamic assisted barrier escape

A. Curran, M. Lee, Univ. of Glasgow (United Kingdom); R. Di Leonardo, Univ. degli Studi di Roma La Sapienza (Italy); M. J. Padgett, Univ. of Glasgow (United Kingdom)

We present experimental evidence of hydrodynamic assisted escape from a potential barrier. Holographic optical tweezers are used to landscape a bistable system composed of two optical traps, separated by 400nm as seen by a Si colloid of radius 400nm. We observe thermally activated transitions between the two metastable states in the system with transition rates that are in agreement with Kramers' theory. Introducing a second bistable system into our experiment allows us to study the behavior of thermally activated transitions in the presence of hydrodynamic interactions.

The two bistable systems are placed in a line separated by a few micrometers. Using camera tracking technologies we track each of the two beads as they hop back and forth within their respective system. The escape events are recorded and any correlation between the two systems are then computed. We consistently find that the number of observed correlations are as expected and that the number of correlations having a positive coefficient are greater than the number of correlations having a negative coefficient. The hydrodynamic interactions assist in the escape from a metastable potential.

Our results are particularly relevant in the context of concentrated colloidal suspensions where hydrodynamic interactions could lead to the formation of higher mobility paths along which it is easier to overcome barriers to structural rearrangement.

8097-27, Session 6

Probability distribution of colloidal nanoparticles in an optical trap

Y. Hu, X. Cheng, D. H. Ou-Yang, Lehigh Univ. (United States)

In a colloidal suspension of nanoparticles, the presence of an optical trap can exponentially enhance the probability of finding the particles in the vicinity of the trap. Intriguing questions arise regarding whether the probably distribution of particle number in the trap follows Poisson approximation, and if so, what is the upper limit of the trapping energy at which Poisson is followed. To answer these questions, we conduct experiments to determine directly the variance and the mean particle number in the trap at different trapping energies and compare with the predictions of the probability theory.

8097-28, Session 6

Particle interactions in colloids are revealed in a nonlinear effect in light transmission

J. Song, D. H. Ou-Yang, Lehigh Univ. (United States)

Studies on interactions between particles in highly concentrated suspensions are rare because the solutions are opaque and the interpretations from methods such as diffusing wave spectroscopy are often complicated.

We propose a simple method of probing particle interactions in opaque solutions by measuring light transmission affected by optically induced particle concentration enhancement. The increase in the particle concentration with the input light intensity depends on the interactions between particles. We demonstrate how this method can be used to determine the single particle trapping energy and the virial coefficients in aqueous suspensions of 190 nm polystyrene spheres.

8097-29, Session 6

Experimental and theoretical study of optical binding forces between two colloidal particles

M. Wei, Lehigh Univ. (United States); J. Ng, C. Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China); D. H. Ou-Yang, Lehigh Univ. (United States)

Optical binding has been proposed to be responsible for the cluster formation of micron size dielectric spheres in coherent light fields. However, the measurement of the forces involved in binding is challenging due to overcome thermal fluctuations. In order to measure these forces, we trap two particles in two highly focusing laser beams created from a coherent laser source. We track the displacement of a particle in the stationary trap when the other trapping beam is blinking. The stationary trapping laser served as a force sensor which is able to isolate non-blinking signals. We report an experimental and theoretical study of optical binding forces between two optically trapped dielectric spheres. Results for optical forces are presented as a function of inter particle separation and respective polarizations. The results are useful to understand various inter-particle effects in dual trapping beams system.

8097-30, Session 6

Tunable multidimensional optical binding of particles in laser beams.

P. Zemanek, O. Brzobohaty, V. Karasek, M. Siler, J. Trojek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

We will present a method that provides flexible real-time modifications of the spatial positions of self-arranged particles in optically bound structures. Particularly we will focus on tuning of the inter-particle distances in one-dimensional array of particles in counter-propagating Gaussian or Bessel laser beams and we will also present the first examples of two-dimensional and three-dimensional self-arranged optically bound structures far from the surfaces.

8097-31, Session 6

Dynamics and Directional Locking of Colloids on Quasicrystalline Substrates

C. M. Reichhardt, Los Alamos National Lab. (United States)

Recent experiments on colloids interacting with a quasiperiodic Penrose lattice created by an optical substrates have found that although for strong substrates the colloids have a quasicrystalline ordering, at intermediate substrate strengths the colloids order into what is called an Archimedean tilling consisting of triangles and squares, while for weak substrates the colloids have a triangular ordering [1]. Here we examine particles such as colloids driven over a quasiperiodic Penrose substrate. For strong substrates and low external drives the colloids form a quasiperiodic pinned state, while at higher drives the moving system exhibits a dynamically induced Archimedean ordering which is aligned with the driving direction [2]. The dynamically induced Archimedean ordering only occurs for driving along the five orientationally ordered directions of the Penrose lattice. For driving along other directions, the particles form either a moving liquid or a moving triangular lattice. We also find that the driving angles at which the Archimedean ordering occurs are associated with a directional locking effect in which the colloids remain aligned with lattice substrate symmetry directions even when the driving force is rotated away from these directions. This directional locking is similar the locking steps observed for particles driven over periodic substrates [3], indicating that orientational ordering of the substrate is sufficient to induce directional locking effects and that translational ordering is not required. Our results have implications for various systems including colloids moving through optical lattices, vortices moving in nanostructured superconductors, and frictional studies of particles on substrates.

8097-32, Session 7

Using optical tweezers to investigate colloidal phenomena

I. Cohen, Cornell Univ. (United States)

Colloids are micron scale particles that are suspended in a fluid. The large size and relatively slow motions of the particles, make these suspensions convenient to image in 3D using confocal microscopy and manipulate at the single particle level using optical tweezers. These tools are revolutionizing our ability to link the microscopic structure of the suspension with the large scale macroscopic material properties. In this talk, I will discuss how we are using these systems to study a vast array of phenomena ranging from statistical mechanics problems including crystallization, defect motion in crystals, and the mechanics of glasses.

8097-33, Session 7

Optical tweezers as a micromechanical tool for studying defects in 2D colloidal crystals

X. S. Ling, Brown Univ. (United States)

In this talk, I'll discuss our experiments on using optical tweezers to create and manipulate defects in 2D colloidal crystals. This work is supported by NSF-DMR.

8097-34, Session 7

Message in a bottle: the statistical behavior of nanoparticles in optical confinement

D. H. Ou-Yang, L. Zhou, J. Junio, Lehigh Univ. (United States)

In an aqueous medium, container surfaces can significantly alter the behavior of suspended nanoparticles. We propose a method to investigate nanoparticle behavior in a boundary-free environment by transiently trapping them with a focused laser beam. While optically confined, as in an optical bottle, these particles are affected by both particle-light and particle-particle interactions. Time-averaged fluorescence imaging produces results in 3D mapping of the nanoparticle concentration in the bottle. We report how we analyze the messages in the bottle, i.e. the statistical behavior of these particles and the optical field intensity distribution.

8097-35, Session 7

Rotational micro-rheology with rotational optical tweezers

G. Maucort, D. C. Preece, T. A. Nieminen, N. R. Heckenberg, H. H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Recently the measurement of the visco-elastic properties of materials at the micron scale has received much interest. However, for biological experiments where the proprieties of the materials change drastically from point to point a localized measurement is necessary. Such measurement is complicated however by the need to obtain a measurement of the viscoelastic response of the material over sufficient frequency range. Optical tweezers represent one way in which such measurements may be achieved. However, it has proved difficult to take measurements of the visco-elastic properties of biological systems due to often complicated biological structures which may lead to differing measurements of visco-elasticity in different parts of the system. We present a method for localized measurement of the complex visco-elastic moduli of fluids utilizing the optical torque created when a birefringent Vaterite particle is exposed to light with modulated polarization. We use this method to acquire the frequency dependent, visco-elastic moduli while minimizing the associated interaction volume. Though a number of studies have looked at the possibility of using optical tweezers for the measurement of visco-elasticy this is the first time to our knowledge that birefringent properties have been utilized to perform such a measurement.

8097-36, Session 8

Optical manipulation of aerosol particle arrays

J. P. Reid, J. S. Walker, R. Power, A. E. Carruthers, Univ. of Bristol (United Kingdom)

Aerosols play a crucial role in many areas of science, ranging from atmospheric chemistry and physics, to drug delivery to the lungs, combustion science and spray drying. The development of new methods to characterise the properties and dynamics of aerosol particles is of crucial importance if the complex role that particles play is to be more fully understood. Optical tweezers provide a valuable new tool to address fundamental questions in aerosol science. Single or multiple particles 1-15 micrometres in diameter can be manipulated for indefinite timescales using optical tweezing. Linear and non-linear Raman and fluorescence spectroscopies can be used to probe particles composition and size. In this paper we will report on the latest developments in the use of holographic optical trapping (HOT) to study aerosols. Although widely used to trap and manipulate arrays of particles in the condensed phase, the application of HOT to aerosols is still in its infancy. We will explore the opportunities provided by the formation of complex optical landscapes for controlling aerosol flow, for comparing the properties of multiple particles, for performing the first ever digital microfluidic operations in the aerosol phase, and for examining interparticle interactions that can lead to coalescence/coagulation. Although aerosol coagulation is the primary process driving the evolution of particle size distributions, it remains very poorly understood. Resolving the time-dependent motion of trapped particles and the light scattering from particles during the coalescence process, we see how HOT can be used to study this fundamental process.

8097-37, Session 8

Optical manipulation of 'drops on rails' in two dimensional microfluidic devices

C. McDougall, Univ. of Dundee (United Kingdom); E. Fradet, C. Baroud, Ecole Polytechnique (France); D. McGloin, Univ. of Dundee (United Kingdom)

In the context of using microfluidic droplets as isolated biological or chemical micro-reactors, control over droplet placement is crucial to successful device implementation. Previously we have demonstrated that optically induced heating of droplets from a focused laser beam can be used to control the formation of aqueous droplets in oil, merge or sort them. We have also demonstrated that more complex operations such as buffering droplets and mixing their contents are made possible by use of holographic or mobile laser beams. The localised heating produced by the focussed laser beam causes localised variations of the interfacial tension of the droplet. Consequently Marangoni flows are generated and exert a force upon the droplet. It is this optically driven force that can be used to move the drop in a controlled manner.

Here we demonstrate a combined mechanical and optical approach to bring a water-in-oil droplet to any desired position on a two-dimensional plane and hold it stationary against a mean flow. This is achieved using far lower laser powers than those required for purely optical manipulation. The technique makes use of the "drops on rails" technique, which mechanically forces droplets to follow predetermined paths on "rails" or holds them stationary on "holes". The laser induced optical forcing is employed for intelligent operations such as stopping, guiding or derailing droplets as they pass through the chip. In this way a droplets under study man be selectively sorted and then held stationary against the flow for prolonged observation.

8097-38, Session 8

Optical torque on a single gold nanorod

P. V. Ruijgrok, N. R. Verhart, P. Zijlstra, A. L. Tchebotareva, M. Orrit, Leiden Univ. (Netherlands)

We report the first quantitative measurements of the optical torque that can be exerted on a single gold nanorod (25 nm diameter, 60 nm length) in a three dimensional, linearly polarized optical trap. The torque is quantified by both the time-averaged amplitude and the relaxation rate of Brownian orientational fluctuations, obtained from polarization dependent white light scattering spectra, and time dependent light scattering respectively. The measurements are in good agreement with calculations where the temperature profile around the hot nanorod is taken into account as an effective, reduced viscosity. We find laser induced heating rates of the trapped nanorod of about 1 degree per milliWatt of trapping power. The maximum optical torque that could be exerted on a single gold nanorod was 100 pN nm, large enough to probe single-molecule processes in soft matter.

8097-39, Session 8

Direct measurement of angular momentum in highly focused light beams

D. C. Preece, A. B. Stilgoe, T. A. Nieminen, N. R. Heckenberg, H. H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

The angular momentum of light beams has been widely used in a number of optical tweezers applications. Such angular momentum is often separated into two distinct parts. Firstly spin angular momentum, which occurs when birengent particles such as Vaterite are exposed to circularly polarized light. Secondly, orbital angular momentum, which occurs when light with an azimuthal phase gradient is incident on a small absorbing particle. Both types of momentum can be used to provoke the rotation of micron sized objects. However spin and orbital components of torque become hard to separate in highly focused beams. Though a number of methods have been tried to measure the exerted torque. Such as using photo detectors positioned to measure the fraction of light split through a polarizing beam splitter. There has been no definitive measure of the torque generated by highly focused laser beam. In this paper we evaluate the torques created in highly focused light beams and discuss the mechanisms by which such torques are created.

Optically driven Archimedes micro-screws for micropump applications

P. L. Baldeck, Univ. Grenoble 1 (France); C. Lin, Central Taiwan

Univ. of Science and Technology (Taiwan); M. Bouriau, Univ. Grenoble 1 (France); G. Vitrant, Institut de Microélectronique Électromagnétisme et Photonique (France)

Archimedes micro-screws have been fabricated by three-dimensional two-photon polymerization using a Nd:YAG Q-switched microchip laser at 532nm. Due to their small sizes they can be easily manipulated, and made to rotate using low power optical tweezers. Rotation rates up to 2400 rpm are obtained with a laser power of 200 mW. A photo-driven micropump action in a microfluidic channel is demonstrated with a non-optimized flow rate of 6pL/min.

This light-induced rotation results from the conservation of momentum that occurs when laser photons are reflected on their helical surface. The optical torque increase with the incident laser power, and with the total reflectivity of the irradiated surface, that has a complex dependency with the micro-screw geometry. An analytical expression is derived to evaluate the angular speed in the steady-state regime. The predicted rotation speeds and its dependency with the screw-number N are in very good agreement with experimental measurements.

This work open the way to the implementation in microfluidics of the most efficient pump design that have been used in the macroscopic word by mankind over centuries.

Light-assisted self assembly using photonic crystal templates

C. Mejia, The Univ. of Southern California (United States); A. Dutt, Indian Institute of Technology Kharagpur (India); M. Povinelli, The Univ. of Southern California (United States)

In this paper, we explore a technique we call light-assisted templated self-assembly. We calculate optical forces on colloidal particles over a photonic crystal slab with a square lattice. We perform full-vectorial electromagnetic simulations of Maxwell's equations by means of the finite-difference time-domain method. Forces are calculated using the Maxwell stress tensor. We show numerically that optical forces can be enhanced by exciting guided resonance modes of the photonic crystal slab. Some of these optically enhanced forces trap particles near the slab while other repel particles from it. The magnitude of the trapping forces is dependent on the Q of the mode. Moreover, the trapping lateral forces form a two-dimensional periodic pattern of trapping positions over the slab, which depend on the resonance wavelength and the polarization of the light. The system should allow the trapping and assembly of two-dimensionally periodic patterns of particles, and tuning the wavelength or polarization of the light source should lead to reconfiguration. We calculate the power required for stable trapping and discuss fabrication of the photonic crystal templates using standard microfabrication techniques.

8097-43, Session 9

Simulations of optical lift

S. H. Simpson, S. Hanna, Univ. of Bristol (United Kingdom); G. A. Swartzlander, Jr., Rochester Institute of Technology (United States)

It has been recently demonstrated that a dielectric semi-cylinder, exposed to plane wave radiation, will rotate into a stable orientation thereafter it will experience a force that is not, in general, parallel to the flow of the momentum carried by the incident light. By analogy with aeronautics, the transverse component of this force can be thought of as ``optical lift", and the semi-cylinder itself, as a ``light-foil". We present a comprehensive examination of this effect using finite difference time domain (FDTD) and discrete dipole approximation (DDA) calculations. The affect of variations in particle size, shape and refractive index on the conditions for stable optical lift are considered. It is found that the phenomenon is common to particles containing precisely two mutually perpendicular mirror planes. For a particular shape of particle in this class the optical size determines the strength of the effect and is associated with Mie type resonances apparent in the magnitude of the lift force. Conversely, the shape itself influences the angular behavior in terms of the stable orientation and the direction of the equilibrium force. Finally, we examine the motion of a light-foil in a viscous medium. The symmetry required to generate optical lift also gives rise to hydrodynamic coupling between translational and rotational motion. As a consequence the conditions for orientational equilibrium are modified and the object acquires a steady velocity. These issues are examined for a range of novel geometries and ways of optimizing the effect are described.

8097-44, Session 9

Pulling particles backward using a forward propagating beam

J. Ng, Hong Kong Univ. of Science and Technology (Hong Kong, China); J. Chen, Z. Lin, Fudan Univ. (China); C. Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Can the scattering force of a forward propagating beam pull a particle backward? A photon carries momentum, so one may expect light will push against any object standing in its path. However, light can indeed "attract" in some cases. For example, small particles will be attracted towards a strongly focused spot in optical tweezers due to the gradient force. But it is probably more appropriate to say that the gradient force "grabs" rather than "pulls", as the particle will remain stable in the optical trap after being drawn to the focus. Here, we discuss another possibility-a backward scattering force which is always opposite to the propagation direction of the beam so that the beam keeps on pulling an object towards the source without an equilibrium point.

In the absence of intensity gradient, using a light beam to pull a particle backwards is counter intuitive. Indeed, this is not possible with a plane wave. However, the situation is more subtle for certain optical beams. Here, we show that it is possible to realize a backward scattering force which pulls a particle all the way towards the source without an equilibrium point. The underlining physics is the maximization of forward scattering via interference of the radiation multipoles. We show explicitly that the necessary condition to realize a pulling force is the simultaneous excitation of multipoles in the particle and if the projection of the total photon momentum along the propagation direction is small, attractive optical force is possible.

8097-45, Session 9

Theoretical studies of nonlinear resonance radiation force exerted on nano-sized objects

T. Kudo, H. Ishihara, Osaka Prefecture Univ. (Japan)

Laser manipulation (LM) is a technique for the mechanical control of small objects using radiation force (RF)[1]. We have previously proposed the LM by using electronically resonant optical response of nanostructures to enhance the RF and to select particular kinds of nanoparticles via quantum confinement effect [2], which has been demonstrated experimentally [3]. This scheme is effective for travelling- and standing-waves, while it is not the case of the trapping by a single focused laser beam because the enhanced dissipative force strongly pushes objects

toward outside the focal point. However, recent relevant experiments report positive results for trapping, showing puzzling phenomena contradicting our conventional understanding of the trapping mechanism [4].

The key element to understand these results is the nonlinear optical response. The laser intensity for single molecular trapping is usually beyond the perturbative nonlinear regime. In this contribution, we elucidate the effective resonant trapping by calculating the radiation force based on the nonperturbative calculation method [5]. The results successfully explain the recent experimental results, and further, we demonstrate how utilizing nonlinear effect enhances the degrees of freedom to manipulate nano-objects, showing novel effects such as “Stimulated Recoil Force” to “pull” the nanoparticles by travelling-waves.

8097-80, Session 9

Spin and orbital angular momenta of light reflected from a cone

M. Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States); A. R. Zakharian, Corning Incorporated (United States); E. M. Wright, College of Optical Sciences, The Univ. of Arizona (United States)

We have examined several retro-reflecting optical elements, each involving two reflections. In the case of a hollow metallic cone having an apex angle of 90º, a circularly-polarized incident beam acquires, upon reflection, the opposite spin angular momentum. However, no angular momentum is transferred to the cone, because the reflected beam picks up an additional angular momentum (this one orbital) that is twice as large but opposite in direction to that of its spin. A 90º cone made of a transparent material in which the incident light suffers two total internal reflections before returning, may be designed to endow the retro-reflected beam with different mixtures of orbital and spin angular momenta. Under no circumstances, however, does it seem possible to transfer any angular momentum from the light beam to the cone without either allowing absorption or breaking the circular symmetry of the system.

8097-46, Session 10

Optimized optical manipulation

M. Mazilu, J. Baumgartl, M. Ploschner, A. C. De Luca, S. Kosmeier, K. Dholakia, Univ. of St. Andrews (United Kingdom)

Special beams such as Bessel beams, Laguerre Gaussian beams or Airy beams are each interesting for various applications in micro-manipulation. But which beam shape, what polarization and back aperture fill-factor is the optimum for trapping, sorting, manipulating or focusing? Here, we present a general method based on optical eigenmodes, that allows the determination of the beam shape optimizing each of the cases considered. The method is applied to optimize trapping, plasmonic based sorting and enhanced whispering gallery mode coupling enabling the Doppler cooling of mesoscopic particles. More precisely, optical eigenmodes (OEi) are solutions of Maxwell’s equation that are orthogonal with respect to a quadratic measure of the electromagnetic field. The intensity, the focal spot size, the linear/angular momentum of the light field are such quadratic measures. Each eigenmode is associated with an eigenvalue corresponding to its measure. Ordering these eigenvalues delivers the field with largest/smallest measure enabling the determination of the optimal beam shape for any specific case.

8097-47, Session 10

Theory of resonant radiation force exerted on single organic molecules near metallic nanogap

H. Ishihara, Y. Mizumoto, Osaka Prefecture Univ. (Japan)

The targets of the laser manipulation have been shifting to nanoscale objects including single molecules. For manipulating nano-objects, we have proposed to utilize an electronic resonance[1], and recently its feasibility has been experimentally demonstrated[2]. On the other hand, there has been growing attention to the nanoparticle trapping by using gap plasmons[3]. A localized electric field with a steep gradient strongly attracts nanoparticles. Since such light electric field has a spatial structure with a single molecular scale, the spatial interplay between the electric field and molecular wavefunctions plays an essential role for the molecular manipulation, and hence, the resonant manipulation by using nanogap is expected to become a powerful tool to control molecular alignment and orientation.

In this contribution, we theoretically calculate the radiation force exerted on molecules near metallic nanogap, where the molecular wavefunctions obtained by the molecular orbital method are incorporated into the discrete dipole approximation method. We can treat the nonlocal response due to the field distribution within a molecule by this method, which enables us to demonstrate the force distribution and torque on a molecule. The results show the possibility of selective control of molecular alignment and orientation near metallic nanogap by resonant laser manipulation.

8097-48, Session 10

Enhanced optical forces in hybrid plasmonic waveguides

X. Yang, Y. Liu, R. F. Oulton, X. Yin, X. Zhang, Univ. of California, Berkeley (United States)

Gradient optical forces have been broadly exploited in dielectric waveguides and cavities for realizing many exciting applications in optomechanics. Metallic nanostructures, with subwavelength optical confinement arising from surface plasmon polaritons, bring new capabilities in optical forces enhancement. Here we numerically demonstrate that the optical force applied on the silicon dielectric waveguide by the silver substrate in hybrid plasmonic waveguide system can be enhanced by more than one order of magnitude compared to the optical force generated between the silicon waveguide and the glass substrate in conventional photonic waveguide system, at wavelength of 1,550 nm. This enhancement arises from the deep subwavelength optical energy confinement and the small mode propagation loss of the hybrid plasmonic mode. The structural dependence of the optical forces and the optimized waveguide design are analyzed with both Maxwell’s stress tensor formalism and the coupled mode theory, in order to reveal the mechanism of this enhanced optical force. We also demonstrate that the optical trapping force applied on a single dielectric nanoparticle with size of 5 nm in water can be strongly enhanced utilizing the hybrid plasmonic mode. The optical trapping potential for the nanoparticle from the hybrid plasmonic mode is approximately 30 times stronger than the one in the photonic mode, due to its strong localization of the optical field in the gap region. Such an interesting result may be useful to design nanoscale optical tweezers to manipulate individual nanoscale objects such as single biomolecules or quantum dots.

8097-49, Session 10

Optical binding with anisotropic particles: Resolving the forces and torques

M. M. Coles, S. N. A. Smith, D. L. Andrews, Univ. of East Anglia Norwich (United Kingdom)

In the phenomenon known as optical binding, optical fields induce significant forces between microparticles of dielectric matter. Most experimental studies have centred on particles of spherical morphology, assumed to be isotropic and able to tumble freely in a fluid. However, when birefringent microcrystals and anisotropic nanoparticles such as carbon nanotubes are held in an optical trap, it is essential to account for their orientation. These particles are susceptible not only to optical forces but also torques, and there is considerable interest in their response to light that conveys angular momentum - especially optical vortices. Before the full effects of such interactions can be fully understood, however, it is necessary to cultivate a thorough understanding of the rotational effects that operate in optical binding with conventional laser radiation. Here, the orienting effect of the radiation on each individual particle, as well as the orienting influences they exert on each other, need robust theory to account for partial alignment with the throughput radiation. The aim of this paper is to develop, using quantum electrodynamics and perturbation theory, analytical expressions for the observables associated with pair-wise optical binding in anisotropic, non-polar particles. The intricacies of weighted rotational averaging and tensor analysis are tackled, deploying newly devised methods to resolve results into forms amenable to experimental application. Analysing the resulting equations allows the identification of terms corresponding to specific properties of the considered particles, including terms reflecting the degree of anisotropy. It is then straightforward to recognise criteria for the validity of commonly held approximations.

8097-50, Session 11

Biophotonics in turbid environments.

T. Cizmar, H. I. C. Dalgarno, K. Dholakia, Univ. of St. Andrews (United Kingdom)

We review recent advancements in laser field optimization within turbid environments. Before laser light enters random, turbid and scattering media its wavefront can be pre-shaped to form latter high intensity focal spots after or within the turbid layers to be further exploited for bio-photonics methods such as optical trapping or nano-surgery to name a few.

The method is based on the field decomposition into a series of orthogonal modes. One of them is selected as a phase reference whilst the remaining once are interferometrically tested for particular phase giving the highest intensity signal when interferning with the reference mode at an intensity probe such as fluorescent particle. When applying the optimal phase for al the modes simultaneously the optimal focus is produced at the intensity probe as all the modes meet in phase.

The original concept where relatively slow spatial light modulators were used to measure and further implement the appropriate holographic encoding was recently enhanced by additional adoptive optical components, acousto-optic modulators and galvo-mirrors, leading to light optimization achievable within sub-second intervals, thus opening up the applicability for rapidly time-varying environments including cell layers and living tissues.

We present an alternative strategy where reducing the spatial coherence along one direction allows simultaneous measurement of number of modes where intervals for optimization scale with root square of number of modes. We show that this strategy is particularly suitable for selected plane illumination microscopy (or light sheet microscopy) within turbid environments.

8097-51, Session 11

Digital holography through multimode fibers

S. Bianchi, R. Di Leonardo, Univ. degli Studi di Roma La Sapienza (Italy)

Optical fibers can guide a light beam across long distances or through turbid media like biological tissues. Multimode fibers can propagate a light beam carrying a large information encoded in the complex coefficients of its expansion in the propagating modes. The main obstacle in using such a set of degrees of freedom comes from the fact that one always ends up having a random speckle pattern at a multimode fiber output. It is natural then to ask whether such a structured noisy pattern could be shaped with a spatial resolution of a single speckle size. Spatial light modulators seem to be the ideal tool for achieving this. We recently demonstrated that phase only modulation can be used to shape a light beam in such a way that, after propagation along a multimode fiber, most of the outgoing light will flow through one or few target spots having the size of a single speckle and arbitrarily located in space. By directly extracting the fiber's end-to-end field propagator we can infer the optimal phase modulation for a desired output, which means that we can have few dynamically reconfigurable target spots. We show that such light spots can optically trap dielectric objects allowing holographic optical micromanipulation with a single multimode fiber. We will also discuss the possibility of imaging using a single multimode fiber endoscope.

8097-52, Session 11

Comparison of design algorithms for fast hologram generation in CUDA

M. P. Persson, D. Engström, Göteborg Univ. (Sweden); J. Bengtsson, Chalmers Univ. of Technology (Sweden); M. Goksör, Göteborg Univ. (Sweden)

We have implemented different algorithms for fast hologram generation, aimed for holographic optical tweezers applications, using the parallel computing architecture CUDA. We compare the performance of different implementations of the Gerchberg-Saxton algorithm and provide guidelines for choosing the best suited version with respect to the application. Included in the comparison are three versions of the Gerchberg-Saxton algorithm, one using fast Fourier transforms for propagation and two different implementations using direct summations. The latter two are mathematically equivalent but show radically different dependence on the number of traps in terms of calculation time. Included is also a "lenses and prisms" algorithm for extremely fast hologram generation. It is found that optimized holograms producing hundreds of traps using an FFT based- or tens of traps using direct summation based Gerchberg-Saxton algorithms may be generated in less than 10 ms. This is well below the response time of most commercially available spatial light modulators and thus the use of non-optimizing algorithms such as the "lenses and prisms" algorithm is no longer motivated in many applications. Accompanying this work is a software package including the implementations used in the comparison. The software is made available free of charge under The GNU General Public License (GPL) along with a graphical user interface for interactive control of holographic optical traps.

8097-53, Session 11

Optical trapping using conical refraction of light

J. F. Donegan, D. O'Dwyer, K. Ballantine, C. Phelan, Y. P. Rakovich, J. G. Lunney, Trinity College Dublin (Ireland)

Conical diffraction of linearly polarised light in a biaxial crystal produces a beam with a crescent-shaped intensity profile. Rotation of the plane of

polarisation produces the unique effect of spatially moving the crescent-shaped beam around a ring. We use this effect to trap microspheres and white blood cells and to position them at any angular position on the ring. Continuous motion around the circle is also demonstrated simply by rotating the polariser continuously. This crescent beam does not require an interferometeric arrangement to form it, nor does it carry optical angular momentum. The ability to spatially locate a beam and an associated trapped object simply by varying the polarisation of light suggests that this optical process should find application in the manipulation and actuation of micro- and nano-scale physical and biological objects. Using the process of cascade conical refraction in which light travels through two biaxial crystals in succession, we can produce a ring beam with a Gaussian spot at the centre of the ring. We show using this geometry that we can trap a particle in the Gaussian beam and in the ring trap simultaneously. We can control both the separation of the particles and also their relative angular position using the linearly polarized conical refraction case.

8097-54, Session 12

Reconfigurable 3-dimensional optical route formed by fiber-optic pseudo-Bessel beam arrays

J. Kim, S. Lee, Y. Jeong, J. Shin, K. Oh, Yonsei Univ. (Korea, Republic of)

Due to its unique non-diffracting and self-reconstructing nature, Bessel beam has been successfully adopted to expand the single optical trap into multiple traps along the longitudinal direction. Here we present a novel implementation of Fourier optics along a single strand of hybrid optical fiber in a monolithic manner that can generate a pseudo-Bessel beam. The incident fundamental mode of an optical fiber is adiabatically transformed to a ring mode by a hollow optical fiber, which serves as a micro annulus aperture in the Fourier transformation. Multiple trapping experiments for both polystyrene beads and living Jurkat cell were realized along the beam. Especially four living Jurkat cells were trapped in a row, which can be applied to celluar level spectroscopy. Furthermore, optical transport of the trapped particles along a 3-dimensional curvilinear optical route was demonstrated by spatially multiplexing pseudo-Bessel beams. The radius curvature of the optical route was smaller than the particle size, which has not been possible in prior micro-fluidic channel technologies. The novel concept to spatially multiplex the fibre optic arrays could form a new all-optical building block to realize reconfigurable transportation of particles in true 3-dimensional space overcoming the prior microfluidic routes. Detailed discussion of optical route formation using fiber optic couplers and fiber lasers will be discussed along with explanation on device fabrication.

8097-55, Session 12

Optical chaining of dielectric particles by two counter-propagating all-fiber Bessel-like beams

S. Lee, J. Kim, Y. Jeong, J. Park, K. Oh, Yonsei Univ. (Korea, Republic of)

Optical chaining of multiple dielectric beads was experimentally demonstrated using two counter- propagating Bessel-like beam generated by multimode interference in optical fibers embedded in polydimethylsiloxane (PDMS) channel. The Bessel-like beam generator was composed of a single mode fiber concatenated with a segment of coreless silica fiber of 1600 um length and a fiberized focusing lens. A Bessel-like beam was achieved by multimode interference along the coreless silica fiber, and the beam maintained an average center beam diameter of 4.9 um over an axial length of 300 um, having a nearly uniform output power within a variation of ±0.25%. The proposed device was designed to be compatible with a continuous wave Yb-doped fiber laser oscillating at the wavelength of 1084 nm in order to provide all-fiber solution. A micro-fluidic system of cross-channel was fabricated using PDMS to embed two counter-propagating fiber probes, which provided an accurate beam alignment and stable delivery of dielectric beads. One dimensional optical potential well was formed along the counter propagating beams, where the dielectric beads were trapped. For the particles with the diameter in the range of 2 to 4.5 um, which is smaller than the central beam diameter, unique chaining of multiple particles was observed, where particles were assembled in a form of chain. By adjusting the optical power we could transport the whole chain of particles along the optical beams. Detailed discussion of the optical chaining of particles is presented along with characterization the optical force.

8097-56, Session 12

Generation of high efficiency vector beams with synthetic phase holograms

G. Mendez, V. Arrizon, R. Ramos-Garcia, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Recently, vector beams (VB) have attracted significant interest due to its quite unique characteristics. In particular, the presence of a strong longitudinal component of the electric field and tighter focusing in comparison to homogeneously polarized beam when the VB have axial symmetry in amplitude and polarization. Several generation methods for obtaining VB have been reported. However, most of them are unstable, complicated and the output efficiency is small.

In 2007, Wang et al. proposed a method to produce arbitrary VB using an amplitude spatial light modulator (SLM) and a common path interferometric arrangement. They use an amplitude hologram to generate VB and they only encode VB with constant intensity distribution. Recently we published two novel phase synthetic holograms (Arrizón et al. 2007) that allow us to encode arbitrary complex scalar fields into phase-only function with high quality reconstruction and efficiency of the encoded field. In this work we present a novel method to generate reconfigurable vector beams with arbitrary polarization states employing these phase synthetic holograms. The method is based on the linear recombination of two orthogonally homogeneous polarized scalar modes, that allow the generation of vector fields with arbitrary spatial varying polarization. The two orthogonally polarized modes are superposed by using a common path interferometer which consists of a 4-f system and a phase SLM. We demonstrate the generation of high efficiency and quality Bessel and Laguerre-Gaussian vector beams of different orders with radial and azimuthal (or any other combination) polarization distributions.

8097-57, Session 12

Vector fields with hybrid states of polarization and their orbital angular momentum

X. Wang, B. Gu, J. Chen, Y. Li, Nankai Univ. (China); J. Ding, Nanjing Univ. (China); C. Guo, Shandong Normal Univ. (China); H. Wang, Nankai Univ. (China)

Vector fields with spatially inhomogeneous states of polarization (SoPs) have become a subject of rapidly growing interest, due to its unique features and novel applications in various realms, such as optical trapping and particle manipulation, micromechanics, and biology. However, the generation of arbitrary vector fields is still a challenge. We describe a convenient approach for generating arbitrary vector fields in a 4f system with a spatial light modulator (SLM) and a common path interferometric arrangement. A computer-generated hologram is introduced onto SLM for performing the field conversion. Realization of a variety of polarization configurations confirms the reliability and flexibility of our method. As examples, we experimentally demonstrate the typical radially and azimuthally polarized fields, high order cylindrical vector fields and vector fields with hybrid SoPs.

It is generally accepted that optically isotropic materials are not

influenced by polarization, whereas anisotropic materials can be. However, we validate that the polarization feature can also influence isotropic materials. We predict a new category of optical orbital angular momentum that is associated with the curl of polarization and a kind of vector field with radial-variant hybrid states of polarization that can carry such novel optical orbital angular momentum. We present a scheme for creating the desired vector fields. Optical trapping experiments validate that the vector fields, which have no additional phase vortex, exert torques to drive the orbital motion of the trapped isotropic microspheres.

8097-58, Session 12

The sonic screwdriver

G. C. Spalding, Illinois Wesleyan Univ. (United States); A. Volovick, Z. Yang, C. Demore, M. P. MacDonald, S. Cochran, Institute for Medical Science & Technology (United Kingdom)

When samples of interest are small enough, even the relatively weak forces and torques associated with light can be sufficient for mechanical manipulation, can offer extraordinary position control, and can measure interactions with three orders of magnitude better resolution than atomic force microscopy. However, as the components of interest grow to slightly larger length scales (which may yet be of interest for microfluidic, “lab-on-a-chip” technologies and for research involving biomedical imaging), other approaches gain strength. This talk includes discussion of the angular momentum carried by sonic beams that we have implemented both to levitate and controllably rotate disks as large as four inches (!) across. Discussion of such acoustic beams complements the discussion of the angular momentum carried by light. Also, these beams are useful for a variety of reasons (not least for aberration correction). Methods, including the use of holographically structured fields, will be discussed.

8097-72, Session 12

Flexible dual-beam optical trapping

P. Zemanek, O. Brzobohaty, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); T. Cizmar, K. Dholakia, Univ. of St. Andrews (United Kingdom)

We present an advanced configuration for optical manipulation of micro- and nano-objects employing adaptive optical element to control properties of more counter-propagating beams overlapping in a sample chamber. This system can eliminate optical aberrations in both pathways, online re-align the system remotely from a computer interface, arbitrarily switch in real time between various beams types (vortex, Gauss, Bessel etc.) and their spatial intensity distributions (beam width, vorticity etc.). We demonstrate variety of applications of this setup ranging from formation of spatial solitons, longitudinal optical binding, precise particle delivery via optical conveyor belt, stable confinement of low-index particles, and controlled rotation or swing of heterogeneous objects.

8097-64, Poster Session

Optical manipulation of aerosols using Surface Acoustic Wave Nebulisation

S. Anand, J. Nylk, C. D. Dodds, Univ. of Dundee (United Kingdom); J. M. Cooper, S. L. Neale, Univ. of Glasgow (United Kingdom); D. McGloin, Univ. of Dundee (United Kingdom)

High density micron sized aerosols from liquid surfaces were generated using surface acoustic wave (SAW) nebulisation. The SAWs are made from a set of interdigitated electrodes (IDT) deposited on a lithium niobate (LiNbO3) substrate and are designed to operate around 12MHz. RF powers of ~235mW are used to achieve nebulisation. Powers below this results in droplet motion across the substrate surface. The nebulisation process generated aerosols of a narrow size distribution with diameter ranging from 0.5-2 µm. We consider ways in which these aerosols can be loaded into optical traps for further study. In particular we look at how SAW nebulisation can be used to load particles into a trap in a far more robust manner than a conventional nebuliser device. We demonstrate trapping of a range of particle types and sizes and analyse the size distribution of particles as a function of the applied frequency to the SAW device. We show that it is simpler to load, in particular, solid particles into optical traps using this technique compared to conventional nebulisation. We also consider the possibilities for loading nanoparticles into aerosol optical tweezers.

8097-65, Poster Session

Brownian movement rectification of microparticles using pulsating ratchets

J. Silva-Barranco, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); U. Ruiz-Corona, Univ. della Calabria (Italy); M. Arias-Estrada, V. Arrizon, R. Ramos-Garcia, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

In recent years, particle transport at microscopic level has become an important research topic which has led to the understanding of directed particle transport subjected to thermal fluctuations. Brownian motors (also called ratchet mechanism) are one of the most interesting phenomena of work generation in nonequilibrium systems under random external forces. In this work, we report Brownian movement rectification of 0.5 micron diameter latex particles using pulsating ratchets. In order to implement the asymmetric potential, a 2D asymmetrical saw tooth phase pattern is displayed on a spatial phase modulator and then transformed into an intensity pattern by using the phase contrast method. This pattern is focused down with a 100x microscope objective obtaining a pattern of ~40x40 square microns at the focal plane. The pattern´s parameters can be dynamically controlled: periodicity, asymmetry, and on/off rate which allows optimization of directed transport. We found that there is an optimum value for the on/off rate and particle diameter/spatial period obtaining an average speed of 0.6 microns/s. The 2D pattern allow us to manipulate a large number of particles, in contrast to previous studies were only one particle has been studied, opening the opportunity to massive sorting of particles.

Optically induced zinc nanoparticles selective deposition on single-mode fiber end

G. J. Ortega, F. Chávez, P. Zaca-Moran, Benemérita Univ. Autónoma de Puebla (Mexico); R. Ramos-Garcia, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); C. F. Mendoza, Instituto Politécnico Nacional (Mexico); G. F. Pérez, Benemérita Univ. Autónoma de Puebla (Mexico); J. G. Gutiérrez, Univ. Autonoma Benito Juarez of Oaxaca (Mexico); O. Goiz Amaro, Ctr. de Investigacion y de Estudios Avanzados del IPN (Mexico)

Metal particles manipulation with radiation pressure of laser light is possible, only if the diameters of these particles are much smaller those of the wavelength of the laser light (Rayleigh particles). In this case, the gradient force is larger than both the scattering and absorption forces. We have made a numerical study considering a Gaussian beam with a fundamental mode that interacts with zinc spherical nanoparticles with different diameters (< 44 um), and submerged into isopropyl alcohol in order to examine the behavior of the radiation pressure (scattering, absorption and gradient force). The results of this study show that the gradient force is greater than other forces only by particles with a certain diameter. Moreover, by using the gradient force of the laser light, the zinc nanoparticles were deposited on a single-mode fiber end. The images obtained by optical microscope and atomic force microscope

show that the particles deposited on the optic fiber end exhibit a uniform distribution of nanoparticles in the core which can be used as optical mirrors, sensors, saturable absorbers, etc.

8097-67, Poster Session

Trapping of nanoparticles in water by evanescent wave near a NSOM probe

B. Liu, L. Yang, Y. Wang, Harbin Institute of Technology (China)

Applying Maxwell stress tensor and 3D FDTD methods, physical properties of nanoparticle trapping by evanescent wave near the NSOM probe, including trapping size, trapping position and role of other forces versus optical trapping force, are revealed. From the distribution of trapping force acted on a nanoparticle along three axis directions, it is found that the nanoparticle tends to be trapped to the aperture edge and center surface of the probe tip. In experiments 120 nm polystyrene particles are trapped in a multi-circular shape and two circles of polystyrene particles are arranged to different positions on the substrate. The results indicate that the NSOM probe is able to trap nanoparticles with lower laser intensity than that required by conventional optical manipulator.

8097-68, Poster Session

Optical trapping of semi-conducting nanowires

S. H. Simpson, S. Hanna, Univ. of Bristol (United Kingdom)

Semi-conducting nanowires lend themselves to a variety of applications. For example, they are ideal candidates for components in novel electronic and optical devices. Evidently, optical trapping has a part to play in the assembly of such structures and there is much experimental work directed toward this goal. Theoretical work, however, is relatively sparse. One reason for this is that the very high aspect ratios involved, prohibiting the use exact methods. Here we investigate the use of the discrete dipole approximation to calculate optical forces on nanowires. Where possible, results are compared with available analytical and semi-analytical techniques, the accuracy is assessed and possible modifications to the algorithm are suggested. Subsequently we investigate the optical forces on nanowires trapped in single and multiple Gaussian beams. The domain between trapping and non-trapping behavior is demarcated, and observed to be highly dependent on the optical environment. Thus, a nanowire which will trap in a single beam, may not trap horizontally in a dual beam system, and a nanowire which will trap in this way may cease to do so if the polarization states of the beam are altered. For single beam trapping, with the nanowire vertically oriented, it is shown that the vertical stiffness decreases exponentially with increasing length, whilst it remains tightly trapped in other respects. Such systems can therefore be used as highly sensitive force or mass sensors. Finally, we show simulations of the thermal motion of optically trapped nanowires and investigate its impact on trap stability.

Optical trapping of single gold nanoparticles with higher order laser modes

A. Huss, R. Jäger, A. M. Chizhik, J. Mihaljevic, A. J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

Optical trapping is one of the most promising tools for nanochemistry and nanoengeneering. Since Arthur Ashkin [1] brought optical trapping to life, many steps forward have been made. To form a stable trap it is required to overcome the scattering and absorption forces, therefore metallic and magnetic nanoparticles cannot be trapped easily. Recently, trapping of single gold nanoparticles in aqueous solutions with a linearly polarized Gaussian beam and fixing them in controlled pattern on the sample surface has been experimentally shown [2,3]. However, to increase the trapping force and stability of the trap the use of cylindrical vector beams (also known as doughnut-modes) has been suggested according to theoretical calculations [4]. Since a focused radially polarized laser mode has higher electric field component in the propagation direction with respect to the linearly polarized Gaussian beam, it provides an advantage for optical trapping. Moreover, the weak in-plane component of the radially polarized laser mode pushes passing nanoparticles into the focus of the beam.

In this work we present our recent experimental and theoretical results upon optical tweezers using a radially polarized light. A home-built confocal microscope setup has been used for focusing a radially polarized laser beam with a high numerical aperture immersion oil objective lens. This allowed us to use the advantages of high-resolution confocal microscopy and cylindrical vector beams for trapping nanometer-size gold spheres.

Micro- and Nanoparticle Optical Trapping Using Cylindrical Vector Beams

S. Skelton, M. Sergides, A. Pawlikowska, Univ. College London (United Kingdom); M. G. Donato, P. G. Gucciardi, A. Irrera, O. M. Maragò, Istituto per i Processi Chimico-Fisici (Italy); P. H. Jones, Univ. College London (United Kingdom)

The vast majority of optical tweezers use a trapping laser beam with a spatially homogeneous state of polarization, such as linear, elliptical and circular polarizations. However, spatial modulation of the polarization of the trapping beam has the potential to add a further degree of control to trapping parameters and allow further optimization of the trap for certain particle types.

Laser beams in which the polarization is directed radially outwards from the beam axis have received significant recent attention due to their interesting focusing properties. These beams contain a polarization singularity along the beam axis where the electric field amplitude is identically zero, and thus exhibit an annular intensity distribution in the far-field. The polarization configuration and ‘donut’ intensity profile result in tighter focusing of the radially polarized beam when compared to a linearly polarized Gaussian beam, producing a smaller transverse size of the focal spot. Furthermore, due to symmetries in the polarization components, the time-averaged axial component of the Poynting vector is zero, thus the scattering force vanishes, making the radially polarized tweezer an ideal candidate for trapping nano-particles.

We investigate the use of radially polarized laser beams for optical trapping of micro- and nano-particles. We present quantitative experimental measurements of the trap spring constants for a wide range of parameters and particle sizes and compare the results to those obtained using the more conventional linearly- and circularly- polarized trapping beams. Additionally, we investigate shaping of the trapping volume for trapping of elongated micro and nanostructures (nanotubes, nanowires).

Discrete complex amplitude filter for ultra long optical tube

J. Wang, Nanjing Univ. of Aeronautics and Astronautics (China) and State Key Lab. of Transient Optics and Photonics (China); Q. Liu, Y. Liu, Nanjing Univ. of Aeronautics and Astronautics (China);

W. Chen, Q. Zhan, Univ. of Dayton (United States)

In this paper, a discrete complex amplitude filter is designed to obtain the focused hollow field with ultra long depth of focus (DOF). As for a high numerical aperture (NA=0.95) objective lens obeying the sine condition, the distribution of the focused field in the focal region can be engineered into a field like a long "tube" with flat wall through manipulating the transmitted amplitude and the phase delay of the field at the incident pupil plane .This complex amplitude of the pupil plane can be discretized into multiple zones with different radius, transmitted amplitude and phase delay. A focused tube field with 9λ depth of focus can be created as an example through separating and averaging of the projected pupil radiation field of dipole array in the focal region. Imperfections of the designed filter will influence the quality of the generated optical tube field. Deviation of the radius, transmitted amplitude and phase in each zone will influence the profiles of the tube field to some extent and these are discussed (Fig.1 (a) and (b)). For the optical trapping and manipulation, this created tube field can expand the manipulated distance and increase the trapped particles' numbers.

Femtosecond laser pulses for chemical-free embryonic and mesenchymal stem cell differentiation

P. Mthunzi, Council for Scientific and Industrial Research (South Africa); K. Dholakia, F. Gunn-Moore, Univ. of St. Andrews (United Kingdom)

Owing to their self renewal and pluripotency properties, stem cells can efficiently advance current therapies in tissue regeneration and/or engineering. Under appropriate culture conditions in vitro, pluripotent stem cells can be primed to differentiate into any cell type some examples including neural, cardiac and blood cells. However, there still remains a pressing necessity to answer the biological questions concerning how stem cell renewal and how differentiation programs are operated and regulated at the genetic level. Indeed, Uchugonova et al, 2008 [1] reported on an urgent requirement in stem cell research on technologies for non-invasive, marker-free observation of growth, proliferation and stability of living stem cells under physiological conditions. In their studies, through the detection of second-harmonic generation signal, they investigated two-photon excited auto-fluorescence of human stem cells and the onset of collagen production of differentiated cells.

Femtosecond (fs) laser pulses have been reported to non-invasively deliver exogenous materials, including foreign genetic species into both multipotent and pluripotent stem cells successfully [2, 3]. Through this multi-photon facilitated technique, directly administering fs laser pulses onto the cell plasma membrane induces transient submicrometer holes, thereby promoting cytosolic uptake of the surrounding extracellular matter [4]. To display a chemical-free method of stem cell differentiation that utilises micro-litre scale volumes of reagents, we report on using a diffraction limited near infrared pulsed laser beam spot for embryonic and mesenchymal stem differentiation. The produced specialized cell types could thereafter be characterized and used for cell based therapies.

Heating effects on NG108 cells induced by laser trapping

I. Verdeny, A. Fontaine, A. Farré, M. Montes-Usategui, E. Martín-Badosa, Univ. de Barcelona (Spain)

Optical tweezers (OT) are an innovative and powerful technique with a wide range of applications in the physical and biological sciences. This novel microtool uses a highly focused laser beam to trap and manipulate microscopic neutral objects. Typical traps in cell biology are generally based on lasers producing from 25 mW to 2 W in the specimen plane. Non-contact force for cell manipulation, force resolution as accurate as 0.1 pN and amiability to liquid medium environments are the main advantages of this technique.

Nevertheless, the response of living matter to the interaction with laser light still remains unclear. Previous studies evaluating the cell response to laser irradiation with OT have already been performed. Several parameters (laser power, irradiation time, wavelength...) have been tested in various types of cells and organisms and different cell functions (cloning efficiency, ability to grow, motility...) and reactions (viability, apoptosis and stress response) have been used to assess damage. However, conclusions do not seem to be unanimous yet.

Photon absorption is a major detrimental process when laser radiation interacts with cells, consequently, generating both photodamage and thermodamage.

Particularly, this work is focused on the damage induced by heating of the sample or thermodamage. The heat shock or stress response is the earliest defence mechanism of cells when subjected to physiologically relevant changes in the environment. This mechanism gives the stressed cell added protection, thus, allowing for continued cell survival. However, high levels of thermodamage can lead to other type of reactions in the cell such as apoptosis or necrosis.

This work aims at assessing the induced laser heating effects on NG108 cells by studying the induction of apoptosis and necrosis on these cells. Furthermore, quantification of the local temperature increase in the focus of the optical trap with the back-focal-plane interferometry technique is also one of the main goals.

Optical tweezers used to assess the effects of viscosity on sperm motility

N. Hyun, C. Chandsawangbhuwana, Q. Zhu, L. Z. Shi, C. Yang-Wong, Univ. of California, San Diego (United States); M. W. Berns, Univ. of California, San Diego (United States) and Beckman Laser Institute and Medical Clinic (United States)

The purpose of this study was to analyze sperm motility in a range of viscous media. Viscous media solutions were made by using varying concentration of methylcellulose yielding 3, 6, 9, and 15 centipoises. Motility parameters were collected using customized tracking software that measures the curvilinear velocity (VCL) and the escape force (Pesc) of an individual sperm. The Pesc was measured by using a 1064 nm Nd:YVO4 continuous wave laser that optically traps motile sperm at a maximum power of 450 mW in the focused trap spot. The VCL was measured frame by frame before trapping. Multiple experiments were preformed to collect motility parameters in increasing viscosity media. To complement our motility data, sperm were labeled with the fluorescent dyes DiOC6(3) and JC-1 to measure mitochondria membrane potential located in the sperm's midpiece. Fluorescence was measured before and during trapping in to provide insight to the sperm energetics under various viscous conditions.

The preliminary results showed that there was a correlation between swimming speed (VCL) vs. viscosity and escape force (Pesc) vs. viscosity. The relationship between VCL and viscosity showed that there was a decreased VCL with increasing viscosity; however there was an increase in Pesc with increasing viscosity. There was no change in

fluorescent intensity between viscous media indicating that there was no change in sperm energetics. The results show that viscosity physically affects the mechanical motility properties of sperm rather than the sperm energetics.

Measuring stall forces in vivo with optical tweezers through light momentum changes

J. Mas, A. Farré, C. López-Quesada, E. Martín-Badosa, M. Montes-Usategui, Univ. de Barcelona (Spain)

The stall forces of processive molecular motors have been widely studied in vitro. Even so, in vivo experiments are required for determining the actual performance of each molecular motor in its natural environment. We report the direct measurement of light momentum changes in single beam optical tweezers as a suitable technique for measuring forces inside living cells, where few alternatives exist. The simplicity of this method makes it convenient for measuring the forces involved in fast dynamic biological processes. We present our measurements of stalling events showing the pulling force of processive molecular motors inside living cells.

Temporal evolution of thermocavitation bubbles using high speed video camera

J. P. Padilla-Martinez, J. C. Ramirez-San-Juan, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); G. Aguilar, Univ. of California, Riverside (United States); R. Ramos-Garcia, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Thermocavitation induced by CW low laser powers in highly-absorbing solution is new field of research that may have useful applications in lithography, micropatterning of metallic thin films and sonoporation among others. Thermocavitation bubbles are always in contact with the substrate due to the high absorption coefficient of the solution. The temporal evolution of these bubbles is quite complex as it has been already demonstrated in short pulsed-laser cavitation. In a previous work, we reported its temporal evolution using indirect methods; however details information cannot be obtained. In this work, a precise description of the bubble dynamics is achieved using a high speed video camera (Phantom V7, Version: 9.1) running to 111,111 frames per second of 64 × 64 pixels resolution. These videos give valuable information on the dynamics like bubble lifetime, maximum radius and collapse time as a function of laser power (62 to 200 mW) and beam waist. For a power laser of 150 mW (at the exit of the microscope objective) the bubble grows regularly without any significant modification of its half-hemisphere shape, reach its maximum radius (~1037 microns) in 180 microseconds and then collapses rapidly in 135 microseconds. Near the collapse, the bubble departs from its semi-spherical shape taking a step-like shape. Bubble´s rebound is weak and not always is observed. The bubble´s radius can be controlled with the beam waist, obtaining larger bubbles for larger beam waist.

An optical manometer-on-a-chip

Y. Jin, K. Crozier, Harvard Univ. (United States)

We present a novel pressure-based approach combining optical trapping with microfluidics to investigate the properties of complex fluids in microscopic environments. In our device, termed a “manometer-on-a-chip”, a shield structure divides a microfluidic channel into two parallel parts. In the center of the narrower ‘side channel’, a polystyrene bead is trapped by a traditional optical tweezer, whereas the wider ‘main channel’ conveys fluids whose behavior we are interested in studying. Because parallel channels always share the same pressure drop when a flow is applied, the displacement of the bead in the ‘side channel’, which we monitor using a video camera, reflects the pressure variation over both channels. The pressure-displacement relation is calibrated by measuring the extension of a bead trapped in a test chip containing a channel with the same cross section as the ‘side channel’ of the actual device. This test chip is connected to an external pressure source. To demonstrate the device, we send oil droplets in water, generated by a T junction structure treated to be hydrophilic, through the manometer, and record the position of the bead trapped in the side channel. Our results illustrate that the device can detect single droplets and differentiate them based on size. The droplets are detected by monitoring the bead position with time. Comparison with calibration show that our device is sensitive enough to resolve a pressure variation below 0.1 Pa. We anticipate that our device will be useful for understanding the behavior of emulsions and multiphase flows.

Plasmonic nanopillar arrays for optical trapping, biosensing, and spectroscopy

A. E. Cetin, A. A. Yanik, Boston Univ. (United States); C. Yilmaz, S. Somu, A. A. Busnaina, Northeastern Univ. (United States); H. Altug, Boston Univ. (United States)

In this work, we propose a plasmonic platform based on monopole antenna arrays that can enable high sensitive biosensing, vibrational spectroscopy and high precision optical trapping at the same time. Perpendicular incident light is coupled to Surface Plasmon (SP) modes through the system. This is one of the significant advantageous over other sensing/trapping platforms based on angled illumination source. The tight localization of plasmonic excitation in nanopillar structure leads to narrow resonances in the spectrum. Hence, we achieve high refractive index sensitivity, ~675 nm/RIU with high figure of merit (FOM), ~112.5. This FOM value is higher than the preceding plasmonic structures based on the localized SP modes. SPs are localized at specific hot spots on the top surface of the gold nanopillars which lead large near-field intensities with enhancement factors of ~9000 highly desirable for surface Raman spectroscopy. The hot spots with high near-field enhancement depend on the polarization of the incident source. We also achieve high optical force, ~350 pN/W/μm^2, from these hot spots which allows optical trapping of nanoparticles with excitation source of low power. Since the location of the hot spots highly depends on the direction of polarization, we can always get the strongest directional force we can achieve from the system. Our proposed structure serves for optical trapping of bioparticles, spectroscopy measurement and real-time biodetection at the same platform which could attract many attentions from wide range of researches and studies.

8097-60, Session 13

Controlling and utilizing optical forces at the nanoscale with plasmonic antennas

A. Lovera, O. J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Plasmonic dipole antennas are powerful optical devices for many applications since they combine a high field enhancement with outstanding tunability of their resonance frequency. The field enhancement, which is mainly localized inside the nanogap between both arms, is strong enough to generate attractive forces for trapping extremely small objects flowing nearby. Furthermore it dramatically enhances their Raman scattering cross-section generating SERS emission. In this talk, we demonstrate how plasmonic antennas provide unique means for bringing analyte directly into hot-spots by merely controlling the optical force generated by the plasmon resonance. This technique is very suitable for immobilizing objects smaller that the

diffraction limit and requires a very little power density. In this work, 20nm gold nanoparticles functionalized with Brilliant Cresyl Blue are trapped in the gap of nanoantennas fabricated with e-beam lithography on glass substrate. The entire system is integrated into a microfluidic chip with valves and pumps for driving the analyte. The field enhancement is generated by a near-IR laser (λ=808nm) that provides the trapping energy. It is focused on the sample through a total internal reflection (TIRF) objective in dark field configuration with a white light source. The scattered light is collected through the same objective and the spectrum of one single antenna spectrum is recorded and analyzed every second. A trapping event is characterized by a sudden red-shift of the antenna resonance. This way, it is possible to detect the trapping of extremely small objects. The SERS signal produced by a trapped analyte can then be studied by switching from the white light source to a second laser for Raman spectroscopy, while keeping the trapping laser on. The trapping and detection limit of this approach will be discussed in detail.

8097-61, Session 13

Holographic tweezers: a platform for plasmonics

M. Dienerowitz, G. M. Gibson, R. W. Bowman, A. Curran, M. J. Padgett, Univ. of Glasgow (United Kingdom)

Optical manipulation of metal nanoparticles has attracted a lot of interest over the past years yet it is still considered challenging1-4. The nanoscale size of the particles as well as their enhanced absorption and reflectivity render them hard to control with standard trapping techniques. A well-known phenomenon from plasmonics is the strong interaction between adjacent plasmon resonances when exited by laser light. In the case of freely floating particles this results in a complex force mechanism displacing metal nanoparticles. It is possible to exploit the resonance to induce attractive as well as repulsive forces expanding the manipulation toolkit for metal nanoparticles5.

We present a nanoparticle workstation incorporating holographic tweezers to manipulate several trapped metal nanoparticles simultaneously. The versatility of the holographic tweezers and the submicron control of our sample stage allow precise particle positioning. In addition we assess each trapped particle by monitoring its specific spectral properties. By changing the distance between two trapped particles we monitor the interaction of their particle plasmons when brought close enough. This in situ monitoring of the changing plasmon resonances has provided new insights into plasmon coupling6. We focus particularly on nanoparticle imaging in our experiments and present a new darkfield microscopy technique which does not limit the numerical aperture of the trapping objective.

Metal nanoparticles have become popular tools for biological applications and enhanced spectroscopy techniques because of their biocompatibility. Improving the manipulation skills available and facilitate measurement techniques helps to advance the controllability of metal nanoparticles employing them as nanometric sensors and antennas.

8097-62, Session 13

Optical trapping in a microfluidic device via surface plasmon resonance on patterned hole arrays

S. Weber, D. J. Day, M. Gu, Swinburne Univ. of Technology (Australia)

The manipulation of polystyrene microspheres via the application of Surface Plasmon Resonance (SPR) based optical effects inside patterned and non-patterned microfluidic device was investigated. Using the Kretschmann geometry, light from a Nd:YAG laser (λ = 1064 nm) is coupled into a 40±2 nm gold film coated onto a glass slide, resting on a glass prism (n = 1.785) via an index matching liquid (n = 1.516). The SPR angle is calculated to occur at 63 ± 1° for an incident wavelength λ = 1064 nm, this is confirmed via experimental observation. A 200x200 µm array of 4 µm holes was etched into the microfluidic devices gold surface using an amplified femtosecond pulse laser (Spitfire, Spectra Physics, 800 nm 1 kHz) and direct multiphoton etching using a 0.70 N.A. NIR objective lens. 15, 10, and 4.3 µm sized microspheres were placed in a sample of phosphorus buffer solution and pumped into the microfluidic chamber using a gravity pump system. The incident light illuminated the patterned region with the power being varied between 20 and 70 mW, both on the SPR angle and when the incident angle is de-turned by 4° off the resonance position. We've observed that via the patterning of the gold surface layer the trapping efficiency can be increased compared to the unpatterned case. We have also demonstrated that the number of trapped microspheres can be controlled by either changing the power of the incident light or by changing the size of the microspheres being trapped.

8097-63, Session 13

Opto-mechanical force measurement of deep sub-wavelength plasmonic modes

J. Kohoutek, D. Dey, A. Bonakdar, A. Sklar, O. G. Memis, R. Gelfand, H. Mohseni, Northwestern Univ. (United States)

We show that the radiation force of a plasmonic antenna can be confined to an extremely small volume. We produce very high field intensities using compression of optical modes by orders of magnitude below their diffraction-limited volume using said antennae, and show significant radiation forces produced by these plasmonic modes. As a source we use a room temperature operated quantum cascade laser (QCL) working in the mid-infrared region of the optical spectrum as well as a commercially available fiber coupled laser operating at 1550 nm. We have used a finite-difference time domain method to simulate the plasmonic antenna to find the optimal resonance conditions, as well as the radiation force map computed by stress tensor method. We have then used electron beam evaporation and focused ion beam milling to fabricate the plasmonic antenna on the facet of the lasers. In parallel, we have developed a method capable of mapping the force with high sensitivity and nanometer spatial resolution, over the device. We have also used a lock-in to get the phase signal from the AFM in non-contact mode. We show that an external force can cause a change in phase of the AFM tip. We will compare our measured data with our FDTD simulation results. The ultra-small mode volume can make it possible in the future to move small objects with a relatively large force. These results also demonstrate the feasibility of novel opto-mechanical devices, such as switches and modulators, at very high speed.

Conference 8098: Physical Chemistry of Interfaces and Nanomaterials X

Sunday-Tuesday 21-23 August 2011 • Part of Proceedings of SPIE Vol. 8098
Physical Chemistry of Interfaces and Nanomaterials X

8098-01, Session 1

Ultrafast single and multiple electron transfer from quantum dots

T. T. Lian, Emory Univ. (United States)

Charge transfer to and from quantum dots (QDs) is of intense interest because of its important roles in QD-based devices, such as solar cells and light emitting diodes. Recent reports of multiple exciton generation (MEG) by one absorbed photon in some QDs offer an exciting new approach to improve the efficiency of QD-based solar cells and to design novel multi-electron/hole photocatalysts. However, two main challenges remain. First, the efficiency of MEG process needs to be significantly improved for practical applications. Second, the utilization of the MEG process requires ultrafast exciton dissociation prior to the exciton-exciton annihilation process, which occurs on the 10s to 100s ps time scale. In this presentation we report a series of studies of exciton dissociation dynamics in quantum dots by electron transfer to adsorbed electron acceptors. We show that excitons in CdSe and PbS QDs can be dissociated on the picosecond timescale to various adsorbates. As a proof of principle, we demonstrate that multiple excitons per QD (generated by multiple photons) can be transferred to adsorbed acceptors (J. Am. Chem. Soc. 2010, 132, 4858-4864). We will discuss the dependence of the electron transfer rates on the size and the nature of the quantum dots and possible approaches to optimize the multiple exciton dissociation efficiency.

8098-02, Session 1

Interfacial electron transfer in colloidal nanocrystals.

M. Jones, D. Woodall, S. Johnson, E. Williams, A. K. Tobias, Jr., K. J. Major, D. Woolford, The Univ. of North Carolina at Charlotte (United States)

Quantum confinement of photo-generated electrons and holes in colloidal semiconductor nanoparticles is well understood and results in a wide array of potentially important properties. Application of nanocrystals in photovoltaics requires rapid and efficient generation of separated charges, which must be transported away from the chromophore to do useful work. These charge separation processes originate from highly delocalized exciton states and can be understood in terms of electron transfer reactions that can localize an electron or hole into a ligand orbital or a nanocrystal trap state.

Electronic coupling of nanocrystal exciton states with states in the surrounding environment strongly influences relaxation dynamics. Nanocrystal charge transfer states typically have low absorption cross-sections, so it is hard to directly probe their role and relative impact on the underlying dynamics. Time resolved fluorescence spectroscopy reflects both radiative exciton recombination rates and non-radiative transitions rates to extrinsic surface or ligand states; however, interpretation of fluorescence transients is not trivial and typical multi- or stretched exponential decay models yield little specific photophysical insight.

I will describe a quantitative analysis method for temperature-dependent time-resolved fluorescence data applied to a series of nanocrystal systems and demonstrate how these data can be used to understand electron transfer dynamics. In addition I will present data obtained using a pulse-rate modulation technique with which we are able to unravel the contribution to these electron transfer dynamics from multi-exciton states. General features of charge transfer reactions are emerging from these analyses, which will be discussed in the context of future photovoltaic materials.

8098-03, Session 1

Nonlinear infrared spectroscopy of interface

W. Xiong, Univ. of Wisconsin-Madison (United States)

In this talk, I am going to cover two topics. First I will discuss our discovery of multiple conformations of Re dyes on nanocrystalline TiO2 film and the different charge transfer mechanisms we observed using 2D IR spectroscopy. Secondly, I will show some results of our recently developed heterodyned time domain SFG spectroscopy. It is a technique with higher sensitivity and better resolution and lineshape fidelity than the popular broadband frequency domain SFG technique. These improvements are critical for measuring spectra of non-compact, low surface coverage and disordered surfaces such as the dye-TiO2 interface.

Charge transfer across interfaces is an important step in many solar energy capture devices, such as dye-sensitized solar cells. Since the charge transfer happens right at the interface, the conformation of the molecules on the surface play a key role on their charge transfer behavior. Using 2D IR spectroscopy we found that there are at least three conformations of the dye molecules on the TiO2 nanoparticle surface. Further, using a transient 2D IR pulse sequence which can correlate the ground and excited electronic states of the dye, we showed that all three conformations participate in the charge transfer process but one of the conformations has a completely different charge transfer pathway. Further research will include monitoring the electron transfer dynamics of each conformation and determining the dye orientations using Sum Frequency Generation Spectroscopy (SFG), which is related to the second topic of my talk.

SFG is an interface specific second order infrared spectroscopy. One of its advantages is the ability to measure the dipole orientation relative to the surface. In the second half of my talk, I will discuss our newly developed heterodyned time domain SFG spectroscopy technique. It is a Fourier transform based technique that has better resolution and lineshape fidelity than the popular broadband frequency domain SFG spectroscopy. Moreover, heterodyned detection significantly improves the sensitivity and also allows a much more intuitive interpretation of the spectra by acquiring the real and imaginary part of it, which is not available using the homodyned detection method. Using heterodyned time domain SFG, we showed there is an inhomogenous binding distribution of a simple aryl diisocyanide molecule on the gold surface, and this result agrees well with recent theoretical work. The sensitivity, resolution, and linshape improvements using the heterodyned time domain SFG spectroscopy are critical for applying SFG on a non-compact, low surface coverage, and disordered monolayer surface such as the dye-TiO2 surface in our charge transfer study.

8098-04, Session 1

AC conductivity of nanoporous metal-oxide photoanodes for solar energy conversion

S. J. Konezny, V. S. Batista, Yale Univ. (United States)

The temperature- and frequency-dependent ac conductivity of nanoporous metal-oxide semiconductors commonly used in technologies for solar photoconversion is analyzed using a model based on

fluctuation-induced tunneling conduction (FITC). The model takes into account the potential barriers at the regions of nanoparticle contact that limit electron transport. In contrast to previous models, quantitative agreement is found with the FITC model with a single set of parameters over the entire temperature range studied. Guidelines for the design of new materials for dye-sensitized solar cells and solar photocatalysis are discussed.

8098-05, Session 2

Calculations of interface states between two polymers: polythiophene and polyselenophene

M. Côté, Univ. de Montréal (Canada)

Organic photovoltaic devices are presently the subject of intense research since they could eventually propose solar energy solutions at a much reduced cost compared to inorganic devices. Presently, electron transport in organic photovoltaic devices is achieved with a fullerene derivative (PCBM) but this solution has some disadvantages. First, the ratio of PCBM to polymer has to be quite high to assume good electronic transport, and second, the relatively high cost of PCBM is not ideal with the goal to reduce the cost of the device. For these reasons, a replacement for PCBM is desirable and an all polymer device solution is viewed as the best avenue. Since polythiophene (P3HT) is ideal for hole transport, its isovalent polyselenophene (P3HS) where sulfur atoms are replaced with selenium atoms might offer an interesting alternative to PCBM. The physical processes in organic devices are quite different from those of inorganic devices. Charge separation in organic devices is achieved by forming an interface between two organic materials with type 2 level alignment. However, because of the large binging energies observed in organic compounds, there is often the presence of H-aggregate states at the junction between the two organic materials. In this presentation, we will report the results of interface states in a blend of polythiophene and polyselenophene. Photoluminescence spectra will be presented along with calculations of these states with the help of the time-dependent density-functional theory.

8098-06, Session 2

Use of nucleating agents for microstructure manipulation of organic photovoltaic blends

N. Stingelin-Stutzmann, Imperial College London (United Kingdom) and ETH Zurich (Switzerland) and Freiburg Institute for Advanced Studies (Germany); J. Nekuda-Malik, Imperial College London (United Kingdom); P. Smith, ETH Zurich (Switzerland)

Poly(3-hexylthiophene) (P3HT) / phenyl-C60-butyric acid methyl ester (PCBM) bulk heterojunction (BHJ) blends are a promising organic photovoltaic system. However, lack of understanding of relevant fundamental relationships between the nano- and microstructure of the blend and electronic processes is hampering further improvement in device performance, and renders straight-forward implementation of even the most simple fabrication protocols to other BHJ binaries challenging. The origin of this complexity is the fact that P3HT/PCBM active photovoltaic layers, as well as many other BHJ systems, consist of a multiphase architecture comprising: 1) phase-separated crystalline P3HT and crystalline PCBM phase regions, and 2) a highly intermixed P3HT/PCBM amorphous phase. While it is well known that charge separation in these structures occurs at the interface between the P3HT donor and PCBM acceptor material, to date, it is unclear at which boundaries (crystalline or amorphous) this process predominantly takes place. We present use of well known clarifiers for the bulk commodity polymer isotactic polypropylene (i-PP), including 1,3:2,4-bis(3,4-dimethyl benzylidene) sorbitol (DMDBS) and an alkyl-substituted 1,3,5-benzenetrisamide, to nucleate P3HT. This nucleation process allows us to modify and control the size of the crystalline regions in P3HT/PCBM blends in an attempt to elucidate the primary region of charge separation. Details of the methods used to manipulate the P3HT/PCBM blend microstructure will be discussed and the correlation between microstructural changes and device characteristics will be presented.

8098-07, Session 2

Ultrafast kinetics in polycrystalline pentacene: Exciton fission

M. W. B. Wilson, A. Rao, Univ. of Cambridge (United Kingdom); R. S. S. Kumar, Istituto Italiano di Tecnologia (Italy); D. Brida, G. Cerullo, Politecnico di Milano (Italy); R. H. Friend, Univ. of Cambridge (United Kingdom)

We report the use of ultrafast transient absorption spectroscopy with sub-20 fs time resolution to directly probe the process of exciton fission in polycrystalline thin films of pentacene. We observe that the overwhelming majority of initially photogenerated singlet excitons evolve into triplet excitons on an ~80 fs timescale independent of the excitation wavelength. This implies that exciton fission occurs at a rate comparable to phonon-mediated exciton localization processes, and may proceed directly from an initial delocalized state. The singlet population is identified due to the brief presence of stimulated emission, which is emitted at wavelengths which vary with the photon energy of the excitation pulse, a violation of Kasha's Rule that confirms that the lowest-lying singlet state is extremely short-lived. This direct demonstration that triplet generation is both rapid and efficient establishes multiple exciton generation by exciton fission as an attractive route to increased efficiency in organic solar cells. However, these results bear significantly on the task of realizing such a solar cell, as it would appear necessary to ensure the formation of ordered molecular aggregates that can support delocalized excitations, as opposed to simply including pentacene moieties in a disordered system.

8098-08, Session 2

On the correlation between structure, morphology, and charge transport in organic molecular films: the tetracene case

G. Tarabella, Consiglio Nazionale delle Ricerche (Italy); L. Lutterotti, Univ. di Trento (Italy); S. Bertolazzi, J. Wuensche, Ecole Polytechnique de Montréal (Canada); N. Coppedé, S. Iannotta, F. Cicoira, Consiglio Nazionale delle Ricerche (Italy); C. Santato, Ecole Polytechnique de Montréal (Canada)

Dielectric surface engineering is a tool to control organic molecular semiconducting films' morphology and structure, which in turn play a pivotal role in establishing films' functional properties.

We report an extended correlation between films morphology, studied by Atomic Force Microscopy, structure, investigated by Grazing Incidence X-ray diffraction (GIXRD), and charge carrier transport in Field Effect Transistor configuration for tetracene films vacuum sublimed on six different dielectric substrates, namely bare SiO2 (reference substrate), OTS, HMDS, parylene C, polystyrene and PMMA. Tetracene is a model molecule exhibiting good charge transport and electroluminescence, attractive for applications such as Light Emitting Transistors. Films on polystyrene showed a mobility of 2·10-1 cm2V-1s-1, the highest reported up to now for tetracene. Films on polystyrene showed the earliest complete substrate surface coverage: at 10 nm of nominal thickness tetracene islands appeared tightly packed and well interconnected.

GIXRD patterns, collected at different grazing incident angles in reflection mode, were analyzed using the Maud software, based on the Rietveld method extended to gain an unprecedented insight on the texture, phases amount, crystallites sizes and r.m.s. microstrains. Two different tetracene phases were identified: the beta phase showed a longer c axis with respect to the alpha one. A strong fiber texture perpendicular to the

sample surface was observed for both phases. Tetracene films grown on polystyrene showed the highest amount of alpha phase and the strongest grain alignment, in agreement with the highest mobility measured.

8098-10, Session 3

Charge transport and recombination in organic solar cells

R. A. Street, Palo Alto Research Center, Inc. (United States)

Organic solar cells have reached about 8% efficiency, but need to be more efficient to compete with other materials. An understanding of the losses of organic bulk heterojunction solar cells requires knowledge of how the heterojunction interface influences the electronic transport and recombination mechanisms. We describe how transient photoconductivity measurements and the cell spectral response provide information about the carrier mobility, recombination mechanisms and the electronic structure. We find that geminate recombination is not a dominant recombination process in P3HT:PCBM or PCDTBT:PCBM cells. Instead, there is good evidence that recombination through interface traps is important. The measurements of the electronic structure show band tail effects attributed to the material disorder. The band tails contribute to suppressing geminate recombination and allowing trap recombination. The role of the interface on the electronic structure and the electronic properties will be discussed.

8098-11, Session 3

Charge generation dynamics at nano-scale interfaces in all-organic and hybrid materials

L. M. Herz, Univ. of Oxford (United Kingdom)

Conjugated polymers and molecules are increasingly used as cheap artificial light-harvesting materials in photovoltaic devices. The large exciton binding energy in these systems necessitates the use of blends comprising at least two materials at whose interface a type-II heterojunction is formed, thus making charge separation energetically favourable.

Examples of all-organic materials are blends of conjugated polymers with single-walled carbon nanotubes (SWNTs) with the latter promising large electron mobilities and percolation paths. We have investigated the charge photogeneration dynamics at the interface formed between SWNTs and poly(3-hexylthiophene) (P3HT) using a combination of femtosecond spectroscopic techniques [1]. We demonstrate that photoexcitation of P3HT forming a single molecular layer around a SWNT leads to an ultrafast (430 fs) charge transfer between the materials. The addition of excess P3HT leads to long-term charge separation in which free polarons remain separated at room temperature. Our results suggest that SWNT-P3HT blends incorporating only small fractions (1%) of SWNTs allow photon-to-charge conversion with efficiencies comparable to those for conventional (60:40) P3HT–fullerene blends, provided that small-diameter tubes are individually embedded in the P3HT matrix.

In addition, hybrid interfaces comprising organic dyes as sensitizer monolayers on metal-oxide mesostructures films have been highly successful when implemented in so-called dye-sensitized solar cells (DSSCs). We have used optical-pump terahertz-probe spectroscopy to explore the photoinduced conductivity dynamics in such mesoporous metal-oxide films [2]. We extract early-time mobility values and compare these to bulk values in order to determine factors limiting electron movement in these systems. In addition, we have utilized terahertz spectroscopy to investigate the influence of surface treatments for the metal oxide on early-time charge dynamics. For example, surface treatment of the mesoporous TiO2 with TiCl4 has been found to be critical to enable efficient operation of DSSCs. However, we find that neither early-time charge mobility nor charge injection rate or decay times are significantly affected by the treatment, which suggests that it may, instead, have an impact on phenomena occurring on longer time scales.

8098-30, Session 3

Giant pseudo-magnetic fields in graphene nanobubbles: locally probing graphene nanostructures with STM and STS

S. A. Burke, The Univ. of British Columbia (Canada); N. Levy, National Institute of Standards and Technology (United States); K. Meaker, M. Panlasigui, A. Zettl, Univ. of California, Berkeley (United States); F. Guinea, Instituto de Ciencia de Materiales de Madrid (Spain); A. H. Castro Neto, Boston Univ. (United States); M. Crommie, Univ. of California, Berkeley (United States)

Recent calculations have predicted that the relativistic charge carriers in strained graphene may behave as if under the influence of an applied magnetic field. This effect, dubbed a “pseudo-magnetic field” since no real magnetic field is present, arises from the special electronic structure of graphene as well as its honeycomb lattice. If the strain corresponds to a triangular geometry, then the strain-induced psudeo-magnetic field is nearly uniform, should give rise to a Quantum Hall Effect. This unusual effect requires the generation of large, non-uniform strains in a specific geometry, making its observation elusive.

The growth of graphene on Pt(111) generates nanoscale bubbles that incorporate strains of ~10% in a three-fold symmetric geometry. These “graphene nanobubbles” appear to arise from the differential thermal contraction between the graphene layer and the Pt(111) substrate when cooling from the growth temperature (1200K) to the measurement temperature (~7K). I will describe our recent low-temperature scanning tunnelling microscopy measurements of the graphene nanobubbles grown under strictly controlled ultrahigh vacuum conditions. Scanning tunnelling spectroscopy measurements, which can be used to locally probe the electronic structure at surfaces, exhibited sequences of peaks that can be attributed to Landau levels arising from strain-induced pseudo-magnetic fields of over 300 Tesla. The observation of such enormous strain-induced pseudo-magnetic fields opens the door for “strain-tronics” or “strain engineering” of the graphene band structure even at room temperature energy scales, as well as the study of charge carriers in extreme magnetic field regimes.

8098-12, Session 4

Modifying the fluorescence properties and determining the quantum yield of a single molecule with a tunable optical subwavelength microcavity

A. I. Chizhik, A. M. Chizhik, D. Khoptyar, S. Bär, Eberhard Karls Univ. Tübingen (Germany); J. Enderlein, Georg-August-Univ. Göttingen (Germany); A. J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

We present experimental and theoretical results on changing the fluorescence emission spectrum of a single molecule by embedding it within a tunable planar microcavity with subwavelength spacing [1]. The cavity length is changed with nanometer precision by using a piezoelectric actuator. By varying its length, the local mode structure of the electromagnetic field is changed together with the radiative coupling of the emitting molecule to the field. Because mode structure and coupling are both frequency dependent, this leads to a renormalization of the emission spectrum of the molecule. We develop a theoretical model for these spectral changes and find excellent agreement between theoretical prediction and experimental results.

We also demonstrate controlled modulation of the radiative transition rate

of a single molecule, which is measured by monitoring its fluorescence lifetime [2]. By comparing the experimental data with a theoretical model, we extract both the pure radiative transition rate as well as the quantum yield of individual molecules. We observe a broad scattering of quantum yield values from molecule to molecule, which reflects the strong variation of the local interaction of the observed molecules with their host environment.

Our technique can be applied to any single quantum emitter of interest, such as dye molecules, semiconductor nanoparticles, carbon nanotubes, etc. Thus, the tunable cavity method makes it a versatile tool for single molecule spectroscopy and quantum yield measurements of individual quantum emitters.

8098-13, Session 4

Electric-field dependent spectroscopy of single nanocrystal systems

S. Johnson, A. K. Tobias, Jr., E. Williams, M. Jones, P. Moyer, The Univ. of North Carolina at Charlotte (United States)

The most common explanation of spectral diffusion and fluorescence intermittency in nanocrystals (NCs) is biexciton annihilation via an Auger ionization process. In this charge-separated state, one electron or hole carrier is trapped on or near the surface while the other remains in the core. The effect of the electric field generated by this charge-separated state has been implicated in a number of studies as the cause of observed dynamics, but remains scarcely explored. The spectra of single CdSe/ZnS nanocrystals at low temperature have shown random spectral diffusion up to tens of meV. Similar shifts were induced under the presence of an applied electric field. This relation suggests that local electric fields could be responsible for spectral phenomena. More recent work shows an electric field effect on blinking and the photoluminescence quantum yield, which suggests modulation of surface trap sites with applied field.

We have designed experiments to explore the complex role of surface states in carrier dynamics. CdSe nanocrystals, with a variety of shells and surface ligands, were patterned onto a glass-mounted interdigitated gold electrode using electron beam evaporation. A modulated electric field was applied using a function generator. Using our homebuilt confocal microscope, we were able to locate individual nanocrystals, and simultaneously collect fluorescence trajectories, lifetimes, and spectra. I will discuss the analysis of these data from which we obtained field-dependent dynamic information about a range of nanocrystal systems. These experimental results and modeling of the charge transfer and relaxation dynamics of confined excitons will advance nanostructure applications.

8098-14, Session 4

Conformation and interactions in single polythiophene polymer chains

D. A. Vanden Bout, T. Adachi, J. Brazard, R. J. Ono, G. Lakhwani, M. C. Traub, J. C. Bolinger, P. F. Barbara, C. W. Bielawski, The Univ. of Texas at Austin (United States)

Morphology of conjugated polymer films is one of the most important parameters determining physical, electrical and optical properties that are crucial for many types of device application including organic solar cells. Although major obstacle for morphological research of these materials is their complexity and heterogeneity, single molecule spectroscopy enables us to simplify the system and make it tractable. Various experiments examined the conformation of polythiophene (P3HT) chains utilizing polarization modulation spectroscopy. Both the excitation and emission anisotropy are examined to directly probe energy transfer to emitting sites along the chains. The measurements show that regioregularity of the polymer side chains has a profound effect on the ordering of the polymer chain even at the single molecule level. Studies will also be presented that examine interchain interactions utilizing model tri-block copolymer which consist of two P3HT chains connected by either a flexible or rigid linker

8098-15, Session 4

Imaging of photoinduced tautomerism in single porphyrin molecules

R. Jäger, A. M. Chizhik, A. I. Chizhik, S. Bär, H. Mack, A. Lyubimtsev, M. Hanack, A. J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

Porphyrins play an important role in nature, e.g. as chlorophyll in photosynthesis. To understand how these processes work and could be imitated, first the basic structures and properties of the porphyrin-molecules have to be understood. Metal-free porphyrins serve as a very important modelsystem in theoretical chemistry to improve computational methods and help to develop such efficient energetic processes as they occur in nature. Although tautomerization has been studied for decades, it is still difficult to say what happens within one single molecule undergoing this basic process. When the tautomers are chemically equivalent, such as is the case for porphyrins and similar symmetric molecules, few experimental methods can be employed for studying ground-state and especially photoinduced tautomerism.

Using the technique of optical imaging combined with cylindrical vector beams, we can determine the 3D-orientation of the excitation transition dipole moment (TDM) of single molecules. [1] As the TDM-orientation changes when the molecule converts from one trans-tautomer into another, we can distinguish between both of them. Recently we were able to visualize the conversion of one single molecule between its trans-forms. [2] Our method allows us to get a closer insight into the photoinduced tautomerism and the difference to the ground-state-process. By varying the substituents of the molecules, its environment and the excitation-wavelength, we are able to reveal new fundamental details of the excited-state tautomerization in single molecules.

8098-16, Session 4

Imaging the transition dipole moment for single CdSe/ZnS quantum dots and SiO2 nanoparticles

A. M. Chizhik, A. I. Chizhik, Eberhard Karls Univ. Tübingen (Germany); T. Schmidt, F. Huisken, Friedrich-Schiller-Univ. Jena (Germany); A. J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

We study the dimensionality, orientation and dynamical effects of the excitation-transition dipole moment for single CdSe/ZnS core-shell nanocrystals [1] and SiO2 nanoparticles [2]. Using an argon ion laser at 488 nm with higher-order laser modes (azimuthally and radially polarized laser modes) for excitation, the three-dimensional orientation of the nanoparticles' transition dipole moment was investigated in a confocal microscope. The comparison of measured and simulated single nanocrystal excitation patterns shows that single CdSe/ZnS quantum dots possess a spherically degenerated excitation-transition dipole. We show that the dimensionality of the excitation-transition dipole moment distribution is the same for all individual CdSe/ZnS nanocrystals, disregarding the difference in core size and irrespective of variations in the local environment. In contrast to the emission-transition dipole moment, which is oriented in one plane, the excitation-transition dipole moment of a single CdSe/ZnS quantum dots possesses an isotropy in

three dimensions.

SiO2 nanoparticles exhibiting strong red-orange photoluminescence were obtained by full oxidation in water of the silicon nanopowder synthesized by CO2 laser pyrolysis of SiH4. Samples of SiO2 NPs embedded in low concentration in a thin polymer layer were prepared by spin-coating a dedicated solution on glass cover slides. The linear transition dipole moment was found to be rather stable and randomly oriented. However, dynamical effects such as fluorescence intermittency and transition dipole moment flipping could also be observed.

8098-17, Session 5

The nature of bound charge pairs at donor-acceptor interfaces

G. D. Scholes, Univ. of Toronto (Canada); G. Rumbles, National Renewable Energy Lab. (United States)

The primary product of exciton photodissociation at a donor-acceptor interface is a bound charge pair, known by various names including bound radical pair, polaron pair, exciplex, etc. The microscopic nature and properties of these species will be discussed and defined. Organic and inorganic heterostructures will be compared. We will ask whether a deeper understanding of bound charge pairs suggests new designs for organic photovoltaics.

8098-18, Session 5

Charge transfer processes at intra- and intermolecular heterojunctions

E. Da Como, Ludwig-Maximilians-Univ. München (Germany)

Photoinduced charge transfer is the primary process in photovoltaics. Here we probe the first steps of charge separation in a series of low-bandgap donor-acceptor copolymers by femtosecond infrared pump-probe spectroscopy. The results are discussed considering the donor acceptor strength of the units within the chain and how this influences the yield of polaron generation. In the second part we will combine the pump-probe experiments with time resolved luminescence to study charge separation at polymer/fullerene intermolecular heterojunctions. Upon doping of the conjugated polymer we report reduced recombination via charge transfer excitons and enhanced polaron formation.

8098-19, Session 5

Beyond the adiabatic limit: charge separation in organic photovoltaic materials

J. B. Asbury, R. D. Pensack, The Pennsylvania State Univ. (United States)

The dynamics of charge separation in photovoltaic polymer blends following photoinduced electron transfer from the conjugated polymer, CN-MEH-PPV, to the electron accepting functionalized fullerene, PCBM, are observed with ultrafast vibrational spectroscopy. The investigators take advantage of a solvatochromic shift of the vibrational frequency of the carbonyl (C=O) stretch of PCBM to directly measure the rate of escape of electrons from their Coulombically bound charge transfer (CT) excitons at donor/acceptor interfaces on ultrafast time scales. The data reveal that the rate of dissociation of CT excitons is temperature independent from 200 to 350 K indicating that excess energy in hot CT excitons plays an important role in mediating charge separation. These observations suggest that conceptual and theoretical descriptions properly taking into account the strong coupling of electronic and nuclear degrees of freedom in organic semiconductors are essential to understand the mechanism of charge separation in organic photovoltaic materials. From a practical stand-point, efforts to develop new low band-gap polymers for organic solar cells should target electron donor and acceptor pairs capable of advantageously redistributing excess energy in hot CT excitons to enable efficient charge separation with minimal donor-acceptor energy level offsets.

8098-20, Session 5

Charge-transfer excitons at semiconductor polymer heterojunctions in efficient organic photovoltaic diodes

F. Provencher, C. Silva, Univ. de Montréal (Canada)

In organic photovoltaic (OPV) diodes based on blends of semiconductor polymers and fullerene derivatives, singlet intrachain excitons on the polymer created by the absorption of light dissociate into geminate polaron pairs (GPP) at the heterojonction. These are bound by a Coulomb potential, so they must then dissociate endothermically to form photocarriers. Alternatively, GPP can relax to form charge transfer excitons (CTX), where the electron and the hole sit on different molecules but are coulombically bound to form excitonic states across the interface. Since CTX can limit the internal quantum efficiency as well as the open-circuit voltage of OPV cells, our focus is to unravel the dynamics of branching from GPP to CTX, and subsequent recombination processes to re-generate intrachain singlet excitons in an efficient OPV blend.

A careful temperature-dependent study of combined spectroscopic methods of time-resolved photoluminescence, transient absorption and quasi-steady-state photoinduced absorption unravels the dynamics of those species on timescales ranging from picoseconds to milliseconds in films of polycarbazole/fullerene derivative blend (PCDTBT/PC70BM).

We find that GPP are precursors to photocarriers and act as a dark reservoir that feeds the CTX. At low temperature, the GPP are easily trapped and they feed the CTX via tunneling, but not the free photocarriers (polarons). At room temperature, the GPP overcome the Coulomb barrier and dissociate more easily into free polarons.

8098-21, Session 6

Excitonic charge separation at organic semiconductor interfaces

X. Zhu, The Univ. of Texas at Austin (United States)

Solar photovoltaics based on organic semiconductors commonly involve excitons. This results from strong Coulomb attraction between an electron and a hole due to the low dielectric constants of molecular materials. In this lecture, I will address the question of how excitons form, relax, multiple, and dissociate in organic semiconductor materials and at their interfaces. My group uses two experimental techniques to probe interfacial exciton dynamics: time-resolved two-photon photoemission spectroscopy (TR-2PPE) and time-resolved electric field induced second harmonic generation (TR-EFISH). The TR-2PPE technique tracks the electron in time and energy domains at it is initial excited, and as it relaxes, multiplies, and transfers. The complementary TR-EHISH technique monitors the transient electric field formed from exciton dissociation and charge separation at the interface. A particularly exciting aspect is the possibility of harvesting these excitons in dynamic time windows that may allow us to design solar cells with efficiency exceeding the so-called Shockley-Queisser limit, which is the thermodynamic limit of conventional solar cells.

8098-22, Session 6

Photogenerated charges in neat poly(3-hexylthiophene) films

G. Rumbles, National Renewable Energy Lab. (United States) and Univ. of Colorado, Boulder (United States); O. Reid, N. Kopidakis, National Renewable Energy Lab. (United States); N. Stingelin-Stutzmann, Imperial College London (United Kingdom); J. Nekuda-Malik, London Ctr. for Nanotechnology (United Kingdom); G. Latini, Consiglio Nazionale delle Ricerche (Italy); C. Silva, Univ. de Montréal (Canada)

The nature of the primary photoexcitation in conjugated polymers has been a subject of interest for a number of years, and two models have emerged: neutral excitons and free charge carriers. While excitons are recognized as the dominant of the two species, there are a small fraction of carriers that appear directly upon photoexcitation that have been detected experimentally either spectroscopically or through conductivity measurements. The fraction of near-instantaneous free charge carriers produced depends both on the chemical structure of the polymer and on the time-scale on which the study is performed. For example, poly(3-hexylthiophene) (P3HT) thin films have been reported to have free carrier yields as high as 15% , when measured on a fast time scale, but as low as 3% when measured on a slow time scale. It is unclear why these numbers are so different, and from where these carriers originate.

This presentation will report studies using flash photolysis, time-resolved microwave conductivity (fp-TRMC) to probe carriers produced in a number of thin films of P3HT of differing molecular weights. By correlating the free carrier yield with the solid-state microstructure of the polymer, and the corresponding electronic absorption spectra, we will propose a model that explains the origins of these carriers.

8098-23, Session 6

The mechanism of ultrafast exciton dissociation in neat regioregular poly(3-hexylthiophene)

G. Latini, Istituto Italiano di Tecnologia (Italy); F. Paquin, P. Karsenti, M. Sakowicz, Univ. de Montréal (Canada); N. Stingelin-Stutzmann, Imperial College London (United Kingdom); C. Silva, Univ. de Montréal (Canada)

Semiconductor polymer films with high molecular order display high apparent intrinsic charge photogeneration yields by a mechanism that has not been unravelled by contemporary literature. We address charge photogeneration dynamics in neat regioregular poly(3-hexylthiophene) by means of transient photoluminescence (PL) and absorption spectroscopies at 10 K. Charges are generated over ultrafast timescales, but furthermore over timescales that compete with the exciton lifetime (~1 ns) by a mechanism that excludes diffusion-limited exciton dissociation. They recombine with distributed rates that lead to delayed PL over microsecond timescales, accounting for >12% of the time-integrated emission intensity in the studied lm microsctructure. By analyzing the spectral bansdhape of delayed PL, we conclude that charges recombine primarily at interfaces between photophysical aggregates comprised of lamellar polymer stacks and electronically uncoupled chains. This highlights the extrinsic role of boundaries between domains of contrasting microstructure in charge photogeneration processes in this important class of materials.

8098-24, Session 6

Ultrafast conformational readjustment through non-adiabatic state crossings in oligofluorenes

J. Clark, Univ. of Cambridge (United Kingdom); G. Lanzani, IIT@ POLIMI, Milano (Italy) and Politecnico di Milano (Italy); S. Tretiak, Los Alamos National Lab. (United States)

A molecule's conformation in terms of whether it is twisted, planar or bent reflects a complex equilibrium resulting from thermodynamic, nuclear and electronic degrees of freedom. Changing electronic state (by absorption, for example) can dramatically alter the conformational minima of the multidimensional potential energy surface (PES). Readjustment to the new equilibrium position generally occurs on the 10-100 ps time scale, depending on the involved vibrational mode frequencies and the dissipation paths. This relaxation can be thought of in the classical picture as a damped oscillator.

Here, we apply an ultrafast pump-push-probe experiment and advanced computational techniques to investigate energy relaxation in oligofluorenes in solution. Results suggest direct observation in the time domain of ultrafast photoinduced planarization of oligofluorenes via internal conversion through non-adiabatic state crossings. By studying dynamic shifts in the stimulated emission band, we observe that conformational relaxation (planarization) in the first excited state (S1) takes place - as expected - on the 10s of picosecond time-scale. This conformational relaxation time is reduced by over two orders of magnitude when exciting a higher-lying (Ag) state as the wavepacket arrives at the S1 state within 100fs already planar. Calculations elucidate the path in configurational space taken by the wavefunction and highlight the role of non-adiabatic state crossings in dissipating the energy. We find a clear correlation between the ultrafast planarization and an intra-molecular charge transfer state whose ultrashort lifetime is exploited in realizing all optical switching in plastic media.

8098-34, Poster Session

Nonlinear optical properties of two dimensional ferroelectric polymer film at the air/water interface

C. Jung, P. Jang, S. Kyu, K. H. Kim, Cheongju Univ. (Korea, Republic of)

Organic materials are generally attractive because of the possibility having exceptionally high nonlinear optic (NLO) coefficient. The most straightforward approach to increase the NLO coefficient is the development of new material through the systematic chemical design of the molecules. Even though the lack of amphiphilicity, the copolymer of vinylidene fluoride and trifluoroethylene,P(VDF-TrFE) makes its monomolecular (Langmuir layer) on the water surface. By stacking this layers onto a solid substrate with appropriate transfer technique, one can establish a well organized two dimensional films with a good non-centrosymmetric crystallinity. In this study, we focused our attention on the formation of polar monolayer on the air/ water interface by using nonlinear optical technique, such as second harmonic generation method. Up to now, many research group have reported the NLO properties of amphiphilic two dimensional films. However, the NLO study from this kind of poor amphiplic film has not been reported yet.

In this work, a copolymer of vinylidene fluoride(70%) and trifluoroethylene (30%) were prepared on the water subphase and the time dependent NLO properties was studied by second harmonic generation method.

8098-35, Poster Session

Modeling interfacial charge transport of Quantum dots using Cyclic Voltammetry

A. K. Tobias, Jr., E. Williams, M. Jones, The Univ. of North Carolina at Charlotte (United States)

Quantum dot applications are numerous and range from photovoltaic devices and lasers, to bio labeling. Complexities in the electronic band structure of quantum dots create the necessity for analysis techniques that can accurately and reproducibly provide these band energies. Cyclic voltammetry (CV) has been used to estimate HOMO/LUMO levels in molecular species and, similarly, can also be used to estimate valence and conduction band levels in quantum dots. Energy and charge transfer between quantum dots and other electron/hole accepting materials can be tuned and optimized according to this data. CV has been utilized in recent research to study effects of electron and hole insertion on quantum dot ensembles and also investigate their band gap energies. These experiments can be done on quantum dots in solution, as thin films, or coated on metal electrodes. CV has potential to become a useful tool in engineering new nanocrystal technology, by providing information necessary for predicting and modeling interfacial charge transfer to and from quantum dots. Despite the potential use of CV analysis, limitations arise due to the physical nature of nanocrystals. Solubility and diffusion come into play in solution-state experiments, while sample degradation is an issue in thin films. Carbon paste electrodes have been used in electrochemical studies to eliminate these issues. I will present data obtained using a carbon paste electrode to investigate energy levels in core CdSe and core/shell CdSe/CdS quantum dots. Importantly, the results of this work allow us to determine HOMO-LUMO energy differences for candidate nanocrystal-molecule electron transfer systems.

8098-36, Poster Session

Modeling exciton dynamics of type II nanocrystals

D. Woodall, A. K. Tobias, Jr., E. Williams, P. Moyer, M. Jones, The Univ. of North Carolina at Charlotte (United States)

Semiconducting nanocrystals are becoming more important in light harvesting devices because of their tunable optical properties, stability, and ease of synthesis. In order to design high efficiency optoelectronic devices, the movement of charges within these nanocrystals needs to be fully understood. Electron transfer models such as Marcus theory exist for molecular systems, but critical parameters such as potential energy curves and electronic coupling strengths of Marcus theory have yet to be applied to nanocrystals. The development of such a model for nanocrystals is problematic because they are complex. Nanocrystals are complex because of inhomogenities in size and shape, surface trap states, and ligand effects, all of which affect electron transfer rates in different ways. Nanocrystals consisting of type II core/shell CdSe/CdS with varying shell thicknesses were synthesized using a colloidal synthesis method. Each sample was characterized by various optical spectroscopies including UV-Vis absorption, steady state fluorescence, and time resolved photoluminescence. Lifetimes were measured at a range of temperatures and were directly analyzed using software previously shown to be effective in predicting carrier trapping and detrapping rates for CdSe/CdZnS core/shell nanocrystals. Computational modeling based on the premises of Marcus theory was performed to simulate experimental results. By combining lifetime measurements with simulations, we establish a kinetic model of nanocrystal exciton dynamics predicting electron transfer rates over a range of temperatures. The development of this model is critical for future design and fabrication of optoelectronic devices such as photovoltaics, photodectors, and chemical sensors.

8098-37, Poster Session

Effect of alloying on the photoluminescence of the CuInS2 nanocrystals

Y. Kim, C. Choi, Korea Institute of Materials Science (Korea, Republic of)

We have developed a novel route to highly luminescent Cd-free core-shell nanocrystals. By simply refluxing as-synthesized CuInS2 nanocrystals with zinc acetate and palmitic acid, highly luminescent CuInS2/ZnS nanocrystals were synthesized. We modified the photoluminescence of the grown nanocrystal by alloying foreign atoms. Nanocrystals with alloyed cores were synthesized by adding selenium and nanocrystals with alloyed shell layers were synthesized by refluxing the as-synthesized CuInS2 nanocrystals with mixture of cadmium acetate, zinc acetate and palmitic acid. It was found that the emission wavelength of the nanocrystals was shifted to longer wavelength side by alloying. The photoluminescence spectra showed clear red-shift without significant minimization of emission intensity. A Detailed study on the emission process of nanocrystals implies that the formation of shell layers with small lattice mismatch minimized mismatch strain generated from the shell layers in contrast to core alloyed nanocrystals.

8098-38, Poster Session

Noise and current-voltage characteristics of structures with porous silicon layer in different gas environments

Z. Mkhitaryan, V. Aroutiounian, S. Geghamyan, Yerevan State Univ. (Armenia)

The experimental research of current-voltage characteristics and low-frequency noise in dry air, dry air+0.1%ammonia, dry air+0.1%(butane+propane), dry air+0.1%spirit (C2H5OH) were done. PS layers were formed using the electrochemical etching of heavily doped (ρ=0.01 Ωcm) p+ type (100)-oriented silicon wafers. The thickness of the PS layer was 3 micro-meters; the porosity was equal to 80 %. The diameter of nanometrical filaments was equal to ~5nm; sizes of pores were equal up to 50nm approximately.

Measurements of noise characteristics were carried out by the method of direct filtration at room temperature in the range of frequencies 3 Hz - 500 Hz. Measuring setup for research of the noise in the semiconductor-gas system included the input chain, a gas cell, low noise preliminary amplifier SR 560 (SRS, USA), the analyzer of the spectrum realized by HANDYSCOPE 2 (Tie Pie Engineering).

Sensitivity diagrams for explored samples are shown after traditional (resistance) and noise measurement, correspondingly. We have shown that the noise sensitivity in the presence of target gas in air is much higher than the sensitivity of the sensor after the measurement of ohmic resistance. The largest change in the characteristics of our samples occurs in the environment of dry air+0.1%ammonia. The possible reason for this is the molecule size of target gas and its adsorption properties. The physical reasons of sensing properties of the investigated samples are detailed discussed in paper.

8098-40, Poster Session

Optical investigation of medicine solutions in micro-droplets form at interaction with laser radiation

V. V. Nastasa, M. Boni, I. Andrei, National Institute for Lasers, Plasma and Radiation Physics (Romania); L. Amaral, Instituto de Higiene e Medicina Tropical UNL (Portugal); M. L. Pascu, National Institute for Lasers, Plasma and Radiation Physics (Romania)

The multiple resistance to treatment, acquired by bacteria and malignant tumors requires finding alternatives to the existing medicines and treatment procedures. One of them is strengthening the effects of cytostatics by modifying their molecular structures through exposure to laser radiation. A method associated with this, is the generation of micro-droplets which contain medicines solutions; the droplets are utilized/ produced as vectors to transport the medicines to targets.

In our studies we try to combine these two methods in order to obtain a new technique to deliver the efficient medicines to targets that can be applied for a relative large number of chemicals. For this purpose we have developed an experimental set-up containing a liquid droplets generator, a tunable laser source used to irradiate droplets, a subunit to measure the laser induced fluorescence signals and a real time recording system for droplet image analysis.

Measurements on different probes, like ultrapure water, commercial grade medicines, newly developed medicines and laser dyes were performed. For some of these samples, the wetting properties were also studied. All these measurements were performed on water-based solutions.

First we show the laser induced fluorescence measurements results on micro-droplets, that exhibit important modifications after the exposure at laser radiation. It was evidenced that the exposures to laser beams/ coherent optical radiation of some medicines solutions in ultrapure water may produce molecular modifications in solutions. These slight modifications of the molecules made them more efficient against bacteria strains.

Secondly, we present results concerning the micro droplets behavior at laser beam interaction for different laser energies and impact geometries.

The laser beam incident on the droplet was emitted at 10 pulses per second or in single pulse regime at 540nm (green) with 6ns FTWHM. The beam focus diameter was 0.1mm and the irradiance in the focus was about 3kW/cm2 . The processes which might take place at the interaction of the laser beam with water microdroplets are: a. Droplet vibration; b. Generation/expulsion of micro/nano droplets at high speed by the initial droplet thorugh loss of material; c.Microdroplet destruction by loosing the contact with the capillary used to generate it; d. Possible heating of the droplet's material although the laser beam wavelength was emitted in green, where the water absorption is negligible; e. Total sputtering in 4π of the droplet, when exposed to a single high power pulse. The effect of the mechanical pressure of light on the microdroplets is investigated in correlation with the superficial tension values for such droplets.

8098-41, Poster Session

Structure and optical properties of noble-metal and oxide nanoparticles dispersed in various polysaccharide biopolymers

V. Djoković, D. K. Bo?anic, V. Vodnik, R. Krsmanovic, Vinca Institute of Nuclear Sciences (Serbia); S. Dimitrijevic-Brankovic, Univ. of Belgrade (Serbia); L. Trandafilovic, Vinca Institute of Nuclear Sciences (Serbia)

The hybrids based on nanostructured noble-metal particles and polymers have been investigated for almost two decades but this subject is enjoying a constant resurgence of interest and activity as a result of the exceptional properties which can be realized from such nanocomposite materials. Since a polymer can be easily designed into almost any shape required by a particular application, the properties of the nanoparticles can be successfully utilized by incorporation of the nanoparticles into polymer matrices. Polymers can also influence the growth and spatial arrangement of the nanoparticles formed within the matrix that makes them convenient templates for the preparation of nanoparticles of different morphologies. Because of possible applications in biotechnology and environmental protection, biopolymers and particularly polysaccharides were recently employed as host materials for metal and semiconductor nanoparticles. The macromolecular chains of these biopolymers possess a large number of hydroxyl groups and they can complex well with metal ions, which in turn enables a good control of size, shape and dispersion of the nanoparticles formed. Here we present the results on the structure and the optical properties of noble metal (Ag, Au), oxide (ZnO) and composite (Ag-Ag2S) nanoparticles synthesized by various methods in different polysaccharide matrices such as chitosan, glycogen, alginate, and starch. The structure of the obtained nanoparticles was studied in detail with microscopic techniques (TEM, HRTEM, HAADF-STEM), while the XPS spectroscopy was used to investigate the effects at the nanoparticle biomolecule interfaces. The antimicrobial activity of the nanocomposite films with Ag and ZnO nanoparticles was tested against the Staphylococcus aureus, Escherichia coli and Candida albicans pathogens. In addition, we will present the results on the structure and optical properties of the tryptophan amino acid functionalized silver and gold nanoparticles dispersed in polyvinyl alcohol matrix.

8098-25, Session 7

Physical chemistry of acridine adsorption onto gold surface: The influence of nanostructure as revealed by near-infrared and tip-enhanced Raman spectroscopy (TERS)

R. M. Balabin, T. Schmid, ETH Zurich (Switzerland); R. Z. Syunyaev, Gubkin Russian State Univ. of Oil and Gas (Russian Federation); R. Zenobi, ETH Zurich (Switzerland)

The surface science of aromatic molecules has long been of interest, both on semiconductor and on metal surfaces, due to their high importance for industry. For example, catalytic purification of petroleum (crude oil) fractions is based on the adsorption/reaction behaviour of sulphur- and nitrogen-containing molecules. In this view, a systematic study of the adsorption and transformation of sulfur and nitrogen compounds on different solids (applicable as catalysts, catalyst components, or adsorbants) is needed. Here we report a detailed study of adsorption of acridine (C13H9N) and a number of its derivatives: benz[a]acridine, benz[c]acridine, etc. Thermodynamic and kinetic data, obtained by solution-phase near-infrared spectroscopy (NIRS), clearly show a great difference of adsorption behavior for flat and nanorough (~4 nm) gold surfaces. Gibbs free energies of -4.57±0.10 vs. -7.67±0.13 kcal mol-1 and adsorption kinetic constants of 26±3 vs. 4160±220 min-1 M-1 were determined for flat and SERS-type surfaces, respectively. This result could be interpreted in terms of the type of adsorption model: adsorption by the conjugated pi-electron system or by the lone pair of the nitrogen atom in the former and latter cases, respectively. The characterization of the polyaromatic monolayer directly at the Au surface, as measured by tip-enhanced Raman spectroscopy in scanning tunneling microscope mode (STM-TERS), has confirmed the dependence of the adsorption parameters on the (nano)roughness of the metal surface. The shift of Raman active vibrations (by 2-8 cm-1) of the molecules at the surface and the appearance of new bands were used as a direct indicator of the adsorption model type. Density functional theory calculations (DFT-B3LYP, DFT-M06) were used to confirm the assignment. A unique possibility of TERS to enhance the molecular Raman signal independent on the surface structure and type was fully realized. The importance of the findings for industry and nanotechnology are discussed.

8098-26, Session 7

Investigation of the influence of surface and heterogeneous radical stages on oscillation modes of methane oxidation

V. Malkhasyan, Yerevan State Univ. (Armenia)

The goal of our work is investigating the role of heterogeneous radical stages in the initiation oscillation modes of methane oxidation at flow conditions.

There is evidence of the existence of oscillations in the process of thermal oxidation of methane, which is accompanied by luminescence. However the mechanism of their appearance is little known. We

supposed and then proved, with the method of mathematical modeling, that one of its reasons could be the influence of nature of the state of the surface on character of dynamic regimes of process.

The short model of chain radical process was considered. The system of differential equations for changes of reagents concentration was solved in quasi-stationary approach for the concentration of some radicals at initial stage of the reaction, when the consumption of methane and oxygen can be neglected.

The luminescence during oxidation of organic compounds is routinely attributes to the recombination of radicals. In an oscillatory mode of methane oxidation of concentration oscillations of radicals will naturally cause oscillations of intensity of a luminescence. When we were varying the rate constants of heterogeneous stages of reaction process as a result we observed damping or swinging oscillations.

Summarizing results it is possible to conclude, that oscillatory regimes of thermal oxidation of methane is strictly connected with the heterogeneous factors that is with the nature of the surface and also revealed conditions, which they can be regulated.

8098-27, Session 7

Nanostructured silicon for surface passivation of solid-state photodetectors

M. E. Hoenk, Jet Propulsion Lab. (United States)

Surface-related instabilities, including especially quantum efficiency hysteresis, have plagued scientific solid-state imaging detectors since the 1970's, when NASA first invested in charge-coupled devices (CCDs) for astronomical instruments in space. Such instabilities are especially problematic in the deep ultraviolet, where photons carry sufficient energy to damage surface coatings, creating defects and traps associated with surface charging, carrier recombination, and dark current generation. Using molecular beam epitaxy to grow a 2 to 3 nm epitaxial layer of delta-doped silicon, we have created a highly stable surface passivation layer that uniquely enables reflection-limited quantum efficiency and completely eliminates quantum efficiency hysteresis in back-illuminated CCDs and CMOS imaging arrays. In this paper we study the physics of surface passivation in delta-doped, back-illuminated silicon imaging detectors. The silicon surface in these detectors is modified by epitaxial growth of silicon, within which a partial monolayer of boron is embedded in the silicon lattice, creating a delta-doped surface. In a delta-doped surface, the highly-localized sheet of dopant atoms creates a quantum well for majority carriers within a few nm of the surface. Here, the bandstructure of the delta-doped surface is calculated using self-consistent calculations of Poisson's equation and the Scrödinger equation, using an eight band k p model of the valence band. Calculations affirm that the potential barrier formed by the delta-doped layer isolates the surface from the bulk. Thus a delta-doped silicon surface is virtually immune to environmentally induced changes in the surface charge that are known to degrade conventional silicon-based detectors. This immunity to surface charge is consistent with the absence of measurable quantum efficiency hysteresis in delta-doped imaging detectors.

8098-28, Session 7

Modulation of CdSe fluorescence using palladium nanoparticles

K. J. Major, M. Jones, The Univ. of North Carolina at Charlotte (United States)

The increasing demands for clean, efficient energy have strongly influenced the direction of nanoscale science. One of the most promising areas of solar energy research lies with cadmium selenide quantum dots (CdSe QDs). Metal nanoparticles have been examined as a means to improve the efficiency of solar energy conversion in QDs. It has been shown that in certain systems the presence of these metal nanoparticles increase electron - hole charge separation thus providing extended times for electron harvesting. Most of the systems currently explored utilize gold nanoparticles, which is unsurprising due to the vast amount of synthetic methods for these particles and their plasmonic effects on the QDs. We seek to further examine metal nanoparticle - semiconductor quantum dot interactions through the study of CdSe - palladium nanoparticle systems. We employ both steady state and time resolved ensemble fluorescence spectroscopy to observe the effects of increasing palladium nanoparticle concentrations on both the fluorescence intensity and lifetime of various CdSe QDs. We find that decreasing separation distance between the particles, whether through increasing palladium concentration or QD shell thickness, leads to a stronger interaction between the particles. We find expected fluorescence quenching of the QDs at higher concentrations of palladium. At low palladium concentrations however we observe a unique fluorescence enhancement of the QDs. We use this data to explore the relative contributions of energy and electron transfer between the particles and determine the conditions under which the maximum effects of these interactions are observed.

Excited state dynamics in carbon nanotubes and graphene nanoribbons for electronics and biological applications

O. V. Prezhdo, Univ. of Rochester (United States)

No abstract available

8098-09, Session 8

Spectroscopic and modelling studies of charge generation in organic donor:acceptor heterojunctions

J. Nelson, Imperial College London (United Kingdom)

Photocurrent generation in organic photovoltaic devices follows from photoinduced charge pair generation at the interface between a donor (usually a conjugated polymer) and an acceptor (usually a fullerene). The efficiency of charge generation depends upon energy of the charge separated state relative to that of any neutral excited states such as triplets, but is also influenced by the specific chemical structure of the donor and acceptor species, the local molecular packing and the ease of energy transfer. We use spectroscopic, optoelectronic and modelling studies to probe these processes in a series of conjugated polymer:fullerene blend systems and relate the results to photocurrent generation in organic solar cells.

8098-31, Session 8

Environmental effects induced by the oxygen-water redox couple in carbon nanotube and graphene electronics

R. Martel, Univ. de Montréal (Canada)

Three terminal transport measurements using a back-gated FET geometry are facilitated by using a degenerately doped silicon wafer covered with a thin silicon oxide layer as the substrate. It has been widely assumed that measurements taken in air are dominated by the Schottky barrier at the contacts, which in turn is linked to the intrinsic properties of the material under study. Here we show that the redox active species present on the surface of the oxide substrate induced a drastic suppression of n-type behavior in FETs and provoke large threshold voltage shifts. By using carbon nanotubes and graphene FETs as testbeds, we investigated the impact of the chemical nature of the substrate and of ambient adsorbates on the field effect switching

behavior of different FETs. Our study revealed that the reduction of n-type conduction occurs when adsorbed water containing solvated oxygen is present on the SiO2 surface. This finding demonstrates that an electrochemical charge transfer reaction is the underlying phenomenon governing the suppression of electron conduction in carbon nanotube and graphene devices.

8098-32, Session 8

Component identification with Raman spectroscopy colocalized with quantitative nano-mechanical mapping for complex polymer systems

S. Hu, N. Erina, C. Su, Bruker Nano Inc. (United States)

Most polymer materials are composed of multiple components. It is critical to be able to identify the chemical components and the concurred mechanical properties in the nanoscale. Raman spectroscopy has been historically been used to probe structural characteristic of materials and investigate the chemical states of the bonds in the materials to indentify the different chemical components with limited resolution. On the other hand, Atomic Force Microscope (AFM) has demonstrated nanometer resolution imaging with localized mechanical property measurements with the newly developed peak force tapping mode. The new technology enabled to quantitatively characterize materials at nanoscale with simultaneous topography and mechanical mapping such as modulus, adhesion and energy dissipation. In this paper we report systematic studies of complex polymer systems combining Raman spectroscopy mapping with quantitative nanomechanical mapping, yielding unprecedented capability to both chemically and mechanically characterize components in the complex polymer systems.

Blends based on thermoplastic Polypropylene (PP) and Ethylene-Propylene-Diene-Monomer (EPDM) rubber, so called thermoplastic vulcanizates (TPVs) in different component ratios have been investigated. TPV are high-performance materials that combine the best attributes of the vulcanized rubber (flexibility and low compression set) with the processing ease of linear thermoplatics. That makes possible to design details with complex profiles with high precision, which has numerous benefits in appliance, electrical, construction, healthcare and packing applications. Raman spectroscopy microscopy can chemically identify the PP and EPDM domains with 1um resolution and give micro-scale distribution of components. Nano-mechanical mapping, performed in the same area, exhibits fine details of the component distribution concurrently, especially the details at the interface transition regions. Combination of the two technologies not only allows us to identify individual component unambiguously but also provides structural information at the interfaces.

8098-33, Session 8

Synthesis and electrochemical FTIR study of Pd-based nanostructured catalysts

A. Chen, R. M. Assumme, S. Chen, C. Asmussen, R. Laurin, Lakehead Univ. (Canada)

Driven by the increasing need for cleaner and more efficient engines in transportation applications, there has been growing interest in the study of the direct electrochemical oxidation of small organic molecules such as formic acid and methanol for the development of fuel cells. Palladium-based nanomaterials with high surface areas have been receiving great attention due to their unique properties, which enable a number of impressive applications in catalysis, fuel cells, hydrogen storage and chemical sensors. Recent studies have shown that the electrocatalytic performance of Pd-based nanomaterials is highly dependent on the composition, morphology and surface conditions of the synthesized materials. In this presentation, we report on the synthesis and electrochemical properties of different Pd-based nanostructured materials.

A variety of Pd-based nanostructured materials including nanoporous Pd networks and PdPt nanodendrites with different compositions have been synthesized using the hydrothermal method. The as-fabricated Pd-based nanostructured materials were characterized by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD). The electrochemical properties of these Pd-based nanomaterials were studied using cyclic voltammetry, chronoamperometry and in-situ electrochemical infrared spectroscopy. Our studies showed that the fabricated Pd-based nanostructures possess a very large surface area and high catalytic activity. The electrocatalytic activity of the different Pd-based nanostructured materials towards the electrochemical oxidation of formic acid will be compared, and the design of high-performance Pd-based electrocatalysts will be addressed in this talk.

8098-39, Session 8

Interaction between single walled carbon nanotubes and specific optically active molecules

H. Chaturvedi, N. O. Maheshwari, Indian Institute of Science Education and Research, Pune (India); J. C. Poler, The Univ. of North carolina at Charlotte (United States)

Novel effects like photon enhanced aggregation are observed in solutions of functionalized SWNTs. SWNTs functionalized with optically sensitive molecules like MEH-PPV, ruthenium dyes exhibits enhanced rate of aggregation, due to charge dynamics and consequently its effect on electrical double layer in solutions. Rate of aggregation for functionalized SWNTs depends on the molecular absorption of the optically active molecule and increases linearly with power in the absorption window. We believe charges are transferred onto the nanotubes from the optically excited molecules, initiating rapid aggregation. DLVO theory has been extensively used to understand larger colloidal solutions. However with high specific surface area and enhanced reactivity DLVO theory needs to be well understood in relation to the nanoparticles. Critical coagulation concentration (CCC), the minimum concentration of ionic species to induce coagulation is experimentally ascertained using absorption spectroscopy and dynamic light scattering measurements on SWNT solutions. Schulze-Hardy rule which correlates CCC to the valence of counterions is theoretically based on DLVO theory thus inheriting various approximations. Modified Schulze hardy law is experimentally plotted for SWNT solutions using different inorganic salts. Effect of light, concentration, surface charges and ionic strength on CCC using various optically active coagulants are investigated for both semiconducting and metallic enriched solutions of SWNTs. Binding and molecular interaction between optically active supramolecules with semiconducting and metallic SWNTS are characterized using high resolution microscopic and spectroscopic techniques. Field effect transistor (FET) based on functionalized SWNT is fabricated using optical and e-beam lithography for electro-optical measurements. Optical effect on electronic transport through the functionalized SWNT devices is characterized. Optical doping of SWNTs is observed due to charge transfer onto the nanotubes from the optically active molecules bound to it. Optically controlled variation in electronic current through the FET device is discerned and scheme for realization of prospective optical switches and functional reliable devices will be presented.

Conference 8099: Biosensing and Nanomedicine

Sunday-Tuesday 21-23 August 2011 • Part of Proceedings of SPIE Vol. 8099
Biosensing and Nanomedicine IV

8099-01, Session 1

Carbon nanotube-mediated siRNA delivery for gene silencing in cancer cells

T. Hong, Vanderbilt Univ. (United States); J. Qiao, Vanderbilt Univ. Medical Ctr. (United States); H. Guo, Vanderbilt Univ. (United States); T. S. Triana, D. H. Chung, Vanderbilt Univ. Medical Ctr. (United States); Y. Xu, Vanderbilt Univ. (United States)

Carbon nanotubes (CNTs) have attracted much attention as a tool for transporting therapeutic molecules into cells; small interfering RNA (siRNA) is among the molecules which can be conjugated to CNTs for drug delivery. siRNA is potentially a promising tool in influencing gene expression with a high degree of target specificity. However, its poor intracellular uptake, instability in vivo, and non-specific immune stimulations have impeded its effect in clinical applications. In order to solve this problem, we have studied two types of CNT-mediated siRNA delivery systems for gene silencing in both neuroblastoma and breast cancer cells. In this study, carbon nanotubes functionalized with two types of phospholipid-polyethylene glycol (PL-PEG) have shown capabilities to stabilize siRNA in cell culture medium during the transfection and efficiently deliver siRNA into cells. Compared to Lipofectamine 2000-mediated siRNA delivery, CNT-mediated siRNA delivery systems yield equal or higher efficiency in silencing target gene expression. Our results have shown that CNT-mediated siRNA can efficiently silence various genes in both neuroblastoma and human breast cancer cells. Although both types of PL-PEGs stabilized siRNA molecules during transfection in cell culture media, PL-PEG 5000-Amine functionalized CNTs showed higher efficiency for gene silencing than CNTs functionalized by DSPE-mPEG 5000, the one without amine group. Based on these fundamental studies, we believe that CNTs hold great potential in mediating siRNA to silence specific genes in various human cancer cells, and will be a novel tool in further clinical applications.

8099-02, Session 1

Ebola virus detection using optofluidic-nanoplasmonic biosensors

A. A. Yanik, M. Huang, O. A. Kamohara, A. A. Artar, J. H. Connor, H. Altug, Boston Univ. (United States)

We demonstrate a label-free optofluidic-nanoplasmonic sensor that can directly detect live viruses from biological media at clinically relevant concentrations with little to no sample preparation. This work is the first demonstration of direct detection of intact viruses using extraordinary light transmission phenomena. So far, the questions remain for the possible limitations of this technique, as the penetration depths of the surface plasmon polaritons are comparable to dimensions of the pathogens. In this paper, we addressed this gap and showed that our nanoplasmonic sensors can reliably detect viruses down to 105 PFU/ml concentrations and operate over a wide dynamic range. Our sensing platform utilizes group specific antibodies for highly divergent strains of rapidly evolving viruses. We demonstrate direction detection and recognition of small enveloped RNA viruses, which make up almost all of the alarming new infectious diseases. Some of these viruses, e.g. the Ebola hemorrhagic fever virus are both emerging infectious and biological threat agent. Patients presenting with RNA virus infections often show symptoms that are not virus specific. Thus, there is great interest in developing sensitive, rapid diagnostics for these viruses to help direct proper treatment. We also tested our platform for the detection of enveloped DNA poxviruses, e.g. the Vaccinia virus, a poxvirus commonly used as a prototype for more pathogenic viruses such as smallpox. This platform, enabling fast and compact sensing of the intact viruses without any mechanical and light isolation, could open up biosensing applications for early and point of care diagnostics.

8099-03, Session 1

Novel, rapid DNA-based on-chip viable bacterial identification system combining dielectrophoresis and amplification-free fluorescent resonance energy transfer assisted in-situ hybridization (FRET-ISH)

M. M. Packard, E. Alocilja, Michigan State Univ. (United States)

Although real-time PCR (RT-PCR) has become a diagnostic standard for rapid identification of bacterial species in clinical and environmental samples, it remains time-intensive due to sample preparation and amplification cycle times and provides no insight into the viability of detected cells. The assay described in this work incorporates on-chip dielectrophoretic separation and concentration of live cells with fluorescence resonance energy transfer assisted in-situ hybridization (FRET-ISH) species identification. In addition, the assay includes a heating step which provides for simultaneous lysis, permeabilization and DNA denaturation via a Kapton® KHLV series (Polyimide Film and FEP adhesive) rectangular insulated heaters. Finally, signal amplification in the form of energy transfer from Syto 9, a non-specific DNA stain, to Hexachlorofluoroscein (HEX) labeled Escherichia coli specific repetitive sequence probes allows confirmation of Escherichia species via FRET-ISH in real time. Identification of viable, and thus pathogenic cells, is achieved completely on chip in less than thirty minutes from receipt of sample compared to multiple hours required by RT-PCR and its requisite sample preparation. The simplicity, speed, and adaptability for detection of any DNA-based pathogen using this technique makes it an ideal candidate for field use, especially in cases of time-sensitive outbreak.

8099-04, Session 1

Localized drugs delivery hydroxyapatite microspheres for for osteoporosis therapy

J. H. Lee, I. H. Ko, Korea Institute of Ceramic Engineering and Technology (Korea, Republic of); S. Jeon, J. H. Chae, E. J. Lee, Hans Biomed Corp. (Korea, Republic of); J. H. Chang, Korea Institute of Ceramic Engineering and Technology (Korea, Republic of)

Hydroxyapatite [Ca10(PO4)6(OH)2, HAp] is the main mineral component of bones and hard tissues in mammals and well known for its high biocompatibility and osteoconductivity. In this study, we synthesized hydroxyapatite microspheres for localized drugs delivery, typically osteoporosis related medicines. The formation of calcium phosphate microspheres were initiated by enzymatic decomposition of urea and accomplished by emulsification process (water-in-oil). The microspheres obtained were sintered at 500 to remove organic compounds remained which potentially causes toxicity. The microspheres with a mean size range of 257 were in a spherical shape. Scanning electron microscope (SEM) indicated that the microspheres have various porous with random size, which maximizes the surface area. We performed load of alendronate and BMP-2 into HAp microspheres by adsorption process. The load of drugs was investigated by using FT-IR analysis. Releases of alendronate and BMP-2 were observed at 37 for 30 days and we found the release of both molecules showed sustained releasing profiles. Finally, animal trial showed the aldendronate loaded HAp microspheres enhanced bone density in osteoporosis model rat after inject the drug loaded microspheres. Our study focused on development of non-toxic drug carrier, high drug loading, its sustained releasing and in vivo animal trial to verify the effectiveness. It was reported that oral dose is not adoptable to alendronate administration because oral administration of alendronate causes gastrointestinal disturbances. Hence, we believe that this material is suitable to locally deliver alendronate for osteoporosis therapy.

8099-05, Session 1

Highly efficient antibody immobilization with multimer protein G bound magnetic silica nanoparticles

J. H. Lee, H. K. Choi, J. H. Chang, Korea Institute of Ceramic Engineering and Technology (Korea, Republic of)

This work reports the immobilization of monomer, dimern and trimer (multimer) protein G onto silica magnetic nanoparticles for self-oriented antibody immobilization. To achieve this, we initially prepared the silica-coated magnetic nanoparticle having about 50 nm diameters. The surface of the silica coated magnetic nanoparticles was modified with 3-aminopropyl-trimethoxysilane (APTMS) to chemically link to multimer protein G. The conjugation of amino groups on the MNPs to cysteine tagged in multimer protein Gs was performed using a sulfo-SMCC coupling procedure. The binding efficiencies of mono-, di- and trimer were 78%, 62% and 54% respectively. However, the efficiencies of antibody immobilization were 71%, 81% and 90% for mono-, di- and trimer, respectively. To prove the enhancement of accessibility by using multimer protein G, FITC labeled goat anti-mouse IgG was treated to mouse IgG immobilized magnetic silica nanoparticles through multimer protein G. FITC labeled goat anti-mouse IgGs were more easily bound to mouse IgG immobilized by trimer protein G than others. Finally, multimer protein G bound silica magnetic nanoparticles were utilized to develop highly sensitive immunoassay to detect hepatitis B.

8099-06, Session 2

Recyclable optical microcavities for label-free sensing

H. K. Hunt, A. M. Armani, The Univ. of Southern California (United States)

Label-free biosensors with high sensitivity and high specificity have shown tremendous potential in medical diagnostics, environmental monitoring, and food safety evaluation. Optical microcavities have very low optical loss, and are therefore uniquely suited to sensing applications that require high sensitivity, particularly when paired with a biochemical recognition element that grants high specificity. The primary limitation of these biosensors, however, is that they are generally single-use systems, unless the recognition element is regenerated. Therefore, the ability to selectively functionalize the optical microcavity for a specific target molecule and then recycle the system, without degrading device performance, is extremely important. Here, we demonstrate a straightforward bioconjugation strategy that not only imparts specificity to optical microcavities, but also allows for biosensor recycling. In this approach, we selectively functionalize the surface of silica microtoroids with a biotin recognition element, using silane coupling agents and N-hydroxysuccinimide (NHS) ester chemistry to graft the biotin onto the surface. We then use a non-destructive O2 plasma treatment to remove the surface chemistry, refresh the recognition element, and recycle the device. The surface chemistry of these devices is demonstrated using XPS, SEM, and fluorescent and optical microscopy. The optical performance of the functionalized and recycled devices is characterized by microcavity analysis. The resulting devices can be recycled several times without performance degradation, and show high density surface coverage of biologically active recognition elements. This work represents one of the first examples of a recyclable, bioconjugation strategy for optical microtoroid resonators, which can be used for label-free detection of biomolecules.

8099-07, Session 2

Surface enhanced Raman scattering (SERS)-based sensing schematics for detection and identification of biological samples

M. E. Hankus, P. M. Pellegrino, D. N. Stratis-Cullum, U.S. Army Research Lab. (United States)

There is a relevant Army need to detect, identify, quantify and differentiate hazardous from benign materials in theatre. These hazardous materials can be energetic, chemical or biological in nature. Raman-based technique are becoming more commonly employed towards this end as they rely on specific vibrations within the molecule from which to produce a fingerprint spectrum, do not suffer from interferences from water, require little to no sample preparation, and can be used with several different excitation sources. Surface-enhanced Raman scattering (SERS) offers all the advantages of Raman, with the added advantage of increased analyte signal. SERS signal enhancements are achieved by irradiating a metalized surface with an analyte in close contact, and then measuring the signal from the chemical and electromagnetic enhancements that occur. In our research, we have characterized several different SERS substrate architectures and determined their applicability to Biological samples. Additionally, we have developed a molecular specific sensor schematic using a duel SERS fluorescence signal.

8099-08, Session 2

Bioconjugation strategies for improved optical sensor performance

C. E. Soteropulos, H. K. Hunt, A. M. Armani, The Univ. of Southern California (United States)

The very low optical loss or high quality factors of silica optical microresonator sensors allow them to behave as very sensitive optical transducers. Therefore, they are a potential platform for real-time biosensing and diagnostics applications. However, their use is currently limited by the lack of high specificity and stable surface chemistries for the attachment of probe molecules. The main challenge when developing a method to functionalize optical devices is the need to maintain the optical performance of the device, while at the same time reliably attaching the probe. One extremely stable method of attaching biomolecules to silica surfaces is based on NHS-ester chemistry as the link between the inorganic surface and the biomolecule. This covalent attachment of the probe provides a robust interaction, and the method used is easily translated to a wide range of biomolecules, such as antibodies and antigens. In present work, we have applied this method to the surface of optical microsphere resonant cavities, and demonstrated quality factors above 1 million after probe attachment, thus verifying that the attachment strategy has minimal impact on the optical performance of the device. Through fluorescent imaging, we have confirmed the bioactivity of the binding site, as well as site stability even after long-term device storage (>30 days). Finally, we have performed resonant cavity detection experiments based on resonant frequency shift measurements using the functionalized devices, further confirming the applicability of this approach for imparting specificity while retaining optical performance.

8099-09, Session 2

Plasmonic biosensing with nanoimprint binary grating using ellipsometry

Y. Chang, R. S. Moirangthem, M. T. Yaseen, P. Wei, Academia Sinica (Taiwan)

An optical label free and high sensitivity plasmonic biosensor is presented based on the phase information of the ellipsometry signal. Plasmonic binary grating were prepared by using soft nano-imprinting

technique which significantly reduce the fabrication cost and can be realized for a transition from a laboratory-scale method to full-scale technology. The adsorption of bio-molecules on the nanostructure surface were investigated both in dynamic and spectroscopic mode by monitoring the change in polarization state or phase of reflected light as a sensing signal using ellipsometry. As a calibration, the bulk sensitivity obtained from our purposed plasmonic binary grating is about 9600 degrees/RIU by assuming a phase measurement accuracy of about 0.0010 as adopted in the literature. Furthermore, the experimental results were compared with an efficient theoretical simulation based on rigorous coupled wave analysis (RCWA).

8099-10, Session 3

CdSe/ZnS quantum dots with interface states as biosensors

T. V. Torchynska, G. Polupan, Instituto Politécnico Nacional (Mexico)

The paper presents the brief review of published results as well as the original study of photoluminescence (PL) and Raman scattering of core-shell CdSe/ZnS quantum dots (QDs) with radiative interface states. First commercially available CdSe/ZnS QDs with emission at 525 nm (2.36 eV), 565 nm (2.20 eV), 605 nm (2.05 eV) and 640 nm (1.96 eV) covered by PEG polymer have been compared in nonconjugated states. PL spectra of nonconjugated QDs are characterized by a superposition of PL bands related to exciton emission in CdSe cores and to hot electron-hole emission via high energy states (2.00, 2.37, 2.75 and 3.04 eV). The high energy states were studded using QDs of different sizes and at different temperatures. It is shown that these PL bands related to interface states. Then the CdSe/ZnS QDs have been conjugated with bio-molecules - anti IL-10 (Interleukin 10) and PSA (Prostate-Specific Antigen) antibodies. It is revealed that the PL spectrum of bioconjugated QDs has changed dramatically with essential decreasing of hot electron-hole recombination flow via interface states. The variation of PL spectra at the bioconjugation is explained on the base of electrostatic interaction and re-charging of QD interface states [1]. The Raman scattering study of nonconjugated and bioconjugated QDs has shown that mentioned antibodies are characterized by the dipole moment that provokes the surface enhance Raman scattering effect [2] in bioconjugated QD samples.

8099-11, Session 3

Characterization of a silicon photonic biosensor consisting of two cascaded ring resonators employing the Vernier-effect to improve sensitivity and interrogation.

T. Claes, W. Bogaerts, P. Bienstman, Univ. Gent (Belgium)

Many applications require label-free biosensors that consist of a transducer that directly responds to a selective affinity interaction between immobilized receptor molecules and analyte molecules.

Silicon-on-insulator ring resonators have already been proven to be excellent transducers that can be incorporated in a dense sensor array capable of multiplexed sensing and moreover can be manufactured with high quality using CMOS-compatible processes. However, ring resonators only have a limited sensitivity, of which an enhancement could not only further improve their detection limit, but it would also enable cheaper interrogation with a broadband light source and integrated wavelength filters.

We propose a sensor that employs the Vernier-effect to enhance the sensitivity of ring resonators with more than an order of magnitude. It consists of two cascaded silicon-on-insulator ring resonators of which only one is allowed to interact with biomolecules.

We designed and fabricated this sensor so that a periodic envelope signal is superposed on the sharp constituent resonance peaks, and experimentally prove that its sensitivity to a changing refractive index (2169nm/RIU) is thirty times larger than that of a single ring resonator. Its detection limit moreover benefits from the sharp transmission peaks that constitute the envelope. Analytical formulas describing the sensors transmission spectrum allow us to accurately track shifts of the envelope signal by data-fitting. Additionally, for the first time on-chip wavelength filtering of the sensor's signal with an integrated arrayed waveguide grating can be presented, making our sensor compatible with cheap interrogation with a broadband light source.

We think that these improvements make silicon-on-insulator ring resonator label-free biosensors even more attractive for many applications.

8099-12, Session 3

Block copolymer modified graphene field effect transistor robust biosensor

S. Guo, M. Ghazinejad, C. S. Ozkan, M. Ozkan, Univ. of California, Riverside (United States)

It is essential to control the electronic properties of graphene field effect transistors (GFETs). After spatially controlled CF4 plasma doping, we succeed in controlling the Dirac point of a GFET covered with cylindrical-morphology polycrystalline block co-polymer (BCP) (Poly(styrene-b-4-vinylpyridne)). The BCP microdomain array assembled on graphene provides a new approach to tune both electron and hole conductivity of graphene simultaneously. The BCP-covered GFET could detect 1mM NaF solution under "dry" conditions in 60s. Time studies showed that the sensor lasted for over 3 months. It was also determined that the orientation and periodicity of the resulting BCP array of cylindrical microdomains facilitate the selective sensing property. These findings pave the way for developing more durable and sensitive graphene-based sensors for chemical or biological applications under ambient conditions.

8099-13, Session 3

Nanoplasmon coupled intracellular optical resonance excitation for ultrasensitive 3D fluorescence cell imaging

M. R. Gartia, A. Hsiao, S. Mayandi, Y. Chen, G. L. Liu, Univ. of Illinois at Urbana-Champaign (United States)

With the goal of creating a platform for enhanced 3D fluorescence cell imaging capability, we have fabricated a nanoplasmonic substrate on which three-dimensional confocal fluorescence cell imaging sensitivity is amplified for more than 100 folds especially for cell membrane and cytoplasm. The observed unprecedented three-dimensional fluorescence intensity enhancement on the entire cell microstructure including cell membrane 10 μm above the substrate surface is attributed to a novel far field enhancement mechanism, nanoplasmon coupled optical resonance excitation (CORE) mechanism which permits enhanced surface plasmon on the substrate being evanescently coupled to Whispering Gallery mode optical resonance inside the spheroidal cell membrane microcavity. This is distinctly different from metal enhanced fluorescence effects because of the fact that metal enhanced fluorescence is a near field effect and only available up to 100 nm above the metal surface. Evidenced by high-resolution vertical slices of cell fluorescence images, the strong intracellular optical resonance modes provide highly intensified laser excitation inside cells and then lead to the huge amplification of fluorescence imaging sensitivity. Further, we have established the theoretical model for coupling of surface Plasmon evanescent wave with whispering gallery mode using coupled mode theory. In addition, preliminary experiment has also been performed using our device to see the early stage of transfection in a cancer cell.

8099-15, Session 3

Kinetic analysis of biomolecular interactions by surface plasmon enhanced ellipsometry

H. M. Cho, W. Chegal, Y. J. Cho, J. M. Won, H. M. Lee, Korea Research Institute of Standards and Science (Korea, Republic of); J. H. Jo, Hannam Univ. (Korea, Republic of)

We present the application of ellipsometry to the phase measurement of surface plasmon resonance (SPR) in biomolecular detection. In this work, the experimental setup for the SPR sensor was based on a custom-built rotating analyzer ellipsometer, which was equipped with a SPR cell and a microfluidic system. We investigate the sensitivity of SPR sensor which is dependent on the thickness and roughness of metal film, alignment of optical system, and stability of microfluidics.

In the drug discovery process, to directly monitor the interaction of small molecule-protein, it is necessary to design a high-sensitivity SPR sensor with a sensitivity of greater than 1 pg/mm2. Our sensor demonstrates a much better sensitivity in comparison to other SPR sensors based on reflectometry or phase measurements. The results of calibration indicate that the phase change, $\delta\Delta$, had an almost linear response to the concentration of ethanol in the double-distilled water solutions. A quantitative analysis of refractive index variation was possible using the results of the ellipsometric model fits for the multilayered thin film on the gold film. Thus, this method is applicable not only to sensor applications, such as affinity biosensors, but also to highly sensitive kinetics for drug discovery. In this paper, we demonstrate how a custom-built rotating analyzer ellipsometer in the SPR condition can be used to directly obtain the interactions and binding kinetics of low-molecular-weight analytes (biotins, peptides) with immobilized ligand (streptavidin, antibody). We achieved a detection limit of lower than 1.0 x10–7 RIU, which is the equivalent of 0.1 pg/mm2.

8099-16, Session 4

Nanobarcoding: a novel method of single nanoparticle detection in cells and tissues for nanomedical biodistribution studies

T. V. Eustaquio, J. F. Leary, Purdue Univ. (United States)

Determination of whether nanomedical devices accumulate in diseased (target) or normal (non-target) tissues, known as nanoparticle biodistribution, is absolutely critical in assessing the safety and efficacy of a given nanoparticle formulation for nanomedical purposes. However, current imaging-based methods of evaluating nanoparticle biodistribution are greatly limited. There is an overwhelming need for a more sensitive and more efficient imaging-based method that ideally can (1) detect small numbers of nanoparticles, even single nanoparticles, (2) associate preferential nanoparticle uptake with histological cell type, and (3) allow for relatively quick and accurate nanoparticle detection in the large, complex in vivo environment. One method that has the potential to fulfill the requirements of an improved nanoparticle detection strategy is in situ polymerase chain reaction (PCR). In situ PCR combines the extreme sensitivity of PCR and the cell-localizing ability of in situ hybridization. Since in situ PCR has had success in detecting viral DNA at a low-copy number inside single cells in a tissue section, which is analogous to the small numbers of nanoparticles that can be present, the in situ PCR technique can be adapted to the detection of single nanoparticles. We propose a novel method for nanoparticle detection that utilizes an oligonucleotide “nanobarcode” conjugated to the nanoparticle surface, which serves to amplify the optical signal from a single nanoparticle via in situ PCR for detection with standard microscopy. Nanobarcoding has the potential to fulfill the specifications of an ideal nanoparticle detection method. Herein, we describe the design process of the nanobarcoding method.

8099-17, Session 4

Surface enhanced Raman spectroscopy and fluorescence based on black silver

Z. Xu, J. Jiang, Y. Chen, M. R. Gartia, G. L. Liu, Univ. of Illinois at Urbana-Champaign (United States)

Surface plasmon-induced enhancements in spectroscopy and optical imaging are investigated on the mass producible black silver substrate (BSS) which is silver coated silicon with homogeneous and dense nanocones structure. On the contrary of highly reflective silver films or silver nanoparticles whose plasmon resonant modes are restricted within a few specific frequencies, the BSS of low reflectivity can efficiently trap and convert incident photons into localized plasmons within a broad frequency range. This unique physical property allows black silver to enhance optical absorption by 12 times from UV to NIR range, enhance surface fluorescence by 30 times and induce 7 more order of enhancement in the surface Raman scattering. Considerable potential of the BSS in high sensitive and broadband optical sensing and imaging is dominant with demonstrating enhanced fluorescence imaging and Raman spectroscopy of Rhodamine and oligo-peptide molecules.

8099-18, Session 4

Afterglow quantum dots for multispectral intraoperative fluorescence imaging

P. T. K. Chin, T. Buckle, Netherlands Cancer Institute (Netherlands); A. Aguirre de Miguel, S. C. J. Meskers, R. A. J. Janssen, Technische Univ. Eindhoven (Netherlands); F. W. B. van Leeuwen, Netherlands Cancer Institute (Netherlands)

Fluorescence molecular imaging is rapidly increasing its popularity in image guided surgery applications. To help develop its full surgical potential it remains a challenge to generate dual-emissive imaging agents that allow for combined visible assessment and sensitive camera based imaging. To this end, we now describe multispectral InP/ZnS quantum dots (QDs) that exhibit a bright visible green/yellow exciton emission combined with a long-lived far red defect emission. The intensity of the latter emission was enhanced by X-ray irradiation and allows for: 1) inverted QD density dependent defect emission intensity, showing improved efficacies at lower QD densities, and 2) detection without direct illumination and interference from autofluorescence.

8099-19, Session 4

Noble metal nanoparticles for LSPR-based optical sensing

W. Fritzsche, T. Schneider, O. Stranik, A. Csaki, Institut für Photonische Technologien e.V. (Germany)

The optical properties of noble metal nanoparticles depend on the excitation of localized surface plasmon resonance (LSPR) by electromagnetic irradiation. The position and intensity of the occurring plasmon band is influenced by particle specific features such as size, shape and material/composition. Important for biosensor applications are changes in the local refractive index of the surrounding medium, which can also cause a detectable plasmon band shift.

Micro spectroscopy to measure the scattering spectra of chosen particles undergoing biomolecular recognition process on the single particle level has been demonstrated successfully. In our experimental setup a spectrometer was coupled to a dark-field microscope by an optical fibre for collecting the emitted light. A small pinhole (150 µm) allows focusing on just one nanoparticle for collecting its optical information. Interparticle distances of larger than 5 µm excludes plasmon coupling effects of adjacent nanoparticles.

Herein, we investigate the sensing potential of different kinds of gold

nanoparticles for detecting DNA immobilization and hybridization. After immobilizing the gold nanoparticle on a glass substrate via silane chemistry, the single-stranded capture oligonucleotide was attached to the particle surface by thiol-gold interaction. Afterwards, single-stranded target DNA with a complementary sequence was hybridized to the capture oligonucleotide. Towards each step the scattering spectra of the particle was recorded. An example for 80 nm gold nanospheres is shown in figure 1. An obvious red shift of the plasmon band could be detected for both capture DNA attachment and target DNA hybridization.

8099-20, Session 4

Vertically emitting photonic bandgap cavity arrays for sensing applications

T. Moein, A. Pandey, Y. Yao, S. M. Durbin, Q. Gan, N. M. Litchinitser, A. N. Cartwright, Univ. at Buffalo (United States)

Highly selective sensing technologies continue to be of considerable interest because of their potential for applications in genetic screening, clinical diagnostics and single-molecule detection, among others. The reduction of the sensing element length scale and the formation of multiple patterned structures on a common substrate is essential for the development of arrayed biosensors. Thus, a patterned nano-structured material is an excellent candidate for such applications.

In this work, we demonstrate a simple and compact gas sensor array based on waveguide-coupled submicron multi-ring photonic bandgap ("bullseye") structures. The "bullseye" structures were patterned inside the SU-8 waveguide using focussed ion beam etching, which enables precise dimensional control in the submicron range. The center of each "bullseye" - the vertical cavity - was functionalized by incorporating analyte sensitive fluorescent molecules. The "bullseye" structures were designed to confine light at the fluorescence wavelength in the transverse direction by photonic bandgap effect. In this way, when excited by a broadband light source incident through the waveguide, the "bullseye" structure emits light in a cone pointing in the vertical direction. We discuss a methodology for translating this technology to biological sensing. In particular, this unique combination of transverse waveguide-based geometry for excitation and vertical detection will be beneficial for micro-fluidic based biological sensor systems.

8099-33, Session 4

A new glucose biosensor based on ECL technology and self-assembly GC electrode including GOx and silver nanoparticle

A. Shokuhi Rad, Islamic Azad Univ (Iran, Islamic Republic of); M. Ardjmand, Islamic Azad Univ. (Iran, Islamic Republic of); M. Jahanshahi, Babol Noshirvani Univ. of Technology (Iran, Islamic Republic of); A. Seyfkordi, Sharif Univ. of Technology (Iran, Islamic Republic of)

Electrogenerated Chemiluminescence (ECL) involves applying a certain electric potential to a chemical reaction, resulting in the oxidation or reduction of the substance which reacts to produce light. We determinate the amount of glucose by its reaction to glucose oxidase (GOx) on the surface of proposed modified electrode which results hydrogen peroxide (H2O2) as side product. After that the reaction between luminol and H2O2 under oxidizing conditions generate dependent light which can be used to analysis. In the current article at first we proposed a convenient method to obtaining a self-assembly modified electrode. A nano based modified glassy carbon electrode (Glucose oxidase / Ag nanoparticles/ cysteamine/ p-aminobenzene sulfonic acid/ GC electrode) were prepared, and the ECL behavior of luminol in the presence of glucose was examined. Compared to the bare GC electrode, the modified electrode incorporating glucose oxidase significantly enhanced the response of the ECL biosensor to glucose due to the enhanced specificity of the modified surface to enzymatic reaction, and the sensitivity of the luminal ECL reaction. Under optimal conditions, the electrode was found to respond linearly to glucose in the concentration range 5.0×10−7 to 8.0×10−3 mol/L, and the detection limit was establish to be a glucose concentration of 4.0×10−8 mol/L.

8099-21, Poster Session

surface plasmon resonance imaging ellipsometry for quantitative analysis for cell-matrix adhesions

W. Chegal, S. Kim, H. M. Cho, Y. J. Cho, D. W. Moon, Korea Research Institute of Standards and Science (Korea, Republic of)

The interaction between live cell and extracellular matrix, termed as cell-matrix adhesion, extensively regulates human biology from tissue and organ developments to the fate of cells. Elucidating functional dynamics of cell-matrix adhesion provide critical clues for understanding cellular phenomena. We developed a novel surface plasmon resonance imaging ellipsometry (SPRIE) method for real-time visualization of cell-matrix adhesion in live cell. In the SPRIE, the null-type imaging ellipsometry technique was integrated with an attenuated total reflection (ATR) coupler to improve contrast and sensitivity of the cell-matrix adhesions and cell-free medium contact regions. In the ATR coupler 30 nm of gold film were grown on the bottom side of the prism and subsequent surface treatment process was followed to anchor live cells. The ATR coupler was installed in the custom-built incubation chamber and the culture fluid was circulated to maintain cells alive. The surface plasmon wave was resonantly coupled with measurement beam and its evanescent characteristic allowed contrast mechanism of cell-matrix adhesions. During experiments cell-free regions were nulled out by adjusting polarizing components in the null-type imaging ellipsometer. In the captured image cell-free region exhibited lowest intensity and cell-adhesions exhibited gray scale values. The distance between cell membrane and top surface of the ATR coupler was calculated by using multi layered thin film model and Jones calculus. SPRIE was applied to multifaceted biological systems, cell division, migration and cell-cell communication. We also investigated shear stress-induced adhesion dynamics in real time. Together these data, we expect SPRIE can be developed for a useful methodology to study the role of cell-matrix adhesion in biological phenomena.

Mechanical properties of elastic honeycomb-patterned microporous substrate as cell scaffold

T. Kawano, Y. Nakamichi, M. Sato, H. Yabu, M. Shimomura, Tohoku Univ. (Japan)

Cell functions are regulated by various mechanical property of extracellular matrix. In particular, elasticity of substrate surface around the cells plays an important role in cellular proliferation, differentiation, migration and signaling.

The measurment of the mechanical property of the extracellular matrix is one of the critical basis of development of new functional biomaterials as scaffold for cell culture and tissue engineering. Previously, various measurements of mechanical properties of two-dimensional planar substrates were developed. However, it is clear discrepancies between cell behaviors in vivo and in artificial planar environments. Here, Here, we reported the preparation of the elastic honeycomb-patterned microporous films (honeycomb films) as three-dimensional scaffold and measurement of surface elasticity and deformation of honeycomb films. The honeycomb films of poly(1,2-butadiene) with hexagonal micron sized pores could be tunable the surface elasticity by changing the photo-cross-linking degree, which are regulated by UV light irradiation. Surface elastic and deformational distributions on the prepared honeycomb films were determined using micro-indentation test using AFM. Analyzing the

cell morphology and focal adhesions of fibroblast on the honeycomb-patterned surface with high elasticity, the fibroblast were well spread and markedly organized large focal adhesions. In contrast, small focal adhesions of cells on surfaces with low elasticity were observed. These results suggested that cell shape and formation of focal adhesions responded to the elasticity of the honeycomb films.

Nanoparticle-aided surface plasmon resonance: engineered nanoparticles for higher sensitivity with functionalities

S. Moon, D. Kim, J. Park, B. Kang, S. Haam, Yonsei Univ. (Korea, Republic of)

Simplicity along with relatively high sensitivity has been a great merit that surface plasmon resonance (SPR) based biosensors hold. As more demands towards molecular sensing emerged, abundant researches focused on enhancing the sensitivity even further appeared. Such include employing of surface nano to micro structures to alter the intrinsic surface sensitivity, switching the figure of merit to a more sensitive measure, and applying nanoparticles as signal enhancement agents. This study introduces use of multi-functional nanoparticles (MFNPs) for active selection of labeled biological samples with amplified optical signature. Particles are composed as gold nanoshell surrounding magnetic nanoclustered core and dielectric inner shell. MnFe2O4 has been reported as an outstanding magnetic resonance imaging contrast agent, which also possesses strong sorting capability in flow-based sorting labchips. Gold nanoshells are known for strong absorption characteristics, which implies that enhanced SPR sensor can replace giant magnetic resonance sensor which requires extreme accuracy in fabrication. As an empirical proof-of-concept, DNAs labeled with MFNPs are successfully sorted in a flow chamber and detected with enhanced sensitivity. Also, a range of structural availability is numerically analyzed to provide a guideline for optimized particle synthesis. The results are expected to open a wide application in terms of directed sensing.

Gold @ silica core-shell nanoparticle for enhanced surface plasmon resonance detection of DNA hybridization in combination with gold nanowire gratings

S. Moon, Y. Oh, D. Kim, H. Lee, H. C. Kim, K. Lee, Yonsei Univ. (Korea, Republic of)

Metallic nanoparticles have drawn much interest due to their distinct plasmonic characteristics especially in imaging and sensing applications. Surface plasmon resonance (SPR) based biosensors have evolved in many ways, among which sensitivity enhancement towards molecular sensing capability came up with strategies to overcome the hard limit of the intrinsic sensitivity of gold thin film. Recently adoption of signal contrast materials has proven successful in biochemical sensing applications. This study employs gold-SiO2 core-shell nanoparticles (CSNPs) as a strong SPR signal contrast agents. To reveal the underlying physics for the contrast mechanism, the particle characteristics were analytically evaluated in terms of light interaction coefficients. We experimentally demonstrate the effect of the CSNPs by applying them to acquire enhanced signal in DNA hybridization sensing scheme. We also applied gold nanowire grating structure on conventional gold thin film to further amplify the intrinsic sensitivity, where localized surface plasmon and locally amplified evanescent fields take parts. The results suggest that CSNPs and the grating structure cooperatively enhance the sensitivity and the role of nanowire gratings was analyzed with numerical methods to allow optimum sensitivity enhancement in terms of fill factor variations. The effects of field localization, amplification and enlarged signature of CSNPs are also discussed.

Silver doped nanomaterials and their possible use for antibacterial photodynamic activity

K. Wysocka-Król, H. Podbielska, Wroclaw Univ. of Technology (Poland)

Bacteria, viruses and parasites elimination from human environment has been one of the most important problem, extensively studied by many researchers. The growing resistance to commonly used disinfection and/or sterilization methods and antibiotics, is one of the major problem in the health care sector. Nanomaterials with tailored antimicrobial features may find applications in this field. One of the promising application of nanomaterials is the antimicrobial photodynamic therapy (APDT), which combines a nontoxic photoactive dye - photosensitizer and nanomaterials properties. Titanium dioxide based material known due to it photocatalytic properties, will be examined. The paper focused on the examination of optical and antibacterial properties of silica- and titania-based nanopowders doped with silver and photosensitizer - Photolon. It is known that silver doped biomaterials inhibit microbial growth and have been examined against various bacteria. Silver may interact with cellular wall and disintegrate it. The main target of silver are structural and enzyme proteins. From the other hand, photosensitizers are able to generate singlet oxygen and free radicals after light exposure that kill microbial cells. Various concentration of Photolon and nanomaterials have been examined to check the fluorescence enhancement and increased antibacterial activity. It was proved that the fluorescence intensity of Photolon increased, depending on silver concentration. Antibacterial study showed that silver doped silica and titania nanoparticles revealed antibacterial activity, but in the presence of Photolon, the antibacterial activity of materials is more effective.

Fluorescence enhancement by a dielectric Bragg resonant cavity

Y. Liu, S. Wang, Y. Park, X. Yin, X. Zhang, Univ. of California, Berkeley (United States)

The strong near-field enhancement of surface plasmon modes can significantly improve fluorescence emission. However, if fluorescent molecules are very close to the metal surface, the fluorescence can be quenched. On the other hand, it is found that purely dielectric structures, such as one-dimensional (1D) periodic gratings or two-dimensional (2D) photonic crystals, can also produce substantial local field enhancement thanks to the resonant photonic modes of the dielectric system. Such a platform based on mere dielectrics normally exhibits much less losses, in contrast to plasmonic structures. Consequently, fluorescence signals can be enhanced without suffering from pronounced quenching.

However, so far 1D or 2D periodic dielectric structures have not shown confined fluorescence emission. Under some conditions, we may want to selectively choose a certain area, sometimes a small one, to locally enhance fluorescence emission and use it for subcellular biosensing applications. Here we demonstrate that based on a 2D dielectric annular Bragg resonant cavity, electromagnetic waves can be focused to a diffraction-limited spot and significantly boost the fluorescence emission. Due to the constructive interference of the in-plane guided wave around the resonance wavelength, the electric field can be focused and amplified considerably. This leads to experimentally observed 20-fold fluorescence enhancement averaged over an area of 4 um2, while theoretically the fluorescence emission can be increased by more than three orders of magnitude at the center of the cavity. Our findings may have broad applications including near-field optical trapping, ultrasensitive chemical and biological sensors and fluorescent microscopy at the single-molecule level.

Nanotechnology in cancer treatment

M. Mironidou-Tzouveleki, K. Imprialos, A. Kintsakis, Aristotle Univ. of Thessaloniki (Greece)

Applications of nanotechnology, which include liposomes, nanoparticles, polymeric micelles, dendrimers, nanocantilever, carbon nanotubes and quantum dots, have significantly revolutionized cancer theragnostics . From a pharmaceutical viewpoint, it is critical that the biodistribution of active agents has to be controlled as much as possible. This aspect is vital in order to assure the proper efficiency and safety of the anticancer agents. These biocompatible nanocomposites show specific biochemical interactions with receptors expressed on the surface of cancer cells. With passive or active targeting strategies, an increased intracellular concentration of drugs can be achieved in cancer cells , while normal cells are being protected from the drug simultaneously. Thus, nanotechnology restricts the extent of the adverse affects of the anticancer therapy. Treatment for metastatic breast cancer, sarcoma in AIDS patients, ovarian and lung cancer is already on market or under final phases of many clinical trials, showing remarkable results. As nanotechnology is perfected, side effects due to normal cell damage will decrease, leading to better results and lengthened patient's survival.

Optical immunosensor for endocrine disruptor nanolayer detection by surface plasmon resonance imaging

A. Karabchevsky, L. Tsapovsky, R. S. Marks, I. Abdulhalim, Ben-Gurion Univ. of the Negev (Israel)

The presence of chemicals, both natural and synthetic, in the environment with the potential to interfere with the endocrine system in both wildlife and humans has in the last decade become a major international concern. Endocrine disrupting compounds (EDCs) such as estrone are especially prevalent in surface and waste-waters [1] in nano-molar concentrations and therefore, there is a need for sensitive analytical device for its monitoring. We have designed a miniature, low cost and fast surface plasmon resonance (SPR) imaging liquid sensor based on the known Kretschman configuration [2]. Due to its stability to water environment and simple bio-immobilization protocol, gold is usually used as SPR biosensing metal nano-layer. However, poor attachment of gold to the glass substrate needs additional layer of few nm Cr or Ti which deform the SPR reflectivity vs. angle curve. Silver, unlike gold, adheres very well to the glass, has very sharp curve but it is oxidizing when introduced to water or air medium, therefore a thin protective layer (<15nm) is needed to prevent oxidation. We used dense and packed thiol (11-mercaptoundecanoic acid (MUA)) layer which protects the silver from oxidation and enable immobilization of Rabbit Anti-Estrone Polyclonal IgG antibody to the thiol layer through linker. 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide and N-hydroxysuccinimide (NHS) were added to make the surface reactive. Shift in the SPR signal indicated the presence of the conjugated material-estrone and a detection limit of 5x10-6 RIU is demonstrated.

‘Listening’ to the spin noise of electrons and holes in semiconductor quantum structures

S. A. Crooker, Los Alamos National Lab. (United States)

The coherence and dynamical properties of spins in semiconductors are usually studied with powerful techniques based on optical pump-probe or spin resonance methods. Such methods are necessarily perturbative, in that one measures the (dissipative) response of the spins resulting from an external drive or excitation field (eg, free-induction decays). However, in accord with the fluctuation-dissipation theorem, the intrinsic fluctuations of the spin system - if experimentally measurable - can also reveal the same dynamical properties (such as g-factors and decoherence times) without ever perturbing the spin ensemble from thermal equilibrium.

This talk describes how we measure electron and hole spin dynamics in semiconductors by passively “listening” to these small spin noise signals [1]. We employ a spin noise spectrometer based on a sensitive optical Faraday rotation magnetometer that is coupled to a digitizer and field-programmable gate array (FPGA), to acquire noise spectra from 0-1 GHz in real time with picoradian/root-Hz sensitivity. In doped (In,Ga)As/GaAs quantum dots, both electron and hole spin fluctuations generate distinct noise peaks whose shift and broadening with magnetic field directly reveal their g-factors and dephasing rates. A large, energy-dependent anisotropy of in-plane hole g-factors is clearly exposed, reflecting systematic variations in the average confinement potential. In contrast with conventional pump-probe studies, noise signals increase as the probed volume shrinks, suggesting possible routes towards non-perturbative, sourceless magnetic resonance of few-spin systems. Quantum spin Hall effect in topological insulators

E. B. Sonin, The Hebrew Univ. of Jerusalem (Israel)

The original motivation of great interest to topological insulators was the hope to observe the quantum spin Hall effect. Therefore if a material is in the topological insulator state they frequently call it the quantum spin Hall state. However, despite impressive experimental results confirming the existence of the quantum spin Hall STATE, the quantum spin Hall EFFECT has not yet been detected. After an introduction addressing topological insulators and the spin Hall effect, I shall discuss whether and how the quantum spin Hall effect could be observed.

Spin injection into silicon using Al2O3, SiO2 and MgO tunnel barriers

O. M. J. van ‘t Erve, C. H. Li, A. T. Hanbicki, B. T. Jonker, U.S. Naval Research Lab. (United States)

We recently demonstrated injection of spin-polarized electrons from an Fe film into Si[1]. The tunnel barrier is the key component in achieving a large spin accumulation in the semiconductor. Here we will compare three different tunnel barriers, Al2O3, SiO2 and MgO, on highly doped Si using three terminal Hanle measurements. Hanle measurements give insight in the spin-accumulation directly underneath the spin injecting contact. We demonstrate the electrical detection of spin accumulation in Si (doped n-type 3x1018 to 6x1019/cm3) up to 500K via injection from a ferromagnetic contact through a SiO2 tunnel barrier formed by plasma oxidation. Lorentzian fits to Hanle curves yield a spin lifetime of ~100 and 320ps for the 6e19 and 3e18 doped Si, respectively. The direct correlation between spin lifetime and carrier concentration in the Si, and that the magnitude of the Hanle signal agrees well with that expected from theory [2], providing clear evidence that the spin accumulation indeed occurs in the Si and not interface states. A spin lifetime of 120ps was obtained for 3e19 n-doped Silicon for both the Al2O3 and SiO2 tunnel barrier. We will present the bias dependence and the temperature dependence of the spin lifetime for the different tunnel barriers. These results demonstrate that spin accumulation in Si can be a viable basis for spin-based devices. Supported by ONR.

Lateral spin injection in germanium nanowires

E. Tutuc, E. Liu, J. Nah, K. Varahramyan, The Univ. of Texas at Austin (United States)

Efficient spin injection from ferromagnetic metals (FM) into semiconductors (SC) is typically suppressed by the conductivity mismatch at the FM/SC contact. Spin injection can be achieved however if the contact resistivity at the FM/SC interface is appropriately engineered [1]. Here we examine the spin injection in n-type, phosphorus-doped germanium nanowires using cobalt as FM contacts, and MgO tunnel barriers for contact resistance engineering. The two-point magneotresistance measurements reveal spin-valve effect, with a low (high) resistance for parallel (antiparallel) polarizations of the FM contacts. Non-local, four-point magnetoresistance measurements, which separate the spin diffusion path from the charge current path, demonstrate that the observed spin-valve effect stems from spin injection in the Ge nanowires. We map out the contact resistance window where lateral spin transport is observed, and manifestly show the conductivity matching required for spin injection. We discuss the implications of these results in the context of the spin diffusion theory.

Hot-electron spin injection and detection in n-doped silicon

Y. Lu, Univ. Henri Poincaré Nancy (France); I. Appelbaum, J. Li, Univ. of Maryland, College Park (United States); M. Hehn, Univ. Henri Poincaré Nancy (France)

Silicon has been known for decades to have an extraordinarily long spin lifetime. Using unique spin-polarized hot-electron injection and detection techniques [1], we have observed unprecedented spin coherence, and extracted very long spin lifetimes of conduction electrons travelling over macroscopic distances [2]. It is necessary to investigate magnetic and electric field controls of electron spin in doped silicon for integration of spintronics into present-day silicon-based microelectronic technology, where impurity doping plays a critical role.

By reversing the Schottky barrier-height asymmetry in hot-electron semiconductor-metal-semiconductor ballistic spin filtering detectors [3], we have achieved the following: (1) demonstration of >50% spin polarization in silicon (Fig.1), resulting from elimination of the ferromagnet/silicon interface on the transport channel detector contact and (2) evidence of spin transport at temperatures as high as 260 K, enabled by an increase in detector Schottky barrier height.

Unlike previous studies with undoped Si, the presence of ionized

impurities in the depletion regions of these doped transport layers gives rise to conduction-band bending that (for sufficient biasing conditions) confines injected electrons for long dwell times. Recently, another unexpected source of non-equilibrium spin dephasing in n-type phosphorus-doped silicon is also observed when temperature and voltage conditions provide a confining electrostatic potential conduction band profile between injector and detector Schottky barriers [4]. In addition to Hanle spin precession features for magnetic fields in the kOe range, we also observe substantial (but incomplete) dephasing with much smaller characteristic widths of ~50-100 Oe (Fig.2). The possibility that this phenomenon originates from transit-time delays associated with capture/re-emission in shallow impurity traps is discussed in light of temperature, voltage, and electron density dependence measurements.

Optical spin orientation in SiGe heterostructures

G. Isella, F. Bottegoni, Politecnico di Milano (Italy); F. Pezzoli, Univ. degli Studi di Milano-Bicocca (Italy); S. Cecchi, Politecnico di Milano (Italy); E. Gatti, E. Grilli, M. Guzzi, Univ. degli Studi di Milano-Bicocca (Italy); F. Ciccacci, Politecnico di Milano (Italy)

Germanium lies between gallium and arsenide in the periodic table, therefore Ge and GaAs features many similarities. In particular, still being and indirect bandgap semiconductor, the absorption properties of Ge are dominated by direct-gap transitions coupling heavy holes (HH) and light holes (LH) states in the valence band with the local minimum of the conduction band (CB) at the Gamma point. As a result, selection rules valid for optical spin orientation in GaAs apply also to Ge. In Ge-based heterostructures strain and quantum confinement effects might be employed to remove the HH-LH degeneracy at Gamma, substantially increasing the polarization of excited carriers. Moreover Ge exhibits centre-of-inversion symmetry, a spin orbit interaction weaker than GaAs and a high compatibility with Si technology, all relevant features for spintronics applications.

We present spin polarized photo emission (SPPE) and photoluminescence (PL) measurements performed on bulk Ge, Ge/Si(100) epilayers and Ge/SiGe multiple quantum wells heterostructures.

SPPE data indicate that compressive bi-axial strain effectively lifts the HH LH degeneracy raising the polarization of injected electrons above the P=50% limit of bulk material.

PL measurements performed on bulk Ge crystal at different excitation energies give insights on the spin relaxation mechanism related to the thermalization of injected carrier at the Gamma point.

In Ge MQWs, direct-gap PL at excitonic resonances indicates that spin injection well above bulk values can be achieved. Part of the polarization is preserved during electron scattering from Gamma to the absolute CB minimum at L, as suggested by the polarization of light associated with indirect-gap transitions.

Spin injection in metal based lateral nanostructures

P. Laczkowski, L. Vila, J. P. Attané, A. Marty, C. Beigné, L. Notin, Commissariat à l'Énergie Atomique (France)

The ability to control and manipulate spin currents, a flow in opposite directions of spin up and spin down without net electrical charge flux, is a key point for the development of new spin based electronic devices in the field of spintronics. Admits the large variety of proposed spin structures [FER08], lateral spin valves (LSV) have recently attracted much attentions, giving the possibility of fabrication of multi-terminal nanostructures. The LSV structure quality can be quantified by its spin signal ΔRs, which is related to the difference of non-local electrochemical potential between the anti-parallel and parallel magnetization states of the electrodes. The spin signal depends mainly on the geometry of the LSV, the quality of the interfaces, and the choice of the used materials.

We will review two basic methods for spin current generation in metal based lateral nanostructures, being current injection with the tunnel or transparent junctions through Ferromagnetic(F)/Nonmagnetic(NM) interfaces, or alternatively at the Ferromagnetic/Paramagnetic interface through the Spin Hall Effect (SHE). Recent experiments using the SHE [VAL09] opened new paths toward the generation and detection of spin current without requirements for magnetic materials neither magnetic fields. In this context, the insertion of materials with large spin-orbit coupling in LSV was demonstrated to be an efficient way to measure the Spin Hall angle [VIL07].

We will also present a technique used to optimize the spin signal of LSV using multi-angle deposition process, avoiding interface contamination and oxidation. Comparison of the spin signals obtained with NM material having either short or long spin diffusion length will be also carried out.

Spin polarized electroluminescence and spin photocurrent in hybrid Semiconductor/Ferromagnetic heterostructures : an Asymmetric Problem

T. Amand, P. Renucci, V. G. Truong, Institut National des Sciences Appliquées de Toulouse (France); H. Jaffrès, Unité Mixte de Physique CNRS/Thales (France); L. Lombez, Institut National des Sciences Appliquées de Toulouse (France); P. H. Binh, Institute of Material Science (Viet Nam); J. George, Unité Mixte de Physique CNRS/Thales (France); X. Marie, Institut National des Sciences Appliquées de Toulouse (France)

The photocurrent obtained under polarized optical excitation and the polarized electroluminescence recorded under forward electric bias have been measured in the same hybrid Semiconductor/Ferromagnetic metal structures (Spin-Light Emitting Diode). The systematic investigations have been performed on devices with different ferromagnetic spin injectors: tunnel barrier of Al2O3 surmounted by a thin Co ferromagnetic layer or MgO tunnel barriers with a CoFeB FM layer. Though a very efficient electrical spin injection is demonstrated with a measured circular polarization of the electroluminescence up to 30% for an external field of 0.8 Tesla, very weak polarizations of the photocurrent are evidenced whatever the nature of the device is [1]. The maximum photocurrent polarization obtained under continuous resonant circularly polarized excitation of the quantum well excitons is about 3%. This demonstrates that the investigated devices do not act as an efficient spin filter for the electrons flowing from the semiconductor part to the ferromagnetic part of these structures though these systems are very efficient spin aligners for electrical spin injection. We interpret the weak measured polarization of the photocurrent as a consequence of the Zeeman splitting of the quantum well excitons which yields different absorption coefficients for the polarized excitation laser with different helicities. This leads to different intensities of photocurrent collected for the two different circularly polarized excitations. This interpretation is confirmed by an experiment exhibiting the same results for photocurrent measured on a device with a non ferromagnetic electrical contact.

8100-09, Session 3

Optically oriented electron spin transmission across ferromagnet/ semiconductor interfaces

T. Taniyama, Tokyo Institute of Technology (Japan)

An understanding of electron spin transmission across ferromagnet (FM)/ semicondcutor (SC) interfaces is vital to the successful development of spitronic devices. Both electron transmission processes from the FM into the SC and from the SC into the FM are highly relevant to providing information about the surest route to achieving high efficiency of spin injection into SC. The aim of this work is to examine the electron spin transmission processes from a GaAs quantum well (QW) into a ferromagnetic metal layer using optical spin orientation method. The sample structure we used consists of an Fe layer or an Fe3O4 layer on a GaAs/AlGaAs QW. Once circularly polarized light irradiates the sample from the normal to the layer plane, spin polarized electrons are excited in the quantum well according to the optical transition selection rules, thereby photocurrent of the spin polarized electrons flows across the interface. Since the photocurrent varies depending on the excited electron spin orientation, measurement of the circular polarization dependence of the photocurrent, i.e., helicity dependent photocurrent, can provide information about the mechanism of electron spin transmission across the interface. One of the most significant results here we observe is a dip appears in the helicity dependent photocurrent at a particular bias voltage for the Fe/GaAs QW sample and even the sign reversal of the helicity dependent photocurrent occurs. The origin of the bias dependence of the helicity dependent photocurrent is discussed in detail using the Breit-Wigner type resonant tunneling process via interface resonant states.

8100-10, Session 3

Spin injection in silicon and germanium

M. Jamet, Commissariat à l'Énergie Atomique (France); A. Jain, L. Grenet, A. Barski, Commissariat à l'Energie Atomique (France); P. Noé, Commissariat à l'Énergie Atomique (France); S. Auffret, P. Warin, J. Hartmann, A. P. Brenac, E. Augendre, V. Baltz, P. Gentile, L. Via, Commissariat à l'Energie Atomique (France)

Spintronics aims at manipulating both charge and spins in semiconductors. It thus requires a robust scheme for injecting polarized current into these materials. Spin injection into GaAs has already been demonstrated optically and electrically. Recently an increasing number of works are performed on spin injection into silicon and germanium since they are the core materials for potential applications and promising candidates for spin polarized transport due to predicted long spin lifetimes. We present results obtained on spin injection from a ferromagnetic layer into silicon (optical detection) and germanium (electrical detection). SiGe quantum wells embedded in a Si-based pin diode are used to optically detect spin-polarized electrons injected into silicon whereas three-terminal and four-terminal geometries are used for electrical non-local detection of spin accumulation in germanium layers. The electron spins are aligned either in-plane using NiFe and Co electrodes or out-of-plane using a CoPt electrode with perpendicular magnetization. Spin injection through an alumina tunnel barrier is carried out to prevent depolarization due to conductance mismatch with silicon and germanium. For spin injection in silicon, the remanent configuration of the CoPt electrode magnetization allows to study spin injection without applying a magnetic field, avoiding spurious effects such as Faraday rotation in silicon. Light polarization of more than 3 percent has been measured and its temperature dependence will be discussed. Preliminary electrical detection of spin accumulation in germanium will also be presented after overcoming the issue of Fermi level pinning at the interface between germanium and the tunnel barrier.

8100-11, Session 4

Magnetization dynamics in the inertial regime: nutation predicted at short time scales

J. Wegrowe, H. Drouhin, Ecole Polytechnique (France)

The well-known Gilbert's equation describes the dissipative dynamics of the magnetic degrees of freedom coupled to a heat bath. We propose to discuss the derivation of the Gilbert's equation from both the point of view the Lagrangian approach [1] and the non-equilibrium thermodynamic (NET) approach.

The derivation based on the Lagrangian approach (used initially by Gilbert in 1955) [1] is performed in the phase space : the angular momentum (with the kinetic energy) is introduced as starting hypothesis. However, the Gilbert equation is a kinetic equation that does not contain any inertial terms for uniform magnetization. This paradoxical situation appeals at least two comments.

(1) On one hand, a full kinetic derivation of the Gilbert equation (with zero kinetic energy) would solve the paradox. Such a derivation is proposed within the NET approach [2]. This derivation is performed in the configuration space of the magnetic degrees of freedom, and not in the phase space (i.e. no need to introduce the angular momentum).

(2) On the other hand, the Gilbert's Lagrangian approach can be pushed to its logical consequences, i.e. a generalization of the equation with the introduction of inertial terms proportional to the second derivative of the uniform magnetization [3]. This derivation is obtained straightforwardly by enlarging the configuration space of the magnetization to the phase space, i.e. to the angular momentum. Beyond, the transient nature of this inertial regime is derived in the framework of the NET theory.

Ferromagnetic nanostructures for magnonic crystals and waveguides

D. Grundler, Technische Univ. München (Germany)

Collective spin excitations in ferromagnets have regained great interest in the course of spintronics research. Recent observations such as spin-wave quantization, localization and interference have stimulated the field of magnonics where spin waves (magnons) are explored in order to carry and process information.[1] We investigate nanopatterned ferromagnetic thin films which form magnonic waveguides [2,3] and magnonic crystals [4], i.e. the magnetic counterpart of photonic crystals. Allowed minibands and forbidden frequency gaps are created by coherent coupling of confined spin wave modes. The devices open intriguing perspectives for the manipulation of spin waves at the nanoscale and the realization of magnetic metamaterials.[5] We gratefully acknowledge collaborations and discussions with M. Becherer, B. Botters, G. Dürr, F. Giesen, G. Gubbiotti, D. Heitmann, M. Kostylev, M. Krawczyk, V. Kruglyak, S. Neusser, J. Podbielski, D. Schmidt-Landsiedel, M.L. Sokolovsky, S. Tacchi, and J. Topp. The research has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under Grant Agreement no. 228673, from SFB 668 and the German Excellence Cluster 'Nanosystems Initiative Munich'.

8100-13, Session 4

Tailoring magnetic relaxation channels at the nanoscale

I. Barsukov, Univ. Duisburg-Essen (Germany)

Controlling spin relaxation is essential for spintronic and spin torque applications. Manipulating spin relaxation allows the adjustment of magnetization reversal speed at microwave frequencies. Moreover, the critical current in spin torque devices can be reduced and tuned. In the experiment it is possible to distinguish between the intrinsic and extrinsic relaxation channels. The latter can be tailored with respect to the intensity and anisotropic behaviour. In particular, methods for inducing elementary relaxation channels of uniaxial symmetry and their impact on the magnetization dynamics are discussed in this presentation.

Fe-based thin films have been studied by means of the ferromagnetic resonance technique, by which the intrinsic and extrinsic relaxation processes can be disentangled. While the former are rather isotropic and can be adjusted via spin-orbit interaction, the latter can be modified in an advanced way. It is shown, how crystalline defects, inhomogeneities of chemical composition, and interface modifications can induce the 2-magnon scattering. Control and systematic manipulation of these parameters allow tailoring the overall spin relaxation in a desired manner.

In cooperation with J. Lindner, R. Meckenstock, H. Wende, P. Landeros, K. Lenz, and M. Farle.

Emergent magnetic monopoles and associated Dirac strings in artificial kagome spin ice

L. J. Heyderman, Paul Scherrer Institut (Switzerland)

Artificial spin ice systems, consisting of two-dimensional arrangements of single-domain nanomagnets, have recently been in the focus of scientific interest since they provide an opportunity to directly study the effects of frustration [1, 2]. Our work has focused on artificial kagome spin ice, with elongated nanomagnets arranged on the kagome lattice forming an array of hexagonal rings. Synchrotron x-ray photoemission microscopy allows direct imaging of the magnetic state of each nanomagnet, having moments pointing in one of two orientations parallel to their long axis. Our recent observations demonstrate the existence of emergent magnetic monopoles and their associated Dirac strings at room temperature in a quasi-infinite nanomagnet array [3]. In an applied magnetic field, monopole-antimonopole pairs nucleate and then separate in an avalanche-type manner along one-dimensional Dirac strings, consisting of overturned dipoles. This behaviour is distinct from conventional domain growth in two-dimensional systems and results in the formation of a ‘stripe phase’ towards the end of magnetization reversal. The observed hysteresis, monopole densities and 1D Dirac-string avalanches are quantitatively explained by Monte Carlo simulations and the results open the way to a controlled manipulation of magnetic charges that may lead to new spintronic devices.

8100-15, Session 4

Indirect localization of a magnetic domain wall mediated by its quasi wall

D. Lacour, Univ. Nancy 2 (France) and Institut Jean Lamour (France) and CNRS (France); F. Montaigne, M. Hehn, Univ. Henri Poincaré Nancy (France); R. Belkhou, Synchrotron Soleil (France); N. Rougemaille, Institut Néel (France) and CNRS (France) and Univ. Joseph Fourier (France); J. Raabe, Paul Scherrer Institut (Switzerland)

The manipulation of a single magnetic domain wall in thin films and nanostructures opened up new insight and opportunities for fundamental and applied researches. Studies have all focused on the control of the pinning and the depinning processes of domain walls on centers localized in the magnetic layer in which the wall moves (active layer). Here we report an indirect localization process of 180° domain walls that occurs in commonly used multilayer nanostructures in which an active and a reference magnetic layer coexist. Combining Scanning Transmission X-Ray Microscopy with micromagnetic simulations, magnetic configurations in both layers have been resolved. The nucleation of a 180° domain wall in the active layer creates a quasi wall in the reference layer atop of the wall. Then the wall and the quasi propagate together. The quasi wall pinning in reference layer is shown to be responsible for this indirect localization process of the domain wall in the active layer.

8100-16, Session 5

Optical pumping of electron and nuclear spins in GaAs/AlGaAs droplet epitaxy quantum dots

T. Amand, G. Sallen, S. Kunz, D. Lagarde, X. Marie, B. Urbaszek, Institut National des Sciences Appliquées de Toulouse (France); T. Kuroda, M. Abbarchi, T. Mano, K. Sakoda, National Institute for Materials Science (Japan)

The spin properties of semiconductor quantum dots are extensively investigated, due to their potential applications in spintronics and quantum cryptography. Quantum dots elaborated by molecular droplet epitaxy are very attractive since they provide strong confinement for carriers as in Stransky-Krastanov grown dots, but in the absence of lattice strain. Here, we review the optical and spin properties of GaAs/AlGaAs droplet dots.

First, we investigate the impact of the dot anisotropy on the optical selection rules for samples grown on [100] and on novel [111] oriented substrates. The single dot emission spectra display exciton and biexcitons, as well charged exciton complexes. The linearly polarized emission dependence of each emission line reveals a departure from the standard optical selection rules. Using a 6-bands k.p model including the electron-hole exchange we show that the exciton fine structure as well as the polar emission diagrams are determined by heavy/ligh-hole state mixing. The physical origin of this mixing is a lowering of the quantum dot confinement potential symmetry.

Second, dynamic nuclear polarization is investigated, revealing that remarkably, even without external magnetic fields, the oriented electron spin can polarize the nuclear spin system. Dynamic polarization of the nuclear spins, up to about 50%, is also demonstrated in a longitudinal magnetic field. Using a time resolved spectroscopy technique, it is shown that the build-up of the dynamic nuclear polarization occurs within a few hundred milliseconds, and increases with the applied external magnetic field.

8100-17, Session 5

Single-electron spin ratchet

S. O. Valenzuela, Institució Catalana de Recerca i Estudis Avançats (Spain) and Catalan Institute of Nanotechnology (Spain) and Univ. Autonoma de Barcelona (Spain)

We describe a spin ratchet at the single-electron level that produces spin currents with no net bias or charge transport. Our device [1] is based on the ground-state energetics of a single-electron transistor (SET). The SET comprises a superconducting island connected to normal leads via tunnel barriers with different resistances that break spatial symmetry. We demonstrate spin transport and quantify the spin ratchet efficiency by using ferromagnetic leads with known spin polarization.

8100-18, Session 5

Single spins in quantum dots and impurities

C. E. Pryor, The Univ. of Iowa (United States)

There are a variety of methods available for confining and manipulating single spins in solid state systems. While heterostructures can be engineered to the requirements of the problem, their variability is a disadvantage compared to identical impurities. I will discuss theoretical calculations of single spins both in quantum dot heterostructures and bound to impurities. These include calculations of the spin state itself, the effective coupling to a magnetic field, the response to an electric field, and include both electrons and holes.

8100-19, Session 5

Nuclear spin dynamics in semiconductor nanostructures

I. Tifrea, California State Univ., Fullerton (United States)

I will discuss recent advances in understanding the nuclear spin dynamics in low dimensional systems. The focus will be on the hyperfine interaction between nuclear and electronic spins and the role this interaction plays on the dynamical nuclear polarization of semiconductor nanostructures. The natural confinement provided by low dimensional semiconductor nanostructures such as quantum wells and quantum dots is responsible for a position dependent nuclear spin dynamics in these physical systems. Consequently, the nuclear spin relaxation time and implicitly the nuclear spin polarization will be position dependent leading to important implications for optical NMR and Faraday rotation experiments. Additionally, numerical simulations prove that nuclear spin diffusion may be reduced in the same conditions. As an example I will discuss the case of a GaAs quantum well. I will present results for Overhauser shifts, measurable in Faraday rotation experiments, and Knight shifts, measurable in optical NMR experiments. In connection with these results I will present results for nuclear spin diffusion and prove its relatively small effect on the overall polarization of As nuclei.

This work was supported by Research Corporation.

8100-20, Session 6

Spin relaxation and spin transport in graphene and the interface of multiferroic oxides

M. Wu, Univ. of Science and Technology of China (China)

Invited talk for SPINTRONICS IV

8100-21, Session 6

Dopants and charge carriers in colloidal semiconductor quantum dots

D. R. Gamelin, Univ. of Washington (United States)

The generation, manipulation, and detection of electron spins in semiconductor nanostructures are all central themes in spintronics and spin-photonics. This talk will describe recent advances in the introduction, study, and manipulation of spins in colloidal semiconductor nanocrystals, focusing on properties of doped nanocrystals such as transition-metal-doped CdSe, ZnO, and ZnSe quantum dots. Topics will include unusual photoluminescence phenomena, magneto-optical spectroscopies, magnetic resonance spectroscopies, photoluminescence dynamics, spin relaxation dynamics, carrier-dopant magnetic exchange interactions, and photon-controlled magnetization. The properties to be discussed underlie many important spin-electronic and spin-photonic phenomena including carrier-mediated ferromagnetism, excitonic magnetic polaron nucleation, and proposed spin-based quantum information processing. Basic aspects of doped quantum dot electronic structures will be discussed in this context.

Inelastic light scattering of hole spin excitations in p-modulation-doped GaAs-AlGaAs single quantum wells

M. Hirmer, M. Hirmer, T. Korn, D. Schuh, Univ. Regensburg (Germany); W. Wegscheider, ETH Zürich (Switzerland); R. Winkler, Northern Illinois Univ. (United States); C. Schüller, Univ. Regensburg (Germany)

We have investigated spin-density excitations of holes in one-sided p-modulation-doped GaAs-AlGaAs single quantum wells by means of resonant inelastic light scattering. The experiments yield a direct measure of the Rashba spin splitting of holes in quantum wells with an asymmetric potential profile. The samples are highly-doped GaAs-AlGaAs single quantum wells with well widths of 15, 20 and 25 nm, and different doping densities. The experiments were performed at temperatures of about 4 K, using a tunable Ti:Sapphire laser and a triple Raman spectrometer with liquid-nitrogen cooled CCD detector. In the low-energy range of the inelastic light scattering spectra, we observe in all samples well-defined excitations with excitation energies between about 1 meV and 4 meV, which can be attributed to spin-density excitations of the two-dimensional hole systems due to polarization selection rules. We interpret the excitations as spin-density excitations, where holes are excited between the Rashba spin-split ground states, performing a spinflip. The strong resonance behavior of the inelastic light scattering process allows us to scan the k dependence of the hole spin splitting. Comparison to k*p bandstructure calculations, performed with the NextNano3 program package, shows good agreement of the measured and calculated k-dependent spin splittings. Details of the spectra show a distinct dependence on the directions of light polarizations with respect to crystallographic axes. In particular, we have detected a doublet structure of the hole spin excitations, which may be attributed to the anisotropic hole spin splitting within the quantum-well plane.

8100-23, Session 6

New insights into nanomagnetism by spin-polarized scanning tunneling microscopy and spectroscopy

H. Oka, P. Ignatiev, S. Wedekind, G. Rodary, L. Niebergall, V. Stepanyuk, D. Sander, J. Kirschner, Max-Planck-Institut für Mikrostrukturphysik (Germany)

Spin-polarized scanning tunneling microscopy (SP-STM) allows imaging and spectroscopic characterization of nanostructures with unsurpassed spatial resolution. Its working principle exploits the dependence of the tunnel current on the relative magnetization orientation of a sample and the magnetic STM tip. We present results by SP-STM, where we investigate the correlation between structural, electronic, and magnetic properties of individual nm small Co islands with several hundred to thousands of atoms. We use external magnetic fields of up to 4 T to tune the magnetic state of both tip and sample, and we extract the corresponding change of the differential conductance of the tunnel junction.

A recent example is our measurement of magnetic hysteresis loops of individual nm small Co islands on Cu(111) at 8 K by SP-STM in external magnetic fields. We find switching fields of up to 2.5 T for islands with roughly 8,000 atoms. The quantitative analysis of these results provides novel insights into the magnetization reversal on the nanoscale, and deviations from the venerable Stoner-Wohlfarth model are discussed.

We also exploit the high spatial resolution of SP-STM in magnetic fields to measure maps of the differential conductance within a single nm-small Co island. In connection with density functional theory calculations we demonstrate for the first time that the spin polarization is not homogeneous but spatially modulated within the Co island. We ascribe the spatial modulation of the spin polarization to spin-dependent electron confinement effect within the Co island [1].

8100-24, Session 6

Magneto-resistance in a lithography defined single constrained domain wall spin valve

C. H. de Groot, Y. Wang, Univ. of Southampton (United Kingdom); D. Claudio-González, Univ. de Guanajuato (Mexico); H. Fangohr, Univ. of Southampton (United Kingdom)

We have measured domain wall magnetoresistance in a single constrained domain wall[1]. In 1999, Bruno[2] proposed that in nanostructured devices the domain wall width can be constricted by geometric means. A sudden large expansion of the magnetic area will constrict the domain wall as the energy cost of increasing the area of the domain wall outweighs the exchange interaction. An H-shaped Ni nanobridge device based on this idea was fabricated by e-beam lithography with the two sides being single magnetic domains showing independent magnetic switching. The bridge connecting between the sides constrains the domain wall when the sides' magnetization line up antiparallel. The magnetoresistance curve clearly identifies the magnetic configurations that are expected from a spin-valvelike structure. The value of the magnetoresistance at room temperature is around 0.1% or 0.4 Ω. This value is shown to be in agreement with a theoretical formulation based on spin accumulation. This is the first inplane transport measurement of an individual nanomagnetic structure.

In this conference we are going to show the experimental realization of this proposed structure and magnetoresistance in a lithographically defined constrained domain wall structure in between two independently switching single magnetic domains. The e-beam lithography and metal lift-off procedures will be introduced as well, such as dose proximity effect correction (PEC), bi-layer lift-off structure.

8100-25, Session 7

Computational studies of model Hamiltonians for strongly correlated materials in the bulk and at interfaces

E. Dagotto, The Univ. of Tennessee (United States)

The current status of computer simulations of model Hamiltonians for transition metal oxides, such as the manganites with the colossal magnetoresistance (CMR) and the high-Tc superconducting cuprates, will be reviewed. It will be shown that state-of-the-art computer simulations involving Monte Carlo simulations of double-exchange models with Jahn-Teller phonons do display the CMR effect, while one-orbital Hubbard models for Cu-oxides (and multiorbital models suitable for the recently discovered superconducting pnictides) have tendencies to pairing in exotic channels. These materials, and others, also play an important role in the novel area of oxide superlattices. A brief review of this field will be presented followed by results of our group with an emphasis on the stabilization at interfaces of novel states that do not have an analog in the materials that form the superlattice when they are in bulk form. Time allowing, recent developments in manganite multiferroics will also be discussed. Here, computer simulations have recently predicted the existence of new phases with unusual arrangements of spin and charge when narrow bandwidth manganites are hole doped.

8100-26, Session 7

Oxide interfaces: spin transport at the nanoscale

T. Banerjee, Univ. of Groningen (Netherlands)

Oxide spintronics is an emerging research direction where the fundamental thrust is on understanding the physics of electron charge/spin/orbital interactions in perovskite oxide interfaces at the nanoscale. Epitaxial interfaces of half-metallic ferromagnets on oxide semiconductors are the building blocks of spintronic devices. Very little is known about spin transport across such interfaces, at the nanoscale, where intriguing phenomena are likely to emerge. In this talk, I will discuss our recent experiments on nanoscale (spin) electron transport across epitaxial interface of La0.67Sr0.33MnO3(LSMO) on Nb:SrTiO3,using the technique of Ballistic Electron Emission Microscopy (BEEM) and illustrate its importance in oxide electronics.

8100-27, Session 7

An antiferromagnetic insulator with voltage controlled surface polarization

P. A. Dowben, N. Wu, X. He, C. Binek, K. Belashchenko, T. Komesu, Univ. of Nebraska-Lincoln (United States)

For the prototypical magneto-electric Cr2O3(0001), we have observed a finite remanent polarization at the surface in spin-polarized photoemission [1], spin polarized inverse photoemission, and X-ray magnetic circular dichroism. This occurs when the antiferromagnetic single domain state is selected in a magneto-electric annealing process. In a magneto-electric material, an applied electric field induces a net magnetic moment. This becomes important to surface magnetism because there is also a finite remanent magnetization at the surface or boundary of magneto-electric antiferromagnets, predicted using symmetry arguments, and recently demonstrated [1]. In the single domain antiferromagnetic state of Cr2O3, the magnetic Cr2O3(0001) surface moment evolves and is robust against surface roughness, which may be useful for device fabrication. The surface polarization has now been measured to be as high as 70 to 80%, at binding energies corresponding to a strongly weighted surface density of states.

This surface magnetic order, combined with the magneto-electric behavior of Cr2O3(0001) enables the investigator to have electric control

of a net magnetic moment at the Cr2O3(0001) surface. The surface magnetic domain structure has also been imaged in X-ray circular dichroism combined with photoemission electron microscopy (PEEM) at the surface of Cr2O3(0001), under conditions of no electric field cooling and with electric field cooling. Consistent with the other measurements, profound differences are observed.

8100-61, Session 7

Spin injection and relaxation in graphene

W. Han, R. K. Kawakami, Univ. of California, Riverside (United States)

Graphene is a unique and promising candidate for spintronics due to its high mobility, gate tunable transport properties, and low intrinsic spin-orbit and hyperfine coupling. However, the spin injection efficiency has been low (< 10%) and spin lifetime is still much shorter (50-200 ps) than predicted theoretically (~ micro seconds). To fulfill the potential of graphene for spintronics, two major advances need to be accomplished; enhance the spin injection efficiency and extend the spin lifetime. In this talk I will focus on the following two results in graphene spintronics. First, tunneling spin injection into graphene is achieved using MgO tunnel barrier. The non-local spin signal is found to be as high as 130 ohms at 300 K, with a spin injection efficiency of 30%. Second, using tunneling contacts to suppress the contact-induced spin relaxation, we observed the spin lifetimes as long as 771 ps at 300 K, 1.0 ns at 4 K in SLG, and 6.2 ns at 20 K in Bilayer graphene. These advances are important for the development graphene for spintronic applications in logic and storage.

8100-28, Session 8

Chemically-driven nanoscopic magnetic phase separation at the SrTiO3(001)/La1-xSrxCoO3 interface

C. Leighton, M. Sharma, M. Torija, Univ. of Minnesota, Twin Cities (United States); J. Gazquez, M. Varela, Oak Ridge National Lab. (United States) and Univ. Complutense de Madrid (Spain); J. Schmitt, C. He, Univ. of Minnesota, Twin Cities (United States); J. Borchers, M. Varela, National Institute of Standards and Technology (United States); S. El-Khatib, Univ. of Minnesota, Twin Cities (United States)

The remarkable functionality of complex oxides provides many opportunities for new physics and applications. The perovskite cobaltites are an excellent example, being of interest in gas sensing, catalysis, ferroelectric memory, and solid oxide fuel cells. From the magnetism perspective they have high conduction electron spin polarization, and a variety of functional ground states. However, the same delicate balance between phases that provides such impressive functionality also leads to a serious problem; it can be difficult to maintain desired properties close to the interface with a dissimilar oxide. In this work, using SrTiO3(001)/La1-xSrxCoO3 as a model system, we have combined epitaxial growth with detailed stuctural characterization (including STEM/EELS imaging), conventional magnetometry, electronic transport, and small-angle neutron scattering (SANS). In the SrTiO3(001)/La1-xSrxCoO3 case we observe the usual degredation in magnetization and conductivity in the very thin film limit. We demonstrate that this is due to nanoscopic magnetoelectronic phase separation in the interface region. Essentially, nanoscopic ferromagnetic (FM) clusters form in an insulating non-FM matrix near the interface, resulting in reduced magnetization and conductivity, even at compositions that display no such phase separation in the bulk. Depth profiling of the chemical composition reveals that this effect has a chemical origin, being due to subtle depth-wise variations in Sr and O content, resulting in reduced hole doping near the interface. Simple thermodynamic and structural arguments for the origin of these variations are provided.

Work at UMN supported by NSF and DoE, at ORNL by DoE, and at UCM by the European Research Council.

8100-29, Session 8

Structural and magnetic properties of the Mn-based antiperovskites from first principles

P. Lukashev, Univ. of Nebraska-Lincoln (United States)

Magnetomechanical coupling in crystals has many practical applications, such as in sensors, magnetic recording devices, etc. Recent experimental and theoretical studies of the magnetoelectric (ME) effect in the nanocomposite structures and in laminates show an enhanced ME coefficient. These materials combine piezoelectric properties of the paramagnetic phase and magnetostrictive properties of the magnetic phase. In my talk I will present density functional theory (DFT) based results of the structural and magnetic properties of antiperovskite compounds, such as Mn3GaN - a potential candidate for practical applications in ME devices. Due to interplay of magnetic and elastic properties these compounds exhibit variety of interesting features, such as invar effect (or even negative thermal expansion) and a near zero temperature coefficient of resistance. I will show that the magnetic structure of antiperovskite compounds (Mn3GaN) can be controlled by a small applied biaxial strain. The lowering of symmetry with the strain causes the local magnetic moments of Mn atoms to rotate from the trigonal $\Gamma 5g$ structure with symmetric curl of spin density in the (111) plane to a monoclinic symmetry structure. As a result, an appreciable net magnetization appears in the strained system. I will also discuss the appearance of the net magnetization in Mn-based antiperovskite compounds as a result of the external strain gradient (flexomagnetic effect). In particular, I will describe the mechanism of the magnetization induction in the Mn3GaN at the atomic level in terms of the behavior of the local magnetic moments of the Mn atoms. I will show that the flexomagnetic effect is linear and results from the nonuniformity of the strain, i.e., it is absent not only in the ground state but also when the applied external strain is uniform. At the moderate values of the strain gradient (0.1%) the flexomagnetic contribution to the net induced magnetization is comparable with the nonlinear contribution, thus making it attractive for practical applications. Finally, I will discuss the possibility of combining Mn3GaN with typical ferroelectric, such as PbTiO3 to form a prototypical magnetoelectric device.

8100-30, Session 8

Spintronic nanoelectronics using graphene based magneto-logic gates

H. Dery, Univ. of Rochester (United States)

We present a novel design concept for a seamless integration of spin-based logic and memory circuits. The building blocks are universal and reconfigurable magneto-logic gates based on a hybrid graphene/oxide/ferromagnet material system. These nano-gates consist of five ferromagnetic electrodes using nonnlocal spin-valve geometries. The logic operations rely on the generation of non-equilibrium spin accumulation when spin polarized electrons tunnel from a ferromagnetic contact into the graphene via a tunnel barrier. Readout of logic operations is triggered by perturbing the magnetization direction of one of the ferromagnetic terminals. This leads to a binary transient current response whose speed and amplitude depend on the RC of the system and on the spin accumulation profile in the graphene layer.

In our simulations we use extracted parameters from recent nonlocal spin-valve measurements in Co/MgO/graphene at room temperature. In addition, we employ spin-transfer torque magnetization writing techniques using all-metallic paths. These path allow significant energy savings compared to the standard spin-transfer torque pillar technique (i.e., if the writing current flows through the tunnel barriers and graphene).

Finally, we present circuit prototypes in which over 100 spin-based logic operations are carried out before any need for a spin-charge conversion. Consequently, supporting CMOS electronics requires little power consumption. Specifically, network search engines are used as a technology demonstration vehicle. We present a spin-based circuit design with smaller area, faster speed, and lower energy consumption than the state-of-the-art CMOS counterparts. This design can also be applied in applications such as data compression, coding, image recognition, and business analytic.

8100-31, Session 8

Spintronics using the graphene, fullerene and other group IV materials

E. Shikoh, M. Shiraishi, Osaka Univ. (Japan)

In the research field of spintonics, studies using group IV elements have recently attracted much attention. Our group has been focusing not only the graphene spintronics, but also the spintronics using other carbon materials and Si. The gigantic MR effect (1.4 million % at 2K) in C60(fullerene)-Co nanocomposites was observed. That MR effect was well explained with our original theory including the Coulomb Blockade regime. The spin transport properties in Si, such as the bias-current dependence of spin polarization in Si, were observed at room temperature. Those researches are also introduced in addition to our topics in graphene spintronics.

8100-32, Session 9

Direct growth of graphene on MgO for spin and charge device applications

J. Kelber, Univ. of North Texas (United States)

We have demonstrated the growth of single and few layer graphene on MgO(111). Graphene/MgO interactions induce a graphene band gap of ~ 0.5-1eV. The importance of graphene/MgO heterojunctions for both conventional transistor and spin transport applications will be discussed.

8100-33, Session 9

The influence of lattice relaxation on the electron-spin motion in ferromagnetic films: Experiment and theory

W. Weber, A. Hallal, T. Berdot, P. Dey, L. Tati-Bismaths, L. Joly, Institut de Physique et Chimie des Matériaux de Strasbourg (France); A. Bourzami, Univ. Ferhat Abbas de Sétif (Algeria); F. Scheurer, Institut de Physique et Chimie des Matériaux de Strasbourg (France); J. Henk, Max-Planck-Institut für Mikrostrukturphysik (Germany); M. Alouani, Institut de Physique et Chimie des Matériaux de Strasbourg (France)

By taking the example of Fe films on Ag(001), we report, first, the discovery of a 180 degrees electron-spin precession in spin-polarized electron reflection experiments, which marks the ultimate limit of spin manipulation in reflection. In fact, this is the largest possible precession angle which can be measured in a single electron reflection. Both experiments as a function of Fe film thickness and ab initio calculations show that the appearance of this giant spin precession depends with utmost sensitivity on the relaxation of the Fe lattice during growth.

Second, the effect of submonolayer MgO coverage on the Fe films is studied. We note that the interface system MgO/Fe(001) has attracted great interest in recent years for its large room temperature TMR, which has been predicted and observed in epitaxial Fe/MgO/Fe(001) tunnel junctions. Although many results have been published concerning the interfacial structure of MgO/Fe, little effort was devoted to elucidate the spin-dependent electron reflection properties of MgO/Fe interfaces. It is thus an open question how MgO is modifying the spin-dependent electron reflection properties of the Fe(001) surface. It is shown in this contribution that the spin polarization direction of the reflected electrons on Fe(001) strongly changes with minute amounts of MgO. Our calculations reveal that the MgO-induced out-of-plane relaxation of the Fe surface layer is responsible for this behavior. Our study points towards the subtle feature that the major change of the spin-dependent electron reflection properties of the Fe(001) surface is already caused by the very first MgO coverage.

8100-34, Session 9

Development of low-RA perpendiuclar-MTJs for spin-RAM application

K. Yakushiji, T. Saruya, H. Kubota, A. Fukushima, S. Yuasa, K. Ando, National Institute of Advanced Industrial Science and Technology (Japan)

MgO-based magnetic tunnel junctions with perpendicularly magnetized electrodes (p-MgO-MTJs) have been attracting a great deal of attention as memory cells in ultra-high-density spin-transfer-torque random access memory (Spin-RAM or STT-RAM) because nanometer-sized perpendicular magnetic cells can have a thermal stability high enough for data retention over 10 years. A p-MgO-MTJ is required to have not only a magnetoresistance (MR) ratio higher than 100% at RT but also a low resistance-area (RA) product. A low RA product is required for matching the MTJ resistance to the resistance of pass transistors. Assuming a Spin-RAM over 1 gigabit (F = 65 nm), it requires the MTJ cells to have an RA product of about 30 Ωμm2. In this study, we have aimed to achieve high MR ratios of more than 100% in p-MgO-MTJs with ultra-low resistance-area (RA) products less than 5 Ωμm2. [1, 2]

We fabricated p-MgO-MTJs with a [Co/Pt]n/CoFeB/CoFe bottom electrode (free layer) and a CoFe/CoFeB/TbFeCo top electrode (reference layer) using C-7100 (Canon Anelva), and successfully attainted high MR ratios of 100% at room temperature and a low RA product of 2 Ωμm2, simultaneously. We have also fabricated various p-MgO-MTJs by changing the composition of the CoFeB insertion layers. The results suggested that the use of an Fe-rich CoFeB layer gave rise to a high MR ratio. Such a high MR ratio in low-RA p-MgO-MTJs is the key to developing ultra-high-density spin-transfer-torque MRAMs.

This work was supported by New Energy and Industrial Technology Development Organization (NEDO).

8100-35, Session 10

Utilization of Rashba spin orbit coupling in a semiconductor channel

J. Chang, Y. H. Park, H. C. Koo, H. C. Jang, S. H. Han, Korea Institute of Science & Technology (Korea, Republic of)

Spin orbit coupling (SOC) in semiconductors couples the spin of electron to its momentum and provides a new way for electrically initializing and manipulating electron spins for future spintronic devices and spin-based quantum information processing. The effective magnetic field induced by Rashba SOC, which is controllable by electric field, in a quantum channel produces spin splitting and population imbalance between spin-up and -down electrons even in the absence of applied magnetic field. It is widely used in the applications in spintronics such as spin field effect transistor and spin Hall effect. In the paper, we present a detection of Rashba SOC using rotational applied field in addition to the Shubnikov-de Haas oscillation, the channel resistance of InAs based quantum channel depending on the alignment between the applied field and the Rashba field and finally oscillatory channel conductance as a function of gate voltage.

8100-36, Session 10

Spin currents in solids: definition and application to semiconductors

F. Bottegoni, H. Drouhin, Ecole Polytechnique (France); G. Fishman, Institut d'Électronique Fondamentale (France); J. Wegrowe, Ecole Polytechnique (France)

The concept of current plays a key role in modern solid state physics. It allows a proper and physically meaningful definition of the transport and dynamical properties. In particular, the spin current (SC) is of crucial importance in spintronics, whose main purpose is the control and the subsequent handling of spin degrees of freedom. However, the concept of SC is still a debated point in medium where the spin-orbit interaction (SOI) cannot be neglected and indeed semiconductors are paradigmatic systems to verify the consistency of theoretical and experimental arguments about the SC. In 2D electron gases, where the Rashba Hamiltonian applies, the standard definition of SC (6 X 6 tensor Jij) is commonly used; this is not the case for 3D systems without inversion symmetry, like bulk GaAs.

We developed a new definition of SC, based on an effective Hamiltonian of the system, given by a momentum operator expansion that is suitable to describe the SC not only in presence of Rashba term, but also when the D'yakonov -Perel (DP) Hamiltonian is included. We prove that a redefinition of the SC is mandatory when dealing with the DP field and we also show how to derive properly source terms, related to "spin transfer torque" complying with the continuity equation for the current. We illustrate our findings in the case of bulk GaAs along different crystallographic directions and in the case of electron tunneling through GaAs barriers with different orientations of the spin.

8100-37, Session 10

Nanomechanical modulation of (Ga,Mn)As

Y. D. Park, Seoul National Univ. (Korea, Republic of)

We present nanomechanical modulation of (Ga,Mn)As magnetic properties including the anomalous Hall effect (AHE) as well as magnetic anisotropy (MA) by realizing mechanically buckled micro-Hall bar structures. From multiple lateral probes along an asymmetrically buckled (Ga,Mn)As beam, we find the modulation of the AHE as function of lateral stress. The origins of the lateral compressive stress stem from lattice mismatch between the sacrificial (Al,Ga)As layer with the diluted magnetic semiconductor (Ga,Mn)As layer. By changing the orientation, from planar Hall effect measurement, we also see a large changes in the MA. From a simple Hall cross structure, we demonstrate a reversible nanomechanical element which mechanically buckled state can be robustly read electronically.

8100-38, Session 10

Electron-beam formation from spin-orbit interactions in zinc-blende semiconductor quantum wells

M. E. Flatté, D. H. Berman, The Univ. of Iowa (United States)

Spin transport in semiconductors can be dramatically modified by spin-orbit interactions, producing such effects as coherent precession without a magnetic field. These effects vanish, however, for transport of unpolarized electrons, as the features generated for an initial electron spin polarized up are complementary to those generated from an initial electron with spin down. An open question is whether the spin-averaged transport of unpolarized spins can be influenced by the spin-orbit interaction in a nontrivial fashion.

Here we describe a dramatic enhancement of electronic propagation along a narrow range of real-space angles which occurs in the presence of Rashba and Dresselhaus spin-orbit fields of specific, different strengths. The angular width of this ''electron beam" depends sensitively on the ratio of the strengths of the Rashba and Dresselhaus fields, and the direction of the beam changes by 90 degrees when the relative sign of the fields changes. This surprising spatial anisotropy, originating from the anisotropic dispersion relations of electrons in the two fields, is due to general features of the energy contour surface of the electrons. Furthermore, the electron-beam formation can be traced, using a stationary phase analysis of the real-space Green's function, to coalescing stationary points. Such beams should appear in two-contact transconductance as well as other transport and scattering phenomena.

8100-39, Session 10

Anisotropic spin dephasing in an (110)-grown high-mobility AlGaAs/GaAs quantum well measured by resonant spin amplification technique

M. Griesbeck, Univ. Regensburg (Germany); M. Glazov, Ioffe Physico-Technical Institute (Russian Federation); E. Sherman, Univ. del País Vasco (Spain); T. Korn, D. Schuh, Univ. Regensburg (Germany); W. Wegscheider, ETH Zurich (Switzerland); C. Schüller, Univ. Regensburg (Germany)

The spin dynamics in zincblende-based two-dimensional electron systems (2DESs) is usually dominated by the D'yakonov-Perel spin dephasing mechanism resulting from the underlying spin-orbit (SO) fields. Due to the symmetry of the SO fields an exception could be found in symmetrically grown and doped AlGaAs/GaAs quantum wells (QWs) grown along the [110] direction, where the Rashba contribution is negligible and the effective Dresselhaus SO field is perpendicular to the sample plane. In such a system the spin dephasing times (SDTs) for in- and out-of-plane crystallographic directions are expected to be strongly different. We observed this spin relaxation anisotropy in resonant spin amplification (RSA) measurements in a sample consisting of a 30 nm wide double-sided δ-doped single QW with a very high mobility of about $3 \cdot 10$ cm^2/Vs. A comparison of the measured RSA traces with the developed theory taking into account the spin dephasing anisotropy yields the resulting SDTs. We found that the ratio of in-plane and out-of-plane SDTs is strongly influenced by the sample temperature, the excitation density, and the initial spin polarization of the 2DES. The observed out-of-plane SDTs in the investigated temperature interval from 4 to 50 K are on the tens of nanoseconds time scale and exceed the previously reported values for (110)-grown systems. We attribute this fact to the precise control of the band profile via MBE growth.

8100-40, Session 11

Synchronization of high power vortex oscillators at multiple of the fundamental frequency.

C. Baraduc, S. Martin, Commissariat à l'Énergie Atomique (France); C. Thirion, Institut NÉEL (France); Y. Liu, M. Dovek, Headway Technologies, Inc. (United States); B. Diény, Commissariat à l'Énergie Atomique (France)

RF vortex spin-transfer oscillators based on low RA magnetic tunnel junctions were investigated. A very high power of excitations has been obtained characterized by a power spectral density containing a very sharp peak at the fundamental frequency and a series of harmonics. The observed behaviour is attributed to the combined effect of Oersted-Ampère field generated by the large applied dc-current and of the spin transfer torque. We furthermore show the synchronization of a vortex oscillation by applying a RF bias current which frequency is twice the oscillator fundamental frequency.

8100-41, Session 11

Coupling of two vortices in spin-valve nanopillars for spin-transfer oscillators

N. Locatelli, Unité Mixte de Physique CNRS/Thales (France)

Spin transfer induced vortex dynamics and the radio-frequency signal thereof have recently focused many interest, in particular to address the issues of coherence and power for spin transfer oscillators. However the signal linewidth obtained for a single vortex gyration is still too large (about 1 MHz). In this work, we will focus on using coupled vortices oscillators. Besides the drastic improvement of the signal coherence, fundamental interests of this system lie in the identification of the excited coupled modes and their selection rules.

The samples are Py(15nm)/Cu(10nm)/Py(4nm) spin-valve nanopillars having a vortex nucleated in each of the magnetic layer. In such systems with interacting vortices, the influence of the various interactions on the dynamical properties is central. Besides the observation of highly coherent vortex oscillations, we demonstrate that the dynamic behaviour is highly dependent on the vortices parameters, notably relative chiralities and polarities. We will compare the results to analytical predictions and simulations, studying the importance of different sources of coupling between the vortices. This work will be extended further to conditions to synchronize arrays of interacting vortex oscillators.

Spin-torque vortex oscillators in nanopillar geometry

D. E. Buergler, V. Sluka, A. Kakay, R. Hertel, C. M. Schneider, Forschungszentrum Jülich GmbH (Germany)

We present experiments on current-induced vortex dynamics in nanopillars fabricated by optical and e-beam lithography from epitaxially grown Fe/Ag/Fe(001) multilayers. The pillar diameters range from 150 to 230 nm, and the Fe layers with thicknesses between 2 and 30 nm are separated by a 6 nm Ag spacer. Both layer magnetizations and the external field are in-plane. We measure current-driven high-frequency (HF) excitations of spin-torque oscillators (STO) with the free layer in the vortex or uniform state. Our ability to switch between them in a given STO enables a direct comparison of STO properties yielding for the vortex state larger emitted HF power and a wider frequency tuning range. Injection locking of the gyrotropic mode to external HF signals reveals for our GMR-based nanopillars a gap of three orders of magnitude between the HF power emitted by one oscillator and the power needed for phase-locking. Finally we modify the sample geometry such that magnetic vortices can be formed in both Fe disks. We study the dynamics of the single and double vortex state and find for the latter a dependence of the excitation frequency on the current polarity that we relate to exchanged roles of free and fixed layer.

8100-43, Session 12

3-dimensional spintronics for ultrahigh density data storage

R. P. Cowburn, Univ. of Cambridge (United Kingdom)

Spintronics could have a revolutionary impact on microelectronics and data storage if it provides the enabling step for transforming today's planar 2-dimensional devices into volume-filling 3-dimensional devices, where the data storage and processing capacity are related to the minimum feature size of the fabrication process, F, by F^-3 instead of F^-2. Although magnetic domain wall devices have been discussed as a possible approach to 3-dimensional architectures (e.g. 'racetrack'), no convincing demonstration has yet been realised. In this talk I describe a new approach to 3-dimensional spintronics. I show that the domain wall is not the only possible topological object in nanostructured magnetic materials; topological kink solitons can also exist in multilayered magnetic materials if anisotropy and interlayer exchange coupling are carefully chosen in the correct proportion. Such solitons can be extremely stable at room temperature, highly compact, and easily injected, detected and synchronously propagated. They are therefore an ideal candidate for the manipulation and storage of digital information. Most importantly, their natural environment is a 3-dimensionally structured one, making them ideal for 3-dimensional architectures. I illustrate one of many potential applications of topological solitons by showing an outline design for an MRAM-like device that could store data at an equivalent areal density in excess of 10 Tbits/inch2 using only 100nm lithography and common magnetic materials.

8100-44, Session 12

Nanoring or nano-elliptic-ring shaped magnetic tunneling junctions and their applications in developing MRAM devices

X. Han, Institute of Physics (China)

A series of nano-elliptic-ring (NER)-shaped magnetic tunnel junctions (MTJs) with the major axis of around 120 nm and minor axis of around 60 nm, and ring width of around 25 nm was fabricated successfully. Magnetic field and current-driven magnetization switching were observed in such NER-MTJs with key stack layers of both spin-valve-type antiferromagnetic (AFM)/ferromagnetic (FM)/insulator (I)/ ferromagnetic (FM) and sandwich-type hard-FM/ I /soft-FM structures. When the electric current density exceeds a critical value of the order of 7.8x10^6A/cm^2 (critical driven current is 0.40 mA), the magnetization of the free (soft-FM) and reference (hard-FM) layer nano-elliptic-rings can be switched back and forth between parallel and antiparallel onion states. Tunneling magneto-resistance (TMR) ratio between 10% and 40% with different thickness of thin Al-O barrier waere measured at room temperature as we apply a magnetic field or a pulsed current. The experiments and micromagnetic analysis show that the spin transfer torque (STT) plays a main switching role in the magnetization reversal and the pulse-current-induced elliptic magnetic field play an assisted-switching role in such NER-MTJs. Compared with our previous studies of nano-ring-shaped (NR) MTJs and Nanoring MRAM, the NER-MTJ has a relative symmetric current driven critical behavior, which is due to the shape anisotropy of elliptic-ring architecture. The NER-MTJs also show the comparative lower switching field or critical current value (or density) and can be as the memery bit cells. Therefore, the manipulation of anisotropy in NER-shaped MTJs open a new way to develop more reliable and easier operational NER-MRAM devices.

8100-45, Session 12

Vortex-gyration-mediated information-signal transfer in one-dimensional arrays of soft magnetic nanodisks

S. Kim, D. Han, Seoul National Univ. (Korea, Republic of)

Low-energy input signals and their transport with low-energy dissipation are the key technological factors in the design of information processing devices. Coupling between different oscillators allows for the possibility of mutual energy transfer between them and the information-signal propagation. Recently, it was found that stimulated vortex gyration is a robust new mechanism for energy transfer between spatially separated dipolar-coupled magnetic disks based on the concept of coupled vortex-core oscillators. The rate of energy transfer from one disk to the other is determined by the two normal modes' frequency splitting caused by dipolar interaction. Here, we present collective vortex gyration modes in one-dimensional arrays of dipolar coupled vortex-state nanodisks, as studied from micromagnetic simulations and analytical derivations of their characteristic band structures that vary with the relative polarization

states. The quantized mode can be referred to as “vortex gyraton”. This mechanism provides the advantages of tunable energy transfer rate, low-power input signal, and low-energy dissipation for magnetic elements with negligible damping. Coupled vortex-state disks might be implemented in applications for information-signal processing.

8100-46, Session 12

Different geometries for spin-transfer oscillators

A. M. Deac, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Several geometries have recently been proposed for spin-transfer oscillators, with the purpose of optimizing the output power and frequency dependence on the applied current, as well as minimizing the external magnetic field required to stabilize the dynamics. The two structures most compatible with applications involve hybrid multilayers, including magnetic films magnetized in the plane, as well as perpendicular to the plane of the layers - acting either as polarizing layer for the current, or as excited/free layer, respectively. The feasibility of both types of devices has been experimentally demonstrated. Here, we present a quantitative numerical comparison between the two.

8100-47, Session 13

Organic spintronics: playing with spins and molecules

S. Sanvito, Trinity College Dublin (Ireland)

Weak spin-orbit and hyperfine interaction make the spin-lifetime in organic molecules and molecular solids reaching up to the second mark. However organic materials have also poor mobilities, so that their spin-diffusion lengths are rather short. These peculiar characteristics position organic molecules in a unique space within Spintronics and one should envision applications where the spins are manipulated close to where they are injected [1]. This is the realm of single molecule spintronics.

In this contribution I will review the current state of the art of the theory of spin-transport and manipulation in organic materials. In particular I will discuss how to manipulate and how to read the spin configuration of a magnetic molecule. I will start by discussing a range of mechanisms for manipulating the spin state of a molecule by means of a static electric field. These are based either on the Stark effect in super-exchanged coupled molecules with two magnetic centers [2] or on electric-field induced tautomeric interconversion [3].

Then I will move to discuss the consequences of such effects on the transport properties of the molecules, addressing both the temperature dependence of the electron transport and the description of the low-bias spin-flip inelastic spectra. Finally I will present results for spin-transport in Mn12 and demonstrate that the magnetic state of the molecule can be read electrically with a single I-V read-out obtained by using non-magnetic electrodes [4].

Electrical spin injection in a hybrid organic/inorganic spin-polarized light emitting diode (spin-LED)

E. Johnston-Halperin, The Ohio State Univ. (United States)

The field of semiconductor spintronics promises the extension of spin-based electronics beyond memory and magnetic sensing into active electronic components with implications for next-generation computing and quantum information. The development of organic-based magnets with room temperature magnetic ordering and semiconducting functionality promises to further broaden this impact by providing a route to all-organic spintronic devices and hybrid organic/inorganic structures capable of exploiting both the multifunctionality of organic systems and the well established spintronic functionality of inorganic materials. Here we report the successful extraction of spin polarized current from a thin film of the organic-based room-temperature ferrimagnetic semiconductor V[TCNE]x (x~2; TCNE: tetracyanoethylene) and its subsequent injection into a GaAs/AlGaAs light-emitting diode (LED). The orientation of this spin current is determined by polarization analysis of the electroluminescence from the LED and is found to be parallel to the magnetization of the V[TCNE]x~2 layer, in agreement with theoretical predictions. Detailed analysis of the optical selection rules in the LED, coupled with control measurements of magnetic circular dichroism in the V[TCNE]x~2 layer, reveals the magnitude of the electron spin polarization to be largely insensitive to both electrical bias and temperature. This successful demonstration of spin injection in a hybrid organic/inorganic structure opens the door to a new class of active, hybrid spintronic devices with the potential for multifunctional behaviour defined by the optical, electronic and chemical sensitivity of the organic layer.

8100-49, Session 14

Semiconductor spin-lasers

I. Zutic, J. Lee, R. Oszwaldowski, C. D. Gothgen, Univ. at Buffalo (United States)

Practical paths to spin-controlled devices are typically limited to magnetoresistive effects, successfully employed for magnetically storing and sensing information. However, spin-polarized carriers generated in semiconductors by circularly polarized light or electrical injection, can also enhance the performance of lasers, for communications and signal processing. While such spin-lasers already demonstrate a lower threshold current for the lasing operation [1-3] as compared to their conventional (spin-unpolarized) counterparts, many theoretical challenges remain. Even in the steady-state regime, several surprises have only recently been revealed. For example, we show that a very short spin relaxation time of holes can be advantageous [4], with the maximum threshold reduction larger than what was theoretically thought possible. We also analyze dynamical operation of spin-lasers and reveal that the spin modulation can improve their performance. Spin-polarized injection can lead to an enhanced bandwidth and desirable switching properties of spin-lasers [5]. Future advances in spin-lasers may depend on progress in magnetic memories and data storage related to the ultrafast magnetization dynamics and timescales for magnetization reversal. Experimental efforts to increase the temperature of electrically-injected spin-lasers have also used quantum dots as the active region [6] and we compare their operation to the lasers based on quantum wells[7]. Supported by NSF-CAREER, ONR, AFOSR-DCT, and DOE-BES.

8100-50, Session 14

Ferromagnet/semiconductor spin-LEDs for optical communication of spin information

R. Farshchi, M. Ramsteiner, J. Herfort, A. Tahraoui, H. T. Grahn, Paul-Drude-Institut für Festkörperelektronik (Germany)

Exciting advances are being made in the field of semiconductor spintronics toward the realization of spin-based transistors and logic architectures [1, 2]. However, for the full implementation of circuits that exploit the spin degree of freedom of electrons, it is necessary to transport the spin information from one device to another. Electrons in semiconductors can carry spin information, but they often suffer from high spin relaxation rates that significantly limit the spin diffusion lengths [3], making electrical transport of spin information highly inefficient.

It is well-known that injection of spin-polarized electrons from a ferromagnetic layer into an underlying semiconductor quantum well structure in so-called spin light emitting diodes (spin-LEDs) leads to the emission of circularly polarized light [4-7]. According to the selection rules in the quantum well, injection of opposite spin polarizations (up or down spin) leads to the emission of opposite light helicities (right- or left-handed). Therefore, the spin information of electrons can be optically transported in the form of light helicity.

In this presentation, we will demonstrate that the spin information associated with electrons injected into the quantum well of a spin-LED structure can be transported optically and retrieved by a second spin-LED. Different ferromagnetic layers, namely Fe and Co2FeSi, are used to inject opposite spins into the emitter LED structure and generate light with opposite helicity. The spin information can be remotely deciphered based on the magnetic field dependence of the photocurrent in the detector spin-LED. This work opens the door for employing light as a functional component in spintronic circuits.

8100-52, Session 14

Spin-orbit interactions in optics

K. Y. Bliokh, National Univ. of Ireland, Galway (Ireland)

We re-examine the problem of the identification of the spin and orbital parts of the angular momentum (AM) of an electromagnetic wave, which has a long history and has posed fundamental difficulties both in quantum electrodynamics and classical optics. We give an exact self-consistent solution in terms of the fundamental photon operators and unify previously disjointed results:

(i) non-canonical orbital AM and spin AM operators obtained for the second-quantized fields;

(ii) non-commutative photon position operator and Berry monopole field in momentum space;

(iii) separation of the spin and orbital parts of Poynting energy flows.

We show that the polarization-dependent non-paraxial part of the orbital AM arises from Berry-phase terms describing the spin-orbit interaction (SOI) of light. A similar effect occurs dynamically upon spin-to-orbital AM conversion in focusing and scattering of polarized light. Other manifestations of the SOI are the spin and orbital Hall effects of light (i.e., transverse shifts of the field centre of gravity) which are described by our position operator and take place even in free space. We apply the general theory to Bessel-beam solutions where the fundamental operators manifest themselves in immediately observable orbital- and spin-dependent intensity distributions.

8100-62, Session 14

Electron and hole spin coherence in semiconductor quantum wells

D. R. Yakovlev, Technische Univ. Dortmund (Germany)

An overview of the effects related to generation, control, and relaxation of the electron and hole spin coherence in III-V and II-VI semiconductor quantum wells will be presented. Spin dynamics has been measured by pump-probe Faraday- and Kerr rotation techniques also with the use of the Resonant Spin Amplification regime. Structures based on GaAs, InGaAs, CdTe, and ZnSe containing resident carriers of low density have been investigated. For all of them a long-living spin coherence (up to 20-40 ns for electrons and few ns for holes) has been found under conditions providing carrier localization. We discuss spin relaxation and spin dephasing mechanisms and dependence of their efficiency on temperature and magnetic field. The role of the charged exciton states for the generation of the carrier spin coherence under resonant excitation is highlighted. The generated spin coherence can be controlled optically and additive and nonadditive contributions of the control pulses are discussed.

8100-53, Poster Session

Simulation and optimization of magnetoresistance in Schottky barrier spin MOSFETs

A. M. Roy, Stanford Univ. (United States); D. E. Nikonov, Intel Corp. (United States); K. C. Saraswat, Stanford Univ. (United States)

Schottky barrier spin MOSFETs have emerged as a strong contender for future logic and memory promising low power consumption and reconfigurable circuits. However the development of these devices has been stymied by low values of magnetoresistance (MR) measured in experiments. Simulation studies have largely focused on diffusion driven or ballistic transport in the semiconductor and a simplistic treatment of spin injecting contacts. Here we demonstrate a novel framework to simulate spin injection and spin transport in semiconductors in the drift-diffusion regime and a tunneling based model for spin injecting contacts thereby enabling simulation and optimization of experimental devices.

The main contributions of this work are

[a] the development of an efficient transfer matrix formalism for spin transport in semiconductors including electric field effects

[b] the prediction of spin saturation effects leading to high magnetoresistance at high electric fields in spite of large resistance area product of the contacts

[c] the development of a Tsu-Esaki tunneling based model for spin injecting contacts accounting for spin accumulation in the semiconductor

[d] the simulation of Schottky barrier spin MOSFETs through a self consistent solution of spin injecting contacts and spin transport in the semiconductor channel

[e] the optimization of material and structure properties (tunnel barrier materials, tunnel barrier thickness, semiconductor doping density etc.) for magnetoresistance of Schottky barrier spin MOSFETs

Our approach and implementation are general and provide a useful tool for experimental research on spin injection and detection in semiconductors.

8100-54, Poster Session

Thickness and substrate dependence of ferromagnetism in Mn doped ZnO thin films

G. Nammalvar, B. Ananthan, B. Lakshmi Narayanan, J. Gurusamy, T. Balasubramanian, National Institute of Technology, Tiruchirappalli (India)

We report the effect of thickness and substrate on ferromagnetism in Mn doped ZnO thin films grown by RF magnetron sputtering. The films of various thicknesses (15, 35 & 105 nm) have been grown on Si (100) and Si (111) substrates. The films have been grown from the 5 mol% Mn doped ZnO target which is prepared by conventional solid state reaction route. The grown films have been characterized by X-ray diffraction (XRD), Photoluminescence (PL), Hall measurement and Vibrating sample magnetometer to study its structural, optical, electrical and magnetic properties, respectively. The XRD result shows that all the films are preferentially oriented along (002) plane and free from the formation of secondary phases. The PL spectroscopy shows that the concentration of defects varies with the film thickness comparatively in both the substrates. This has been well acknowledged by our Hall measurements. It has been found that the observed ferromagnetism is strongly influenced by film thickness as well substrate surfaces. The presence of dopants in the films has been confirmed by Energy dispersive spectroscopy. The important features have been discussed in detail.

8100-55, Poster Session

Defect induced Raman active modes in Mn doped ZnO thin films

A. Aravind, K. Hasna, M. K. Jayaraj, Cochin Univ. of Science & Technology (India)

Zinc oxide is a II-VI semiconductor with a wide direct band gap of about 3.37 eV at room temperature. Among the various growth techniques of ‘Mn’ doped ZnO thin films, pulsed laser deposition (PLD) offers the advantages such as deposition at relatively high oxygen pressure, high deposition rate and growth of highly oriented crystalline films at low substrate temperature. The substitution of ‘Mn’ in ZnO host lattice affects the lattice dynamical properties. Raman scattering provides a great deal of information in the optical modes of vibrations at the center of Brillouin zone. The parameters of Raman mode such as frequency, line width and lifetime provide the basic information of lattice dynamics. The PLD grown films were analysed using x-ray diffraction (XRD), scanning electron microscopy (SEM), UV-Vis-NIR spectroscopy and Raman spectroscopy. Good optical quality of the films was confirmed from the transmittance of the film greater than 80% in the visible region. The presence of non-polar E2high and E2low Raman modes in thin films indicates that ‘Mn’ doping didn’t change the wurtzite structure of ZnO. The intensity of E2high mode and the peak position shifted towards the lower frequency with increase of ‘Mn’ concentration. Apart from the normal modes of ZnO the Zn1-xMnxO ceramic targets shows two additional modes at 332 cm-1 (I2) and 524 cm-1 (I4).The modes I2 and I4 are assigned as multi-phonon scattering considering the two phonon process in the disorder lattice due to Mn doping.

8100-60, Poster Session

Numerical study of spin diffusion effects on the spin transfer torque effect and the dynamics of domain walls

D. Claudio-González, Univ. de Guanajuato (Mexico); A. Thiaville, J. E. Miltat, Univ. Paris-Sud 11 (France)

We report the observation of an increase of DW velocity at steady-state that can be as high as 21.5% due to spin diffusion when implementing a method that couples micromagnetics with the semiclassical transport model proposed by Zhang and Li [S. Zhang and Z. Li, Phys. Rev. Lett. 93, (2004) 127204]. Experimental measurements of two of the quantities that can be associated with the non adiabatic component, the so-called beta term [T. Taniguchi et al., IEEE Trans. Magn. 44, (2008) 2636][J. Bass and W. P. P. Jr, Journal of Physics: Condensed Matter 19, 183201 (41pp)] used to model spin transfer torque (STT) effects in Ni80Fe20 nanowires [A. Thiaville et al., Europhys. Lett. 69, (2005) 990] makes relevant the use of spin diffusive models to analyze and study the dynamics of domain walls (DWs). The geometry considered in this study corresponds to a semi infinite Ni80Fe20 nanowire featuring a single domain wall. Unlike previous approaches, we explicitly take spin diffusion into account along with experimentally measured values to show that these parameters can truly define the non adiabatic spin torque and that spin diffusion causes an effective beta value which is responsible for velocity increase observed.

8100-63, Poster Session

Revealing the long spin lifetimes of holes in self-assembled (In,Ga)As quantum dots via spin noise spectroscopy

Y. Li, S. A. Crooker, D. L. Smith, N. A. Sinitsyn, Los Alamos National Lab. (United States); D. Reuter, A. D. Wieck, Ruhr-Univ. Bochum (Germany); D. R. Yakovlev, M. Bayer, Technische Univ. Dortmund (Germany)

“Spin noise spectroscopy” is a recently-developed technique that uses optical Faraday rotation to passively measure the intrinsic spin fluctuations of electrons and holes in semiconductor systems. As guaranteed by Fluctuation-Dissipation Theorem, the frequency spectra of the spin noise alone reveals dynamic spin properties such as spin lifetimes and Lande g-factors. Here we use spin noise spectroscopy to measure the spin relaxation of holes that are confined in self-assembled (In,Ga)As/GaAs quantum dots (QDs) grown by molecular beam epitaxy. Owing to their p-type wavefunctions, holes experience much less hyperfine interaction with nuclei as compared with confined electrons, leading (in principle) to long spin decoherence times which are favorable for potential qubit applications. In zero applied magnetic field, we observe a narrow spin noise peak centered at 0 Hz, indicating long hole spin relaxation times of a few hundred nanoseconds. In transverse magnetic fields, we observe that a portion of the 0 Hz peak still remains (in addition to the expected noise peak at the hole Larmor precession frequency), which we attribute to the presence of an effective hyperfine field arising from dipole-dipole interactions between the hole spin and the nuclear spins. We suppress these hyperfine fields using applied longitudinal magnetic fields, and observe hole spin lifetimes further enhanced by over one order of magnitude at low temperatures. Systematic studies as a function of temperature and applied field allow us to identify different regimes of spin relaxation.

Conference 8101: Carbon Nanotubes, Graphene, and Associated Devices IV

Tuesday-Wednesday 23-24 August 2011 • Part of Proceedings of SPIE Vol. 8101
Carbon Nanotubes, Graphene, and Associated Devices IV

8101-01, Session 1

Recent progresses in carbene functionalization of SWCNTs and graphene

Q. Zhang, C. Liu, Nanyang Technological Univ. (Singapore)

In this talk, we will focus on our recent progresses in carbene functionalization of single walled carbon nanotubes (SWCNTs). The influences of carbene-based covalent functionalization on the electrical properties of an isolated m-SWCNT, a semiconducting (s)-SWCNT, and a mixture network of both m- and s-SWCNTs are studied. We find that the functionalization does not reduce the conductance of m-SWCNTs significantly. It does deactivate the semiconducting feature of s-SWCNTs. Interestingly, the influences of the functionalization are reversible upon thermal annealing under ambient conditions.1

8101-02, Session 1

structure reactivity of single-walled carbon nanotubes for various diazonium reagents and its application for separation by electronic types

W. Kim, Kyungwon Univ. (Korea, Republic of)

Diazonium salts are reported to selectively react with metallic Single-Walled Carbon Nanotube (SWNT) over semiconducting SWNT and we showed that covalently attached chemical groups can alter the densities of individual SWNT in a predictable and highly controllable manner, enabling SWNT separation by electronic types. In this study, we investigated the structure reactivity of SWNT with diazonium salts having different electron donating or withdrawing functional groups, analyzed their influence on the reaction selectivity using UV-Vis-nIR absorption spectroscopy, and developed structure-reactivity relations to understand and correlate the reactivity of a number of electron acceptors. Metallic SWNT react preferentially with diazonium salts over semiconducting SWNT in all diazonium studied, however the reactivity as well as the selectivity for metallic SWNT of this reaction strongly depends on the functional groups attached to the diazonium salts. Diazonium salts having electron withdrawing groups (Cl) have higher reactivity metallic for SWNT than those having electron donating groups (OH or COOH), thus lower selectivity for metallic SWNT, which would lower the separation efficiency in the following separation process. We also show that covalently attached functional groups can alter the densities of individual SWNT in a predictable and highly controllable manner, and the density increase of SWNT due to the attached functional groups varies. These results together with the structure reactivity of SWNT with different diazonium reagent are utilized for SWNT separation by electronic types and diameters.

Pillared graphene nanostructure: a new 3D carbon hybrid architectures

M. Ghazinejad, S. Guo, R. K. Paul, M. Ozkan, C. S. Ozkan, Univ. of California, Riverside (United States)

Using chemical vapor deposition technique a novel 3D carbon nano-architecture called a pillared graphene nanostructure (PGN) is synthesized in situ. The fabricated novel carbon nanostructure consists of CNT pillars of variable length grown vertically from large-area graphene planes. A one-step CVD process for large-area PGN fabrication through combination of surface catalysis and in situ vapor-liquid- solid mechanisms is described. The dependence of the morphology of the large-area PGN on the synthesis process conditions was investigated by optical microscopy, SEM, TEM, HRTEM, and Raman Spectroscopy techniques. The highly crystalline interface between the CNT pillar and graphene floor confirmed the seamless contact between the two carbon allotropes. Moreover, to tune the PGN architecture, arrays of catalyst particles with controlled size and separation distance are fabricated using block copolymer films as template. This strategy yields tunable diameter and separation distance of pillar carbon nanotubes, and provides control over the amount of final carbon structure surface area. The successful transfer of the large area PGN onto arbitrary substrates, while keeping the 3D architecture intact, was also accomplished. The new synthesis methodology offers a promising pathway for fabricating novel 3D nanostructures with huge potential in hydrogen storage and supercapacitors, and provides a powerful means to fulfill Department of Energy’s targets for energy storage.

8101-04, Session 1

Centimeter-scale metrology of CVD graphene on glass

J. Reiber Kyle, A. B. Guvenc, C. S. Ozkan, M. Ozkan, Univ. of California, Riverside (United States)

In this work, we demonstrate a high-throughput metrology method for measuring the thickness and uniformity of entire large-area chemical-vapor deposition (CVD) grown graphene sheets on arbitrary substrates. This method utilizes fluorescence quenching microscopy (FQM), a novel technique for visualizing graphene that is based on the discovery that graphene quenches fluorescence via resonant energy transfer. Fluorescence quenching is visualized by spin-coating a solution of polymer mixed with fluorescent dye onto the graphene then viewing the sample under a fluorescence microscope. Graphene regions are identified by dark regions in the fluorescence image of the sample. The contrast between graphene and the substrate can be customized by controlling the thickness of the dye layer. Currently, FQM has only been used to visualize graphene-oxide and exfoliated graphene samples and has been unable to achieve quantitative characterization of the graphene samples. In this work, we calibrate the fluorescent quenching by the graphene layers, measuring the contrast between graphene and the substrate for different graphene layer thicknesses and dye layer thicknesses. Using the results from our fluorescence quenching calibration, we quantify the thickness and uniformity of entire CVD-grown samples. This is achieved by creating a large-scale, high-resolution fluorescence montage image of the entire graphene sample using a microscope with a motorized stage. Next, we identify graphene layers by histogram-based segmentation of the image based on contrast relative to the substrate. This work introduces a new method for graphene quantification that can quickly and easily identify the graphene layer thickness throughout the entire graphene sample.

8101-05, Session 1

Hierarchical large-area graphene materials and functionalization

C. S. Ozkan, Univ. of California, Riverside (United States)

I will first describe the patterning of biomolecules on graphene layers to modulate their electronic properties. Single stranded Deoxyribonucleic Acids (ssDNA) are found to act as negative potential gating agents

that increase the hole density in single layer graphene. Current-voltage measurement of the hybrid ssDNA/graphene system indicates a shift in the Dirac point and intrinsic conductance after ssDNA was patterned. The effect of ssDNA was to increase the hole density in the graphene layer. Next I will describe block co-polymer patterning of large-area graphene layers grown by chemical vapor deposition which enables spatially controlled fluorine plasma doping to provide a tuning mechanism for the Dirac point. Poly(styrene-b-4-vinylpyridne) with cylindrical-morphology polycrystalline block co-polymer was employed in the patterning process. X-ray photoelectron spectroscopy (XPS) characterization revealed the existence of fluorine after doping graphene; high doping levels could be achieved just in 10s. The BCP-Graphene composite FET has been used for the detection of chemical agents including NaF. Finally, I will describe a new class of graphene material in the form of a three dimensional architecture called pillared graphene nanostructure (PGN), which is a combination of the two allotropes of carbon including graphene floors and carbon nanotube pillars. We developed a one step chemical vapor deposition process for large-area PGN fabrication via a combination of surface-catalysis and in-situ vapor-liquid-solid mechanism. We also developed a process by which PGN layers can be transferred onto arbitrary substrates. Single and multilayer stacked PGN are envisioned for future ultra-large and tunable surface area applications in hydrogen storage and super-capacitors.

8101-06, Session 2

Unique thermal properties of graphene: prospects of thermal management applications

A. A. Balandin, Univ. of California, Riverside (United States)

As the electronic industry moves towards few-nanometer-scale CMOS and 3D IC designs thermal management becomes crucially important for achieving high performance and reliability of advanced electronic chips [1]. One approach for mitigating the self-heating problems is finding materials with very high thermal conductivity, which can be integrated with Si ICs or used as fillers in the next generation of the thermal interface materials (TIMs). In 2008, we discovered that graphene reveals extremely high intrinsic thermal conductivity, which can exceed that of bulk graphite [2-3]. We explained this fact by the fundamental difference in the low-energy phonon transport in 2D graphene and 3D graphite [4-6]. Thermal conductivity of graphene layers depends strongly on their geometrical size, coupling to the adjacent substrate or capping layers, edges roughness and defect concentration. I will overview the experimental and theoretical results for the thermal conductivity evolution of the few-layer graphene (FLG) considering two limiting cases of the phonon transport limited by the intrinsic and extrinsic effects. The use of graphene as interconnects and heat spreaders in advanced 2D and 3D computer chips will also be discussed. The last section of the talk will have a description of the data for graphene TIM materials.

The work was supported by SRC-DARPA Functional Engineered Nano Architectonics (FENA) center and ONR project on Graphene Quilts for Thermal Management.

8101-07, Session 2

Investigating the nanoscale surface chemistry of graphene

K. F. Kelly, Rice Univ. (United States)

In this talk, I will review our recent success in applying probe microscopy to understanding the chemistry of graphene and graphitic nanoparticles. We have used STM to compare the morphology and defect density in graphene grown on copper foils by liquid-phase epitaxy to that produced by other methods such as mechanical exfoliation and pyrolysis of silicon carbide. In addition, we have applied a similar analysis to the characterization of chemically suspended graphitic nanoparticles. Lastly we obtained an atomic-scale view of the fluorination and defluorination. Coupled with these studies, we performed chemical characterization of these systems using Raman microscopy.

8101-08, Session 2

Scanning Raman spectroscopy of nanostructured graphene: Doping due to presence of edges

S. Heydrich, M. Hirmer, T. Korn, J. Eroms, D. K. Weiss, C. Schüller, Univ. Regensburg (Germany)

We have investigated nanostructured graphene layers, which were prepared on exfoliated graphene single layers via electron-beam lithography and oxygen-based reactive ion etching, by means of scanning Raman spectroscopy. The peak positions, peak widths and intensities of the characteristic phonon modes of the carbon lattice have been studied systematically in a series of samples. In nanopatterned samples, where periodic arrays of holes (a so called antidot lattice) with typical hole diameters on the order of a few tens of nanometers and periods of a few hundreds of nanometers were prepared, we found a systematic stiffening of the G band mode, accompanied with a line narrowing, while the 2D mode energies are found to be linearly correlated with the G mode energies. We interpret this as evidence for p-type doping of the graphene antidot lattices [S. Heydrich et al., Appl. Phys. Lett. 97, 043113 (2010)]. Moreover, we have detected and analyzed a two-phonon mode at about 2450 wavenumbers in single layer plain graphene. Wavelength-dependent measurements show that it can be interpreted as a LO-LA mode from the K point of the Brillouin zone. A detailed analysis of the electron-phonon coupling strength of this mode shows that it is of the same order of magnitude as that of the G mode. This would have significant implications for the upper limit of carrier mobilities in intrinsic graphene layers.

8101-10, Session 3

Highly selective CNTFET based sensors using metal diversification methods

P. Bondavalli, L. Gorintin, G. Feugnet, Thales Research & Technology (France)

This contribution deals with Carbon Nanotubes Field Effect transistors (CNTFETs) based gas sensors fabricated using a completely new dynamic air-brush technique (patented) for SWCNTs deposition. The extreme novelty is that our technique is compatible with large surfaces, flexibles substrates and allows to fabricate high performances transistors exploiting the percolation effect of the SWCNTs networks achieved with extremely reproducible characteristics. This technique is extremely interesting considering that it is suitable for industrial transfer. More precisely, we have developed a machine which allows us the dynamic deposition on heated substrates of SWCNT solutions, improving dramatically the uniformity of the SWCNTs mats. The CNTFETs have been developed for gas sensing applications. Indeed we have fabricated arrays of CNTFETs achieved using different metal electrodes (patented approach) to exploit the change of metal/SWCNTs junction characteristics as a function of the gas detected in order to identify a sort of electronic fingerprinting. This phenomenon is related to the change of the metal work function and so of the Schottky barrier and seems to be extremely selectivity. Results concerning exposure to NH3, NO2, DMMP, that will be extensively shown at the conference, at different concentration (from 100ppb to 10ppm) demonstrate that each gas interacts in a specific way with each CNTFET. For example, , for the same concentration, CNTFET fabricated using Pt are more sensitive than those fabricated using gold electrodes for DMMP. Inversely, CNTFET fabricated

using gold electrodes are more sensitive than those fabricated using Pt electrodes for NH3.

8101-11, Session 3

Printed CNT transistors with high on-off ratio and linearity

G. Gu, R. Liu, Y. Ling, X. Lu, Univ. of Massachusetts Lowell (United States)

We report an all-printed flexible carbon nanotube (CNT) thin-film transistor (TFT). All the CNT TFT components, including the source and drain electrodes, the TFT transport channel, and the gate electrode, are printed on a flexible substrate at room temperature. A high ON/OFF ratio of over 1000 was achieved. The all printed CNT-TFT also exhibits bias-independent transconductance over a certain gate bias range. This all -printed process avoids the conventional procedures in lithography, vacuum, and metallization, and offers a promising technology for low-cost, high-throughput fabrication of large-area flexible electronics on a variety of substrates, including glass, Si, indium tin oxide and plastics.

8101-12, Session 3

Light-triggered conducting properties of a random Carbon Nanotubes network in a photochromic polymer matrix

R. Castagna, Istituto Italiano di Tecnologia (Italy) and Politecnico di Milano (Italy); C. Sciascia, Istituto Italiano di Tecnologia (Italy); A. R. S. Kandada, Politecnico di Milano (Italy); M. Meneghetti, Univ. degli Studi di Padova (Italy); G. Lanzani, Istituto Italiano di Tecnologia (Italy); C. Bertarelli, Politecnico di Milano (Italy) and Istituto Italiano di Tecnologia (Italy)

It is well known that photochromic materials reversibly change their colours due to a photochemical reaction that takes place when the material is irradiated with photons of suitable energy. This peculiar feature has been exploited to develop smart sunglasses, filters and inks. With a proper molecular design it is possible to enable modulation not only of colour but also of other properties such as refractive index, dipole moment, nonlinearity or conductivity by a photoswitching of the molecular structure. The approach herein followed consists in modifying, upon irradiation, the properties of another component the photochromic molecule is coupled to. In particular, the switching features of photochromic systems are matched with the intriguing peculiar properties of carbon nanotubes (CNTs). A photochromic polyester has been properly synthesised to be used as switching polymer matrix coupled with a network of CNTs. Irradiation of the polymer/CNTs blend results into a light-triggered conductance switching. Supported by electrical and spectroscopic evidences, we argue that the reversible electrocyclization, experienced by the polymer under UV-vis illumination, affects the inter-tube charge mobility resulting in a dramatic overall resistance variation. Differently from previous literature, based on single molecule approach,[1-3] we obtain blended films by simple solution techniques, with sheet-resistance modulation larger than 50%, FET characteristic, good thermal stability and remarkable fatigue resistance at room conditions.

CdSe/ZnS coated single layer graphene photovoltaic devices

S. Guo, J. Reiber Kyle, W. Wang, M. Ozkan, C. S. Ozkan, Univ. of California, Riverside (United States)

Large-area flexible and transparent optoelectronic devices were fabricated through non-covalent interaction between CdSe/ZnS quantum dots and single layer graphene. Single layer graphene was synthesized via CVD method. Pyridine was utilized for capping the quantum dots and the pi-pi interaction between pyridine and graphene enable QD immobilized on the surface of graphene. The photo induced charge transfer was confirmed by photoconductivity measurements. Quantum dots decorated graphene device display good photo-switching property which could be utilized for long wavelength sensitive sensor. Further construction of layered solar cell was accomplished with graphene and QDs layer by layer assembly technique.

8101-14, Session 3

Optical and structural modifications and characterization of ion- irradiated glassy polymer carbon

M. A. Abunaemeh, Alabama A&M Univ. (United States) and Ctr. for Irradiation of Materials (United States); M. Seif, Alabama A&M Univ. (United States); A. Elsamadicy, The Univ. of Alabama in Huntsville (United States); D. Ila, Alabama A&M Univ. (United States) and Ctr. for Irradiation of Materials (United States)

The TRISO fuel that is planned to be used in the GenerationIV nuclear reactor consists of a fuel kernel of UOx coated in several layers of materials with different functions. We are looking at the ion irradiation induced optical structural modifications of the glassy polymeric carbon (GPC) microstructure and their effect on the mechanical and physical properties. GPC is considered as a potential replacement for the pyrolytic carbon coatings, with a function of diffusion barrier for the fission products. We irradiated GPC samples with 1 MeV protons, 5 MeV Ag and Au ions. We chose protons to simulate the effects of neutrons. During the nuclear fission of 235U, the fission fragment mass distribution has two maxima around 98 and 137 that would best fit Rb and Cs However, both ions are hard to produce from our SNICS source therefore we chose Ag (107 amu) and Au (197 amu) as best replacements

8101-15, Session 4

Radio-frequency transmission of graphene layer

H. S. Yoon, J. Y. Oh, W. Kim, J. Y. Kang, J. Lim, J. Kim, S. C. Jun, Yonsei Univ. (Korea, Republic of)

Graphene has shown high potential to be used as interconnects in the field of high frequency electrical devices. In this study, we demonstrate the effect of graphene geometry on the microwave properties using the measurements of S-parameter in range of 500 MHz - 40 GHz. Graphene used in this study was fabricated by mechanical cleavage of highly oriented pyrolytic graphite and CVD method. High frequency properties of graphene, such as impedance, insertion loss, R, L, G and C were extracted from S-parameters at room temperature condition. We confirm that impedance and resistance decrease with increasing the number of graphene layer and w/L ratio. This result shows proper geometry of graphene to be used as high frequency interconnects.

8101-16, Session 4

Carbon nanotube terahertz spectroscopy: study of absorption and dispersion properties of SWNT and MWNT

H. Lamela, E. Dadrasnia, Univ. Carlos III de Madrid (Spain); J. Lampin, Institut d'Electronique, de Microélectronique et de Nanotechnologies (France); M. B. Kuppam, F. Garet, J. Coutaz, Univ. de Savoie (France)

Carbon nanotubes (CNT) have been widely investigated because of their unique properties in view of applications in electronics and mechanics (Dresselhaus, et al., Springer, 2000). Their structures and properties have been studied by several means such as photonic emission, scanning, microscopy and tuning fields. It appears that several physical parameters of CNT's are within the terahertz (THz) frequency range (Ugawa, et al., Phys. Rev. B 60, 1999, Hilt, et al., Phys. Rev. B 61, 2000) like the plasma frequency and the phonon frequency. In addition, GHz CNT transistors have been demonstrated and THz CNT transistors are predicted (Burke, Nanosensing: Materials and Devices, SPIE, 2004). Therefore, THz spectroscopy of CNT samples is nowadays subject to intense researches. THz time-domain spectroscopy (TDS) is certainly the best tool to perform these studies, as it leads to the simultaneous determination of both the refractive index and absorption coefficients of the material over a very large frequency band, extending from typically 0.1 THz up to several THz (Mittleman, Springer Series in Optical Sciences, 2003, Duvillaret et al., Topics in Quant. Electron., 739, 1996). First reports on THz spectra of CNT obtained by THz-TDS have been published in the late 90's (Ugawa, et al., Phys. Rev. B 60, 1999.), and more recent papers have permit to define precise physical models to describe the THz properties of CNT films (T.-I. Jeon, et al., J. Appl. Phys. 98, 2005, C. Kang, et al., Phys. Rev. B 75, 2007, Kim, et al., J. Korean Phys. Soc. 50, 2007, E. P. J. Parrott, et al., Adv. Mat.21, 2009).

In this paper, we report on the optical and electrical properties of single-walled CNT films (SWNT), pure or F-doped, investigated by THz-TDS. The SWNT electromagnetic properties are modeled with a Drude model to describe the free carrier contribution associated to a Maxwell-Garnett model that accounts for the composite tubular structure of the films. The calculated spectra of the absorption coefficient and index of refraction for pure SWNT and F-doped SWNT are demonstrated. At the conference, we will present corresponding experimental results as well as the effect of various ranges of filling factor and geometrical factor in these two SWNT samples and multi-walled carbon nanotubes (MWNT).

This work is supported by MITEPHO project (www.uc3m.es/portal/page/portal/grupos_ investigacion/optoelectronics/european_projects/mitepho) which is coordinated by GOTL research group in Carlos III de Madrid University with foundation grant agreement number 238393 (EU-FP7) in order to develop compact tunable dual-mode diode lasers and terahertz spectroscopy in sensing and biomedical applications.

8101-18, Session 4

Electronic cooling in a single flake of bi-layer graphene studied by ultrafast spectroscopy

E. Da Como, T. Limmer, J. Feldmann, Ludwig-Maximilians-Univ. München (Germany)

Graphene and few-layer graphene have demonstrated unique electrical properties such as ballistic transport and gigahertz switching frequencies in field effect transistors. Recently, the applications of graphene have entered the optoelectronics arena, with devices such as ultrafast photodetectors. Here, not only the transport properties are of interest, but also the optical response in terms of light absorption, electron-hole generation and carrier relaxation. In order to understand the operation of such devices and expand the application of graphene in optoelectronics, it becomes crucial to understand photocarrier relaxation with very high time resolutions.

In this communication, we report the first experiments probing the carrier relaxation on a single flake of bi-layer graphene with femtosecond resolution. Bi-layer graphene flakes have been obtained by mechanical exfoliation of natural graphite and do not show signatures of extrinsic carrier doping. We have probed carrier relaxation by ultrafast pump-probe spectroscopy in the femtosecond time scale, with a unique range of probe energies spanning between 1.2 to 0.25 eV. This allows us for obtaining snapshots of the carrier population distribution after the initial photoexcitation pulse at 1.55 eV. By modeling the carrier distributions as two separated Fermi-Dirac distributions for electrons and holes we extract carrier temperatures and cooling rates. Our analysis shows that carriers loose half of their energy within the first 500 femtoseconds by carrier-phonon scattering. The results are relevant for graphene optoelectronic devices and give valuable information for the understanding and modeling of hot carrier transport in ultrafast graphene devices.

8101-19, Session 4

Low-frequency 1/f noise in graphene field-effect transistors

A. A. Balandin, Univ. of California, Riverside (United States)

Unique properties of graphene, such as its extremely high electron mobility, saturation velocity and breakdown current density make this material promising for future high-frequency and mixed-signal electronics. We have recently discovered that graphene has superior intrinsic thermal conductivity [1], which improves its prospects for practical applications in nanometer scale devices. Most of the proposed applications require low levels of the electronic 1/f noise, which dominates the noise spectrum at low frequencies. The up-conversion of noise, unavoidable in electronic systems, results in increased phase noise of the systems. Thus, it is important to investigate the noise level in graphene field-effect transistors and identify its sources. In this talk, I will overview the results of our experimental study of graphene devices [2]. A special attention will be given to the noise sources in these devices and the effects of aging and environmental exposure on their characteristics. I will present an experimental proof that the measured noise originates in the graphene channel itself rather than in contacts. The obtained results can be used for graphene device optimization for electronic and communication applications.

The work at UCR was supported by the DARPA - SRC Focus Center Research Program (FCRP) through its Center on Functional Engineered Nano Architectonics (FENA).

8101-21, Session 5

Highly conductive, printable, and stretchable hybrid silver-carbon nanotube composites

K. Chun, Y. Oh, J. H. Rho, J. Ahn, Y. Kim, H. R. Choi, S. Baik, Sungkyunkwan Univ. (Korea, Republic of)

Conductive films with stretchability have received considerable attention for emerging electronic devices where arbitrary transformation in shape is required. Here we report highly conductive, printable and stretchable hybrid silver(Ag)-multi-walled carbon nanotube(MWNT) composites developed by blending and hot rolling ionic liquid, polyvinylidenefluoride copolymer, Ag flakes and MWNTs decorated with Ag nanoparticles [1]. The one-dimensional, flexible and conductive nanotubes constructed effective electrical networks among the Ag flakes, and the contact interface was improved by the self-assembled Ag nanoparticles on nanotubes. The maximum conductivities of the hybrid Ag-MWNT composite were 5710 S/cm at 0 % strain and 20 S/cm at 140 % strain where the film was ruptured [1]. The printable hybrid composite

with remarkable stretchability and conductivity might find practical applications in future electronic devices. [1] Kyoung-Yong Chun, Youngseok Oh, Jonghyun Rho, Jong-Hyun Ahn, Young-Jin Kim, Hyouk Ryeol Choi, and Seunghyun Baik, “Highly conductive, printable and stretchable composite films of carbon nanotubes and silver”, Nature Nanotechnology, 5(12), 853-857, December, 2010

8101-22, Session 5

Digital data transmission performance of CVD grown few-layer graphene ribbons

A. B. Guvenc, J. Lin, M. V. Penchev, C. S. Ozkan, M. Ozkan, Univ. of California, Riverside (United States)

We investigated the electrical characteristics and digital data transmission performance of few-layer graphene ribbons grown by chemical vapor deposition. Data transmission measurements were accomplished on graphene field effect transistors (FETs) fabricated on Si/SiO2 substrates. The mobility values were calculated from the transconductance, g = dIds/dVgs, in which Ids and Vgs values are acquired from back gate measurements. Data stream is randomly generated and uploaded to a waveform generator which generates the stream and transmits it repeatedly with the desired frequency. The signal was applied on the sources of the FETs and collected from the drains of the same devices. During the data transmission measurements no back gate voltage was applied. Collected data was first filtered with a low pass filter, to clear the noise and the high frequency parasitic effects then the output of the filter was used to create the eye diagrams of the devices and by using these eye diagrams, the bit error rates, attenuation values, quality factor values and maximum data transmission values are calculated. Graphene ribbons having a mobility of 2,180 cm2V-1s-1 can sustain data rates up to 90 megabits per second at 100 nm length and behave as RLC lines, thus the bandwidth is inversely proportional to resistance caused by defects in the graphene layers and the inductance and capacitance of the ribbons. Improving the graphene mobility to highest measured values (~200,000 cm2 V-1s-1) and using structures with multiple coplanar transmission lines in parallel could carry the bandwidth beyond the terabits per second level.

8101-23, Session 5

Ultra thin films of carbon nanotubes for sustainability monitoring in civil engineering: New insight on promising nanosensors

B. Lebental, E. Norman, Ecole Polytechnique (France); A. Ghis, Commissariat à l’Énergie Atomique (France); C. Cojocaru, Ecole Polytechnique (France)

In recent years, requirements in terms of service-life of civil engineering structures have become more and more stringent, so that the focus of designers and owners is now set on structural durability. Foreseeing structural failures and repairing damaged structures at an early stage has become a major stake. This is the incentive for the world-wide development of various in-situ monitoring techniques for structural materials.

However, to this day, no existing sensor features the resolution required to investigate in-situ structural materials at the micro- and nanoscale. This is a major lack, as micro and nanoscale features play a significant role in the durability of cementitious materials. From this perspective, IFSTTAR, CEA-LETI and LPICM have set themselves the long-term goal to devise together innovative nanoscale structural health monitoring solutions using single-walled carbon nanotubes based nanosensors.

We will present two promising devices, ultrasonic nanotransducers for microporosity assessment and field-effect transistors for humidity monitoring, which both rely on ultra-thin SWNT films for sensing, either by electromechanical or adsorption effect. Processing of ultra-thin films by techniques such as dielectrophoresis, spray or CVD growth, as well as thickness assessment by AFM or MEB will be the focus of our contribution. We will emphasize the relationship between high quality of the films and final sensing features of the devices.

8101-24, Session 5

A review of carbon based supercapacitor

P. Bondavalli, Thales Research & Technology (France)

The contribution deals with the state of the art and the critical analysis of studies concerning the fabrication of electric double layer capacitor (EDLC) also called super or ultracapacitors fabricated using carbon nanotubes (CNTs). From the first work in 1997, it was clear that supercapacitors achieved using carbon nanotube as electrodes showed very interesting results and that they could outperform traditional technologies based on activated carbon. Different methods to fabricated CNT based EDLC have been proposed in order to improve the performances (meanly energy densities and power), for examples CNT mats achieved by filtration, direct growth on metal collector or deposition using air-brush technique. The advantages and drawbacks of all these techniques will be analyzed. Recently, after a pause of some years, there has been a peak in the scientific community interest surely connected with the new challenges related to the research of new systems for the smart management of energy and to very hot topics such as the electric vehicles. This has been translated in a lot of new studies in the domain.We will focus our attention on the more interesting ones. We can also point out, for example, an increasing interest for supercapacitors achieved on flexible substrates for new kind of applications. Finally, we will try to find the coherence for the different research works and their related potential to strike the market : specific capacitance, energy and power densities, cost, versatility.

8101-33, Session 5

Graphene-based broadband optical modulator

M. Liu, X. Yin, Univ. of California, Berkeley (United States); F. Wang, X. Zhang, Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

Data communications have been growing at a speed even faster than Moore’s Law, with a 44-fold increase expected within the next 10 years. Data Transfer on such scale would have to recruit optical communication technology and inspire new designs of light sources, modulators, and photodetectors. An ideal optical modulator will require high modulation speed, small device footprint and large operating bandwidth. Silicon modulators based on free carrier plasma dispersion effect and compound semiconductors utilizing direct bandgap transition have seen rapid improvement over the past decade. One of the key limitations for using silicon as modulator material is its weak refractive index change, which limits the footprint of silicon Mach-Zehnder interferometer modulators to millimeters. Other approaches such as silicon microring modulators reduce the operation wavelength range to around 100 pm and are highly sensitive to typical fabrication tolerances and temperature fluctuations. Growing large, high quality wafers of compound semiconductors, and integrating them on silicon or other substrates is expensive, which also restricts their commercialization. In this work, we demonstrate that graphene can be used as the active media for electroabsorption modulators. By tuning the Fermi energy level of the graphene layer, we induced changes in the absorption coefficient of graphene at communication wavelength and achieve a modulation depth above 3 dB. This integrated device also has the potential of working at high speed.

8101-25, Poster Session

Fabrication of transparent and conductive chemically converted graphene films by dip-coating technique

F. Ait medjane, R. Wendelbo, Abalonyx AS (Norway); S. Karazhanov, Institutt for Energiteknikk (Norway)

Transparent conductive films (TCFs) are crucial components in modern electronics. They are generally produced from indium thin oxide (ITO) and due to globally diminishing stocks of indium, are becoming more expensive. In addition, for many future applications, electrodes will need to be flexible, a development that can not be accomplished by ITO . Graphene is widely considered to be an ideal material for the use as TCFs because of its unique two-dimensional structure, remarkable electrical conductivity, and optical transparency to visible and near-infrared light as well as excellent mechanical properties. Graphene based TCFs are cheaper, far more flexible than traditional ITO films. Currently, mechanical cleavage of graphite is able to make high quality graphene reaching a millimeter size but with a very low yield. Alternatively, chemical exfoliation starting from the oxidation of graphite is an efficient process to produce graphene on a large scale and at low cost, combined with post-reduction processes.

Here have developed, a simple and low cost approach for preparing TCFs using CCG dispersions and polycations. Graphene films were deposited onto glass and silicon substrates at ambient temperature by the dip-coating technique. An automated high-throughput set-up was developed for the purpose, by using a commercial robotic arm to dip 24 substrates in parallel. The set up include in house made instrumentation for on-line measurement of conductivity and transmittance. The properties of the obtained films were characterized by SEM, TEM, XPS and Raman spectroscopy. The resulting CCG films show promising electrical and optical properties.

8101-29, Poster Session

The enhanced mechanism of the CNTs/TiO2 core-shell nanotubes

J. Syu, C. Chen, J. He, National Taiwan Univ. (Taiwan)

After pre-patterned electrodes, we connected the nanotubes by e-beam lithography followed by Ti/Au (70 nm/30 nm) E-gun system. We connected the nanotubes which one side was carbon nanotubes (CNTs) and the other side was TiO2. The IV characteristic is asymmetric due to asymmetric connection. The thickness of TiO2 film is about 4 nm from transmission electron microscopy. Compared to the TiO2 nanotubes from others' research, the gain was at the same order of magnitude with ours under illuminated but our response time and reset time were faster than the TiO2 nanotubes. Our multi-walled carbon nanotubes (MWCNT) are metallic and make no response for the light. Upon illumination, the e-h pairs are generated and the electrons reach to the conduction band of TiO2 and transfer to the CNTs. And the unpaired holes were left behind in the TiO2. Since MWCNT behave as conducting wire, there is no possibility of accumulation of the electrons on CNT side. That will prevent the electrodes and holes from recombination so they can increase the density of the carriers. This enhances the electron-hole separation and helps in the faster growth of the photocurrent. When illumination is turned off, the photo-generated e-h pairs will stop. And the excess electrons in the CNT side transfer to the TiO2 side for recombination with the holes which is a very fast process.

8101-30, Poster Session

Computational study of negative differential resistance in graphene bilayer nanostructures

K. M. M. Habib, S. Ahsan, R. K. Lake, Univ. of California, Riverside (United States)

Although graphene has fascinating electronic properties featuring the Dirac fermion with high mobility and a long coherence length, lack of a band-gap reduces its utility for conventional electronic device applications.

A tunable bandgap can be induced in bilayer graphene by application of a potential difference between the two layers. The simplest geometry for creating such a potential difference consists of two overlaying single layer graphene nanoribbons (GNRs) with one placed on top of the other.

Each GNR is independently contacted so that one GNR is held at ground while the other has a bias applied to it. Independently contacting the top and bottom GNR maximizes the voltage drop between them. Such a geometry and biasing scheme would occur, for example, in a cross-bar architecture. Numerical simulations, based on density functional theory and the non-equilibrium Green's function formalism, show that transmission through such a structure is a strong function of applied bias. The calculated current voltage characteristics mimic the characteristics of resonant tunneling diode featuring negative differential resistance.

Semi-empirical tight binding model predicts that these characteristics prevail in large structures as well.

8101-32, Poster Session

Hydrogen storage in single-walled carbon nanotubes purified by microwave digestion method

N. Yuca, N. Karatepe, Istanbul Teknik Üniv. (Turkey)

Hydrogen is considered to be a clean energy carrier. However, the most serious barrier to potential uses is the development of feasible hydrogen storage systems. The discovery of high hydrogen storage capacity of carbon nanotubes (CNTs) makes up alternatives for hydrogen storage systems. To reach the full potential of the CNTs, many problems still need to be solved, including the development of an easy and effective purification procedure, since synthesized CNTs contain impurities, such as amorphous carbon, carbon nanoparticles and metal particles. These impurities impede utilization of the unique properties of CNTs. Also, as-synthesized CNTs usually have both ends closed, which may hinder their adsorption and capillarity properties. Therefore, a purification procedure should involve both opening the tubes ends and the elimination of the impurities to increase hydrogen storage capacity of CNTs.

In this study, the hydrogen adsorption on single-walled carbon nanotubes (SWCNTs) was investigated. SWCNTs were firstly synthesized by chemical vapor deposition (CVD) of acetylene (C2H2) on a magnesium oxide (MgO) powder impregnated with an iron nitrate (Fe(NO3)3-9H2O) solution. The synthesis parameters were selected as: the synthesis temperature of 800°C, the iron content in the precursor of 5% and the synthesis time of 30 min. The microwave digestion method was applied for the purification of the synthesized SWCNT materials. Nitric acid (HNO3) was used in the removal of the metal catalysts. Purification experiments were carried out at three different temperatures (120, 150 and 200 °C), three different acid concentrations (0.5, 1 and 1.5 M) and for three different time intervals (15, 30 and 60 min). The hydrogen storage capacities of the purified materials were measured using volumetric method at the liquid nitrogen temperature and gas pressure up to 100 bar and the effects of the purification conditions such as temperature, time and acid concentration on hydrogen adsorption were investigated.

Conference 8102: Nanoengineering: Fabrication, Properties, Optics, and Devices VIII

Tuesday-Wednesday 23-24 August 2011 • Part of Proceedings of SPIE Vol. 8102
Nanoengineering: Fabrication, Properties, Optics, and Devices VIII

8102-01, Session 1

Leaky-mode resonance photonics: an applications platform

R. Magnusson, The Univ. of Texas at Arlington (United States)

Incident light induces resonant leaky modes on dielectric and semiconductor layers patterned in one or two dimensions. Properly designed resonance structures may support a collection of complex, interacting waveguide modes providing interesting, novel spectral expressions. Here we present applications that include bandpass and bandstop filters, laser mirrors, polarizers, wave plates, ultrasensitive biosensors, absorption-enhanced solar cells, security devices, tunable filters, nanoelectromechanical display pixels, and dispersion/slow-light elements. We summarize the physical basis for this technology and provide numerous designed and fabricated device examples. Key issues in design and fabrication will be discussed. In particular, we invented and implemented highly accurate, label-free, guided-mode resonance (GMR) biosensors that operate in narrow-line reflection or transmission. The sensor is based on the high parametric sensitivity inherent in the fundamental resonance effect. As this sensor technology has high-value applications in medical diagnostics, drug discovery and development, industrial process control, and environmental monitoring, it is being commercialized. Moreover, the arsenal of optical components can be extended by use of the resonance concept. We have designed and fabricated a variety of bandstop and bandpass filters at differing spectral bands. Similarly, wideband polarizers fashioned in a single resonant layer have been fabricated and characterized showing high-quality response. We have designed ultra-wideband reflectors as well as new types of wave plates using a multilevel architecture. In general, these devices exhibit a minimal layer count relative to their classical multilayer thin-film counterparts. Another interesting pursuit relates to wideband tuning of these filters that is achievable by perturbing the structural symmetry using nano/microelectromechanical (MEMS) methods. Mixed metallic/dielectric resonance elements exhibit simultaneous plasmonic and leaky-mode resonance effects. Thus, leaky-mode resonance photonics technology is an enabling applications platform with interesting prospects.

8102-02, Session 1

Ultraslow photon diffusion in aperiodic nanostructure arrays

T. Rich, N. Lawrence, Boston Univ. (United States); J. Zhang, S. Cabrini, Lawrence Berkeley National Lab. (United States); L. Dal Negro, Boston Univ. (United States)

Stochastic models of the transport of photons through disordered media suggest that it is possible to create photonic materials that support ultra-slow diffusion of light, known as Sinai sub-diffusion. In disordered lattices, these stochastic processes are non-Markovian due to the effect of long-range correlations, and photon diffusion is significantly slowed down, according to a mean squared displacement that varies as t^β, where β<1. In this work, based on multiple scattering Monte Carlo calculations and electrodynamics computations (Finite Difference Time Domain), we present our design and demonstration of complex photonic media with ultraslow photonic sub-diffusion over broad frequency spectra. Nanofabrication and optical characterization results of anomalous photon diffusion in aperiodic waveguide structures and two-dimensional nano-pillar arrays will also be presented. Characterizing the relationship between disorder and anomalous transport will allow for the engineering of novel materials whose transport properties can be actively tuned. Such precise control of the photon transport characteristics has not yet been demonstrated and will offer profound advancements in the ability to develop novel optical devices such as optical buffers for solar and on-chip energy harvesting applications.

8102-03, Session 1

Experimental confirmation of fluorescence enhancement using one-dimensional GaP/SiO2 photonic band gap structure

J. Gao, A. M. Sarangan, Q. Zhan, Univ. of Dayton (United States)

In this paper we report the experimental confirmation of the fluorescence enhancement effect using one-dimensional photonic band gap (1D PBG) structure. The 1D PBG structure consists of periodic multi layer thin films with gallium phosphide (GaP) and silicon dioxide (SiO2) as the alternating high and low index materials. Strongly enhanced evanescent field can be generated at the last interface due to the combination of total internal reflection and photonic crystal resonance for the excitation wavelength. Meanwhile, the 1D PBG structure is designed as an omni-directional reflector for the red-shifted fluorescent signal emitted from the surface bounded molecules. Such an omni-directional reflection helps to improve the collection efficiency of the objective lens and further increase the detected fluorescent signal. Compared with the commonly used bare glass substrate, an average enhancement factor of 62 times has been confirmed experimentally with quantum dots as fluorescent markers. This fluorescence enhancer may find broad applications in single molecular optical sensing and imaging.

8102-04, Session 1

Aperiodic arrays of Er3+:SiNx pillars for light emission enhancement at 1.55um

N. Lawrence, L. Dal Negro, Boston Univ. (United States); S. Cabrini, J. Zhang, Lawrence Berkeley National Lab. (United States)

The engineering of optical devices in silicon (Si) has the potential to revolutionize the optoelectronics industry by providing a solution to interconnect bottleneck problems and enabling low-cost, high-performance applications ranging from inter and intra-chip interconnects and communication to integrated optical bio-sensing. The development of fully Si-based lasers can result in the mass production of high-performance optoelectronic components and systems through integration with CMOS technology, however, the progress limited by the lack of efficient light emission from Si. To overcome this, variation in the local density of photon states (LDOS) can be created by altering the surrounding environment to enhance material light emission. Unlike periodic photonic structures, Deterministic Aperiodic Structures (DAS) possess unique light localization and anomalous transport properties related to far richer spectral features, however, unlike random media, DAS are defined by the iteration of simple mathematical rules yielding repeatability. To exploit the unique light localization properties of these structures we have fabricated pillar arrays of Erbium (Er) doped Silicon-Rich Nitride (SRN) based on DAS using electron beam lithography and inductively coupled plasma (ICP) varied geometry to optimize the emission enhancement around 1.55 m. An over 30 fold increase in the volume normalized PL is measured along with angularly resolved emission profiles and emission time dynamics (TRPL). The experimental results have been interpreted using the null-field theory formulation (T-matrix) for systems of particles of arbitrary shape. These results suggest that light localization effects in engineered pillar arrays can lead to strong radiative enhancement for CMOS compatible on-chip integration.

8102-05, Session 1

Scattering optics resolves nanostructure (Keynote Presentation)

J. Bertolotti, E. G. van Putten, D. Akbulut, W. L. Vos, Univ. Twente (Netherlands); A. Lagendijk, FOM Institute for Atomic and Molecular Physics (Netherlands); A. P. Mosk, Univ. Twente (Netherlands)

Scattering of light is usually seen as a nuisance in microscopy. It limits the penetration depth and strongly deteriorates the achievable resolution. However, by gaining active spatial control over the optical wave front it is possible to manipulate the propagation of scattered light far in the multiple scattering regime. These wave front shaping techniques have given rise to new high-resolution microscopy methods based on strong light scattering. This is based on the realization that scattering by stationary particles performs a linear transformation on the incident light modes. By inverting this linear transformation, one can focus light through an opaque material and even inside it. An extremely high resolution focus can be obtained using scatterers embedded in a high-index medium, where the diffraction limit for focusing is reduced by a factor n. We have constructed a scattering lens made of the high-index material Gallium Phosphide (GaP) which is transparent over most of the visible spectrum and has the highest index of all nonabsorbing materials in the visible range. This yields a focal spot resolution of less than 100 nm, and it seems theoretically possible to create a focus of order 70 nm. We will discuss how the system resolution of a fluorescence microscope using this lens could be pushed even higher.

8102-06, Session 2

A photonic DNA processor: concept and implementation

T. Nishimura, Y. Ogura, K. Yamada, Osaka Univ. (Japan); H. Ymamoto, Univ. of Tokushima (Japan); J. Tanida, Osaka Univ. (Japan)

To deal with molecular information at a molecular level based on external signaling, a photonic DNA processor is a primal processing core of a nanoscale information system that works in molecular environment, for example, in situ. Use of photonic signals enables remote and spatio-temporal control of the processor. As an implementation example, we report a photonically-controlled DNA nanomachine which identifies and processes molecular information and implements physical processing as reporting the result using fluorescence signal. The nanomachine has two hairpin DNAs incorporating azobenzene and forms a tweezers-like structure. The hairpin structures are opened by ultraviolet-light irradiation, and a single-strand region is exposed to activate functionality in recognizing a target molecule. In contrast, visible-light irradiation makes the hairpin DNA close to inactivate the sensing function, and it releases the captured molecule. During activated term, the nanomachine changes its tweezers-like structure depending on existence or absence of the target molecule: the nanomachine transmutes into the closed state from the open state (initial state) by binding to the target molecule. Depending on the state, the nanomachine generates a fluorescence signal owing to fluorescence resonance energy transfer. In experiments, we demonstrated that the fluorescence intensities changed depending on existence and absence of the target molecule under photonic activation and inactivation. The result indicates that the nanomachine obtained information on the target molecule, changed the state, and reported the information to the outside world. In addition, we confirmed experimentally the functionality in measuring the concentration of the target molecule.

8102-07, Session 2

Threshold current calculations and optical cavity optimization for PbSe/PbSrSe MQW structures

M. Khodr, Hariri Canadian Univ. (Lebanon)

Threshold current is a key parameter in the design and proper operation of quantum well lasers. In this publication, threshold current analysis and calculations are done on four PbSe/Pb0.934Sr0.066 Se quantum well laser structures: SQW, SCH-SQW, MQW, and MMQW. The current work is a continuation to previous publications where energy levels, modal gain, optical confinement, and total losses were published for these four structures assuming the energy bands are non- parabolic. The threshold current as a function of total losses, cavity length, and cavity end mirror reflectivity was obtained for these structures. It is shown that the threshold current decreases with a decrease in the cavity length and then increases at a critical cavity length. The effects of non-parabolicity on the threshold current values are more obvious for short cavities and decreases with an increase in cavity. Whether the SQW or the MQW is the better structure depends on the loss level. At low loss, the SQW laser is always better because of its lower current density where only one QW has to be inverted. At high loss, the MQW is always better because the phenomena of gain saturation can be avoided by increasing the number of QW's although the injected current to achieve this maximum gain also increases. Owing to this gain saturation effect, there exists an optimum number of QW's for minimizing the threshold current for a given total loss. At this typical value, the effects of non-parabolicity on the threshold current values can be neglected without loss of accuracy. However, there is a 20% shift in the output lasing energy that cannot be neglected.

8102-08, Session 2

Sub-micron channels for optofluidic bacterial analysis

A. E. Vasdekis, D. Psaltis, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Isolated cell analyses have attracted substantial attention in recent years due to their unique capability to reveal single target dynamics, commonly masked in population level studies. To this end, the most common techniques used are hydrodynamic trapping in microfluidics, due to the possibility of performing highly multiplexed measurements, but also due to their capacity to control the cells' growth conditions [1].

Similar efforts in bacteria however, have not reached yet such sophistication levels, primarily due to the absence of microfluidic architectures capable of microbial handling [2]. Such methodologies would potentially revolutionise drug research, especially within the field of antibiotic persisters [3].

To address this, we have developed a hybrid fabrication method based on electron-beam and cast-moulding lithography for PDMS microfluidics with sub-micron resolution. We will discuss the performance and limitations of this method, and our recent results in handling few and single bacteria. Integrated methods for high-throughput size determination will be also discussed.

8102-09, Session 2

Nano-imprint of photonic-plasmonic nanostructures on bio-polymers

D. Lin, Boston Univ. (United States); H. Tao, Tufts Univ. (United States); S. Y. Lee, Boston Univ. (United States); F. Omenetto, Tufts Univ. (United States); L. Dal Negro, Boston Univ. (United States)

Nanostructures have been extensively exploited to construct photonics and plasmonics device for light emission (lasers, LEDs) and optical biosensing. Current optical platforms are based on widely used substrates such as quartz, silicon, and other semi-conductor materials. Novel polymers, such as silk biopolymer, which are biocompatible and biodegradable, have emerged to expand the functionality of current photonics devices for biomedical applications. However, the nanofabrication of photonic-plasmonic nanostructures on top of these solvent-sensitive bio-polymers poses unique challenges. Here, we demonstrate a rapid nanoimprint method capable to fabricate at room temperature both nano-hole patterns and gold nanoparticle arrays on protein-based biopolymer (silk) substrates. Nano-hole structures are imprinted with mold of Si pillars, while gold nanoparticle patterns are predefined on a donor mold, and then transfer-imprinted onto the surface of a silk film. By this approach, various patterns with feature sizes down to 25nm scale can be reliably fabricated and scaled over cm2 areas. The SEM images of imprinted nanostructures on silk and actively doped (luminescent) polymer layers demonstrate that a mold can be completely replicated onto a silk substrate with high fidelity. This technique provides an attractive approach to fabricate large-area nanostructures on the surface of solvent sensitive polymers with nanoscale resolution and at low cost. Since the imprint procedure relies on mechanical deformation, it preserves the biological, chemical and physical properties of biopolymers, and therefore it is applicable for implantable devices and environmental monitors.

8102-10, Session 3

Nanotechnologies for efficient solar energy conversion and storage

L. A. Eldada, SunEdison (United States)

The immense gap between solar energy's tremendous potential and our utilization of it to produce electricity can be overcome over time by increasing the efficiency of the conversion and storage processes, which are today well below their theoretical limits. We present nanotechnologies that improve the conversion efficiency of solar energy into electricity, and enhance the round-trip efficiency of energy storage systems. We describe nanostructures that enhance light concentration, light trapping, photon absorption, charge generation, carrier multiplication, hot electron extraction, charge transport, and current collection in photovoltaic systems, as well as nanomaterials that enhance the efficiency of electrochemical processes, boost gravimetric and volumetric energy densities, reduce the rate of self-discharge, increase the peak power rating, and extend the cycle life of secondary batteries and ultracapacitors.

8102-11, Session 3

Analytical approach to 3D device modeling of nanoarchitectures for solar energy conversion

A. Wangperawong, S. F. Bent, Stanford Univ. (United States)

Recently there have been many new experimental device architectures utilizing vertical nanojunctions to decouple light absorption from charge carrier collection. Despite great experimental work in the field, theoretical studies have been limited. We have developed models that for the first time describe the device performance of nanostructured solar cells in three dimensions, distinguishing between isolated and interdigitated nanojunctions. Our analytical approach is a powerful tool for designing nanostructured solar cells of various architectures and materials that can be both efficient and cheap. Beyond photovoltaics, other applications include photoelectrochemical cells and photocatalytic devices.

8102-13, Session 3

Optimization of the spray parameters for ZnO based hybrid solar cells

A. Vasudevan, S. Jung, T. Ji, Univ. of Arkansas (United States)

Global energy demand has been increasing drastically and major share of this demand is met from fossil fuels. Fossil fuels being non-renewable, efforts are being made to tap energy efficiently from renewable energy sources. Among renewable energy sources, solar energy is a major energy source and solar cells are used to convert it into electrical energy. Solar cells currently used are silicon based because they have higher efficiency than cells from other materials but the manufacturing cost is high. Though cheaper cells can be fabricated using organic materials because it solution processable, the efficiency is very low. The low efficiency of organic solar cells is due to the low mobility of the carriers, the efficiency can be improved if inorganic materials are incorporated. The incorporated inorganic material provides better transport to the carriers generated by organic material. Hybrid solar cells with ZnO nanorods as the inorganic and P3HT and PCBM as the active layer reported in literature is usually prepared by spin coating. The major drawback of using spin coating technique is that large area fabrication is not possible. Large scale production is feasible if these cells can be prepared by spray coating. We will discuss the fabrication of these cells by spray coating technique. The dependence of efficiency of the cell on the active layer thickness, substrate temperature and spray parameters like pressure of the carrier gas will be studied. By comparing the efficiency of the cells prepared under different conditions the optimum condition for preparing efficient hybrid solar cells will be determined.

8102-14, Session 4

An active matrix arrayed microphone with acoustic bandwidth response

Y. Hsu, I. Kymissis, Columbia Univ. (United States)

We have demonstrated a monolithically integrated two dimensional (8X8) active matrix microphone fabricated on a flexible polymer piezoelectric sheet (polyvinlyidene difluoride) which uses thin film organic field effect transistors to both locally amplify the piezoelectric charge signal and switch individual elements, allowing for sensing site localization. The integrated design of the sensor and amplifier eliminates a previously dominant parasitic capacitance, allowing an acoustic bandwidth response, and the flexible, thin film form factor allows maximum versatility in applications. Each sensor element is controlled by an organic thin film transistor. The switch transistor is sized significantly smaller than the amplifying/sensing transistor to optimize the cell isolation, on/off characteristic, and parasitic load. The sensor element converts the charge response of the polyvinlyidene difluoride (PVDF) sheet into a current signal, overcoming downstream parasitic charge sharing from both switch transistors and interconnects.The device is tested using both turbulent air current and far field acoustic excitation in this work. Our design extends the bandwidth of a locally amplified piezoelectric sheet sensor to the acoustic range, and demonstrates a monolithically integrated active matrix sensing architecture capable of sensing in the acoustic range and mapping both boundary layer and far field acoustic excitation for a variety of applications.

8102-15, Session 4

Low temperature zinc oxide nanorod synthesis for gas detection applications

M. Roddy, S. Jung, T. Ji, Univ. of Arkansas (United States)

Devices fabricated on silicon substrates can have limited applications due to material costs and non-biocompatibility. Glass and flexible polymer substrates are inexpensive and biocompatible making them an excellent choice of substrate for sensor design due to their broad range of potential applications; however require low processing temperatures unlike conventional silicon based devices. To address this low temperature processing requirement of substrates, Zinc Oxide (ZnO) nanords have been grown on glass and polymer substrates using a low temperature wet chemical synthesis process. Substrates were seeded with ZnO nanoparticles synthesized in methanol and then annealed at 125°C. The substrates were then inverted and placed in a sealed container of nanorod growth solution in a sealed container for 6 - 8 hours at 90°C. The resulting nanorods ranged from 1 - 2 µm in length and 50 - 150 nm in diameter. Samples were characterized with Scanning Electron Microscopy and X-ray Diffraction. The synthesis process was optimized to create vertically aligned single crystal nanorods suitable for gas detection with a proprietary interdigitated electrode design. The mechanism for gas detection is an upward shift in the conduction band structure of ZnO nanorods as gas is absorbed on its surface which results in a measureable increase in conductance. A gas sensor was fabricated with the optimized ZnO synthesis process and its response characterized using CO in N2 at standard temperature and pressure at concentrations from 150 ppm to 10,000 ppm.

8102-16, Session 4

UV detector from ZnO naorods with electrodes resembling a wheatstone bridge pattern

A. Vasudevan, S. Jung, T. Ji, Univ. of Arkansas (United States)

Detectors currently used for UV detection are Si based and photomultiplier tubes. These detectors being bulky and less sensitive, we need to find an alternative material that could improve the sensitivity and to build portable detector. Past work by different authors show that ZnO based photo detectors have better sensitivity even at room temperature, also have characteristics like radiation hardness, chemical stability and high temperature stability. The structure of the ZnO detectors can be of the following types (1) p-n junction diode (2)schottky barrier type (3) Metal-semiconductor-metal type, of these metal-semiconductor-metal type detector is simple and cheaper for fabricating. Usually metal-semiconductor-metal structure detectors use simple interdigitated electrode but the sensitivity of these detector can be improved if better electrode design is chosen. We will use electrodes that are designed in square pattern which almost resembles a wheatstone bridge and this new improved design enhances the collection of carriers and also miniaturization of the detector. The nanorods for the detector will be grown by solution growth technique and rods of different length will be grown to know how it affects the response of the detector. To study how the response of the detector depends on the length of the interdigitated fingers and spacing between the interdigitated fingers, electrodes of different dimension will be fabricated. The response of the detector will be determined from I-V measurements made with and without UV light of wavelength 365nm for different bias voltage.

8102-17, Session 4

Polyaniline nanofilms as a base for novel optical sensor structures

V. Va?inek, J. Bocheza, S. Hejduk, K. Witas, J. Vitasek, Technical Univ. of Ostrava (Czech Republic)

Polyaniline hydrochloride was prepared by the oxidation of aniline hydrochloride with ammonium peroxodisulfate in dilute hydrochloric acid. The polyaniline films were produced during the polymerization on the microscope glass surfaces immersed in the reaction mixture. The thin film was created and its thickness has been about 100 nm. We have measured the spectral transmittance together with temperature changes. The polyaniline thin film is conductive and we observed changes in optical transmittance spectra and reflective spectra with electric current. Optical spectra have been measured in range from 380 nm to 1010 nm.

The electric conductivity has been changed with silicate substrate. This substrate influenced the free electrons distribution and therefore the optical properties of polyaniline. Due to electric current going through the nanofilm its sensitivity to temperature has been increased. We also observed two specific spectral windows. The first one was characterized by its insensitivity to temperature; the second one has been temperature sensitive. The central wavelength of insensitive window is about 500nm. This property can be the base for novel sensors structures.

We used Ocean Optics USB spectrometer for evaluation of spectral changes. Wideband white light halogen source from the same manufacturer has been applied as a light source. Small polarizing dependence of reflected light has been observed too.

8102-18, Session 4

Behavioral modeling of monolithically integrated tri-axis capacitive accelerometer based on metal MUMPs

M. S. Khan, COMSATS Institute of Information Technology (Pakistan); A. A. Iqbal, S. A. Bazaz, Ghulam Ishaq Khan Institute of Engineering Science and Technology (Pakistan)

This paper presents the behavioral modeling of monolithically integrated tri-axis capacitive accelerometer using standard MetalMUMPs process. The behavioral modeling is done to verify the design, structural, modal and electrostatic performance of the designed three axis capacitive accelerometer. The designed accelerometer is 3.2mm×3.5mm in size, designed for sensing the acceleration of 25g in three axis, has 0.291µg/√(Hz), 0.316µg/√(Hz), and 2.84µg/√(Hz) mechanical noise floor for in-plane(x & y) and out-of-plane(z) axes respectively. The total sense capacitance along x, y and z-axes is 68.5fF, 100fF and 6.19pF respectively. Sensitivity of 2.568fF/g, 4fF/g and 0.252pF/g is obtained for in-plane (x and y) and out-of-plane (z) axes respectively. The resonance frequency for the designed accelerometer is 800Hz and 2500 Hz for in-plane and out-of-plane axis. The results obtained by behavioral modeling are compared with the analytically calculated results using Matlab, which are approximately the same.

8102-19, Session 4

Optical and FTIR spectral studies on PZT multilayer thin films

G. N. Venkatesan, P. Jegatheesan, B. Karthikeyan, National Institute of Technology, Tiruchirappalli (India)

Dielectric resonance became an important theme in the physics of composites and fascinated by physicists for many decades due to its potential application in photonic crystals. Lead zirconate titanate Pb(ZrxTi1−x)O3, PZT, which exhibits pyroelectric, piezoelectric and electro-optical properties. This material is promising candidate for practical applications like infrared detectors, ferroelectric non-volatile random access memories, optical modulators, optical waveguides, multilayer capacitors and for MEMs applications. One can tune its physical properties by varying ‘x’ in the composition as mentioned Pb(ZrxTi1-x)O3. In the current work we report Pb(ZrxTi1-x)O3 based multilayer thin films with different Zr/ Ti ratio where x =0.35, 0.40, 0.60 and 0.65. These films are prepared through sol- gel spin on technique. Films are coated onto Pt (111)/Ti/SiO2/Si (100) substrate.

X- ray diffraction studies show that the films are switching its phase from rhombohedral to tetragonal phase when the Ti concentration increased. Optical absorption measurements are done on the reflective mode between the wavelength regime 200 to 1100 nm. Spectra show interference effects. To analyze the local structure variation Fourier Transform Infrared spectral measurements are done through KBr pellet technique. Variation in the IR band is expected due to phase change affecting the lattice parameters and it reflects in the IR frequency. The absorption band in FTIR is attributed to TiO6 and ZrO6 stretching and bending in the octahedral normal modes and the stretching vibration is the motion of Ti (Zr) and O. We analyzed the optical and structural properties.

8102-20, Session 4

Periodical microstructures induced by IR femtosecond laser pulses on silicon surface for color marking

S. Makarov, National Research Nuclear Univ. MEPhI (Russian Federation)

We investigate basic regimes for ripples formation by IR ($\lambda \approx 744$ nm) femtosecond laser pulses on silicon surfaces and topological evolution of quasi-periodic surface nanostructures with increasing laser irradiation dose (the product of the number of pulses and laser fluence). We demonstrate possibility of controllable and theoretically predictable surface color-marking, which is developing of the new method of surface colorizing by writing laser-induced periodical structures.

8102-21, Session 5

Fabry-Perot scanning probe for aperture-based near-field optical microscopy

A. A. Kuchmizhak, Y. N. Kulchin, O. B. Vitrik, Institute for Automation and Control Processes (Russian Federation)

In present paper we present a new type of interferometric aperture-based probe for near-field optical microscopy based on a fiber optic Fabri-Perot microresonator with a nanosized aperture milled in one of its mirrors. The dependence of resonant modes spectral shift $\delta\lambda$ in the Fabri-Perot microresonator on the distance between the output aperture and the test object was obtained by using finite-difference time-domain (FDTD) method. It was shown theoretically that minimal longitudinal resolution of the method is defined by the Q-factor of the resonator. In accordance with numerical data obtained, proposed method allow one to achieve the value of longitudinal and lateral resolutions more then $\lambda/15$ and $\lambda/40$ correspondently.

The spatial resolution not worse than 120 nm, which corresponds to ~ $\lambda/14$ at wavelength λ = 1550 nm was experimentally demonstrated using proposed probe based on the fiber optic Fabry-Perot interferometer (Q-factor~5*10^4) with the 100-nm-sized circular aperture milled in its output mirror with the focused ion beam. A further increase in spatial resolution of the proposed method can be achieved by using resonators with higher Q factor.

8102-22, Session 5

Nanoscale organic light-emitting transistors: NanoOLETs

J. Kjelstrup-Hansen, L. Tavares, R. M. de Oliveira Hansen, H. Rubahn, Univ. of Southern Denmark (Denmark)

Light-emitting organic crystalline nanofibers made from small molecules exhibit a wide range of extraordinary optical properties [1] such as intense, anisotropic luminescence, waveguiding, electroluminescence and lasing. For lighting and display purposes, the defect free morphology of the nanofibers, the high quantum yield and the easy tunability of the color by changing the molecular building blocks are especially important.

The application of such nanostructures as electrically driven light-emitters requires integration with suitable metal electrodes for efficient carrier injection. Here, we implement two different methods for achieving such nanofiber integration. The first method is based on initially preparing the nanofibers by epitaxial growth on a special growth substrate (muscovite mica) and subsequently transferring them to a suitable device substrate by a recently developed roll-on transfer technique [2]. The second method relies on growing the nanofibers directly between the metal electrodes on a substrate that has been specially designed to guide the nanofiber growth [3]. We present results of both techniques in terms of morphological, optical and electrical characterization and demonstrate how appropriate biasing with an AC gate voltage enables electroluminescence from organic nanofibers. The electroluminescence occurs in the close vicinity of the electrodes (space charge region) and thus the characteristic dimension of the lighting transistor is on the nanoscale.

Deposition of sol-gel sensor spots by nanoimprint lithography and hemi-wicking

M. B. Mikkelsen, R. Marie, Technical Univ. of Denmark (Denmark); J. H. Hansen, H. O. Nielsen, DELTA (Denmark); A. Kristensen, Technical Univ. of Denmark (Denmark)

We present a method for homogeneous deposition of sol-gel sensor materials, which enables fabrication of sensor spots for optical pH and oxygen measurements inside plastic containers. Using the principle of hemiwicking [Quéré, Physica A (2002)], a deposited droplet is guided by posts imprinted in the surface and fills the imprinted structure automatically, not being sensitive to alignment as long as it is deposited inside the patterned area. A periodic pattern of posts is imprinted into a polycarbonate substrate, and a droplet of the sol-gel sensor material is deposited on the structured surface, where after it spreads, guided by the imprinted posts. The layer thickness of the deposited film is determined by the geometry of the posts and surface energy.

Hemiwicking is an effective method to immobilize a low viscosity liquid material in well-defined spots on a surface, when conventional methods such as screen- or stamp-printing do not work. On length scales of the order of the microstructure period, surface tension will govern the shape of the liquid-air interface, and the liquid will climb up the pillars to keep a fixed contact angle with the sidewalls. The surface to volume ratio is therefore constant all over the surface of the liquid spread by hemiwicking, when considering length scales larger than the microstructure period. Material redistribution caused by solvent evaporation, i.e., the “coffee ring effect” [Deegan et al., Nature (1997)], can therefore be avoided because the evaporation rate does not vary on length scales larger than the period of the pattern.

8102-24, Session 5

Design issue analysis for InAs nanowire tunnel FETs

S. S. Sylvia, M. A. Khayer, Univ. of California, Riverside (United States); K. Alam, East West Univ. (Bangladesh); R. K. Lake, Univ. of California, Riverside (United States)

InAs nanowire-tunnel-FETs (NW-TFETs) are being considered for future, beyond-Si electronics.

They offer the possibility of beating the ideal thermal limit to the inverse subthreshold slope of 60 mV/dec and thus promise reduced power operation.

However, whether the tunneling can provide sufficient ON-current for high-speed operation is an open question.

In this work, for a p-i-n device, we investigate the source doping level necessary to achieve a target ON-current (1 micro A) while maintaining a high I(ON)/I(OFF) ratio (1E6) for a range of NW diameters (2-8 nm). Our approach uses a fully-discretized 8 band k.p model combined with the non-equilibrium Green's function (NEGF) formalism.

The electrostatics is calculated using a finite difference solution of Poisson's equation. With a fixed drain bias voltage and a maximum gate overdrive, we compare the performance of the inverse subthreshold slope (SS) and I(ON)/I(OFF) ratio as a function of NW-diameter and source doping. Increasing the source doping level increases the current as a result of the reduced screening length and increased electric field at source which narrows the tunnel barrier.

However, since the degeneracy is also increasing, it reduces the effective energy window for tunneling which, in turn, tends to decrease the current for a given voltage.

This leads to an optimum choice of source doping considering the inverse SS and I(ON)/I(OFF) ratio for these TFETs.

8102-25, Session 5

Carrier leakage in Ge/Si core-shell nanocrystals for lasers: core size and strain effects

M. R. Neupane, R. K. Lake, Univ. of California, Riverside (United States); R. Rahman, Sandia National Labs. (United States)

Ge/Si core-shell nanocrystal lasers have been proposed because of their compatibility with existing Si based technology. They exhibit size dependent stimulated emission and reduced threshold current density. In such structures, lasing is obtained at lower current density because of large carrier confinement and a favorable density of states for population inversion. A recent experimental report suggested an increase in the light emission probability because of increased radiative lifetimes, however the performance is exponentially dependent on the temperature due to the current leakage mechanism. This hole current leakage mechanism is governed by the thermionic lifetime of the confined carrier which is determined by the height of the barrier over which the hole must be emitted. Higher thermionic lifetime indicates a minimal escape rate of the carriers from the core to the confining shell barrier. In this paper, we calculate the thermionic lifetimes as a function of the Ge-core size and strain. Our method also provides a novel and accurate barrier calculation that is required for the leakage current formulation by capturing the bound and extended eigenstates, well below the band edges, and corresponding eigenvalues using the atomistic tight binding method as implemented in NEMO3D. In addition, the effect of both core size variation and strain on the leakage current, and on other fundamental but important electronics and optical parameters will be presented.

8102-26, Session 6

3D tectons as functional nanostructures for self-assembled functional thin films towards nanophotonics

A. Attias, D. Bléger, D. Kreher, F. Mathevet, A. Bakhma, Univ. Pierre et Marie Curie (France); A. Bocheux, F. Charra, L. Douillard, C. Fiorini-Debuisschert, Commissariat à l'Énergie Atomique (France)

In order to achieve the nanometer-scale control over the positioning and organization of functional molecules into monolayers at surfaces, we developed an original approach allowing the exact positioning of (photo)active organic molecules on the substrate (graphite) leading to the formation of nanostructured functional thin films. Here we present a strategy aimed at the decoupling of molecules from the surface, by lifting photoactive entities a few Å above the surface while maintaining the lateral organization of the array. This is achieved by using 2-level based building blocks. While the first level allows the precise organization of the building blocks on HOPG at the solid-liquid interface at room temperature, the second level is a photoactive compound, namely a chromophore. We will present a series of such building-block exhibiting tunable wavelength emission. This strategy results in the precise organization of chromophores arrays (subwavelength-sized photon sources) a few Å above the conducting surface, as determined by scanning tunneling microscopy (STM), opening interesting perspectives for applications in nanophotonics.

8102-28, Session 6

Boost nonlinearity by monolayer graphene

T. Gu, Columbia Univ. (United States)

Graphene exhibit interesting optical properties such as high kerr nonlinearity, absorption saturation, Faraday rotation, but in all those experiments light has TM polarized component and thus hard distinguish the graphene effects from the substrate. Here we comformally place the CVD grown graphene on suspended silicon membrane, and send TE polarized light into the pattern defined on the suspended semiconductor membrane. It is observed that the refractive index of the media is sensitive to the light intensity, indicating the silicon's nonlinear effect is enhanced by the graphene cladding since the TE mode like doest not direct interact with the one atom thick graphene sheet. Further discussions on the mechanism and fabrication are performed.

8102-29, Session 6

Exciton polariton coupling and enhanced emission in SiC nanocrystals

G. Polupan, T. V. Torchynska, Instituto Politécnico Nacional (Mexico)

The essential interest in last decade appears to different applications of SiC nano crystals (NCs) such as porous SiC (PSiC) or SiC NC composite layers. The large band gap of SiC NCs makes them the good candidates for blue and ultraviolet (UV) light emitter diodes and full-color displays. SiC-based homoepitaxial structures, new types of PSiC-based photodiodes and UV gallium nitride photodetectors grown on PSiC substrates have been reported recently [1].

The paper presents the results of SiC nanocrystal characterization using photoluminescence, its temperature dependence, scanning electronic microscopy (SEM) and X-ray diffraction techniques. Photoluminescence study of porous SiC layers with different SiC NC sizes reveals the intensity stimulation for high energy PL bands. The investigation of temperature dependences of high energy PL bands has shown that these PL bands related to different excitons in SiC NCs. The intensity enhancement of exciton-related PL bands in big size (50-250nm) SiC NCs is attributed to exciton recombination rate increasing due to the realization of exciton weak confinement and exciton-polariton coupling. The numerical simulation permits to estimate the optimal SiC NC size for exciton-polariton coupling. The comparison of experimental and numerically calculated results will be presented as well.

8102-30, Session 6

Advanced patterning for patterned magnetic media

E. A. Dobisz, R. Ruiz, G. Zeltzer, T. Hirano, K. Patel, D. Kercher, T. Wu, F. Rose, O. Hellwig, J. Lille, T. Albrecht, Hitachi Global Storage Technologies, Inc. (United States)

Patterned media is a solution to provide data bit thermal stability for future generation disk drives. Patterned bit media is not expected in the disk drive manufacturing until densities of 1 Tb/in2 or greater. If the bits were to be placed on a square lattice, 1 Tb/in2 would correspond to a dot period of 25 nm. The specifications for the patterned media geometry and accuracy are determined by the required magnetic switching field distribution of the magnetic bits and the recording head. One of the major contributors to a wider switching field distribution is a variation in island size. From configurations of today's write heads, the shape of the future bits may be rectangular rather than square or round. A bit aspect ratio of 2:1, corresponds to a track pitch of 36 nm and a downtrack bit pitch of 18 nm at 1 Tb/in2.

Because of the tighter distribution of island sizes, e-beam lithographically guided self assembly of PS-b-PMMA is shown to narrow the island size distribution and the magnetic switching fields of patterned magnetic bits over bits patterned by e-beam lithography alone. Self assembly allows the multiplication of the density of the patterns to 1 Tb/in2 or greater. In addition, we show e-beam writing strategies to minimize e-beam write time and exploit the pattern correction of directed self assembly. We also show techniques to address different shape bits. The application of e-beam directed self assembly to fabricating imprint templates and imprinted patterned media is demonstrated at densities up to 1 Tb/in2.

8102-31, Session 6

Advanced holographic methods in EUV interference lithography

B. Terhalle, A. Langner, B. Päivänranta, C. David, Y. Ekinci, Paul Scherrer Institut (Switzerland)

Extreme ultraviolet interference lithography (EUV-IL) has recently been attracting growing interest as a fabrication tool for high-resolution periodic nanostructures due to its various fundamental features, e.g. high throughput, large depth of focus etc [1]. Consequently, the technique has been successfully applied to a variety of nanofabrication problems until now [2].

The most common experimental scheme in EUV-IL involves the illumination of a mask containing several diffraction gratings with a spatially coherent beam in order to overlap first-order diffracted beams at a certain distance from the mask and record the resulting interference pattern in a suitable photoresist. This way, the fabrication of high resolution one- and two-dimensional periodic nanostructures becomes possible. So far however, the existing experimental realizations are mostly limited to rather simple symmetries such as one dimensional line patterns or two-dimensional dot arrays [3].

In this contribution, we extend the above concept and study the generation of more complex pattern geometries using EUV-IL. In particular, we demonstrate the use of five or more interfering beams for the fabrication of sub-100nm quasiperiodic nanostructures. Furthermore, we investigate the generation of complex beam shapes such as EUV-vortices and Bessel beams and discuss potential applications for future use in EUV-IL.

8102-32, Session 6

Fabrication of complex structures with an array of nanopinhole cameras

H. S. Leipner, Martin-Luther-Univ. Halle-Wittenberg (Germany); N. Geyer, Max-Planck-Institut für Mikrostrukturphysik (Germany); F. Syrowatka, H. Cheng, B. Fuhrmann, Martin-Luther-Univ. Halle-Wittenberg (Germany)

There is a big demand of reliable lithographic techniques to produce a wide array of different nanostructures. Colloidal lithography has been proven to produce precise arrays of particles on a broad range of substrates. More complicated nanostructures are required for applications in real-time chemical and biological sensors, based e. g. on the effect of localised surface plasmon resonance. This powerful technique is sensitive to shape, size, interparticle distance, and composition of metallic nanoparticles and the dielectric surrounding. Metallic nanostructures are required for negative refractive index metamaterials as well. In this work, we present a method for the fabrication of ordered arrays of complex structures, which combines colloidal lithography with the principle of a pinhole camera well known in optics. By using atomic beams in high vacuum instead of light, it is possible to overcome the problem of the diffraction limit for small apertures with nanometer dimensions. There are no geometrical or chromatic aberrations, since no refracting elements exist. Limitations exist due to the finite size of the nanopinholes, which lead to a certain blurring of the replica deposited on the substrate. However, compared to focused ion beam technique or electron beam lithography, the method is rather simple and has a broad applicability.

8102-33, Session 6

Synthesis of surface patterned YAG:Ce/TiO2 nanocomposite films as converter layer for white LEDs.

A. Revaux, G. Dantelle, Ecole Polytechnique (France); D. Decanini, A. Haghiri-Gosnet, Ctr. National de la Recherche Scientifique (France); C. Weisbuch, J. Boilot, T. Gacoin, Ecole Polytechnique (France)

Rare-earth doped oxides are well-known for their applications in light emitting devices. In the case of white LEDs, micron-sized YAG:Ce particles are commonly deposited on blue LED chips to produce an additional yellow component. To avoid losses due to backscattering effects, we propose to control separately the down-conversion and the extraction of light instead of using micron size luminescent particles acting simultaneously as both converters and scatterers. Very stable suspensions of luminescent YAG:Ce nanoparticles, with a crystallite size of 25 nm, were synthesized by a glycothermal method at relatively low temperature (300°C). A protected annealing process in a silica matrix, allowed further treatment of these nanoparticles at high temperature without any aggregation and growth and a significant improvement of their optical properties. The obtained colloidal nanoparticles were finally incorporated into a sol-gel matrix of TiO2. Thanks to the relative matching of refractive indexes between TiO2 and YAG, and to the sub-wavelength size of YAG particles, the resulting films are nearly transparent (i.e non scattering). When used as light converters for white LEDs, these films could offer the opportunity to diminish the backscattered light absorption losses. We showed that the surface of these sol-gel TiO2 films can be periodically patterned by soft nano-imprint lithography. The diffraction due to the obtained photonic crystal at the surface offers the opportunity to control the extraction the converted light. We investigate how the angular distribution of the emitted light depends on the chosen geometry.

8102-34, Session 7

Types, characterization, and applications of carbon nanotube grades

K. O. McElrath, Carbon Nanotechnologies, Inc. (United States)

Carbon Nanotubes are a quite complex class of materials. As such, there is no easy way to characterize the many grades available for purchase from scores of companies and distributors. The simplest classification that has found widespread use is single wall or multiwall, SWNT or MWNT. An alternate classification is either fullerene polymer molecules or nanoscale carbon fibers. This paper is concerned with the fullerene polymer sub-class of carbon nanotubes. Fullerene science and technology began in 1985 with the discovery of C60, the molecule officially called buckminsterfullerene by the American Chemical Society, and “buckyballs” by the discoverers.

Fullerene nanotubes are a new class of electrically and thermally conducting polymers that are also useful for structural applications since they are strong, stiff, tough, resilient and durable. Similar to other polymers, they are polydisperse. We use a three level description of structure; primary, secondary and tertiary to describe this polydispersity. At the primary structure level, fullerene nanotubes have diameter, length and number of wall distributions. These three components contribute to the molecular weight distribution of the grade. These primary structural elements influence the character of the secondary structure called ropes or bundles. Similar to traditional semi-crystalline polymers, the fullerene polymers attract each other through van der Waal forces and bundle together. These bundles or ropes can be crystalline or non-crystalline. The arrangement of these bundles in macro dimensions creates the tertiary structure. This paper will illustrate this hierarchical characterization approach for a grade of fullerene nanotubes targeting high electrical conductivity applications.

8102-35, Session 7

The low-threshold nonlinear optical effects in suspensions of dielectric alpha Al2O3 nanoparticles, dispersed in dielectric organic immersion oil.

V. Dzyuba, V. Milichko, Y. N. Kulchin, Institute for Automation and Control Processes (Russian Federation)

This report presents the results of the study the low-threshold nonlinear optical effects in suspensions of dielectric alpha Al2O3 nanoparticles, which are dispersed in dielectric immersion oil. It was found that the refractive index of nanoparticles suspension changes in the weak laser radiation field of visible range (intensity did not exceed 0,2kW/cm2) and it is a function of intensity and frequency of the incident radiation. Nonmonotonic nonlinear additive to the refractive index (nonlinear refraction) was substantiated theoretically and confirmed experimentally as well as additive numerical values were calculated. Maximum absolute value of this nonlinear additive to refractive index was 10-4. The proposed theory of nonlinear optical properties formation in these suspensions of wide-dielectrics nanoparticles presented the results which consistent with experimental results.

We also investigated the transmission spectra of suspensions of nanoparticles in liquid matrices of different chemical composition and the theoretical assumption about the causes of the difference spectra and optical properties of nanoparticles in various matrices was given. The results of these studies could form the basis for a deeper investigation of suspensions of dielectric nanoparticles, both in liquid and in solid dielectric matrices as well as allow for creation of new types of nanostructured materials for electronics and laser optics.

8102-36, Session 7

Enhancement of optical nonlinearity in β-AgVO3 nanobelts by incorporation of Ag nanoparticles

M. R. Parida, C. Vijayan, Indian Institute of Technology Madras (India)

The synthesis of Silver vanadium oxides (SVO) with well-controlled size, morphology, and chemical composition can offer great opportunities for exploring their novel optical properties and for the fabrication of nanodevices. These nanostructures of SVO are synthesized by a simple hydrothermal reaction and characterized by standard techniques. The XRD pattern of the as-prepared β-AgVO3 can be indexed to the phase of β-AgVO3 monoclinic structure. The HRSEM image shows the diameter of the nanobelts to be in the 100-300 nm range with length upto several micron which is also conformed from TEM. The optical nonlinearity is measured by the Z-scan technique using 5 ns pulse of Nd-Yag laser. The results indicate strong nonlinear absorption which is fitted theoretically two photon absorption process followed by saturable absorption process. The values of two photon absorption coefficient and saturation intensity are calulated. Ag nanoparticles are supported on β-AgVO3 synthesis by the same hydrothermal technique by increasing the concentration of silver nitrate in synthesis reaction. The HRSEM and TEM images conform that there is no definitive interface relations between the particles, the branches and the stem. They are separated by grain boundaries. There is an enhancement of optically nonlinearity observed in this system compared to undoped SVO. The values of two photon absorption coefficient and saturation intensity are found to be enhanced that because of surface plasmon effect.

8102-37, Session 7

Effect of nano-particles on the dynamic and thermal characteristics of composite materials

M. Seif, M. A. Abunaemeh, Alabama A&M Univ. (United States)

The effect of the nano-silica fillers and dispersion parameters on the mechanical and thermal properties of graphite/epoxy composite materials have been investigated. The dispersion of nano-particles in epoxy resin is carried out using sonication method. The study summarizes the effect of different nano-silica concentrations on the tensile strength of the Epoxy. Modal analysis has been used to determine the vibration properties and damping parameters. The vibration characteristics of nano-composites have been compared with neat epoxy resin. Moreover, the effects of nano-silica fillers on the thermal conductivity and the glass transition temperature of the epoxy resin have been studied. The results show that nano particles have a direct effect on the thermal conductivity and glass transition temperature of the new composite materials. This will allow the possibility of developing new composite materials that will have certain thermal and dynamic properties for wide applications.

8102-38, Session 7

fabrication of quartz nanoneedles by using Cr thin films as wet etching masks

M. Hung, J. Liou, C. Chang, National Central Univ. (Taiwan)

Quartz crystals are widely used in many engineering fields due to their exceptional piezoelectric, optical, and many other properties. Micro/nano-structured quartz is crucial for miniaturization of quartz devices and many potential MEMS/NEMS applications. The manufacturability for quartz crystals, however, is very limited. Unlike the silicon wet etching that generally has simple etching patterns, the wet etching of quartz crystals results in complex and poor symmetric patterns. Thus,

to fabricate elaborate micro/nanoscale quartz structures is usually not straightforward and requires expensive dry etching processes.

In this manuscript, we present a study of the fabrication of quartz nanoneedles by wet etching. Chromium is evaporated on the Z-cut quartz surface and serves as the etching mask. The deposition process is tuned to certain conditions for Cr atoms to accumulate and form nanosized individual Cr islands. Ammonium bifluoride solutions are used as the etchant. Due to the particular etching anisotropy of quartz crystal orientation, nanoneedles can be formed. By controlling the Cr nanoparticle distributions and etching time, quartz nanoneedles of different sizes are produced. The lengths and shapes of the nanoneedles are observed using scanning electron microscope (SEM) to study the anisotropy of the quartz etching and the mechanism of the needle formation. We have successfully produced very sharp and high aspect ratio nanoneedles with lengths of few micrometers. The growth rate of nanoneedles is found to be increased with the etching time but have a maximum value. The experimental results fit well with our simulated predictions. This study may have potential impacts in quartz MEMS/NEMS.

8102-39, Session 7

An alternative approach to fabricate metal nanoring structures based on nanosphere lithography

Z. A. Lewicka, V. L. Colvin, Rice Univ. (United States)

In this work we present an improved, cost-effective fabrication method for metal ring-shaped nanostructure arrays based on nanosphere lithography. Periodic arrays of symmetric nanorings, non-symmetric nanorings, and nanocrescents with different sizes were fabricated using a simple method that includes self-assembled monolayer formation, plasma treatment and sputter deposition of metal. Lower cost and higher throughput were achieved due to the replacement of focused ion beam milling with reactive ion etching usually used in other methods. The dimensions of ring-like structures could be controlled by the size of the polystyrene spheres, the amount of deposited metal and the argon plasma etching time. These nanostructures may be made of essentially any metal and be used as elements in optoelectronic nanodevices.

8102-40, Session 7

fabrication and optical characterization of nanopore Si

H. Jin, G. L. Liu, Univ. of Illinois at Urbana-Champaign (United States)

Nanopore Si has been applied to demonstrate advantages in various fields such as photovoltaic, biosensing, DNA sequencing, and also particle sorting. The optical and mechanical properties provide enhanced solar conversion efficiency, surface enhanced Raman effects, elongation of DNA, and also blocking of vapor phase molecules. Typical fabrication of nanopores would utilize e-beam lithography followed by DRIE. Focused ion beam may also be utilized. The use of such methods are time consuming in formation of nanopores on a relatively larger area. Another approach would be the use of anodized aluminum oxide (AAO), by applying a voltage to high purity aluminum foil (99.999%) in oxalyic acid. The non-lithographic fabrication method would enable cost effect approach of nanopore fabrication. However, the use of aluminum foil based AAO results in a film that is too thick to transfer the nanopore features to another substrate.

In this paper, the fabrication and the optical properties of nanopore Si is presented. Aluminum is evaporated on the surface of N-type Si by e-beam evaporation. Nanopore structure is formed by a two-step AAO formation in oxalyic acid. Diameter size from 30 to 80 nm is achieved, depending on the condition of anodization and etch. Deep reactive ionic etch (DRIE) is done, with AAO as the mask layer. The nanopore AAO template allows etching depth of up to 700 nm. Parameters that affects the fabrication are evaluated. Optical properties of various pore depth is discussed.

8102-41, Poster Session

Efficient approach for the calculation of transmission and reflection spectra of photonic crystal waveguide devices

R. Chen, Y. Lin, Lunghwa Univ. of Science and Technology (Taiwan)

Photonic crystal (PC) waveguide devices have inspired great interest because of their potential in realizing compact photonic integrated circuits. To design a PC waveguide device, it is important to know its transmission and reflection spectra. Among the various simulation techniques, the finite-difference time-domain (FDTD) method is popularly employed due to its versatility in dealing different structures. However, the traditional approach to calculate the transmission and reflection spectra by the FDTD method is a task of both time and memory demanding. A sizable computational cell must be used and several pulses covering different ranges of frequencies must be sent down the waveguide and the field amplitudes are monitored at two proper locations. The monitored field profiles are then Fourier transformed to obtain the transmission and reflection spectra. In this work, we propose a more efficient approach to obtain these spectra. First, the PC-based absorbing boundary condition proposed by Koshiba is employed instead of the popularly used perfectly matched layer boundary condition. Second, the reflected pulse is obtained by subtracting from a reference input waveform. To demonstrate the effectiveness of this approach, a T-junction in square lattice PC is simulated. A computational cell of only 40 x 36 lattice constants can be used for the proposed approach, compared to 150 x 80 lattice constants for the traditional approach. Accordingly, the simulation time is reduced to only one tenth of that using the traditional approach.

Design of sharp waveguide bends with a wide high-transmission bandwidth in triangular photonic crystal slab

R. Chen, Y. Lin, Y. Lin, Lunghwa Univ. of Science and Technology (Taiwan)

Photonic crystal slabs (PCSs) have received considerable attention due to their potential in high-density photonic integrated circuits. Optical confinement is provided via the photonic bandgap in the plane of periodicity and via refractive index in the vertical direction. By removing one row of air holes, a single-line-defect waveguide can be obtained. Some sharp waveguide bends in PCSs have been proposed but their high-transmission bandwidths were limited. In this work, we design a 60-degree waveguide bend with a wide high-transmission bandwidth (~ 9.8% of the center frequency, or 150 nm at the wavelength of 1550 nm) in a triangular PCS. Within the high-transmission bandwidth, power reflection at the bend is found to be lower than 2% of the input power. Based on this 60-degree bend, a sharp 120-degree bend with a compact device area is proposed. A similar transmission efficiency is also found for this 120-degree bend.

The principle of the proposed sharp bends is as follows. First, the adjacent air holes along the two sides of the single-line-defect waveguide is enlarged such that the waveguide becomes single-mode. Second, a mirror plane is introduced at the bend region to improve the power transmission. This is done by further enlarging three air holes at the bend region and by moving inward one of them such that a photonic crystal mirror plane is formed. Numerical simulation is performed by employing the finite-difference time-domain method and power transmission and reflection spectra are calculated by launching pulses and by Fourier transformation.

Nano and micro structures imaging based on asymmetric Bragg diffraction

A. V. Kuyumchyan, American NanoScience and Advanced Medical Equipment, Inc. (United States); D. A. Kuyumchyan, Riverside Community Colleges (United States); A. Snigirev, I. Snigireva, European Synchrotron Radiation Facility (France); M. V. Grigorev, E. V. Shulakov, Institute of Microelectronics Technology and High Purity Materials (Russian Federation)

We present results of focusing and imaging properties of lens-crystal system for hard x- ray radiation; consisting of such elements as parabolic refractive lens made from beryllium and asymmetric mono crystal from silicon. The beryllium refractive lens has advantages like small absorption, high efficiency and high spatial resolution.

This work demonstrates for the first time a phenomenon of image transmission using the Bragg diffraction of focused x-ray beam from asymmetric mono crystal. For recording the magnification X-ray phase contrast was used asymmetric mono crystal Si (220) with factor asymmetry b=9 at the x-ray energy 17 keV. The experimental investigations have been conducted on the station BM-5, ESRF, France.

The peculiarities of redistribution of intensity are investigated both experimentally and theoretically when the focus of refractive lens is moved across the optical axis. The intensity distribution along the optical axis is also investigated. We elaborate a computer program for theoretical study of image transmission based on lens - crystal system with asymmetric Bragg diffraction. The calculation is based on the use of Kirchhoff propagator in a paraxial approximation and fast Fourier procedure. The intensity map on the plane perpendicular across the optical axis is calculated for any parameters, including the phase shift of the test object.

Fabrication of Multiple Si Nanohole Thin Films from Bulk Wafer by Controlling Metal-Assisted Etching Direction

S. Shiu, T. Lin, K. Pun, H. Syu, S. Hung, C. Lin, National Taiwan Univ. (Taiwan)

Crystalline Si photovoltaic modules still have high production cost due to significant consumption of the Si wafer. Reducing the large amount of Si material consumption is thus a critical issue. Here we develop a two-step metal-assisted etching technique for forming vertically-aligned Si nanohole thin films from bulk Si wafers. The formation of Si nanohole thin films includes a series of solution processes: deposition of Ag nanoparticles in an AgNO3/ HF aqueous solution, formation of Si nanohole arrays at the first-step metal-assisted etching, and side etching of the roots of the nanohole structure at the second-step metal-assisted etching. All the processes can proceed at around room temperature. A Si nanohole thin film with an average hole size of 100 nm and a thickness of 5μm-20 um was hence formed at the top of the wafer. Afterwards, the Si nanohole thin film was transferred onto alien substrates. The Si nanohole thin film has the crystal quality similar to the bulk Si wafer. The above bulk Si substrate can be reused. With similar processes, other Si nanohole thin films can be formed from the above recycled Si wafer. The hole size and thickness are similar. The Si wafers recycled will significantly reduce the material consumption of Si. Thus, such technique is promising for lowering the cost of Si solar cells.

Design and fabrication of 3D dielectrophoretic chip on separating 2-type of bacteria

C. W. Su, Tatung Univ. (Taiwan)

With the improvement of quality of life, people want to have better medical treatment. MEMS technology is applied by biotechnology such as PCR chip, detection chip, separated chip and etc. Biological, chemical, or medical processes involving complex fluids with embedded particles often require preparative separation of particles, cells, or even molecules that are needed for the subsequent procedures.

In this research, the MEMS technologies which is applied to make the 3D electrodes with the 3D electric field. The structure of biochip is consisted of PDMS flow channel, copper electrode and glass. In order to achieve DEP performance, we utilize CFD-ACE+(Computational Fluid Dynamics) to simulate the effect of the sharp electrodes, wide electrodes and narrow electrodes. We deposited 50μm of copper as electrodes on glass and 50μm of PDMS as flow channel. We use the 3D DEP chip to separate yeast cells and aspergillus niger. We succeded in trapping yeast cells at 5Mhz, 10Vpp, and separating the different cells. Compared with typical planar DEP devices, the proposed 3D DEP chip, presents an increased DEP force in the vertical direction. The electric field will become wider than before. Fabrication 3D electrodes on glass can result in lower costs and less time-consumong. The chip we fabricated is demonstrated that the electrodes which is fabricated by MEMS technologies can manipulate the bioparticle. As the result, the trapping or levitation effect can be achieved at a lower voltage and with a reduced heating of the solution.

A model of photoconductivity of porous silicon

L. S. Monastyrsky, B. Sokolovskii, Ivan Franko National Univ. of L'viv (Ukraine)

It is presented a model of the photoconductivity of porous silicon in the conditions of homogeneous generation of photocarriers. By the finite element method it is calculated the stationary photoconductivity and the time evolution of photoconductivity after instantaneous shutdown of light. Dependences of the stationary photoconductivity and relaxation time of photoconductivity on the velocity of surface recombination of nonequilibrium carriers at the surfaces of pores, radius of pores and average distance between them are analyzed. It is shown that increase of the surface recombination velocity leads to decreasing both the value of stationary photoconductivity and the time of photoconductivity relaxation, with at lower values of the distance between the pores these changes being more significant. Decrease of the relaxation time at the expense of changing the surface recombination velocity can reach almost one order of magnitude. The latter occurs in the materials with high level of porosity when the area of pore's surface per unit volume is large. The results of modeling show that peculiarities of the photoconductivity of porous silicon is of interest for manufacturing gas sensors.

Investigation of 0-3 composites for novel capacitors and energy storage

A. Buchsteiner, H. S. Leipner, J. Glenneberg, C. Ehrhardt, M. Zenkner, T. Grossmann, S. Ebbinghaus, H. Beige, Martin-Luther-Univ. Halle-Wittenberg (Germany)

Up to now, rechargeable batteries are mostly used for energy storage purposes.

However, their electrochemical working principle limits the field of application.

Capacitors with very high energy densities are an alternative approach for energy storage. They can be very quickly charged/discharged and have long lifetimes.

We develop novel capacitors on the basis of 0-3 composites, where nanoparticles of perovskites are embedded in a matrix material. Specific organic surfactants of the nanoparticles force their uniform distribution in the matrix.

These new materials combine the electrical advantages of ceramics and glasses/polymers (high permittivities and breakdown voltages) and can easily be processed as thin films.

Engineering of Photonic Crystal Waveguide Defects for Slow Light Applications

V. Janyani, Malaviya National Institute of Technology (India)

In recent years photonic crystal waveguides (PCWs) made of

silica and air holes have provided a new approach for dispersion

compensation and slow light generation, due to the design flexibility obtained by variation in the geometric parameters of the holes and corresponding tailoring of the effective refractive index. For slow light generation, a large value of group index is desirable to slow down the light. At the same time, however, the bandwidth of the range over which the slow light is achieved and the dispersion produced in the signal as a result of slow-down of the pulses of become much significant.

The signal propagates through the ‘defect’ in the PCW which is obtained by removing one linear row of air holes in the hexagonal-lattice photonic crystal. The effect of the rows nearest to this line defect have been found to have much influence on the propagation characteristics of the signal and on the slow light generation process. This paper proposes a new geometry of PCWs, which uses carefully designed elliptical holes in the two rows adjacent to the defect through which the signal propagation takes place. These elliptical holes are shifted along the longitudinal direction in such a way that the arrangement provides a delay-bandwidth product which is significantly higher than that previously reported in literature. The paper discusses the theory behind the design process and the principle of operation, and necessary numerical results are presented to verify the behavior claimed.

Developments of high-sensitive DNA sensors (Keynote Presentation)

N. Ogata, Chitose Institute of Science and Technology (Japan)

Pure DNA which is isolated from Salmon roe has a huge high molecular weight of over billion and can form a strong and uniform film and the double helical structure of DNA has a characteristic feature of intercalation of various optical dyes among stacked layers of nucleic acid bases to enhance optical properties of dyes ,so that applications of DNA as materials are now possible in such areas as photonics, separation process or biomedical materials. Recent research results on DNA-lipid complexes have shown various attractive applications such as E/O or O/E devices, optical memories, switches and sensors1-4. It was reported2 to study on possibility of basic optical characteristics, such as refractive indices, absorbance and fluorescence intensity, and photochromic properties, of spiropyran-doped DNA-cetyltrimethylammonium (CTMA) complex films, which were derived from DNA from Salmon, which showed potential applications to optical switches5, 6. Although DNA-lipid complexes showed promising potentials for optical functional devices such as switching or signal processing devices, their response speeds were relatively slow to apply them to practical uses. It was shown5, 6 that much faster response speed (switching times) could be attained by increasing the excitation light intensity. Thus, applications of DNA photonic devices have been widely studied in the world7-10

The large enhancements of optical properties of the dye-intercalated DNA lead us to apply the dye-intercalated DNA as various sensors with a high sensitivity to detect environmentally toxic gases such as dioxine, NOx or carbon monoxide. This paper retorts on DNA sensors for the further applications of DNA as materials. Also, bio-medical applications of DNA sensors such as alcohol or glucose sensers will be reported.

Novel DNA-cationic lipid complexes and their application as gate dielectrics

L. Cui, Univ. of Connecticut (United States); X. Wei, Case Western Reserve Univ. (United States); L. Zhu, Univ. of Connecticut (United States)

In this study, we report molecular shape and size effects of lipid tails on the mesophase self-assembly of various cationic lipids complexed with double-stranded DNA. The molecular shape of the cationic lipids changes from rod-like (a cyanobiphenyl imidazolium salt) to discotic (a triphenylene imidazolium salt), and finally to cubic [a polyhedral oligomeric silsesquioxane (POSS) imidazolium salt]. An increase in the cross-sectional area of the hydrophobic tails with respect to the hydrophilic imidazolium head induces a negative spontaneous curvature of the cationic lipids. As a result, a morphological change from lamello-columnar phase for the DNA-cyanobiphenyl imidazolium salt (DNA-rod) and DNA-triphenylene imidazolium salt (DNA-disk) complexes to an inverted hexagonal phase for the DNA-POSS imidazolium salt (DNA-cube) complex is observed. The DNA-rod complex has a typical smectic A (SmA) lamellar morphology, while the DNA-disk complex has a double lamello-columnar phase. However, when the lipid tail changes to POSS, an inverted hexagonal morphology is achieved. Their application as the gate dielectrics in transistors will be briefly introduced.

Optical and electrical properties of DNA-CTMA biopolymers in Metal-Biopolymer-Metal photodetectors

B. Zhou, Univ. at Buffalo (United States); S. J. Kim, Univ. of Miami (United States); C. M. Bartsch, E. M. Heckman, F. Ouchen, Air Force Research Lab. (United States); A. N. Cartwright, Univ. at Buffalo (United States)

The application of a DNA biopolymer into an electro-optic device is investigated. Specifically, a complex of DNA with cationic surfactant hexadecyltrimethylammonium chloride (CTMA) is used to obtain organic-soluble DNA material. In order to increase the electrical conductivity of the DNA biopolymer, PEDOT:PSS is added to DNA-CTMA. Optical and electrical conductivity properties of the DNA-CTMA and DNA-CTMA-PEDOT are investigated. CW absorbance and time-resolved photoluminescence of the resulting DNA samples were studied experimentally. Both DNA samples demonstrated absorbance peaks at ~260 nm and photoluminescence at ~470nm. The PEDOT doped DNA polymer shows shorter lifetime (260ps) than the undoped DNA biopolymer; which may be indicative of charge transfer from the DNA-CTMA to the PEDOT in the composite biopolymer. Interestingly, the PL lifetime was observed to decrease in both cases with increasing excitation in an air ambient. Specifically, after excitation with a high power ultrafast (~150fs) UV (266nm) pulse in air, the lifetime decreases dramatically after a few minutes of exposure. This is most likely due to photo-oxidation that results in trap creation on the polymer surface and an increase in the non-radiative recombination. In order to investigate the photoconductivity, metal-biopolymer-metal (MBM) ultraviolet photodetectors with interdigitated electrodes were fabricated. The optical responsivity of these MBM UV photodetectors increased as the electron transport length (the space between the MBM fingers) were decreased to the nano-scale. Prospects for the use of these materials in optical devices will be discussed.

Modeling of stochastic kinetics for process of photochromic dye semi-intercalation into DNA-based polymeric matrix

A. C. Mitus, G. Pawlik, J. Mysliwiec, A. Miniewicz, Wroclaw Univ. of Technology (Poland); J. G. Grote, Air Force Research Lab. (United States)

The semi-intercalation of an azo-dye Disperse Red 1 (DR1) molecule into a biopolymeric material made of deoxyribonucleic acid (DNA) complexed with the cationic surfactant hexadecyltrimethyl-ammonium chloride (CTMA) formulated recently [1,2] has successfully explained the main experimental results [3] of laser dynamic inscription of diffraction gratings: short response time, low diffraction efficiency, single-exponential kinetics and flat wavelength dependence [4]. In this paper we generalize the analytic model of Ref. [1] to account for a more realistic dynamics of DNA-CTMA matrix. To this end we use Monte Carlo method to study the spatial distribution of local voids and calculate void - void correlation functions, which play the central role for the kinetics of photoinduced trans - cis - trans cycles of DR1 dye under the polarized laser light illumination. We formulate a stochastic master equation which generalizes the simple model of Ref. [1]. We also address the topic of non - exponential grating inscription in modeling and in recent experiments. DNA architectures for templated material growth

A. S. Finch, J. Sumner, U.S. Army Research Lab. (United States)

We will present a methodology that allows for the coupling of biology and electronic materials, where double stranded DNA serves as a template for electronic material growth. Self-assembled DNA structures allow for a variety of patterns to be achieved on the nanometer size scale that are difficult to achieve using conventional patterning techniques. Herein, we describe the procedures for the creation of self-assembled DNA nanostructures in aqueous and non-aqueous media, and their subsequent deposition onto substrates of interest. DNA self assembly under non-aqueous conditions has yet to be presented in literature, and is necessary if unwanted oxidation of certain electronic substrates is to be avoided. Solubilization of the DNA in non-aqueous solvents is achieved by replacing charge stabilizing salts with surfactants. Retention of DNA hierarchical structure under both conditions will be presented by observing the structures using AFM imaging, gel electrophoresis, and circular dichroism spectroscopic studies.

Evanescent field excitation of Cy5-conjugated lipid bilayers using optical microcavities

L. M. Freeman, The Univ. of Southern California (United States) and Univ. of California, San Diego (United States); Y. Dayani, S. Li, H. Choi, N. Malmstadt, A. M. Armani, The Univ. of Southern California (United States)

Whispering gallery mode optical microresonators are devices used for performing ultra-sensitive optical detection. Although the majority of the sensor research has been focused on label-free detection strategies for diagnostics, a whispering gallery mode device is ideally suited to perform fluorescent label-based biodetection as well. However, previous research using optical microcavities to excite fluorescent molecules has focused

on cavity quantum electrodynamics applications and fundamental studies of the interactions of large fluorescent nanoparticles with the resonant cavity.

In the present work, a method for forming self-assembled lipid bilayers, a mimic for cell membranes, on a spherical microresonator is developed. Solid-supported lipid bilayers, which are approximately 5nm thick, have been shown to accurately model cell membranes, and researchers use lipid bilayers in combination with fluorescent microscopy when developing theoretical models for the transport of molecules across the cell membrane. The bilayer-nature is verified using both fluorescent resonance energy transfer and fluorescence recovery after photobleaching. The evanescent tail of the microresonator is used to excite a Cy5-conjugated lipid located within the bilayer while the underlying optical device behavior is characterized at 633nm and 980nm. The emission wavelength of the Cy5 dye and the optical performance (Q factor) of the microcavity agree with theoretical predictions.

8103-12, Session 4

Influence of DNA on J-aggregate formation of cyanine dyes

Y. Kawabe, S. Kato, Chitose Institute of Science and Technology (Japan)

DNA plays an important role for the enhancement of luminescence from some organic dyes. On the other hand, interaction of dyes with DNA sometimes stimulates the formation of dye aggregates in solutions and solid films.

Studying the absorption and circular dichroic (CD) spectra for the solutions of PIC coexisting with DNA and polyvinylalcohol in aqueous solutions, we found that J-aggregates of pseudo-isocyanine (PIC) were formed with lower dye concentration than ever. The details of the effects from the dye concentration, the ratio to DNA, and the type of counter ions were investigated and optimized. One example is that J-aggregate peak has the largest magnitude when the molar ratio of DNA base pair/PIC was 1/4. The J-aggregate characteristics were reproduced after fabricating films from the solution, the fact would be important for development of devices.

More than 20 types of water soluble cyanine dyes were studied by the same methods. Most of dyes show aggregates (not always J-aggregates) by interacting with small amount of DNA, and these aggregates dissociated with the addition of excess DNA. Concentration dependences of photoluminescence intensity and CD spectra suggest that the optical characteristics are strongly influenced by molecular size. Mechanism of dye-DNA interactions will be discussed.

Photodegradation of melanin thin films by UV lithography

C. W. Farley III, A. Kassu, A. Sharma, Alabama A&M Univ. (United States)

Effect of ambient humidity on the photodegradation of melanin is investigated using an interferometric technique to fabricate gratings on thin films. A low power 355 nm diode laser is used to fabricate gratings on melanin thin films, while a 1 mW He-Ne laser is used to probe grating formation. Effects at several different UV intensities, ranging from 1 mW to 30 mW, and ambient humidities, ranging from 15% to 98%, are investigated on melanin thin films of two different thicknesses; 22 nm and 40nm. It is found that humidity has a significant effect on the rate of photodegradation of melanin. It is also found that existing gratings on melanin thin films can be enhanced by raising ambient humidity. These results have implications in the biological evolution of many mammals; as well as implications in fabrication and effective lifetime of organic electronics. The interferometric technique used shows great promise for fabricating grating to analyze photodegradation of different biomolecules under varying conditions. A simple mathematical model is also developed to help explain the contribution of light intensity and ambient humidity to the photodegradation of melanin.

Studies of charge transport in DNA films using the time-of-flight (TOF) technique (Keynote Presentation)

P. P. Yaney, T. Gorman, Univ. of Dayton (United States); F. Ouchen, J. G. Grote, Air Force Research Lab. (United States)

Measurements were carried out on a variety of DNA-based films, including as-received DNA (molecular weight, MW>1000 kDa), DNA with MW<1000 kDa and DNA doped with conductive additives. The test specimens were spin-coated or drop-cast films on ITO-coated quartz slides with a gold charge-collecting electrode. To protect the films from atmospheric influences, the TOF devices were coated with a ~200 nm polyurethane passivation layer. A quadrupled 10 ns, pulsed Nd:YAG laser with output at 266 nm was used for charge injection. The photoconductive responses ranged from mildly to strongly dispersive with hole mobilities in DNA materials films ranging between 7E-6 to 7E-5 cm2/V-s.

Bio-dielectrics based on DNA-Ceramic hybrid films for potential energy storage applications

N. Venkat, Univ. of Dayton Research Institute (United States); D. Joyce, F. Ouchen, Air Force Research Lab. (United States); P. P. Yaney, Univ. of Dayton (United States); K. M. Singh, Air Force Research Lab. (United States); T. Miller, UES, Inc. (United States); S. R. Smith, Univ. of Dayton Research Institute (United States); J.

G. Grote, R. R. Naik, Air Force Research Lab. (United States)

The potential of DNA-based dielectrics for energy storage applications was explored via the incorporation of high dielectric constant (ε) ceramics such as TiO2 and BaTiO3 in the DNA bio-polymer. The DNA-Ceramic hybrid films were fabricated from stable suspensions of the nanoparticles in aqueous DNA solutions. Dielectric characterization revealed that the incorporation of TiO2 (rutile) in DNA resulted in enhanced dielectric constant and decreased dielectric loss factor (tan δ) relative to DNA in the entire frequency range of 1 kHz-1 MHz. Variable temperature dielectric measurements, in the 20-80°C range, of both DNA-TiO2 and DNA-BaTiO3 films revealed that the ceramic additive stabilizes DNA against large temperature-dependent variations in both ε and tan δ. The bulk resistivity of the DNA-Ceramic hybrid films in the case of both TiO2 and BaTiO3 additives was measured to be two to three orders of magnitude higher than that of the control DNA films, indicating their potential for utilization as insulating dielectrics in capacitor applications. Results based on a comparison of the temperature-dependent dielectric behavior of DNA and DNA-CTMA complex films as well as their frequency-dependent polarization behavior are also discussed.

Effective bio-imaging using two-photon absorbing nanoparticles

K. Lee, Hannam Univ. (Korea, Republic of)

This presentation discusses the synthesis and use of nanoparticles with two-photon absorption for bioimaging. We present the synthesis of two-photon chromophores capable of forming fluorescent nanoparticle in the aggregated state. These chromophores are further complexed with materials like polysiloxane and phospholipids to aid their transport to and penetration of tumor cells. Derivatives of 4-bis(cyanostyryl)benzene (CSB)-based quadrupolar isomeric molecules (a- and b-CSB-TPs) were designed to produce enhancement in fluorescence quantum yield and two-photon absorption cross-sections for the nanoaggregate form. This and other two-photo absorbing materials were successfully incorporated in hyperbranched polysiloxysilane (HBPS) materials containing terminal carboxylic acid and quaternary ammonium groups. These polymers exhibited desirable characteristics, including amphiphilicity for nanoparticle formation, and contained various terminal groups for surface-charge control on the nanoparticles or for further bioconjugation for targeted imaging. Aggregation induced fluorescence was further observed in polymeric nanomicelles The fluorescent nanomicelles have two unique features: (1) It gives much brighter fluorescence emission than mono-fluorophore. (2) The biocompatible nanomicelles with amphiphilic copolymers [e.g., phospholipids-PEG (polyethylene glycol)] make the encapsulated fluorophores more stable in various bio-environments and easier for further conjugation with bio-molecules. After chemical and optical characterizations, these fluorescent nanomicelles are utilized as efficient optical probes for in vivo sentinel lymph node (SLN) mapping of mice.

Two-photon absorbing chromophores for photodynamic therapy: molecular engineering and in vivo applications

C. Monnereau, Univ. de Nantes (France); P. Lanoë, Univ. de Rennes 1 (France); T. Gallavardin, O. Maury, C. Andraud, Ecole Normale Supérieure de Lyon (France)

Photodynamic therapy (PDT) is a therapeutic approach based on the light induced production of cytotoxic molecular singlet oxygen, through irradiation of a photosentisizer near a tumoral tissue. In recent years, it has been used with success in the treatment of certain cancers and gliomas at their early stages ; however, it suffers from one major limitation that hinders a more widespread use in cancer therapy : due to biological absorption and scattering of the incident light, it is impossible to efficiently activate a conventional photosentisizer through more than few millimeters of tissue, making non-invasive deep tissue and organ therapy practically impossible.

Two-photon activation of the sensitizers, using lasers with wavelengths around 800-900 nm could be a very advantageous strategy to overcome these limitations. This range of wavelengths corresponds to the domain of transparency of human tissues, which would allow deeper penetration of the light. Another advantage is the highly confocal character of two-photon excitation, leading to very localized sensitizer activation, which is ideal to avoid undesirable damages of healthy tissues in the tumor's surroundings.

In spite of all its promises, two-photons PDT is still in its infancy, and practical issues now have to be addressed:

1/ Relatively few two-photon chromophoric structures that can efficiently sensitize singlet oxygen have been reported so far. Thus, we believe that molecular engineering has to be performed, with an accent put on the establishment of structure/ properties relationships

2/ Two photons chromophores require a large conjugated carbon backbone, which makes them very hydrophobic compounds : chemical modification have therefore to be carried out, in order to allow their dispatching within the physiological medium, and cellular up-take.

These two aspects will be discussed in our presentation. The first part will deal with recent results in our group concerning the structural optimization of chromophores for two-photon induced dynamic therapy. The second part will focus on new "cargo" systems that we have recently developed, owe to a general strategy recently established in the group.1

All optical switching in a photochromic dye-doped biopolymeric matrix

J. Mysliwiec, A. Malak, J. Sikora, A. Miniewicz, Wroclaw Univ. of Technology (Poland); I. Rau, Polytechnical Univ. of Bucharest (Romania); F. Kajzar, Polytechnical Univ. of Bucharest (Romania) and Univ. of Angers (France)

All optical switching has been studied using the Optical Kerr Effect (OKE) configuration in a biopolymer matrix containing a photochromic molecule. The biopolymer system consisted of a deoxyribonucleic acid blended with cationic surfactant molecule cetyltrimethyl-ammonium chloride suitable for optical quality thin film fabrication. The excitation beams inducing birefringence were delivered from a continuous wave lasers at 473 and 532 nm and chopped using a variable frequency chopper. Additionally auxiliary nanosecond pulses coming from Nd:YAG laser were used. The birefringence was instantaneously monitored by a weak non-absorbed light from a cw He-Ne laser working at 632.8 nm under crossed polarizer system. An excellent switching times in the range

of microseconds and full reversibility of the studied processes have been observed.

8103-24, Session 6

Tunable dye lasers based on DNA-surfactant-dye complexes

T. Chida, Y. Kawabe, Chitose Institute of Science and Technology (Japan)

There have been several studies of laser action from dyes incorporated into deoxyribonucleic acid (DNA) complexes, because fluorescence was strongly enhanced by molecular isolation due to the intercalation or binding to the double helix structure of DNA. We have already demonstrated the amplified spontaneous emission (ASE) and laser action from several dyes, such as a hemicyanine, (4-[4-(dimethylamino) styryl]-1-dococylpyridnium bromide) or several types of cyanines doped in DNA-surfactant films.

In this presentation, we will show recent achievements on DNA dye lasers. First, we succeeded to generate tunable laser emissions from solutions including the hemicyanine and DNA- cetyltrimetylammonium (CTMA) complex in a Littrow type cavity. The concentration of the dye and DNA-CTMA, and also the ratio of both were optimized (about 1.0 x 10 3 mol/l for the dye and DNA-CTMA 20 times concentrated), obtaining the laser emission in the range about 600 ~ 630 nm under the pumping by a green nano-second pulsed laser. The conversion efficiency was 3 % and their beam divergence was 0.016 rad.

We also succeeded to prepare DNA laser medium by using another method, by which dye complex was prepared by immersing the DNA-CTMA into aqueous solution of the dye, resulting in dyed DNA polymers. We employed eosin Y which is a water soluble xanthene compound, and observed ASE emission from fabricated films.

An Investigation on films used for chemcial and biological sensors

M. J. Curley, A. K. Chilvery, T. V. Kukhtareva, C. W. Farley, Alabama A&M Univ. (United States)

Bioterrorism as well as the use of explosive devices have been a key threat not only in Iraq and Afghanistan but also on the southern border of the United States. Biosensors as well as chemical sensors are mandatory in the field of sensing the existence of detrimental gases like methyl isocyanides, sensing the presence of bacteria's like anthrax and detecting the presence of explosives like RDX, TNT's etc. These biosensors combined with a low power lasers for remote sensing should be able to be used for biological and chemical detection. In this paper we also mentioned the importance of study of micro-organisms in the synthesis of nanomaterials is a possible viable alternative to the more popular physical and chemical methods currently in use. We shall discus the development of green and energy saving technologies in materials synthesis, environmentally caring nanoparticle synthesis processes that do not use toxic chemicals. Optimizing the characteristics and fabrication of biosensors with different nanoparticles for selective and sensitive detection will be performed. Testing using the method of Stimulated Emission Raman Scattering (SERS), FTIR, SEM and AFM measurements in our laboratories shall be disclosed. We have also investigated the presence of two photon compounds and Rhodamine B to determine if the prototype sensor will amplify the signals of biological agents as well as explosives. The results in this paper are promising in developing a Chemical and Biological sensors for the use in the Department of Defense, USDA and commercial applications.

Synthesized nanomaterials based on extracellular soluble fungal poliketide

N. Radu, Institutul National de Cercetare (Romania); M. Ferdes, Polytechnical Univ. of Bucharest (Romania); C. Corobea, D. Donescu, Institutul National de Cercetare (Romania); I. Rau, Polytechnical Univ. of Bucharest (Romania)

Monascorubrin obtained in submerged media of different fungal strain from Monascaceae family can be used as biomaterials, in order to obtain nanoproducts with therapeutic properties. In this respect, using soluble monascorubrin obtained in submerged media and isopropylmiristate as conditioning agent, nanodispersions was obtained, with dimensions under 100 nm (determined by dynamic light scattering). The first preclinical tests performed on the main raw materials revealed that these nanodispersions could be used as adjuvant in skin disorders having an important role in tissular reparation in case of derma lesions.

8103-27, Poster Session

Characterization of some nanamaterials based on insoluble fungal poliketide

N. Radu, Institutul National de Cercetare (Romania); M. Ferdes, Polytechnical Univ. of Bucharest (Romania); C. Corobea, D. Donescu, Institutul National de Cercetare (Romania); I. Rau, Polytechnical Univ. of Bucharest (Romania)

Biopigments obtained in solid state biosynthesis was used as raw materials in order to obtain bioproducts used in the dermatology treatment. The main formulation was nanomaterials with dimensions under 60 nm according to dynamic light scattering measurements. The new nanoproducts which contain three biopigments biosynthesized on rice were characterised by fluorescence diffraction, FT-IR and mass spectrum, and the results indicate the presence in the nanoproduct of main poliketide based on monascorubrin and monascorubramin.

In this paper the main results concerning characterisation and possible applications of these new nanoproducts will be presented and discussed.

Conference 8104: Nanostructured Thin Films IV

Nanostructured Thin Films IV

8104-01, Session

Green nanotechnology (Keynote Presentation)

G. B. Smith, Univ. of Technology, Sydney (Australia)

Nanotechnology, in particular nanophotonics, is proving essential to achieving green outcomes of sustainability and renewable energy supply at the scales needed. Coatings, composites and polymeric structures used in windows, roof and wall coatings, energy storage, insulation and other components in energy efficient buildings will increasingly involve nanostructure, as will solar cells. Nanostructures have the potential to revolutionize thermoelectric power and hence solar thermal power, and may one day provide efficient refrigerant free cooling.

Nanomaterials enable us to optimize optical, opto-electrical and thermal responses to this urgent task. Optically harmonization of material responses to environmental energy flows involves two aspects, large changes in spectral response over limited wavelength bands and tailoring responses to environmental dynamics. The latter includes engineering angle of incidence dependencies and switchable (i.e chromogenic) responses. Nanomaterials can be made at sufficient scale and low enough cost to be both economic and to have a high impact on a short time scale. Issues that must be addressed however include human safety, plus property changes induced during manufacture, handling and use outdoors. Some unexpected multiple bonus' have arisen in this work, for example the savings and environmental benefits of cool roofs are manifold and extend beyond the more obvious benefit of substantial reduced heat flows from the roof into the building.

8104-02, Session 1

Surface multiplasmonics

A. Lakhtakia, The Pennsylvania State Univ. (United States)

Surface plasmon-polariton waves are guided by planar interfaces of metals and homogeneous dielectric materials. At a give frequency, only one SPP wave is possible. If the dielectric material is periodically nonhomogeneous in the thickness direction, multiple SPP waves are possible, leading to exciting possiblities for optical sensing and solar cells.

8104-03, Session 1

Broad band plasmonic superabsorption and anti-reflection

K. Kempa, Boston College (United States)

Collective resonances, plasmons, of conducting electrons in structured metals can dramatically enhance light transmission and trapping. The effective medium, metamaterial approach is a convenient framework for guiding studies of such systems. We have demonstrated earlier how the plasmonics of the Escheric and Babinet series of metallic, planar structures, can benefit from this approach. The talk will briefly review the relevant background, but will focus on the superabsorber action of such structures. In particular, we demonstrate that ultra-thin semiconducting layers, sandwiched between thin structured metallic layers nearly perfectly absorb, in a wide frequency band, when one of the metallic layers is a checkerboard. We show, that while microscopically this effect is a result of a resonant coupling between surface plasmons of the various interfaces, the exceptionally broad-band response is a result of the metamaterial action of this self-Babinet structure. We also show, how a broad-band anti-reflection action can be achieved by employing ITO coated, Escheric structures near the percolation threshold.

8104-04, Session 1

High-throughput nanofabrication of plasmonic structures and metamaterials with high resolution nanostencil lithography

S. Aksu, A. A. Yanik, R. Adato, A. A. Artar, M. Huang, H. Altug, Boston Univ. (United States)

In this talk, we will demonstrate a novel fabrication approach for high-throughput fabrication of engineered infrared plasmonic antenna arrays and metamaterials with high resolution nanostencil lithography (NSL)1. NSL technique, relying on deposition of materials through a shadow mask, offers the flexibility and the resolution to fabricate radiatively engineered nanoantenna arrays for excitation of collective plasmonic resonances. Spectral measurements and electron microscopy images faithfully confirm the feasibility of NSL technique for large area patterning of nanorod antenna arrays, plasmonic dimers (such as bowties) and metamaterials with high resolution that is achievable by electron-beam lithography. Furthermore, we show nanostencils can be reused multiple times to fabricate same structures with identical optical responses repeatedly and reliability. This capability is particularly useful when high-throughput replication of the optimized nanoparticle arrays is desired. In addition to its high-throughput capability, NSL permits fabrication of devices on surfaces that are difficult to work with electron/ion beam techniques. Nanostencil lithography is a resist free process thus allows the transfer of the nanopatterns to any planar substrate whether it is conductive, insulating or magnetic. As proof of the versatility of the NSL technique, we show fabrication of plasmonic structures and metametarials in a variety of designs on traditional and unconventional substrates. High-resolution Nanostencil Lithography enables plasmonic substrates and metamaterials supporting spectrally narrow far-field resonances with enhanced near-field intensities. Overlapping these collective plasmonic resonances with molecular specific absorption bands can enable ultrasensitive vibrational spectroscopy2. We will also present our recent results on spectroscopic identification of proteins with antenna arrays fabricated by nanostencil lithography.

8104-05, Session 1

Spatiotemporal-photothermal and photoacoustic conversions with local plasmon resonators

K. Namura, M. Suzuki, K. Nakajima, K. Kimura, Kyoto Univ. (Japan)

Recently, we demonstrated the self-assembly of Au nanoparticles/ structured dielectric layer/ Ag mirror sandwiches, namely, the local plasmon resonator, by using a dynamic oblique deposition technique1. Due to strong interference, their optical absorption can be controlled between 0.1% and 100% by changing the thickness of the dielectric layer. Now we notice that photothermal conversion efficiency can be spatiotemporally tuned by using the local plasmon resonators. This work is the feasibility study of their application to the spatiotemporally controlled nanoheaters.

We prepared local plasmon resonator chips on a single substrate by oblique deposition and measured the absorption spectrum on each element. In order to evaluate the heat generation from the chips, we measured the temperature of the water, with which a small cell created

on a chip was filled, irradiating the laser of the wavelength of 785 nm. Photoacoustic measurement was also done on the chip, irradiated with the laser, of which intensity was modulated sinusoidally.

The local plasmon resonator with high absorption heats up the water on itself higher and generates stronger photoacoustic signal than that with low absorption. Furthermore, the photoacoustic signal from the local plasmon resonators with high absorption is stronger than that from an Ag thin film by two orders of magnitude between 50 kHz and 100 kHz. These results suggest that heat generation from the Au nanoparticle layer can be spatiotemporally controlled by the interference and incident light intensity.

Monitoring the reactivity of Ag nanoparticles for different atmospheres by using in situ and real time optical spectroscopy

V. V. Antad, L. Simonot, D. Babonneau, S. Camelio, F. Pailloux, P. Guérin, Univ. de Poitiers (France)

Surface differential reflectance spectroscopy (SDRS), an optical characterization technique, is sensitive enough to observe the minute changes in surface plasmon resonance (SPR) of noble metal nanoparticles (NPs), which is a collective oscillation of the electrons owing to their interactions with electromagnetic radiations, causing sharp absorption of light in the visible range. This SPR is extremely sensitive not only to the morphology and organization of the noble metal NPs but also to the chemical atmosphere surrounding them.

Hence, taking SPR as a signature phenomenon in the Ag NPs, we have studied their reactivity for different gases and their ions using an optical mean. For this purpose, a dedicated in-situ SDRS set-up has been mounted on a magnetron sputtering machine, with which real time optical characterizations were possible not only during the deposition of Ag NPs but also during their exposure to gases such as O2, N2, Ar, either non-ionized or partially ionized.

This optical study reveals the reactivity of Ag NPs with non-ionized O2 in the form of changes in the SPR characteristics (width, amplitude and position of the absorption band) in contrast to N2 and Ar. Moreover, this study also elaborates the increased reactivity of Ag NPs due to the partially ionized gases where, on one hand, complete disappearance of the SPR can be seen in case of O2(+) and on the other hand, increased reactivity in Ag NPs can be seen for the N2(+) gas, whereas Ar remains non-reactive in both forms.

8104-07, Session 1

Surface plasmon resonance of super-periodic metal nano-slits structures

H. Leong, J. Guo, R. G. Lindquist, The Univ. of Alabama in Huntsville (United States)

We investigate surface plasmon resonance in super-periodic metal nano-slits arrays. A super-periodic metal nano-slits array consists of periodic metal nano-slits and periodic defects in the nano-slits array. Our simulation and experimental results show that spectral peaks measured in the zeroth order transmission and the first order diffraction reveal the surface plasmon resonances in the super-periodic metal nano-slits structure. The resonance wavelength can be tuned accordingly by adjusting the nano-slits period or the super-period of the device. The new metal nanostructure device functions as a resonant optical diffraction grating and can be used for integrated nano-fluidic surface plasmon sensors.

8104-08, Session 2

Nanostructure effects and the performance of optical interference coatings

O. Stenzel, U. Schulz, N. Kaiser, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

The theory of “classical” optical interference coatings is based on assumptions like ideal homogeneity and isotropy of the materials, as well as absolutely smooth and infinitesimally thin interfaces between the individual coating materials. Within the framework of these assumptions, there exists an elaborated theoretical apparatus for solving design and characterization tasks for optical coatings. At the same time, coating deposition techniques have been perfected in order to match with the requirements of homogeneity and smoothness of these coatings in practice.

Remaining discrepancies between the theoretically predicted and practically achieved coating performance can - at least partially - be attributed to the violation of the above-mentioned ideal assumptions. But a closer look on this matter reveals a more differentiated picture: Nanostructure effects can be tackled as additional degrees of freedom for coating design, and can lead to useful property combinations that are inaccessible to “classical” coatings prepared on the basis of the traditionally available coating materials.

This presentation deals with practical examples, where explicit violations of the usually assumed perfect homogeneity and smoothness of the coatings have resulted in novel and innovative coating material properties or coating designs. Examples include:

- Effects of noble metal islands embedded in semiconductor films: applications in photovoltaics

- Antireflection effects of nanostructured surfaces: motheye-structures

- Effects of nanoporosity in oxide films on refractive index, thermal shift and mechanical stress: balanced coating properties

The examples demonstrate the possible benefits of the exploitation of nanostructure-caused effects in interference coating science and technology.

8104-09, Session 2

Using a single anisotropic thin film as a phase retarder for oblique incident wave

Y. Jen, S. Wang, C. Lin, M. Lin, National Taipei Univ. of Technology (Taiwan)

This work presents a wide angle phase retarder by using a single anisotropic Ta2O5 columnar thin film. The single anisotropic Ta2O5 columnar thin film can provide phase retardation between p-polarization and s-polarization to modulate the polarization state of light reflected from the prism-coupling system (BK7 prism/anisotropic thin film/air). In experiment, glancing angle deposition technique is used to prepare single layer film of Ta2O5 tilted nanorod array with thickness 270nm. In this analysis, we use wave tracing based on the Berreman calculus to calculate the variations of reflection coefficient, transmission coefficient on the interface and the variations of phases of ordinary and extraordinary waves in the anisotropic thin film when the electromagnetic wave is incident to the prism-coupling system. The phase retardation is observed about δ=100°(±5°) over the angle ranged from 61° to 75° and the wavelength ranged from 630nm to 680nm. A linearly polarized incident ray can be reflected as a specific elliptical polarized ray uniformly over the region. In addition, the phase retardation is varied smoothly over the designated range when the deposition plate is rotated from 90° to 45° with respect to the plane of incidence.

8104-10, Session 2

Quenched transmission of light through ultrathin metal films

N. A. Mortensen, S. Xiao, Technical Univ. of Denmark (Denmark)

It is well known that the transmission of light is prominent for an ultrathin metal film with the thickness comparable to its optical penetration depth. When the film is periodically modulated by subwavelength apertures, intuitively one expects that the ultrathin film could transmit even more light since less material is blocking the light. To much surprise, it was recently predicted by means of analytical and numerical calculations that the transmission can nevertheless be totally suppressed. This nontrivial phenomenon is opposite to the widely known extraordinary optical transmission of light through periodically modulated optical thick metal films, which was first reported by Ebbesen et al. Subsequently, the quenched transmission of light through ultrathin films pierced with periodic arrays of subwavelength apertures was experimentally demonstrated. In this paper, we experimentally demonstrate quenched transmission of light through ultrathin films when the films are periodically structured. We used E-beam lithography technology to fabricate the devices and free-space measurement setup to characterize them. The measured results show the transmission is significantly suppressed, which is an opposite phenomenon as compared with the extraordinary optical transmission of the light through the film when perforated by the subwavelength holes. We emphasize that the measurement demonstrates less light transmitted through the gold disks array. The physics behind it is also discussed and it turns out that this abnormal phenomenon is ascribed to the surface plasmon resonance effect.

8104-11, Session 2

Optical properties of UT-shaped plasmonic nanoaperture antennas

M. Turkmen, S. Aksu, A. E. Cetin, A. A. Yanik, H. Altug, Boston Univ. (United States)

The subject of light transmission through optically thin metal films perforated with arrays of subwavelength nanoholes has recently attracted significant attention [1]. In this talk, we will present numerical and experimental results on optical properties of a multi-resonant UT-shaped plasmonic nanoaperture antenna for enhanced optical transmission and near-field resolution. We will propose different structure designs in order to prove the effect of geometry on resonance spectrum and near-field enhancement. Theoretical calculations of transmission spectra and field distributions of UT-shaped nano-apertures are performed by using three-dimensional finite-difference time-domain method [2]. The results of these numerical calculations show that transmission through the apertures is indeed concentrated in the gap region. In addition to theoretical calculations, we also performed a lift-off free plasmonic device fabrication technique based on positive resist electron beam lithography (EBL) and reactive ion etching in order to fabricate UT-shaped nanostructures. For further confirmation of the multi-resonant behavior, we checked the individual U-and T-shaped nano-aperture antenna responses. We also studied the parameter dependence of the structure to determine the control mechanism of the spectral response. Theoretical calculations are supported with experimental results to prove the enhanced field distribution and multi-resonant behavior which can be suitable for infrared detection of biomolecules, wavelength-tunable filters, optical modulators, and ultrafast switching devices.

8104-12, Session 2

Optical birefringence in a bideposited nanorod array with symmetric and periodic structure

Y. Jen, C. Yu, M. Lin, C. Lin, National Taipei Univ. of Technology (Taiwan)

A new kind of nanorod array grown with two orthogonal bideposited directions is fabricated and measured its birefringence optical property. The Ta2O5 nanorod arrays composed of several subdeposits are fabricated by serial bideposition (SBD) technique. Each nanorod consists of several identical units and each unit consists of symmetrical sections ABA. The deposition planes for section A and section B are perpendicular to each other. The bideposited symmetric nanorod arrays can be equivalent to a homogeneous layer of the equivalent refractive index and phase thickness. For normal incident ray, the polarization-dependent refractive indices and phase thicknesses of the film are presented as functions of wavelength and optical constants of each layer. The transmittance spectra of symmetrical sections have a pass band property as the equivalent refractive indices are real. With each subideposition thickness of 5 nm, samples bideposited at flux angles 65°, 70°, 75° and 80° are prepared. The principal indices associated with the two orthogonal polarizations are measured by ellipsometer. According to principal indices database, a phase retardation between the two orthogonal polarization directions can be designed for a specific wavelength. In order to apply the multilayered structure in changing the polarization state, a match layer is designed and arranged in the layered system to reduce the difference between the two orthogonal polarization transmissions.

8104-13, Session 3

Effective properties of metamaterials

C. Rockstuhl, C. Menzel, T. Paul, E. Pshenay-Severin, M. Falkner, C. Helgert, A. Chipouline, T. Pertsch, Friedrich-Schiller-Univ. Jena (Germany); W. Smigaj, J. Yang, P. Lalanne, Univ. Bordeaux 1 (France); F. Lederer, Friedrich-Schiller-Univ. Jena (Germany)

Optical properties of nanostructured thin films, i.e. metamaterials, are usually linked to the assignment of an effective permittivity and permeability and, if polarization conversion occurs, chirality. To consider the underlying constitutive relations as valid, it is required that only weak spatial dispersion occurs. At operational frequencies of optical metamaterials close to resonance this assumption ceases to be valid. In consequence, a description using effective material properties tends to be inadequate and new approaches are required. We outline here our latest achievements along this direction and discuss two approaches.

The first assumes that if effective properties are pointless since they explicitly depend on the frequency and the incidence angle, a more primary source of information is sufficient to quantify metamaterials, i.e. the polarization resolved complex transmission and reflection; leading to a characterization of metamaterials in terms of Jones matrices. We discuss the implications of such description and show that all metamaterials can be categorized into five classes only, each supporting distinguishing properties which we disclose. Experimental results of measured complex Jones matrices of three-dimensional metamaterials underline the applicability of this approach.

The second approach resorts to an effective description but restricts its consideration entirely on a dispersion relation, characterizing the propagation of light in bulk metamaterials, and an impedance, characterizing the coupling of light into and from metamaterials to their surroundings. Feasible definitions of both properties linked to a single Bloch mode are discussed and metamaterials are introduced which can be homogenized while considering only the properties of this single mode.

8104-14, Session 3

On dipole emission from an infiltrated chiral sculptured thin film

S. S. Jamaian, T. G. Mackay, The Univ. of Edinburgh (United Kingdom)

This study was motivated by the prospect of harnessing chiral sculptured thin films (CSTFs) as optical sensors based on chemiluminescent emission. A dipole source positioned inside a CSTF was considered. The void regions of the CSTF were filled with a fluid of refractive index greater than unity. The theory describing the emitted field far from the dipole source was developed, using a spectral Green function formalism. A combination of inverse and forward homogenization techniques were used to estimate the relative permittivity parameters of the infiltrated CSTF. This involved the extended Bruggeman homogenization formalism, which accommodates constituent particles that are small compared to wavelength but not vanishingly small. Our numerical studies, based upon a titanium oxide CSTF, revealed that left circularly polarized (LCP) light was preferentially emitted through one face of the CSTF while right circularly polarized (RCP) light was preferentially emitted through the opposite face, at wavelengths within the Bragg regime. A red shift in the centre wavelength for the preferential emission of LCP/RCP light took place as the refractive index of the infiltrating fluid increased from unity. Furthermore, this red shift was accentuated when the size of the constituent particles in the homogenization model was increased. In addition, as the refractive index of the infiltrating fluid increased from unity, the bandwidth of the preferential LCP/RCP emission regime was observed to decrease.

8104-15, Session 3

Homogenization of metallic metamaterials and electrostatic resonances

D. Felbacq, Univ. Montpellier 2 (France); F. Zolla, Institut Fresnel (France); B. Guizal, Univ. Montpellier 2 (France)

It has been noted that the usual approaches for homogenization (e.g. Bruggeman) could lead to singularities when considering composites comprising materials with positive and negative permittivities. This situation is specifically encountered in the field of metamaterials, in particular in the visible range. The question then arises to unerstand if these resonances are just artifacts or possess, on the contrary, a clear physical meaning.

In this work, we study the homogeneous properties of a bidimensional structure that is made of a periodic set of metallic wires embedded in a dielectric host medium. The structure is considered in a region of wavelengths that are much larger than the period of the structure. The work comprises a theoretical part where we develop a two-scale approach to the homogenization of the structure. As it is the case for the common physical approach, it leads to an effective permittivity with strong (electrostatic) resonances as well. The theoretical results, and the presence of resonances, are confirmed by numerical computations based on a rigorous modal approach. In the numerical results we consider specifically the case of silver and gold nanowires, described by a dispersive negative permittivity. We show that the main parameters for the onset of resonances is the optical filling ratio of the structure. Keeping in mind the possibility of performing experiments, it is far easier to keep the geometrical filling ratio constant and to consider strongly dispersive materials in the range of wavelengths considered. Here, besides the crucial fact that they are widely used in nanotechnology, silver and gold nanowires comply with our needs in the visible region of the spectrum.

8104-16, Session 4

Engineering the optical response of hybrid plasmonic systems: fano resonances and applications for sensing

A. Farhang, B. Gallinet, O. J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

We study the optical response of hybrid plasmonic systems composed of nanoparticles in strong interaction with a thin film. While the latter supports propagating surface plasmon-polaritons, the former supports localized plasmon resonances. Engineering the coupling between these two families of modes produces extremely sharp optical resonances - so-called Fano resonances - characterized by narrow spectral features and a very strong near-field enhancement. Furthermore, these features can be easily tuned by changing the geometry of the system: materials, film thickness, spacing between particles and film, or the shape of the particles. We show that it is possible to a large extent to determine a priori the spectral response of the coupled system, by analyzing the spectral responses of its individual components (i.e. the infinite film and the localized particles), in particular their modal overlap in the optical density of states space. With this approach, we design specific structures where individual particles, dipole antennas, or more complex arrangements of metallic nanoparticles are coupled to a metallic thin film. A conventional e-beam lithography followed by lift-off is used for their fabrication. Hybrid plasmonic systems prove extremely efficient for sensing: the strongly localized near-field associated with Fano resonances makes them very responsive to their environment and significantly enhances the figure of merit for sensing, when compared to individual structures such as isolated thin films or isolated nanoparticles.

Metamaterial and nanoplasmonic toolkit for spectroscopy and biosensing

H. Altug, Boston Univ. (United States)

No abstract available.

8104-18, Session 4

3D characterization of a TiO2-based photoanode for solar cells

G. Divitini, Univ. of Cambridge (United Kingdom); A. Li Bassi, Politecnico di Milano (Italy); F. Di Fonzo, Instituto Italiano di Tecnologia (Italy); C. S. Casari, V. Russo, Politecnico di Milano (Italy); X. Peng, C. Ducati, Univ. of Cambridge (United Kingdom)

The performance of dye-sensitized (DSSC) and hybrid solar cells crucially depends on the structure of the photoanodes on the micro- and nano-scale. Transmission electron microscopy (TEM) is a good candidate for investigating such length scales, but the limitation of conventional TEM to extract only bi-dimensional information hinders our ability to have a full understanding of the three-dimensional structure and properties. We instead apply advanced TEM techniques to characterize a photoanode prototype, combining high resolution crystallographic studies with three-dimensional information obtained from dark field electron tomography. In this work we present the study of a TiO2-based photoanode where the titania layer has been produced via pulsed laser deposition. We employed a dual beam FIB (FEI Helios Nanolab) to prepare a cross-section of a polymer heterojunction solar cell based on said photoanode and acquired a tilt series in a FEI Tecnai F20 (200 kV acceleration voltage). The photoanode TiO2 layer is composed by small (10-20 nm) crystalline particles assembled in columnar aggregates, which constitute a forest-like film with high porosity. Such a hierarchical structure combines a large surface area with good electrical transport properties, leading to promising performance. The characterization provided information on

surfaces and interfaces of the nanocrystalline titania, as well as a view of the fine scale cell architecture after the infiltration of the polymer hole transporter.

8104-19, Session 4

Antireflective Nanostructured Thin Films and Their Applications in Solar Cells

J. He, National Taiwan Univ. (Taiwan)

It is of current interest to develop the antireflection (AR) coatings with nanowire arrays (NWAs) since the ability to suppress the reflection over a broad range of wavelengths and incident angles plays an important role in the performance of optoelectronic devices, such as photodetectors, light-emitting diodes, optical components, or photovoltaic systems. Superior AR characteristics of NWAs, including polarization-insensitivity, omnidirectionality, and broadband working ranges are demonstrated in this study. These advantages are mainly attributed to the subwavelength dimensions of the NWAs, which make the nanostructures behave like an effective homogeneous medium with continuous gradient of refraction index, significantly reducing the reflection through destructive interferences. The relation between the geometrical configurations of NWAs and the AR characteristics is discussed. We also demonstrated their applications in solar cells. This report paves the way to optimize the nanostructured optoelectronic devices with efficient light management by controlling structure profile of nanostructures.

8104-20, Session 4

Microspot surface enhanced fluorescence biosensing from sculptured thin films

A. Karabchevsky, Ben-Gurion Univ. of the Negev (Israel); C. Khare, B. Rauschenbach, Leibniz-Institut für Oberflächenmodifizierung e.V. (Germany); I. Abdulhalim, Ben-Gurion Univ. of the Negev (Israel)

Nano-sculptured thin films (STF) are prepared by the glancing angle deposition technique and take different forms of nano columnar structures. Varieties of STFs are investigated to find the optimum structure for biosensing based on the surface enhanced fluourescence (SEF). Comparative study is presented from STFs containing variety of nano structures different in their shape, height (h), tilt angle with respect to the surface ( ), thickness (d), arrangement, etc. The highest enhacement factor of the fluorescent signal is found for Ag based STFs on Si(100) giving an enhancement factor of x71, where h=400nm, d=75nm, =23o relative to Ag closed film using fluorescent dye Rhodamine 123. Based on this a demonstration of an E-coli bacteria sensor and fluorescent antibody sensors are presented. Bound antibody to the thiol self assembly monolayer on sample surface is then quantified by means of the fluorescent signal. Upon excitation of the fluorophore by Hg source light, a CCD camera with a controlled exposure time detects the pattern of fluorescent antibody/E-coli bacteria colonies on the STF surface. A fiber optic holder attached to the microscope allowed quantitative measurement of the fluorescence spectrum on a microspot.

8104-21, Session 5

Intimate effects of surface functionalization on biosensing performances with porous silicon microcavities

C. Gergely, L. Massif, M. Martin, E. Estephan, M. Saab, Univ. Montpellier 2 (France); C. Larroque, Univ. Montpellier 1 (France); V. Agarwal, Univ. Autónoma del Estado de Morelos (Mexico); F. Cuisinier, Univ. Montpellier 1 (France)

We study the effect of different surface functionalization methods on the sensing performances of porous silicon (PSi) microcavities when used for detection of various biomolecules. Previous research on porous silicon demonstrated versatility of these devices for sensor applications based on their photonic responses. The interface between biological molecules and the Si semiconductor surface is a key issue for improving biomolecular recognition in these devices.

PSi microcavities were fabricated to reveal reflectivity pass-band spectra in the visible and near-infrared domain. To assure uniform infiltration of proteins the number of layers of Bragg mirrors was limited to five, the first layer being of high porosity. In one approach the devices were thermally oxidized and functionalized to assure covalent binding of molecules. Secondly, the as etched PSi surface was modified with adhesion peptides isolated via phage display technology and presenting high binding capacity for Si. Functionalization and molecular binding events were monitored via reflectometric interference spectra as shifts in the resonance peaks of the cavity structure due to changes in the refractive index when a biomolecule is attached to the large internal surface of PSi. Improved sensitivity is obtained due to the peptide interface linkers between the PSi and biological molecules compared to the silanized devices. We investigate the formation of peptide-Si interface layer via vibrational FTIR spectroscopy, X-ray photoelectron spectroscopy and atomic force microscopy. When monitored via fluorescence and biphoton microscopy we observe that PSi microcavity structures strongly confine and localize light emission resulting in enhanced photoluminescence of the infiltrated molecules.

8104-22, Session 5

Infiltration of Fe3O4-nanoparticles into porous silicon with respect to magnetic interactions

P. Granitzer, K. Rumpf, Karl-Franzens-Univ. Graz (Austria); K. Ali, M. Reissner, G. Hilscher, Technische Univ. Wien (Austria); L. Cabrera, P. Morales, Consejo Superior de Investigaciones Científicas (Spain); P. Poelt, T. Uusimäki, M. Sezen, M. Albu, Technische Univ. Graz (Austria)

Mesoporous silicon (PS) is used as matrix for infiltration of Fe3O4 nanoparticles (5 and 8 nm). The structure and magnetic behaviour of such composites are investigated and a correlation between the morphology of the nanocomposite (structure of the matrices, size and distribution of Fe3O4 particles) and the magnetic properties of the system is figured out. Magnetic exchange interaction is excluded due to capping of the particles. This system shows a superparamagnetic (SPM) behaviour at room temperature and becomes ferromagnetic (FM) at lower temperatures. The transition temperature between SPM and a blocked state depends on the particle size, their coating and on their magnetic interactions. Dipolar coupling between the particles can be influenced by varying the PS morphology as well as by the filling factor. The blocking temperature (TB) of the composite is tunable and changes due to the variation of dipolar coupling of the Fe3O4-particles (distance between particles). To gain deeper information about the stoichiometric homogeneity and spatial distribution, dual electron energy loss spectroscopy is employed. This method provides areal and volumetric densities of each element over the investigated area. Electron tomography, a method to get full 3D characterization in the nanometer scale, is utilized whereas from reconstructions various parameters of the composite morphology can be obtained (size and spatial distribution of the particles and dependence of the local curvature of the pore walls with respect to the preferred docking site). These results together with the magnetic data lead to a more detailed knowledge of the Fe3O4/silicon nanocomposite system.

8104-23, Session 5

Controlled skeletal progenitor cell migration on nanostructured porous silicon/silicon micropatterns

V. Torres-Costa, V. Sánchez-Vaquero, Á. Muñoz-Noval, M. J. Pérez-Roldán, E. Punzón-Quijorna, D. Gallach, L. González-Méndez, Univ. Autónoma de Madrid (Spain); A. Valsesia, G. Ceccone, European Commission Joint Research Ctr. (Italy); M. Manso-Silván, G. Martínez-Muñoz, Univ. Autónoma de Madrid (Spain); F. Rossi, European Commission Joint Research Ctr (Italy); A. Climent-Font, J. P. García-Ruiz, R. J. Martín-Palma, Univ. Autónoma de Madrid (Spain)

Nanostructured porous silicon (nanoPS) shows photoluminescence and wide-scale adaptable wettability as a result of its particular surface morphology and chemistry. These properties can be simultaneously exploited for the preparation of surface micropatterns to mimic cellular function. Surface patterns of nanoPS and Si can be engineered through high-energy ion-beam irradiation and subsequent anodization. Human skeletal progenitor cells are sensitive to one- and two-dimensional patterns and focal adhesion is inhibited on nanoPS areas. In spite of this anti-fouling characteristics, studies on patterns with reduced Si areas show that cells conform to nanoPS pathways favoring migration through cell protrusion, body translocation and tail retraction from two parallel Si traction rails. Moreover, migration can be blocked and cells tend to arrange when grid patterns with the appropriate dimensions are fabricated. The experimental results confirm that progenitor cells are able to exploit nanoPS anti-fouling designs by adapting to it for migration purposes.

8104-24, Session 5

Nanostructured porous silicon dioxide films as substrate for on-chip visible light photonic devices

C. W. Gladden, M. Gharghi, Univ. of California, Berkeley (United States); J. G. Valentine, Vanderbilt Univ. (United States); X. Zhang, Univ. of California, Berkeley (United States)

A variety of photonic devices are available at telecom wavelengths, implemented using on-chip silicon (n= 3.5) waveguides where silicon oxide (n=1.5) can serve as a lower index substrate with sufficient contrast. However, waveguides made of materials suitable for visible light (e.g. silicon nitride n=1.9) can become lossy on top of oxide especially when the mode index is reduced by confinement. A Si-photonics compatible low index substrate can enable realization of on-chip photonic devices in the visible range.

We have developed a porous silicon dioxide substrate with exceptionally small pore sizes and low solid filling fraction. The index can be less than 1.2 while maintaining less than 2nm RMS surface roughness over thicknesses up to 10 micron. The films are generated by electrochemical etching of silicon in acid/organic solution. Thickness, porosity, and pore size can be controlled by adjusting voltage, time, and solvent concentration. To obtain filling fractions as low as 15% we repeatedly oxidize and chemically remove the surface layer of silicon inside the porous network. Finally, the substrates are fully oxidized at high temperature to convert the remaining silicon network into silicon dioxide.

The smoothness and small pore size enables subsequent fabrication of devices on the substrate with very little interface scattering. While other low index geometries (such as aerogel and nanowire) have limited functionality due to surface roughness and processing, our easy to fabricate, fully Si-photonics and bio compatible substrates allow implementation of chip level visible wavelength devices such as single mode waveguides or transformation optics.

8104-25, Session 5

Investigation of the interfaces of a metal/porous silicon nanocomposite and its influence on the physical properties

K. Rumpf, P. Granitzer, Karl-Franzens-Univ. Graz (Austria); K. Ali, M. Reissner, G. Hilscher, Technische Univ. Wien (Austria); P. Poelt, M. Albu, Technische Univ. Graz (Austria)

Metal-nanostructures are electrochemically deposited within the pores of porous silicon to achieve a hybrid material with specific magnetic properties. The metal structures can be precipitated with various geometries and different spatial distributions depending on an accurate control of the deposition conditions. This method allows to deposit structures as spheres, ellipsoids or wires with a size up to a few micrometers whereas the diameter corresponds to the pore-diameter. Furthermore small Ni-particles between 3 and 6 nm can be deposited in a densely packed arrangement on the pore walls forming a quasi metal tube. Analysis of this tube-like arrangement by transmission electron microscopy shows that the distribution of the Ni-particles is quite narrow, which means that the distance between the particles is smaller than 10 nm. Such a close arrangement of the Ni-particles assures magnetic interactions between them. Due to their size these small Ni-particles are superparamagnetic but dipolar coupling between them results in a ferromagnetic behaviour of the whole system. Moreover, to investigate the interface in more detail electron energy loss spectroscopy is employed, whereas in using multiple linear least square fitting procedure, EELS fine structure and absolute edge energy information can be added to map the oxygen bounded in different phases (SiOx, metal-oxide). Magnetic measurements show an anisotropy between easy axis and hard axis magnetization which corresponds to the behaviour of a metal tube. This composite is an interesting candidate for integrable magnetic and magneto-optic devices and also for spin-injection from a ferromagnetic metal into silicon.

Nanostructured Lu2O3:Eu3+ phosphor thin film

N. V. Babayevskaya, A. S. Bezkrovnyi, P. V. Mateychenko, O. M. Vovk, R. P. Yavetskiy, Institute for Single Crystals (Ukraine)

Nowadays oxide scintillating films are considered as promising materials for digital medical imaging. Lu2O3:Eu3+ is an inorganic scintillator which was introduced as one of the most perspective material for X-ray detectors due to excellent scintillation properties, chemical stability as well as high light conversion efficiency (approximately 80 % of CsI:Tl). To obtain thin films of high optical quality possessing spatial resolution in the submicron range the uniform, smooth phosphor layers free from pores and cracks are necessary. Different methods are known to produce close-packed thin films [1]. Sol-gel technology is one of the most promising approaches to obtain nanostructured, transparent films with controlled thickness and homogeneous distribution of activator in the phosphor lattice [2,3]. The aim of this study is to obtain and characterize nanostructured Lu2O3:Eu3+ films with submicron thickness.

Simple sol-gel method has been used to fabricate homogeneous, transparent Lu2O3:Eu3+ (Eu3+=5 at. %) films with thickness in the 200-1200 nm range (1 - 6 layers) on sapphire substrates. The film morphology and structure has been studied by atomic force microscopy, scanning and transmission electron microscopy. The formation conditions of homogeneous films with average crystallite size of 10-50 nm have been determined. The luminescent properties of Lu2O3:Eu3+ films depending on annealing temperature and their thickness have been studied.

A double positive thin film comprising silver-pillar arrays at visible wavelengths

C. Yu, Y. Jen, J. Jhou, W. Wang, National Taipei Univ. of Technology (Taiwan)

A thin film comprising silver-pillar arrays is deposited on a glass substrate by continuously rotating the substrate about its normal via glancing angle deposition. During deposition the rotation speed and the deposition rate are kept at 10 rpm and 1 nm/s, respectively. The deposition angle of 89 degree with respect to the substrate normal is chosen due to the fact that the lager deposition angle results in the higher porosity of the film. Here we use the effective-medium theory to investigate the magnetic responses in a pair of silver pillars. The simulated result shows that the conduct and displacement currents are induced as the applied electric field is perpendicular to the major axis of the pillar at normal incidence. A larger overlapping of the length of the pillars causes a stronger magnetic field, leading to the larger positive real part of the equivalent permeability of the film. Walk-off and polarization interferometers are employed in measuring the transmission and reflection coefficients of a 230nm-thick silver-pillar arrays film with a diameter of 175 nm in the visible regime. Experiment result shows its real parts of the equivalent permeability and permittivity are 2.441 and 0.846 at a wavelength of 639 nm, respectively. Together with our previous study, it is possible to grow metamaterials covering the whole quadrant in the permittivity-permeability diagram at visible wavelengths.

8104-42, Poster Session

Tungsten nanostructured thin films obtained via HFCVD

O. Goiz Amaro, Ctr. de Investigacion y de Estudios Avanzados del IPN (Mexico); F. Chávez, P. Zaca-Moran, G. J. Ortega, G. F. Pérez, N. Morales, Benemérita Univ. Autónoma de Puebla (Mexico); C. F. Mendoza, Instituto Politécnico Nacional (Mexico); R. Peña, Ctr. de Investigacion y de Estudios Avanzados del IPN (Mexico)

By using the Hot Filament Chemical Vapor Deposition (HFCVD) technique tungsten thin films were deposited on both amorphous quartz and silicon substrates. To achieve this, a tungsten filament was heated at 1500 oC during one hour maintaining a constant pressure of 460 mTorr. The whole process was carried out into a quartz tube. Besides the filament temperature, and substrate temperature were determinant in the deposition of the tungsten. The latter was established at 750 oC in order to cover the substrate by a 200 nm tungsten thin film. The thin films were characterized by means of Scanning Electron Microscope, Atomic Force Microscope and X-Ray Diffraction. SEM micrographs revealed that the films have no more than 200 nm in thickness while XRD show evidence of the films crystallize in the (alfa)-tungsten modification. On the other hand, AFM shows a uniform surface composed with semi-spherical shapes whose diameters are below than 200 nm. To the naked eye, the as-deposited films exhibit a highly mirror-like appearance.

8104-43, Poster Session

Study on magnetic metamaterials of aluminum nanostructures in the visible range

Y. Jen, W. Wang, C. Yu, National Taipei Univ. of Technology (Taiwan)

In this work, the optical properties of pillar arrays of metal-dielectric-metal nanostructures are investigated. Based on the finite-difference time-domain (FDTD) simulation, the magnetic field reversal is observed due to the fact that the phases of the electric fields oscillating in the top and the bottom pillars are in the opposite directions. The anti-phase electric fields are coupled in the dielectric layer and the equivalent permeability of the film is negative. Compared with the dielectric pillar sandwiched by the Ag pillars, the aluminum(Al)-dielectric-aluminum(Al) film has a good transmission property because of its low absorption and large real part of dielectric constant at the short wavelengths. Whereas Ag pillar exhibits transverse plasmon mode around the wavelength of 350 nm, Al has the dipolar plasmon resonance at the wavelength of 250 nm. Moreover, the simulation result shows the strong magnetic field reversal in Al-SiO2-Al nanostructures of diameters 175 nm is induced at the wavelengths from 400 nm to 600 nm. The thicknesses about the structure are 100 nm for Al and 70 nm for SiO2 of the film is 270 nm. The blue-shift of the inverse magnetic intensity occurs as the diameters of the pillars decrease from 175 nm to 150 nm. Such the films provide a good candidate for achieving optical magnetic metamaterials in the visible regime.

Anisotropic optical property of an asymmetric bidepostion TiO2 film: fabrication and measurement

Y. Jen, C. Lin, T. Yu, C. Lai, National Taipei Univ. of Technology (Taiwan)

To develop diverse anisotropic thin films, asymmetric bideposition technique is introduced to fabricate tilt columnar TiO2 films with biaxial optical property. The asymmetric bideposition is achieved using two different opposite deposition angles (α+,α-) at the same pitch thickness or two different pitch thicknesses (d+,d-) at the same two opposite deposition angles. The two sets of TiO2 columnar thin films associated with deposited subdeposits (d+,d-)=(20,10) and (30,10) are prepared at the opposite deposition angles (α+,α-)=(70,-40), (70,-50), (80,-40), and (80,-50). Columnar thin films with various column angle and biaxial properties are measured their planar birefringence and three principal indexes. The larger column angle leads to lower planar birefringence and principal indices. Experimental result indicates that an anisotropic thin film deposited at (α+, α-)=(80,-50) with deposited subdeposits (d+, d-)=(30,10) could be applied in a prism coupling system (BK7 prism/ TiO2 anisotropic thin film/air) to have enhanced polarization conversion reflectance (PCR). As the film thickness is 887 nm, there is over 60% of PCR detected at the incident angle ranged from 55 degree to 75 degree.

The nanostructure and morphology of biodegradable PLLA films with DBS nanofibrils

W. Lai, Tamkang Univ. (Taiwan)

The morphologies and nanostructures of neat 1,3:2,4-dibenzylidene-D-sorbitol (DBS) and DBS/poly(L-lactic acid) (PLLA) films have been investigated by polarizing optical microscopy (POM) and scanning electron microscopy (SEM). The morphology of neat DBS samples prepared from solution had unspecific structures, and no fibrils formed. In comparison, DBS molecules self-assembled into fibrils with diameters ranging from 100 nm to 1 μm when samples were prepared from the melt. The DBS fibrils were also found in DBS/PLLA systems, but the average diameter was only around 20 nm. The DBS architectures could be well tuned by varying the DBS contents and PLLA crystallization temperatures. Micron-sized fibrillar rings or disks due to the aggregation of DBS nanofibrils were found using SEM in samples with DBS contents more than 3 wt% and crystallized above 120 oC. Meanwhile, “concentric-circled” PLLA spherulites were observed by POM. The DBS nanofibrils largely formed at the circles, but some nanofibrils formed beyond the circles and were dispersed in the PLLA spherulites. These dispersed nanofibrils affected the orientation of PLLA lamellae and caused a change in birefringence, yet the growth rate of PLLA was not

significantly influenced by the formation of DBS nanofibrils. In addition, porous PLLA structures could be obtained by solvent extraction of the DBS nanofibrils.

Effect of solar radiation on photovoltaic characteristics of Si-P3HT core-shell nanowire solar cells

S. Tsai, Nntionai Taiwan Univ. (Taiwan); H. Chang, C. Lin, H. Wang, J. He, National Taiwan Univ. (Taiwan)

We report an hybrid inorganic-organic solar cells (HSCs) fabricated by regioregular poly(3-hexylthiophene) (P3HT) on the n-type silicon (n-Si) nanowire arrays (NWAs). P3HT tends to order at n-Si NWAs under simulated sunlight, leading to a remarkable enhancement of power conversion efficiency (η) from 0.96% to 2.31% and broadband external quantum efficiency (EQE) values under AM 1.5G illumination for 90 minutes because of the core-shell structure (shown in fig. 1). The efficiency enhancement under simulated sunlight results from the increase in open-circuit voltage (Voc), short-circuit current density (Jsc) and fill factor (FF) due to the improved crystallinity of P3HT further characterized by absorption, external quantum efficiency (EQE), and Raman measurements.

Nanowire arrays with controlled structure profiles for maximizing optical collection efficiency

H. Chang, K. Lai, Y. Dai, H. Wang, C. Lin, J. He, National Taiwan Univ. (Taiwan)

The Nanowire array (NWA) layers with controlled structure profiles fabricated by maskless galvanic wet etching on Si substrates are found to exhibit extremely low specular reflectance (< 0.1 %) in the wavelengths of 200-850 nm. The significantly suppressed reflection is accompanied with other favorable antireflection (AR) properties, including omnidirectionality and polarization-insensitivity. The NWA layers are also effective in suppressing the undesired diffuse reflection. These excellent AR performances benefit from the rough interfaces between air/NWA layers and NWA layers/substrate and the decreased nanowire densities, providing the gradient of effective refractive indices. The Raman intensities of Si NWAs were enhanced by up to 400 times as compared with the signal of the polished Si, confirming that the NWA layers enhance both insertion and extraction efficiencies of light. This study provides an insight into the interaction between light and nanostrucutres, and should contribute to the structural optimization of various optoelectronic devices.

Three methods of fabricating controlled Si nanowire arrays by self-assembling templates and etching for broadband and omnidirectional antireflection

H. Wang, K. Tsai, K. Lai, Y. Lin, Y. Wang, J. He, National Taiwan Univ. (Taiwan)

Ordered arrays of silicon nanowires have attracted great attentions because their unique properties and many potential applications in renewable energy technologies. However, it remains a challenge to fabricate such an ordered array with large scale, well-controlled and periodicity less than 100 nm (diameters less than 60 nm). Here, we demonstrate three methods for the fabrication of large scale ordered silicon nanorwires arrays using reactive ion etching (RIE) or metal-assisted chemical etching though colloidal lithography or anodic aluminum oxide (AAO) templates. Si NWAs with desirable diameters could be obtained by shrinking the sizes of colloidal lithography or the pore sizes of AAO templates. The porous anodic alumina membrane with self-organized ordering is employed as the mask for the high-throughput patterning formation of hexagonal-close-packed hole array. Ordered arrays of silicon nanowires with 100 nm in periodicity (50 nm in diameter) can be cost-effectively fabricated. The reflection can be eliminated effectively over broadband regions by controlled NWAs; i.e., the wavelength-averaged total reflectance is decreased to 10.0 % at the wavelengths of 200-850 nm. The resulting nanostructures might have great potential applications in photovoltaics.

Polarization anisotropy of oblique-aligned ZnO nanowire arrays

C. Chen, National Taiwan Univ. (Taiwan); J. Huang, National Cheng Kung Univ. (Taiwan); K. Lai, National Taiwan Univ. (Taiwan); Y. Jen, National Taipei Univ. of Technology (Taiwan); C. Liu, National Cheng Kung Univ. (Taiwan); J. He, National Taiwan Univ. (Taiwan)

We demonstrated that a combined method of modified oblique-angle deposition and hydrothermal growth to grow a novel photonic metamaterial based on single crystalline ZnO nanowire arrays (NWAs) with highly oblique angles (75o - 85o), exhibiting large artificial in-plane birefringence and optical polarization degree in emission. The giant in-plane birefringence (0.11), exceeding by a factor of 10 that of natural quartz. The strong optical anisotropic in emission due to the optical confinement was observed. Unlike the conventional oblique-angle-deposited thin films, the NWAs also showed light emitting ability, leading us to conclude that the oblique-aligned NWAs not only could be applied in passive photonic components, such as optical waveplates and optical isolators, but also can open up important technological applications in polarized light sensing and emission devices.

Properties of RF sputtered ZnO thin films under different oxygen flux

Z. Guo, Shanghai Univ. (China)

The microstructures, optical, and mechanical properties of zinc oxide (ZnO) thin films deposited on glass substrates by rf magnetron sputtering were studied. Microstructures were examined using atomic force microscopy (AFM) and X-ray diffraction (XRD), respectively. Optical property was measured by photoluminescence spectrum. The mechanical properties were measured by nanoindentation. The crystalline structures of ZnO thin films are well ordered with high c-axis (002) orientations and the crystallinity is strongly affected by O2 flux. Surface morphologies of ZnO thin films are smooth and grains grow and distribute uniformly. The hardness and Young's modulus of ZnO thin films are ranged from 8.2 to 10.4 GPa and 105 to 120 GPa, respectively.

The stability of carbon nanostructures in silicon oxycarbide materials

J. V. Ryan, Pacific Northwest National Lab. (United States); P. Kroll, The Univ. of Texas at Arlington (United States); C. G. Pantano, The Pennsylvania State Univ. (United States); V. Shutthanandan, Pacific Northwest National Lab. (United States)

Silicon oxycarbide (SiOC) is a metastable material that has generated interest because of the great flexibility in properties that is attainable with a change in carbon-to-oxygen ratio. These materials have exhibited a strong propensity to include carbon-carbon - "free carbon" - bonding within the structure regardless of synthesis method, although the relative amounts can be controlled to some degree. Despite strong experimental evidence for the presence of this phase as nanostructures, models of the composite system have had difficulty producing a stable structure bonded to the matrix. Characterization techniques sensitive to ordered bonding in the length scale of roughly 0.5 to 5nm such as fluctuation electron microscopy (FEM), Raman spectroscopy, and nuclear magnetic resonance along with compositional studies by x-ray photoelectron spectroscopy and nuclear reaction analysis were used to produce a new view of the structural role of carbon in SiOC materials. Through coupling of these experimental approaches with molecular dynamics modeling, a new theory on the stability of these nanostructures is presented here.

8104-27, Session 6

Tunable Stoichiometry of BCxNy Thin-Films through Multi-Target PLD with In situ Ellipsometry

J. G. Jones, R. Jakubiak, A. R. Waite, L. Sun, Air Force Research Lab. (United States); M. Lange, Air Force Institute of Technology (United States); N. R. Murphy, Air Force Research Lab. (United States)

Much interest has been shown in Boron Carbon Nitride, BCxNy, with B4C, C, and BN each individually having unique properties: B4C - high hardness and stability, C - high thermal conductivity and electrical semi-conductivity, and BN - insulating with high band gap. Using these bulk materials in conjunction with pulsed laser deposition (PLD) provides stoichiometric material transfer from each laser target material to substrate surface, which when combined with multiple targets and a programmable mirror system provides tunability of the stoichiometry of the resulting thin-film. Initial laser pulses onto a target material create island growth that coalesces into a uniform film above a thickness threshold of a few nanometers. In situ ellipsometry allows determination of optical properties of a thin-film during growth including the real component of the index of refraction (n) and the extinction coefficient (k), which when coupled with a model provides for a real-time virtual measurement of thickness during deposition. Ellipsometry can be used to detect the transition of island growth to uniform film growth, but after the film becomes opaque no more optical variations can be detected. Two 5cm diameter targets, one graphite and one boron-nitride, were rotated inside a UHV deposition chamber evacuated to a base pressure below 0.1 mPa, while a Lambda Physik 248nm excimer laser was triggered in a synchronized fashion with a high speed galvanometer mirror system thereby delivering a programmable number of 250mJ 20nsec duration pulses on each target. Results presented will include stoichiometry of the thin-films measured with XPS.

Study on the structure and optical properties of plasma-polymerized ZrNxCyOz thin films

H. Jiang, L. Sun, General Dynamics Information Technology (United States); J. T. Grant, Univ. of Dayton Research Institute (United States); A. Reed, Air Force Research Lab. (United States); W. Su, General Dynamics Information Technology (United States); R. Jakubiak, Air Force Research Lab. (United States)

A modified room temperature PECVD process was used to prepare plasma-polymerized (PP-)ZrNCO thin films, using tetrakis(diethylamido) Zr (IV) (TEDAZ) as a precursor. The structure and optical properties of the films were characterized by XPS, FT-IR, Raman, AFM, SEM, UV-Vis and spectroscopic ellipsometry. The preliminary results show that although there is no oxygen components in the monomer or carrier gases (N2 and Ar), due to the residual moisture and oxygen in reaction areas, the resulting PP-ZrNxCyOz films contained a certain amount of oxygen, from 15 to 30 atm%, depending upon the processing conditions. Additionally, the refractive index of the films does not scale proportionately with metal atom concentration as has been observed for PP - ferrocene, titanium isopropoxide and tetraphenyl lead. This suggests that morphological features that affect the film density such as microvoids have significant influence on the optical properties of the films. Further studies include a systemic investigation of the titanium analogue of TEDAZ to elucidate structure-property relationships that will have import when both organo-metallic precursors undergo co-polymerization to form broadband, UV protective coatings.

8104-29, Session 6

An investigation on magnetic responses in Ag-SiO2-Ag nanosandwich structures

Y. Jen, J. Jhou, C. Yu, National Taipei Univ. of Technology (Taiwan)

In this work, we investigate magnetic responses in various Ag-SiO2-Ag nanosandwich structures at visible wavelengths. The two electric resonant modes corresponding to the in-phase (symmetric) and anti-phase (asymmetric) electric dipole on the top and the bottom nanopillars are observed by the finite difference time domain (FDTD) simulation. In the asymmetric resonant mode, the phases of electric fields oscillating in the top and bottom pillars have opposite directions, leading to a virtual current loop that induces the magnetic field reversal. The nanosandwich structure produces a large enhancement of the magnetic field as the thickness of SiO2 nanopillar decreases. By increasing the diameter of nanopillars from 125 nm to 160 nm, the inverse magnetic response wavelength shifts from 550 nm to 650 nm. On account of the magnetic field reversal caused by the anti-phase electric dipole coupling, the real part of the equivalent permeability of the film is negative. Therefore, the wavelength range associated with the intensity of inverse magnetic response is tunable by varying the size of Ag-SiO2-Ag nanosandwich structure. The analysis can be applied to interpret extraordinary optical properties such as negative index of refraction from an Ag-SiO2-Ag sandwich array prepared by glancing angle deposition.

8104-30, Session 7

Sculptured thin films: nanorods, nanopipes, nanosmiles

D. Gall, Rensselaer Polytechnic Institute (United States)

Atomic shadowing during physical vapor deposition causes exacerbated growth of surface protrusions and leads to a chaotic 3D layer growth, which can result in the development of well-separated nanorods, nanosprings, or nanopipes, which are surprisingly regular and have potential applications ranging from fuel cell electrodes and pressure sensors to self-lubricating coatings and nanoactuation. Glancing angle deposition (GLAD) causes particularly strong atomic shadowing and can be used to systematically investigate the effect of shadowing on the morphological evolution. These extremely rough layers cannot be described as a chaotic perturbation from a flat surface. However, using a model which describes them as a nanorod array with an average rod width that follows power law scaling results in experimental curves where all metals converge on a single master curve which exhibits a discontinuity at 20% of the melting point, associated with a transition from a 2D to a 3D island growth mode, and a single homologous activation energy of 2.46 for surface diffusion on curved nanorod growth fronts, which is applicable to all metals at all temperatures. Also, under extreme shadowing conditions, the conventional structure zone model is simplified as there is a direct transition from an underdense (zone I) to a dense (zone III) structure at ~50% of the melting point.

8104-31, Session 7

Electrophoretic deposition of Cu-In composite nanoparticle thin films for fabrication of CuInSe2 solar cells

B. Liu, W. Guo, K. Hagedorn, IMRA America, Inc. (United States)

Electrophoretic deposition (EPD) is traditionally used in ceramic industry for coating micron-sized ceramic particles. In this work, we applied EPD to metal nanoparticles in liquid solvents and successfully produced thin films of Cu-In composite nanoparticles. The nanoparticles were produced with pulsed laser ablation in the same liquid solvents. Pulsed laser ablation has recently been recognized as a promising method for producing high purity nanoparticles. We first demonstrated femtosecond pulsed laser ablation production of nanoparticles of various metals including elemental Cu, In, Ga, Se and their binary alloys and compounds. We found that the overall composition was preserved during laser ablation, which provided means of compositional control for thin film applications. The colloids were stable against agglomeration without stabilizing chemicals, and the mechanisms were explained based on charging of nanoparticle surfaces via electrochemical interaction with ambient solvents. We also found that the surface charge density was sufficient to enable migration of the nanoparticles in solvents under an electric field. The success of EPD of metal nanoparticles was explained based on charge transfer between the nanoparticle surfaces and the electrode. With atmospheric pressure annealing in selenium vapor, we have produced polycrystalline CuInSe2 films, and effective solar cell structures have also been made. The whole process was performed in non-vacuum ambient conditions, and can also be applied to flexible substrates such as metal foils. These results open up a new route of non-vacuum fabrication of thin film CuInGaSe2 solar cells.

8104-32, Session 7

X-ray absorption fine-structure and optical studies of AlZnO nano-thin films grown on sapphire by pulsed laser deposition

Y. Lan, Z. Wei, M. H. Wang, Z. R. Jiang, National Taiwan Univ. (Taiwan); S. P. Liu, National Chung Hsing Univ. (Taiwan); J. Chen, National Synchrotron Radiation Research Ctr. (Taiwan); R. Horng, D. Wuu, National Chung Hsing Univ. (Taiwan); Z. C. Feng, National Taiwan Univ. (Taiwan)

Al-doped ZnO can replace tin-doped indium oxide (ITO) as a transparent conductive oxide (TCO) for optoelectronic applications. We investigated nanometer scale AlZnO thin films on sapphire from pulsed laser deposition (PLD) in 350-650°C. Synchrotron radiation X-ray absorption fine-structure spectroscopy at O K-edge showed that Al-doped ZnO can't form alloy at 350°C without Al-O bonding feature, Al-O transition of AZO550 is stronger than AZO650, and crystalline qualities of AZO550 and AZO650 are much better than AZO350. Raman scattering and 266nm excitation micro-PL measurements further confirm these results. Al-doped ZnO at 350°C has weak and broad Raman and PL signals. Comparing Raman spectra between AZO550 and AZO650, the peak of E2 (high) mode is observed in AZO550 but not in AZO650. The E2 (high) mode is strong and narrow in AZO550. PLD grown AlZnO film on sapphire could get a better crystalline quality at 550°C than 350°C and 650°C.

8104-33, Session 7

Janus-like 3D tectons as functional nanostructures for self-assembled functional thin films towards nanophotonics

A. Attias, D. Bléger, D. Kreher, F. Mathevet, Univ. Pierre et Marie Curie (France); A. Bocheux, F. Charra, L. Douillard, C. Fiorini-Debuisschert, Commissariat à l'Énergie Atomique (France)

In order to achieve the nanometer-scale control over the positioning and organization of functional molecules into monolayers at surfaces, we developed an original approach allowing the exact positioning of (photo)active organic molecules on the substrate (graphite) leading to the formation of nanostructured functional thin films.. Here we present a strategy aimed at the decoupling of molecules from the surface, by lifting photoactive entities a few Å above the surface while maintaining the lateral organization of the array. This is achieved by using 2-level based building blocks. While the first level allows the precise organization of the building blocks on HOPG at the solid-liquid interface at room temperature, the second level is a photoactive compound, namely a chromophore. We will present a series of such building-block exhibiting tunable wavelength emission.This strategy results in the precise organization of chromophores arrays (subwavelength-sized photon sources) a few Å above the conducting surface, as determined by scanning tunneling microscopy (STM), opening interesting perspectives for applications in nanophotonics.

8104-34, Session 8

Multifunctional organic-inorganic hybrids based on bacterial cellulose membranes

S. J. L. Ribeiro, Univ. Estadual Paulista (Brazil)

Bacterial cellulose (BC) is produced by Gluconacetobacter xylinus strains in the form of highly hydrated (98% water) membranes. The chemical structure is the same of the one found for plants cellulose but BC presents a pure cellulose network, free of lignin and hemicellulose, composed of a random assembly of ribbon shaped fibers less than 100 nm wide. The unique properties provided by the nanometric structure have lead to a number of commercial products including dietetic fibers, headphone membranes, special papers, and textiles, medical applications including temporary skin substitution, contact lenses, optoelectronic devices (e-paper, OLEDs). We have been exploring this multifunctional character studying luminescence properties, photochromism and different application of BC as biomaterials. -Photochromism is been explored by preparing BC membranes containing polyoxometalates and metal colloids. Light induced redox process (W6+ W5+) and tunning of the plasmon resonance energy

of metal (Au-Ag) colloids lead to different colors and photochromic materials; -Luminescence is being explored by obtaining lanthanide containing luminescent species in the BC structure. Emission efficiency is observed to strongly depend on the specific interactions between the BC host and the lanthanide compounds. BC membranes are also being used as substrates for flexible organic light emitting diodes and emission efficiencies are found to be of the same order of glass OLED´s. -Finally biomedical applications is being addressed. BC is being for decades used as substitutes for the skin in the treatment of difficult wounds. In our work antibacterial activity is being added to BC membranes by using Ag colloids and propolis.

8104-36, Session 8

Chromogenic behaviours of silver containing mesoporous titania films

L. Nadar, N. Destouches-Castagna, N. Crespo-Monteiro, F. Vocanson, Y. Lefkir, S. Reynaud, Univ. Jean Monnet Saint-Etienne (France)

Multicolour photochromism was reported few years ago on nanoporous titania films loaded with silver nanoparticles (NP). The formation of heterogeneous silver nanoparticles under UV light gives the films a brown color, whereas illuminations under a colored visible light change the film color to almost the same color as that of the incident light. This photochromic behaviour was interpreted as resulting from a selective oxidation of nanoparticles whose size corresponds to a surface plasmon resonance band centered on the illumination wavelength.

The use of mesoporous titania films as host matrix for the growth of silver nanoparticles is likely to lead to homogeneous NP size distributions and to changes in the photochromic behaviour. We firstly investigate the effects of three reduction processes on the formation of silver nanoparticles in mesoporous titania films. The later are impregnated with silver salt and then either exposed to UV laser light, chemically treated or annealed. Depending on the reduction process the in situ grown NP can be confined inside the mesopores or not, leading to different NP size distributions and to various film colors. These three TiO2/Ag nanocomposite films also exhibit different photochromic behaviours when exposed to visible laser radiations. We characterize the color changes as well as the NP deformation and oxidation under visible illuminations and we propose new mesoscopic mechanisms to interpret our results.

8104-37, Session 8

Electron microscopy characterization of some carbon based nanostructures with application in divertors coatings from fusion reactor

V. Ciupina, Univ. Ovidius Constanta (Romania); I. G. Morjan, C. Lungu, National Institute for Lasers, Plasma and Radiation Physics (Romania); R. Vladoiu, G. Prodan, M. Prodan, Univ. Ovidius Constanta (Romania); V. Zarovschi, National Institute for Lasers, Plasma and Radiation Physics (Romania); I. Stanescu, M. Contulov, A. Mandes, V. Dinca, Univ. Ovidius Constanta (Romania)

Nanostructured carbon materials have increasingly attracted the interest of the scientific community, because of their fascinating physical properties and potential applications in high-tech devices. In order to prepare nanostructured carbon-tungsten nanocomposite for the divertor part in fusion applications, the original method thermionic vacuum arc (TVA) was used in two electronic guns configuration. One of the main advantages of this technology is the bombardment of the growing thin film just by the ions of the depositing film. Moreover, the energy of ions can be controlled. Thermo-electrons emitted by an externally heated cathode and focused by a Wehnelt focusing cylinder are strongly accelerated towards the anode whose material is evaporated and bright plasma is ignited by a high voltage DC supply.

The nanostructured C-W films were characterized by Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM) and Atomic Force Microscopy (AFM). Tribological properties in dry sliding were evaluated using a CSM ball-on-disc tribometer. The C-W films were identified as a nanocrystals complex (5 nm average diameter) surrounded by amorphous structures with a strong graphitization tendency, allowing the creating of adherent and wear resistant films. The friction coefficients (0.15 - 0.35) of the C-W coatings was decreased more than 3-5 times in comparison with the uncoated substrates proving excellent tribological properties. C-W nanocomposites coatings were designed to have excellent tribological properties while the structure is composed by nanocrystals complex surrounded by amorphous structures with a strong graphitization tendency, allowing the creating of adherent and wear resistant films.

8104-38, Session 8

Optical investigation on plasmonic effect of the nanostructured Surface Plasmon Resonance sensor chips fabricated by Langmuir-Blodgett technique

C. Yeon, S. Sung, H. Kim, J. Kim, Ajou Univ. (Korea, Republic of)

The surface plasmon resonance (SPR) has been widely employed for biosensor applications because of the capability for label-free detection of biomolecular interactions. However, the sensitivity of SPR sensor is lower than the conventional labeling immuno-sensing methods. The metal nanostructure-amplified surface plasmon resonance analysis has been investigated to enhance the sensitivity. We used trigonal pyramid Au nanostructured SPR chips for SPR sensitivity enhancement and took a theoretical approach by evaluating optical properties of the Au-nanostructures and nanostructured SPR chips in the point of localized surface plasmon (LSP)- surface plasmon polariton (SPP) conjugation.

We used the Langmuir-Blodgett (LB) method for preparation of defect-free and large-area silica-nanoparticles-monolayer as a template for the fabrication of nano-scaled Au patterns on an Au substrate for surface plasmon resonance. Well organized, trigonal pyramid shaped Au nano-structures were able to construct on 34 separate chips in one fabrication process. The dimensions of trigonal pyramid nano-structures were precisely controlled by changing the particle diameter of the silica LB template as follows: 150, 300, 500, and 700 nm.

The nano-structure patterned substrate fabricated with 300 nm-sized silica nanoparticles demonstrated a sensitivity enhancement up to 120 % compared to a conventional SPR chip when 20% aqueous ethanol solution was used as an analyte. To improve the optical basis of the enhancement in the sensitivity, we measured the SPR curves to wavelength. Also we tried to measure UV-visible spectra of the Au nanostructured pattern in the attenuated total reflectance (ATR) mode to observe the LSP mode of each Au nanostructure.

Conference 8105: Instrumentation, Metrology, and Standards for Nanomanufacturing, Optics, and Semiconductors V

Wednesday-Thursday 24-25 August 2011 • Part of Proceedings of SPIE Vol. 8105 Instrumentation, Metrology, and Standards for Nanomanufacturing, Optics, and Semiconductors V

8105-04, Session 2

Strategies for Nanoscale Contour Metrology using Critical Dimension Atomic Force Microscope

N. G. Orji, R. G. Dixson, A. E. Vladar, M. T. Postek, National Institute of Standards and Technology (United States)

Contour metrology is one of the techniques used to verify optical proximity correction (OPC) in lithography models. The use of these methods, which are known as resolution enhancement techniques (RET), are necessitated by the continued decrease in feature sizes. Broadly speaking, RET are used to compensate for lithography errors such as corner rounding caused during image transfer from the mask to the wafer and subsequence processing. Contours extracted from the printed features are used to verify the OPC models. Currently, the scanning electron microscope (SEM) is used to generate and verify the contours. The critical dimension atomic force microscope, a reference instrument in lithography metrology, has been proposed as a supplemental instrument for contour verification. This is mostly due to the relative insensitivity of the CD-AFM to material properties, the three dimension data, and the ability to make the instrument traceable to the SI unit of length.

However, although the data from the CD-AFM is inherently three dimensional, the planar two dimensional data required for contour metrology is not easily compared with the top-down AFM data. This is mostly due to the effect of the CD-AFM tip and the scanning strategy. In this paper we outline some of the methods for acquiring contour data using the CD-AFM. Specifically, we look at different scanning strategies, the effect of tip types, contour extraction methods, and imaging modes. We compare contours extracted using our method to those acquired using the SEM and helium ion microscope.

8105-05, Session 2

Sidewall slope sensitivity of CD-AFM metrology

A. M. Cordes, SEMATECH North (United States)

CD-AFM is a metrology technique used as a reference measurement system to support accurate control of critical dimensions in precision high volume manufacturing. To test the process range of the AFM, we use a controlled variation in the sidewall across a range of samples to test measurement sensitivity over a critical range of probe types and scan parameters. We find sharp cutoff points in the ability of particular probes and modes to accurately track sidewall variation. We further use cross-section SEM and HR-TEM data as a reference check on the accuracy of CD-AFM sidewall measurements under varying scan conditions.

8105-06, Session 2

High precision surface-profile metrology by scanning the repetition rate of femtosecond pulses

W. Joo, Y. Kim, Y. Kim, J. Park, S. Kim, KAIST (Korea, Republic of)

We report high precision surface-profile metrology using femtosecond pulse lasers as a low-coherence Interferometric light source. Unequal-path non-symmetric Twyman-Green interferometer is configured to test large-sized optics with small-sized reference surfaces, which is only feasible with ultrafast mode-locked pulses of the repeated temporal coherence and high spatial coherence. The time delay between the pulses from the reference and target optics is precisely scanned by tuning the repetition rate of femtosecond pulses referenced to the Rb clock of a time standard. This enables us to perform traceable high precision surface metrology following the SI definition of the meter and remove all the moving parts from the interferometer.

8105-07, Session 2

Progress in the development of the metrological Scanning Probe Microscope at NMIA

J. Herrmann, B. Babic, C. Freund, M. B. Gray, M. T. L. Hsu, M. Lawn, J. Miles, National Measurement Institute of Australia (Australia)

The design, manufacture and assembly of a metrological Scanning Probe Microscope (mSPM) is well underway at the National Measurement Institute Australia (NMIA). The mSPM is the key instrument in NMIA's SPM metrology facility, traceably linking dimensional measurements at the nanoscale with the realization at NMIA of the SI definition of the metre.

Here, we give an overview of recent progress in the establishment of the mSPM facility at NMIA and present first results of its operational and metrological characteristics.

The mSPM incorporates a quartz tuning fork oscillator-mounted tip operating in non-contact mode, a flexure-hinged, piezo-actuated three-axis translation stage providing a measurement volume of 100 µm × 100 µm × 25 µm, and a plane mirror differential heterodyne interferometry system for traceable measurement of the displacements between the scanned sample and the fixed probe. To achieve the target combined uncertainty of 1 nm for the position measurement, the mSPM body is designed to minimize uncertainties caused, in particular, by thermal expansion and distortion, alignment errors (particularly Abbé errors) and environmental vibrations. The interferometry system is designed to achieve high resolution and bandwidth to facilitate its use for closed-loop position control. The selection of materials with low thermal expansion coefficient for the manufacture of the mSPM body and the low power dissipation of the SPM probe detection system contribute to the excellent temperature stability of the instrument.

8105-10, Poster Session

ZnO nanorod arrays as antireflection layers for III-V solar cells

L. K. Yeh, National Taiwan Univ. (Taiwan)

Single-junction GaAs solar cells were grown by metal organic chemical vapor deposition with Veeco turboDisc E450 As/P system. The solar cells were fabricated with standard processes, including the top contact (Ti/Au) formed by photo-lithography and e-beam evaporation, followed by the mesa definition with the area of 2×2 mm2, and the deposition of the bottom contact (Ge/Au). The syringe-like ZnO NRAs were synthesized using the one-step hydrothermal process. Before the synthesis, a 200-nm SiO2 passivation layer was deposited on the device by e-beam evaporation to prevent the potential shortage caused by the conductive ZnO. Subsequently, a ZnO seed layer was deposited by e-beam evaporation on SiO2 for the following growth of ZnO NRAs. The samples

with ZnO seed layers were then placed downward, positioned at the bottom of the beaker, and heated to 95 ºC for 3.5 hours in the aqueous solution containing zinc nitrate hexahydrate (10 mM) and ammonia. Finally the obtained syringe-like NRAs were cleaned with ethanol and dried in air ambiance.

8105-23, Poster Session

Development of multichannel rotating-polarizer ellipsometers based on generic data acquisition method

Y. J. Cho, W. Chegal, H. M. Cho, Korea Research Institute of Standards and Science (Korea, Republic of)

A data acquisition method based on a novel Fourier analysis of irradiance waveform was introduced to capture Fourier coefficients for multichannel rotating-element ellipsometers [1]. Most of detector line arrays used for common rotating-element ellipsometers are integrating photometric detectors because their output signals are proportional to not only the light intensity but also the integration time. For earlier studies [2], the photodiode arrays did not respond when the light amount accumulated in each pixel during an integration time was read out and the status was initialized. To reflect this effect, measured exposure is corrected by the primary approximation of the non-response time [3]. To obtain accurate Fourier coefficients without the approximation, we adopt a discrete Fourier transform on the exposures measured with a detector-dependent non-response time and an arbitrary integration time. This analysis gives a generic function that encompasses the Hadamard transform [3] or the discrete Fourier transform, depending on the specific conditions. Thus, the novel Fourier analysis is applicable to various line arrays with either non-overlap or overlap readout-mode timing. To assess the effects of the generic Fourier analysis, we built a multichannel rotating-polarizer ellipsometer composed of a white light source, a fixed polarizer, a rotating polarizer, a sample, a fixed analyzer, and a spectrometer in which the fixed polarizer is introduced to remove source polarization. The ellipsometric data for SiO2 thin films on c-Si were measured with the custom-built ellipsometer, using the novel Fourier analysis with various numbers of scans, integration times, and rotational speeds of the polarizer.

8105-26, Poster Session

Vector modulation method for north finder capability gyroscope

O. Celikel, F. Sametoglu, H. Sozeri, TÜBITAK National Metrology Institute (Turkey)

This paper deals with the implementation of Vector Modulation Method (VMM) to an open-loop North Finder Capability Gyroscope (NFCG), designed in TUBITAK UME (National Metrology Institute of TURKEY). The method proposes a use of a secondary modulation/demodulation with AD630 to derive voltage information, depending on the periodic variation of the orientation of the sensing coil sensitive surface vector with respect to geographic north at laboratory latitude in time domain. The resultant DC voltage of the secondary modulation/demodulation circuit, proportional to 1st kind Bessel function based on Sagnac Phase Shift for 1st order, is obtained as a throughput vector modulation together with Earth rotation.

8105-09, Session 3

Verification of scatterometer design and data processing

W. Zhao, Helmut-Schmidt-Univ. (Germany); C. F. Hahlweg, Helmut-Schmidt Univ. (Germany)

Scatterometric applications demand strategies for the selection from the various basic scatterometer principles as well as detailed design rules to fit the final optical instrument, the data processing and user interface into the requirements of the application in scope. In recent years we proposed methods based on the optical properties of various basic measurement structures to support the synthesis process for scatterometers, including the decision for the structure itself.

In continuation of last years paper on design rules for catadioptric scatterometers the present paper is dedicated to the metrological verification of the proposed design methods for devices with elliptical mirrors in off-axis alignment. Further questions of data processing and analysis, especially the necessary coordinate transformations and calibration procedures will be discussed, practical examples included.

8105-11, Session 3

IR nanoscopy and nanoimaging

J. H. Rice, Univ. College Dublin (Ireland)

Infrared (IR) spectroscopy is a well developed method for characterizing chemical composition. Imaging materials using IR spectroscopy is extremely valuable where sample heterogeneity presents challenges to analysis using topographical imaging alone, such as in pharmaceuticals or cell biology. Optical imaging using far-field methods is limited by diffraction to length scales at approximately equal to lambda/2. We present a technique for infrared nanoimaging and nanospectroscopy based on an induced resonant motion phenomena to enable IR imaging with a resolution beyond the diffraction limit. Our method enables the surface features of a sample to be chemical characterized via inspection of the resulting local IR spectra and images. This was achieved by combining a phase matched optical parametric oscillator laser as the IR source and an atomic force microscope as the detection mechanism. The technique applys a diffraction limited tuneable excitation source and the resulting light-matter interaction is probed by the AFM tip resulting in IR imaging with nanoscale resolution. We apply this method to image protein bio-systems with a spatial resolution < lambda/100.

8105-12, Session 3

Quantification of the systematic and random measurement uncertainty of a polarimetric scatterometry system designed for enhanced E-field device characterization

T. M. Fitzgerald, Univ. of Dayton Research Institute (United States); M. Marciniak, S. Nauyoks, Air Force Institute of Technology (United States)

Enhanced E-field metamaterials feature the careful selection of restricted nanoparticle or nanofeature geometries and complementary materials to develop nanoscale-level extremely high local electric field strengths when the metamaterial is illuminated by appropriate electro-magnetic energy. Enhanced E-field metamaterials improve sensitivity and spectral location of remote sensing techniques such as Localized Surface Plasmon Resonance (LSPR) and facilitate extremely low concentration detection of compounds or biological factors of interest. Early detection at low concentration levels can allow for the medical treatment of life-threatening conditions such as Alzheimers and the rapid detection of hazardous airborne biological agents. A unique model-based Dual-Rotating-Retarder (DRR) polarimetric scatterometry system has been

developed to characterize enhanced E-field metamaterials by measuring their effective medium full Mueller-matrix (Mm) scatter characteristics at wavelengths of 544 and 633 nm and 3.39 and 10.6 m. The system has been enhanced by automation, addition of multiple light sources, an improved sample positioning and orientation interface, and enhanced data-analysis software. The system features multiple systematic and random uncertainty sources. Systematic measurement errors are reduced by generation of eigen-polarizations and measurement of their angularly dependent scatter response due to position dependent surface scatter from optical components. Random measurement errors are reduced by careful application of system condition number and a rigorously model based measurement analysis. Several measurement examples for canonical Fresnel targets and enhanced E-field geometries are presented. The goals are to improve understanding of application of effective medium theory to Metamaterials and to improve instrument sensitivity to allow polarimetric probing of enhanced E-field "meta-atoms."

8105-13, Session 4

Experimental investigation of non steady state photo-EMF effect induced by 1-D light pattern and its application for Talbot self images localization

I. Guizar-Iturbide, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); L. G. de la Fraga, Ctr. de Investigación y de Estudios Avanzados del IPN (Mexico); P. Rodríguez-Montero, S. Mansurova, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Recently, the analytical expression for non-steady-state photoelectromotive force (photo-EMF effect) current density in a case of light distribution containing only odd harmonics had been derived, and the results demonstrated, that the photo-EMF current was proportional to the sum of the squares of the spatial harmonics visibilities. Furthermore, an adaptive photodetector based on the photo-EMF effect, have been proposed for efficient localization of the Talbot patterns or self-images (planes with minimal and maximal visibility) generated by periodical object in real time, high spatial resolution and without any image processing. Here, we present the experimental analysis of the photo-EMF effect induced by an arbitrary 1-D periodical light pattern and the possibility for localization of the Talbot self-images was also investigated.

8105-14, Session 4

Linear variable filter based oil condition monitoring systems for offshore windturbines

B. R. Wiesent, D. G. Dorigo, A. W. Koch, Technische Univ. München (Germany)

A major part of future renewable energy will be generated in offshore wind farms. The used turbines of the 5 MW class and beyond often feature a planetary gear with 1000 liters lubricating oil or even more. Monitoring the oil aging process gives early indication of necessary maintenance and oil change. Thus maintenance is no longer time-scheduled but becomes wear dependent thus providing ecological and economical benefits. This paper describes two approaches based on a linear variable filter (LVF) as dispersive element in a setup of a cost effective infrared miniature spectrometer for oil condition monitoring purposes. Spectra and design criteria of a static multi element detector and a scanning single element detector system are compared and rated. Both LVF miniature spectrometers are appropriately designed for the suggested measurements but have certain restrictions. LVF multi-channel sensors combined with sophisticated multivariate data processing offer the possibility to use the sensor for a broad range of lubricants just by a software update of the calibration set. An all-purpose oil sensor may be optained.

8105-16, Session 4

Two-photon fluorescence near-field pH measurement for mitochondria activity

Y. Kanazashi, Y. Li, T. Onojima, K. Iwami, Y. Ohta, N. Umeda, Tokyo Univ. of Agriculture and Technology (Japan)

A proton distribution in the vicinity of mitochondria attracts interest due to its influence to a necrotic cell death. Mitochondria produce by ATP using proton concentration gradient generated across the membrane. Accordingly, pH distribution in the vicinity of mitochondria changes from time to time. However, if mitochondria are exerted by physical and/or chemical stresses, proton concentration gradient disappears and ATP couldn't be produced. As a result, the necrotic cell death happens. This process is considered as a part of the reason of the necrotic cell death. Therefore, it is expected that measuring pH distribution in the vicinity of mitochondria leads to clarification of a mechanism of the necrotic cell death. However, it is very difficult to measure pH in vicinity of mitochondria accurately, because a spatial resolution of the conventional microscope is limited.

In this study, we propose pH measurement method based on two-photon fluorescence excitation of dual wavelength pH sensitive dye and scanning near-field optical microscopy (SNOM) to improve spatial resolution. This method utilizes a femtosecond pulse laser to generate two-photon absorption and excites the dye locally. Then the fluorescent signal is collected by a near-field probe. The fluorescent signals for each wavelength are detected separately by cooled photomultiplier tubes, and their intensity ratio is calculated as a figure of pH. The calibration of the pH using proposed method is achieved, and temporal variation of the pH by dropping acid is successfully observed.

8105-17, Session 4

Real-time monitoring of indium bump reflow and oxide removal enabling optimization of indium bump morphology

F. Greer, M. R. Dickie, T. J. Jones, M. E. Hoenk, S. Nikzad, Jet Propulsion Lab. (United States)

Flip chip hybridization, also known as bump bonding, is a packaging technique for microelectronic devices which directly connects an active element or detector to a substrate readout face down, eliminating the need for wirebonding. Indium bump technology has been a part of hybridization for many years and has been extensively employed in the infrared imager industry. However, obtaining a reliable, high yield process for high density patterns of bumps can be quite difficult in part due to the tendency of the indium bumps to oxidize during exposure to air. In this study, plasma, thermal, and wet chemical methods were screened to determine their ability to remove indium oxide from indium bumps and reflow them. Plasma processes using methane, argon, and/or hydrogen were developed to remove indium oxide from indium bumps after prolonged air exposure. A novel hardware configuration was developed to optically monitor indium bump morphology in real time during reflow to optimize and control the process and therfore, the indium bump contact angle, to obtain unique, highly wetted bump morphologies. These methods were tested by fabricating fully hybridized visible CMOS detectors and imaging a standard test pattern. The results of these tests, and a discussion of the mechanisms and merits of the different plasma chemistries and approaches will be discussed.

8105-18, Session 4

Light confinement by structured metal tips for antenna-based scanning near-field optical microscopy

J. D. Jambreck, Fraunhofer-Institut für Integrierte System und

Bauelementetechnologie (Germany); M. Böhmler, Ludwig-Maximilians-Univ. München (Germany); M. Rommel, Fraunhofer-Institut für Integrierte System und Bauelementetechnologie (Germany); A. Hartschuh, Ludwig-Maximilians-Univ. München (Germany); A. J. Bauer, Fraunhofer-Institut für Integrierte System und Bauelementetechnologie (Germany); L. Frey, Fraunhofer-Institut für Integrierte System und Bauelementetechnologie (Germany) and Chair of Electron Devices, Friedrich-Alexander-University Erlangen-Nuremberg (Germany) and Erlangen Graduate School in Advanced Optical Technologies (SAOT) (Germany)

Scanning near-field optical microscopy (SNOM) aims at imaging nanostructured samples with sub-wavelength resolution. For antenna-based SNOM, a large ratio of the near-field signal to the background signal resulting from far-field excitation and detection is highly desirable. In this work, we improve this ratio in the case of sharp conical metal tips by optimizing the local field enhancement, the origin of the near-field signal, using focused ion beam (FIB) structuring. Electrochemically etched conical metal tips are widely used for antenna-based SNOM. Compared to these quasi-infinite structures, finite length antennas and particle-like probes are expected to provide stronger field enhancement. To limit the effective size of our probes, we fabricated surface plasmon Bragg reflectors in suitable distance to the tip apex. These reflectors are realized by appropriate multiple FIB structuring all around the tip.

The design of the structures and the fabrication strategies are discussed. Scanning electron microscopy images, optical raster scans at the targeted wavelength, and optical spectra at different positions of the tips before and after FIB modification are analyzed. An increase of the light confinement of 60 % is observed after structuring the tips as determined from the apex-to-shaft contrast in confocal PL images. The results show that optimized design, FIB patterns, FIB parameters, and structures are crucial to achieve increased signal-to-background-ratios.

8105-19, Session 4

See-through-silicon inspection applications study based on traditional silicon imager

W. Zhou, D. Hart, N. Bock, R. Shervey, Rudolph Technologies, Inc. (United States)

See-through-silicon inspection is becoming an essential quality control method for semiconductor manufacturing in three-dimensional integrated circuit (3DIC) and chip-stacking and related industries such as crack inspection in solar panel manufacturing. Due to silicon's band-gap structure silicon wafers are transparent to light beyond 1.2 micron wavelength range, so silicon-based detectors have very low sensitivity to this wavelength range. InGaAs detectors are typically favored for such applications, even with much higher cost, larger pixel size and smaller detector resolution.

This paper discusses a series of studies to improve silicon-based imagers' detection signal-to-noise ratio for this see-through-silicon inspection application. Silicon based detector sensitivity increases when light wavelength shifts shorter from 1.2 micron. But both photon penetration depth and percentage of penetrated photons drop accordingly. Non-through-penetrated photons are scattered in all directions both at the wafer top surface and inside of the silicon material. A portion of scattered photons will be collected by inspection optics and reach the imager eventually, to cause a white noise background in images out of silicon based detectors. This essentially results in low image contrast.

Effectively removing this background noise is the key to fundamentally improve the signal-to-noise ratio of silicon based detectors for this application. We studied a series of methods, including simple image processing methods, advanced frequency domain analysis and reference subtraction, and compared each method's pros and cons for industrial inspection applications.

8105-20, Session 4

Whole field curvature and residual stress determination of silicon wafers by reflectometry

C. S. Ng, A. K. Asundi, Nanyang Technological Univ. (Singapore)

Reflectometry, a simple whole-field curvature measurement system using a novel computer aided phase shift reflection grating method has been improved to certain extend. The similar system was developed from our earlier works on Computer Aided Moiré Methods and Novel Techniques in Reflection Moiré, Experimental Mechanics (1994) in which novel structured light approach was shown for surface slope and curvature measurement. This method uses similar technology but coupled with a novel phase shift system to accurately measure surface profile, slope and curvature.

In our previous paper, "Stress Measurement of thin wafer using Reflection Grating Method", the surface curvature and residual stresses were evaluated using the versatility of the proposed system. The curvature of wafers due to the deposition of backside metallization was evaluated and compared with a commercially stress measurement system from KLA-Tencor.

In this paper, some aspects of the work is extended. Our proposed system is calibrated using a reference flat mirror and spherical mirror certified by Zygo Coporation. The mirrors together with the camera calibration toolbox allow the system to acquire measurement accuracy that is demanded by semiconductor industry. Finally, the results obtained from Reflectometry are compared and contrast with results from KLA Tencor System.

8105-21, Session 5

Common-path laser encoder system for nanopositioning

C. Wu, C. Cheng, Tamkang Univ. (Taiwan)

Scanning probe microscopy and nanoimprint are powerful and promising techniques for nanotechnology. In order to get precise dimensions of microstructures, the dis-placement sensor is required for precise displacement feedbacks. Out of all displace-ment sensors, the laser encoder has been an important subsystem and widely adopted for advanced manufactures such as semiconductor industry. However, the used laser encoders inevitably suffer from environmental disturbances or noises, which mainly result from atmospheric influences, background vibration, thermal drift, and elec-tronic high frequency noises. In this paper, a common-path laser encoder for nanopositioning is proposed. Based on the common-path optical configuration, our system can offer high stability and high resolution displacement measurements. An expanded laser source is focused on the grating scale. The grating then diffracts the focus beam. The zero order diffraction beam overlaps partially with the first one. This interference beam is divided into two parts by the polarization beam splitter (PBS). When the grating scale moves delta(x), the Doppler effect will induce the phase variation phi =2*pi*delta(x)/d in first order diffracted beam. Here d is the grat-ing pitch. According to the Jones calculation, the light intensities on the detectors D1 and D2 can be written as: I1 proportional to 1+cos(phi) and I2 proportional to 1+cos(-phi), respectively. As the phase difference PHI=2*phi between I1 and I2, the displacement delta(x) of the grating scale can be obtained by the following equations: delta(x)=PHI*d/(4*pi). The principle of the displacement measurement and the method of the positioning method will be detailed and the system performance will be provided.

8105-22, Session 5

Quasi static short range lidar for volume scatterometry

C. F. Hahlweg, Helmut-Schmidt Univ. (Germany)

In continuation of previous publications the use of short range Lidar techniques for measuring volume scatter behaviour of semi-transparent materials is investigated with focus on budget designs power modulated FMCW devices in GHz range. Standard components as supplied for telecom transmission lines are used. A main topic is the definition of the scatter geometry for goniometric measurements. Further the use of short range Lidar in imaging scatterometers is discussed. Theoretical and practical investigations are presented.

8105-24, Session 5

Rapid defects detection of bonded wafer using near infrared polariscope

C. S. Ng, A. K. Asundi, Nanyang Technological Univ. (Singapore)

Wafer bonding has emerged as an important processing step in wide range of MEMS manufacturing applications.During the manufacturing process, even in the modern clean room, small defects result from trapped particles and gas exist at bonded interface. Defects and trapped particles may exist on the top and bottom of the wafers, or at the interface of bonded wafer pair. These inclusions will generate high stress around debond region at the wafers bonded interface. In this paper, inspection at the bonded interface will be the area of investigation.

Since silicon wafer is opaque to visible light, defect detection at the bonded interface of silicon wafer is not possible. Due to the fact that silicon wafer is transparent to wavelength greater than 1150nm, an Near Infrared Polariscope which has showed some promises on residual stress measurement on silicon devices has been adapted and developed. This method is based on the well known photoelastic principles, where the stress variations are measured based on the changes of light propagation velocity in birefringence material. The results are compared and contrast with conventional Infrared Transmission Imaging tool (IRT) which is widely used to inspect the bonded silicon wafer.

In this research, the trapped particles that are not visible via conventional infrared transmission method are identified via the generated residual stress pattern. The magnitude of the residual stress fields associated with each defect are examined qualitatively and quantitatively. The stress field generated at the wafers bonded interface will look like a ‘bow tie’ pattern.

8105-25, Session 5

Circular Si waveguides from bulk Si by using laser reformation technique

S. Hung, S. Shiu, J. Chao, C. Lin, National Taiwan Univ. (Taiwan)

Silicon is on the verge of the choice for the photonics industry. Sub-wavelength optical wires fabricated using CMOS (Complementary Metal-Oxide-Semiconductor) materials and techniques promise economic integration of optics and electronics. On the CMOS transistor layer, which necessitates thermal conduction through the silicon substrate, the SiO2 layer typically has a thickness of below 100nm. However, such thin SiO2 underneath the Si waveguide creates excessive optical loss into Si substrate. It makes an incompatibility for the integration of optics and electronics. Here, we pesent a novel method to fabricate Si/SiO2 waveguides from regular Si wafers using laser reformation technique. Deep silicon ridges were firstly created using typical lithography and dry-etching processs. Then, high-power excimer laser was used to illuminate the Si ridges. Under proper illuminating condition, the top portion of Si ridges would be melted and reshaped to circular-profile structure. The principle of laser reformation is to melt the Si ridges by a high-power laser pulse. During the period of liquid-phase Si, the surface tension forces the surface area to be the minimum, so the Si ridges are transformed to a circular-profile structure. Finally, high-temperature oxidation process was used to oxidize the unmelted portion below the top reformed structure. The circular cross section has a maximum diameter of about 600nm. The final oxidation of the unmelted neck, still over 1 um long, prevents optical loss due to negligible light coupling from the waveguide to the substrate. This technique allows great flexibility in design and fully compatible with the CMOS circuitry.

8105-27, Session 5

Development of cavity ring-down ellipsometry with spectral and submicrosecond time resolution

V. M. Papadakis, Foundation for Research and Technology-Hellas (Greece); M. A. Everest, Foundation for Research and Technology-Hellas (Greece) and George Fox Univ. (United States); K. Stamataki, Foundation for Research and Technology-Hellas (Greece) and Univ. of Crete (Greece); S. Tzortzakis, B. Loppinet, P. Rakitzis, Foundation for Research and Technology-Hellas (Greece)

Cavity-enhanced ellipsometry, using nanosecond pulsed lasers and without moving parts, is demonstrated to have submicrosecond time resolution. The ellipsometric phase angles are measured from the Fourier transform of the cavity ring-down experimental signals, with a sensitivity 0.01 degrees. The technique is applied to highly reflective surfaces, including total internal reflection, where the samples are placed within the evanescent wave. The technique can be generalized to broadband sources, such as from supercontinuum generation, allowing spectral resolution of thin films and monolayer samples.

Conference 8106: Nanoepitaxy: Materials and Devices III

Wednesday-Thursday 24-25 August 2011 • Part of Proceedings of SPIE Vol. 8106
Nanoepitaxy: Materials and Devices III

8106-01, Session 1

Development and performance of zinc selenide nanowire based photodetectors

M. King, S. McLaughlin, D. Kahler, A. Berghmans, D. Knuteson, M. Aziz, N. B. Singh, Northrop Grumman Electronic Systems (United States)

This work will showcase recent developments in the growth and performance of zinc selenide (ZnSe) nanowire (NW) based photodetectors. Specifically the ability to transition from single NW devices to arrays of detectors will be discussed. We have demonstrated the growth of semiconducting nanowires (NWs) using the physical vapor transport (PVT) method and have found that the growth orientation can be controlled to generate NW arrays. These arrays show promising optical properties, including high transparency and for photoluminescence a high ratio of band edge/deep level defect emission. Such properties are critical for producing high quality photodetectors.

As-grown material was also used for fabrication of photodetectors. Metal-semiconductor-metal (MSM) structures were fabricated from an array of ZnSe NWs and Ti/Au contacts. The array of devices was tested using a 150W tungsten halogen lamp and an automated probe station. Current-voltage plots from -20 to 20V show generally symmetric behavior, with schottky barriers from the Ti/Au contacts. Upon illumination through a microscope objective lens, the nanowire devices showed orders of magnitude increases in photocurrent. These results will provide the foundation for developing nano-avalanche photodiodes (nanoAPDs), in which p-type and n-type NWs will be utilized to create high efficiency, low noise junctions.

8106-03, Session 1

Nanowire based heterostructures: fundamental properties and applications

A. Fontcuberta i Morral, M. Heiss, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Nanowires are filamentary crystals with a diameter of few to a hundred of nanometers. Thanks to their dimensions they are the perfect playground for fundamental studies and for improving devices such as solar cells. Nanowires are typically obtained by the vapor-liquid-solid method in which a metal catalyst is used for the gathering of the precursor species and nanowire growth. In most of the cases gold is used, though it has been shown to affect negatively the electronic and optical properties of semiconductors.

We fabricate ultra-high purity GaAs nanowires by avoiding the use of gold and by the use of molecular beam epitaxy (MBE) [1]. MBE offers also the unique possibility of growing with epitaxial quality on the nanowire facets [2]. Prismatic quantum wells and Stranski-Krastanov quantum dots are obtained with a very high quality, as demonstrated by the optical spectroscopy measurements [3,4]. Finally, we show how these nanowires are excellent candidates for the fabrication of solar cells [5] and high mobility transistors by using a modulation doped structure.

Poole-Frenkel effect and phonon-assisted tunneling in GaAs nanowires

F. Leonard, Sandia National Labs., California (United States)

We present electronic transport measurements of GaAs nanowires grown by catalyst-free metal-organic chemical vapor deposition. Despite the nanowires being doped with a relatively high concentration of substitutional impurities, we find them inordinately resistive. By measuring sufficiently high aspect ratio nanowires individually in situ, we decouple the role of the contacts and show that this semi-insulating electrical behavior is the result of trap-mediated carrier transport. We observe Poole-Frenkel transport that crosses over to phonon-assisted tunneling at higher fields, with a tunneling time found to depend predominantly on fundamental physical constants as predicted by theory. By using in situ electron beam irradiation of individual nanowires, we probe the nanowire electronic transport when free carriers are made available, thus revealing the nature of the contacts.

CuO thin-film and nanowire for e-textile applications

J. Han, NASA Ames Research Ctr. (United States); A. J. Lohn, N. P. Kobayashi, Univ. of California, Santa Cruz (United States); M. Meyyappan, NASA Ames Research Ctr. (United States)

Device fabricated from materials in low dimensional structures can provide performance enhancement as well as open a new application. Integration of electronics into textile, referred as e-textile, offers an opportunity of future electronics. Here, copper (Cu) and copper oxide (CuO) based nanostructures are embedded for e-textile. Metallic Cu wire is utilized for a growth substrate, which is simultaneously used as a fiber

of mesh textile. Among various metals, Cu is promising as it is non-toxic and relatively abundant on earth. The motivating factor in Cu is ease growth of nanostructure; the nanowire and thin-film are synthesized by self-catalytic vapor-solid growth. Simply heating Cu with oxygen gas can form CuO nanowire and thin-film according to the growth conditions. As key building blocks in e-textile, memory, transistor, and interconnect are presented. The resistive memory is comprised of CuO thin-film sandwiched within two orthogonal Cu fibers. For a metal semiconductor field effect transistor (MESFET), Schottky junction is used for gate to channel barrier. The Cu fiber and CuO thin-film are devoted for the gate and channel, respectively. For an interconnection, the neighboring fibers are electrically connected by transforming CuO nanowire into Cu nanowire. The thermal reduction of CuO is proved to be effective to make conductive nanowires.

8106-09, Session 2

Growth of Group III nitrides: from films to nanowires to hybrid structures

A. Davydov, D. Tsvertkov, A. Motayed, I. Levin, K. A. Bertness, N. A. Sanford, J. B. Schlager, A. Sanders, P. Blanchard, J. E. Maslar, National Institute of Standards and Technology (United States)

In addition to traditional thin film structures, Group III nitride nanowires (NWs) have attracted considerable attention due to their high structural quality and unique physical properties enabling their use in nanoelectronics. To realize new applications, the controlled fabrication of NWs with defined geometries and electronic properties as well as their integration with planar device structures are required. Thus, it would be beneficial to develop a combination of 2D (films) and 3D (NWs) growth processes in a single reactor using traditional nitride technology to enable fabrication of novel hybrid structures.

In this paper the enhanced capabilities of horizontal Halide Vapor Phase Epitaxy (HVPE) reactor are demonstrated by growth of: (a) GaN NWs and nanotubes (NTs), (b) GaN NW core/shell n/p epitaxial heterostructures (p-type shell over n-type core), (c) AlN NWs, and (d) GaN films on top of AlN NWs. Examples from (a) include the first demonstrations of vapor-liquid-growth growth of GaN NWs and vapor-solid growth of GaN NTs by HVPE. The [0001]-oriented GaN NWs were grown on Al2O3 (0001) substrate from catalytic gold particles and were 1 μm to 5 μm in length and 50±10 nm in diameter. The [0001]-oriented GaN NTs were grown by casting GaN shells over InN NWs with subsequent removal of InN core material by thermal decomposition and/or chemical etching. GaN NTs were 1 μm in length with typical wall thickness of 40±10 nm.

The growth models, nanostructures/films/substrates epitaxial relationships, and correlation of growth conditions to the morphological/structural/electronic properties of NWs, NTs and hybrid structures will be presented in details.

8106-10, Session 2

InGaN/GaN nanostructures grown by selective area growth for solid-state lighting

T. Yeh, Y. Lin, L. Stewart, P. D. Dapkus, B. Ahn, S. Nutt, The Univ. of Southern California (United States)

Ordered GaN nanorod and nanosheet arrays were successfully grown by selective area growth using metalorganic vapor phase deposition (MOCVD). Hexagonal GaN nanorods with six non-polar planes and vertical nanosheets with parallel continuous non-polar sidewalls were grown on the patterned c-plane GaN bulk material using a pulsed MOCVD growth mode. A wurtzite crystal structure in the rods was confirmed by high-resolution transmission electron microscope (HRTEM) analysis. Unlike the general III-V nanowires, no stacking faults were found in the GaN nanorods eliminating the possible influence of the stacking faults on the electrical conductivity along the nanorods. InGaN/GaN multiple quantum wells (MQWs) were grown on GaN nanostructure arrays. Cross-section TEM images reveal a core-shell heterostructures on GaN nanorods and nanosheets. Photoluminescence measurements were performed to confirm the light emission from the MQWs. Strong emission peaks were observed from the nanostructures. We believe the dominant emission peak results from the large exposed surface area of the nonpolar {1-100} sidewalls of GaN nanostructures. Active regions formed on nonpolar planes have reduced piezoelectric fields and potentially increase the radiative recombination efficiency for the LED applications.

This work was supported in part by NSF through Award ECS-0507270 and by the Center for Energy Nanoscience, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Basic Energy Sciences under Award Number DE-SC0001013.

8106-12, Session 3

Towards epitaxial integration of metallic nanostructures into photonic devices

S. R. Bank, A. M. Crook, H. P. Nair, V. D. Dasika, The Univ. of Texas at Austin (United States)

The epitaxial integration of metals and semiconductors offers tantalizing possibilities to realize new functionality from (nano)photonic devices. Unfortunately, metals are typically relegated to the periphery of semiconductor devices, due to practical challenges associated with their integration, including interfacial instability and epitaxial incompatibility. ErAs and the other semimetallic rare-earth monopnictides provide a potential pathway to integration, because they may be epitaxially integrated with high-quality III-V semiconductors as both nanostructures and films, with thermodynamically stable interfaces. Such materials could greatly benefit the field of plasmonics where progress towards active devices, such as light-emitting diodes that make use of the Purcell enhancement, is hampered by the design constraint that metallic (nano) structures must remain at the device periphery. Indeed, this limitation renders even structures as simple as a quantum well/dot surrounded by parallel metal plates exceedingly challenging to fabricate. We show how this and other similarly tantalizing structures can now be grown directly in a single epitaxial growth run, using ErAs and III-V semiconductors.

We review our on-going efforts to epitaxially integrate semimetallic hetero- and nano-structures into the heart of III-V devices, highlight some important device applications, and discuss key challenges. In particular, we examine the optical quality of III-V material surrounding the ErAs nanostructures and demonstrate that high-quality III-V emitters may be brought into very close proximity to ErAs nanostructures, ~10 nm, without degrading their emission characteristics.

This finding is very promising for harnessing Purcell enhancements in light-emitting diodes.

The authors acknowledge ARO, AFOSR, and NSF for support.

8106-13, Session 3

Integrated amplifying nanowire FET for surface and bulk sensing

C. O. Chui, K. Shin, Univ. of California, Los Angeles (United States)

Quasi-one-dimensional semiconductor nanowires are uniquely suitable for very high sensitivity detection applications. Their large surface area-to-volume ratio and tiny volume are respectively attractive for surface sensing, e.g. biochemical molecules, and bulk detection, e.g. radiation. Commonly configured as the substrate-gated field-effect transistor (FET) channel, the exposed semiconductor nanowires atop an insulator layer have exhibited very high detection sensitivity on immunoglobulins and nucleic acid molecules. For charged biomolecule sensing in particular, the charge-to-current signal transduction occurs at the nanowire FET front-end which thereby minimizes parasitics and thus noise. This scheme additionally requires no imaging equipments and the sensors themselves are readily interfaced and integrated with readout electronics. The detection sensitivity, and especially the limit of detection (LOD) and limit of quantification (LOQ) that takes into account the blank and signal

noise, however, needs to be further improved before its deployment in portable diagnostic and detection platforms.

In this talk, a transformative nanowire FET structure will be disclosed that significantly boosts the sensitivity through a built-in amplification mechanism with lowest possible parasitics. This is accomplished through the seamless integration of a sensing nanowire with an amplifying nanowire FET. The development of the novel amplifying nanowire FET sensor prototypes as well as their surface and bulk sensing characterizations will be discussed. Preliminary experimental data will also be presented revealing around 1 order of magnitude sensitivity improvement in solution pH and cancer protein detection. Finally, an appreciable improvement in photodetection sensitivity will be illustrated over the generic nanowire FET sensors.

8106-14, Session 3

Fabrication and in situ testing of solid-state all nanowire Li ion batteries

A. A. Talin, D. Ruzmetov, H. Lezec, V. Oleshko, A. V. Davydov, S. Krylyuk, National Institute of Standards and Technology (United States)

The ability to measure the morphological, chemical, and transport characteristics with nanoscale resolution in electrochemical energy storage devices is critical for understanding the complex interfacial reactions and phase transformation that accompany cycling of secondary batteries. In this paper we will describe the use of an all-nanowire Li ion battery for in situ characterization of charge and discharge reactions. The nanobatteries consist of a metalized core, a LiCoO2 cathode, LiPON solid electrolyte, and a thin film Si anode. Measuring several micrometers in length and several hundred nanometers in diameter, the nanobatteries can be readily imaged in a transmission electron microscope. We test the nanobatteries using a piezo actuated electrical nanoprobe. In addition to being well suited for in situ electrochemical testing, nanowire batteries may also have other advantages, such as superior strain accommodation. To investigate this hypothesis, we also characterize in situ thin film batteries fabricated using similar methods.

8106-15, Session 4

Thin film semiconductor strain engineering for optoelectronic devices

M. S. Leite, E. Warmann, H. A. Atwater, California Institute of Technology (United States)

Historically in materials science, the limited number of substrates available in bulk form significantly limits epitaxial growth versatility. We suggest an approach to elastically relax the strain of single crystalline layers and, therefore, engineer its band gap energy. By transferring coherently-strained ultrathin III-V semiconductor films from their original substrates to a handling support, full strain relaxation occurs and the material unit cell assumes its bulk value ax. For the successful fabrication of this new template, 40 nm thick dislocation-free films are grown on a substrate, e. g. InxGa1-xAs on InP or GaAs. A viscoelastic wax support is used to coat the epitaxial film, which allows for film relaxation and mechanical support. Once the film is relieved from the substrate by a selective chemical etch it fully relaxes. The crystalline film, independent of the alloy composition, is always compressed with respect to the wax because of the difference between the shear modulus of the two materials. Thus, it is stable against crack formation. The film is then bonded to a handle cheap substrate, e. g. SiO2/Si. X-ray diffraction and transmission electron microscopy measurements were used to quantify the template relaxation and reconstruct its unit cell, in very good agreement with Vegard's Law. Photoluminescence measurements showed the dependence of band gap offset and strain relief. The creation of a dislocation-free template with arbitrary lattice parameter has the potential for new crystalline material designs for technologies such as solar cells, which will be discussed.

Transport in fused InP nanowire device in dark and under illumination: Coulomb staircase scenario

T. Yamada, Santa Clara Univ. (United States) and Univ. of California, Santa Cruz (United States); H. Yamada, Univ. of California, San Diego (United States); A. J. Lohn, N. P. Kobayashi, Univ. of California, Santa Cruz (United States)

Detailed DC electron transport analysis is performed for a device consisting of fused conical indium phosphide nanowires (InP NWs) bridging two hydrogenated n+-silicon electrodes. These NWs are a few microns long and 100 nm wide. The current-voltage (I-V) plot at room temperature exhibits an unusual staircase shape with a period of ~1 V in dark, but under increasing light illumination, the device conductance gradually increases and the staircase gradually disappears. We explain this observation in terms of the Coulomb staircase scenario - a tiny Coulomb island is created between two tunneling barriers (possibly around the fused portion) and transport is dominated with tunneling. Electrons tunnel in and out of the Coulomb island in a correlated manner, resulting in the staircase I-V in dark. Light illumination raises the electron quasi-Fermi level and the relevant tunneling barriers are buried, causing the staircase I-V to disappear. Although multiple NW pairs bridge electrodes, one pair practically dominates transport. This is because tunneling depends exponentially on the barrier width with the sensitivity as small as Angstroms (hence this is the principle of STM), and unavoidable scattering in physical dimension around the tunneling barriers will result in a significant conductance difference from one NW pair to another. Based on the Coulomb island dimension deduced from the voltage period, NWs are shown unintentionally n-doped with 10^15-16 cm^-3. The quasi-Fermi level difference in dark and under light

illumination is about 25-85 meV, and this is interpreted as a tunneling barrier height.

8106-21, Session 5

Local carrier dynamics in InGaN quantum wells studied by scanning near-field optical microscopy

A. Kaneta, M. Funato, Y. Kawakami, Kyoto Univ. (Japan)

The progress of growth technology has led to the achievement of highly efficient InGaN-based light-emitting diodes (LEDs) in the violet to blue spectral region. However, further improvement of emission efficiency is required, overcoming the problem of the efficiency droop. Many research groups have studied emission mechanism in InGaN quantum wells (QWs). However, most of them were based on macroscopic spectroscopy. The emission mechanism is unclear because nanometer scale potential fluctuation is strongly correlated with recombination dynamics in InGaN QWs. Therefore, nanoscopic spectroscopy is necessary to clarify the correlation between local structures and recombination mechanisms of InGaN QWs. To date, we have developed temporally and spatially resolved photoluminescence (PL) spectroscopy using a scanning near-field optical microscope (SNOM) to investigate the recombination dynamics in InGaN single QWs (SQWs). As an example, we have succeeded in clarifying the correlation between the radiative/nonradiative recombination processes and threading dislocations as well as carrier diffusion/localization processes by comparing SNOM-PL mapping and atomic force microscope taken at the same scanning area. However, a conventional SNOM based on one fiber probe cannot detect the detailed carrier motion diffused out of an aperture. Therefore, we have developed a dual-probe SNOM, where a photoexcitation probe is fixed at specific position while a light collection probe is scanned around the photoexcitation probe, and succeeded in visualizing the anisotropic carrier diffusion in an InGaN SQW. Thus, it is worth emphasizing that this technique can be a versatile tool for assessing photonic phenomena such as transport and recombination processes of various elemental excitations.

Growth of ZnO-based nanorod heterostructures and their photonic device applications

J. Yoo, S. T. Picraux, Los Alamos National Lab. (United States); G. Yi, Seoul National Univ. (Korea, Republic of)

Position-controlled and vertically-aligned semiconductor nanoscale heterostructures can serve as ideal components for photonic devices because the structures provide not only integratable building blocks but also give unique properties such as enhanced light absorption, waveguiding, and large active volumes compared to thin films and bulk materials. This good versatility and performance of photonic devices based on nanomaterials can be accomplished by fabrication of nanorod heterostructures with compositional modulation along either the axial or the radial direction. Semiconductor nanorods are particularly promising since high-quality semiconducting building blocks can be easily obtained. Additionally, growth of semiconductor nanorods can give insight into the nanoepitaxial growth on various substrates. Such novel nanoepitaxy techniques make it possible to fabricate monolithic integrated circuits and sophisticated quantum devices on otherwise incompatible substrates.

Here, we present research results on ZnO nanorod heterostructures and their photonic device applications from the viewpoint of using position-controlled growth for integration and fabrication of quantum structures for controlling physical properties. In this research, we used a combination of catalyst-free metal-organic vapor phase epitaxy and lithographic techniques to prepare position-controlled vertically aligned ZnO nanorod heterostructures. Using the combined approach, ZnO/MgZnO and ZnO/InxGa1-xN nanomaterial heterostructures were prepared successfully. The position-controlled ZnO-based nanomaterial heterostructures exhibited quantum confinement indicating the formation of well-defined heterostructures. Based on these structures three-dimensional nanoarchitecture photonic devices such as light-emitting diode arrays and embedding quantum structures are demonstrated.

8106-26, Session 6

Metal-organic frameworks: charting a course to device integration

M. D. Allendorf, Sandia National Labs., California (United States)

Among the new classes of nanomaterials created during the past decade, metal-organic frameworks (MOFs) are possibly the most versatile. MOFs represent the “inside out” of nano: these supramolecular, crystalline materials are nanoporous and display record-setting surface areas. Unlike many other nanoporous materials, MOFs are inorganic-organic hybrids composed of an organic “linker” group connected to a metal ion such as Zn(II). This feature creates unprecedented synthetic flexibility, combining the vast organic reaction chemistry with rational structural design enabled by metal-linker coordination bonds. As a result, both pore geometry and chemical features can be tailored for specific applications, which to date include gas storage, separations, drug delivery, and chemical sensing. However, integration of MOFs with electronic devices is still in its infancy, even though their highly ordered structure suggests the potential for defect-free electronics in the single-digit nm scale. This presentation will provide an introduction to MOFs and their properties that are attractive for use in electronic devices. Specific examples developed will then be presented, including growth of thin films on micro-electromechanical systems (MEMS) for chemical sensing, nanolithography to create nanoparticles and nanowires from silver-infiltrated frameworks, and luminescent MOFs in which manipulation of nanoscale structure enables the spectrum, intensity, and timing of light output to be tuned. Finally, we will introduce a roadmap to MOF device integration intended to stimulate new research efforts and interdisciplinary collaboration.

Enhanced conductivity of ErAs nanoparticle containing tunnel junctions via bandgap engineering

R. Salas, E. M. Krivoy, A. M. Crook, H. P. Nair, S. R. Bank, The Univ. of Texas at Austin (United States)

Low-loss tunnel junctions are essential components of a number of optoelectronic devices and are particularly important for serially connecting the junctions in multijunction solar cells. Placing semimetallic ErAs nanoparticles at the pn junction greatly enhances tunneling currents by breaking the band-to-band tunneling process into two smaller back-to-back Schottky barriers. Modifying the size and density of the embedded ErAs nanoparticles provides a route to enhance the conductivity of the junctions. In addition, tuning of the Schottky barrier height through compositional grading of the III-V material can further improve the conductivity by lowering the bandgap of the material at the interface of the barrier. We investigate the combined benefits of both techniques in this work by refining the growth parameters of the nanoparticles and digitally grading the GaAs to In(x)Ga(1-x)As on the n-type side. Samples were grown on a Varian Gen II molecular beam epitaxy system on n-type GaAs (100) substrates. Abrupt junctions and compositionally graded junctions of varying thicknesses and strains were grown with and without nanoparticles at the interface. Graded regions were kept thin to avoid increased optical absorption and performance degradation. Preliminary results show a 7x improvement in the forward bias current over abrupt nanoparticle junctions. Further enhancements are anticipated with the use of lattice matched dilute-nitrides for the n-type side and mixed arsenide-antimonide-nitrides for the p-type side. These improvements in conductivity have the potential to advance the performance of many optoelectronic devices, especially concentrator multijunction solar cells.

8106-28, Session 7

Nanocomposites for thermoelectric power generation: rare-earth metal monoantimonide nanostructures embedded in InGaSb and InSbAs ternary alloys

N. P. Kobayashi, T. Onishi, Univ. of California, Santa Cruz (United States); E. Coleman, G. S. Tompa, Structured Materials Industries Inc. (United States)

Technologies that can harvest untapped waste heat energy by utilizing thermoelectrics are gaining strong attention. Thermoelectrics that convert heat directly into electric power are solid-state heat engines in which energy conversion efficiency is limited by the second law of thermodynamics. Thermoelectric figure of merit (ZT) depends on three material properties; electrical conductivity, thermal conductivity, and Seebeck coefficient. ZT of a thermoelectric material needs to be at least 1.0 to envision practical implementations. Despite extensive investigation on both material and device aspects of thermoelectrics to improve energy conversion efficiency, traditional bulk semiconductors have been suffering from ZT ~1.0 or below for many years. Maximizing ZT simply requires that electrical conductivity and Seebeck coefficient be high to reduce Joule heating and to increase energy conversion efficiency while thermal conductivity needs to be low to maintain temperature gradient across a thermoelectric material. Unfortunately these three material properties are closely correlated each other in homogeneous bulk semiconductors. Recent demonstrations that employ various semiconductor materials tuned at the nanometer-scale (nanomaterials) have shown great promise in advancing thermoelectrics. Among a wide range of nanomaterials, we focus on “nanocomposites” in which semimetallic nanostructures are epitaxially embedded in a ternary compound semiconductor host to tune the three material properties independently. We demonstrate co-deposition of erbium monoantimonide (ErSb) and In1-xGaxSb or InAsySb1-y ternary alloy to form nanometer-scale ErSb structures within the ternary alloys using low-pressure metal organic chemical vapor deposition (LP-MOCVD). The grown nanocomposites are structurally and thermoelectrically analyzed to assess their potential for advanced thermoelectric power generation.

8106-29, Session 7

Growth of semimetallic ErAs films epitaxially embedded in GaAs

A. M. Crook, H. P. Nair, D. A. Ferrer, S. R. Bank, The Univ. of Texas at Austin (United States)

We investigate the critical growth parameters for expitaxially embedding ErAs films in GaAs, with application to electronic and photonic devices. Traditionally, growth of GaAs on ErAs films resulted in antiphase domain formation, due to the additional rotational symmetry of the rocksalt crystal structure of ErAs, compared with the zincblende GaAs. We leverage the recent discovery that, below a critical areal density during growth, surface erbium adatoms will preferentially incorporate into subsurface ErAs nanoparticles. As compared to traditional layered heterostructure growth, this method offers the advantage that a thin layer of GaAs floats on the surface and remains registered to the substrate, preventing antiphase domain formation during subsequent III-V growth. Samples were grown on a Varian Gen II solid-source molecular beam epitaxy system to investigate the role of ErAs growth rate and GaAs cap thickness on the formation of a surface ErAs nanoparticle layer - one of the experimentally observed failure mechanisms for the embedded growth mode. High resolution transmission electron microscopy (HR-TEM) was used to characterize the integrity of the film as well as to observe the formation of antiphase domains in the GaAs overgrowth. By keeping the GaAs cap sufficiently thin and the ErAs growth rate sufficiently low, we show full ErAs films can be embedded in GaAs without exceeding the critical areal density of surface erbium for formation of a surface ErAs nanoparticle layer. This approach provides a path towards the realization of plasmonic devices based on the epitaxially integration of a semimetal/semiconductor system.

Dopant and heterostructure profiles in semiconducting nanowire

D. E. Perea, S. T. Picraux, Los Alamos National Lab. (United States)

The fundamental operation of many silicon and germanium nanowire devices relies on the ability to controllably modulate the composition to create both heterostructures as well as and modulation-doped nanowires with compositionally-abrupt junctions. The vapor-liquid-solid (VLS) growth process is an approach to bottom-up nanowire synthesis that provides an apparently straightforward route to axial heterostructure formation and dopant incorporation. However, the formation of abrupt heterojunctions remains a challenge utilizing VLS growth from the conventional gold catalyst. Moreover, controlled doping with electronic impurities also remains an important challenge in large part due to a lack of a technique or tool sensitive enough to directly quantify the distribution and dopant concentration in individual nanowires. In this talk, I will discuss use of atom probe tomography (APT) as a tool to directly map the 3D dopant distribution and axial heterojunction profiles between Si and Ge nanowires. Dopant depletion studies along the nanowire growth axis reveal a long depletion profile of hundreds of nanometers which is much longer compared to the Si-Ge heterojunction width which is on the order of the nanowire diameter. A dopant incorporation model suggests that the interfacial width depends on the solute solubility in the liquid catalyst. I will further discuss a new approach of using a liquid AuGa alloy catalyst to create a sharper axial heterojunction in Ge-Si, relative to that obtained using pure Au. Finally, I will conclude with some results of increasing the pn-junction sharpness in Si and Ge nanowires using an alloy catalyst.

8106-34, Session 8

Ultralow-voltage and efficient electrostatic precipitation using metal catalyzed silicon nanowhiskers

J. Oh, A. P. Nayak, Univ. of California, Davis (United States); S. Kaya, Ohio Univ. (United States); M. S. Islam, Univ. of California, Davis (United States)

This paper presents our experimental results on gas ionization at atmospheric pressure at very low bias voltages (less than 100 Volts) using gold-catalyzed silicon nanowhiskers. An advantageous combination of field enhancement on nanoscale silicon tips, surface states introduced by defects, metal impurities and bandgap widening through quantum confinement contributes to such lowering of ionization voltage. Usual range of ionization voltage is 5,000 - 15,000 Volts in standard electrostatic precipitators used for pollution control in oil and coal-fired industrial power plants or in the removal of toxic and harmful solid particulate from the gas exhaust stream. Our results show that VLS processes offer distinctive benefits by synthesizing nanostructures with unrivaled dimensions along with high density of surface states contributed by the impurities and immobilized free radicals on the whisker-surface.

8106-35, Session 8

Indium phosphide nanowires integrated directly on carbon fiber

A. J. Lohn, T. J. Longson, N. P. Kobayashi, Univ. of California, Santa Cruz (United States)

Much attention has been given to integration of group III-V semiconductors onto silicon platforms to combine superior optical and electrical properties of group III-V semiconductors with mature processing capabilities of silicon. Less effort however, has been directed towards integration on other group IV elements such as carbon. Carbon fiber is generally utilized as a structural material in a wide variety of products because of its light weight and large stiffness and tensile strength. Carbon fiber can also offer additional advantages of large electrical and thermal conductivities when integrated with group III-V semiconductors . We have demonstrated the growth of a group III-V semiconductor binary alloy, indium phosphide (InP), directly on carbon fibers thereby enabling a union of semiconductor and structural materials. Carbon fibers with diameter approximately 500 nm were prepared by electrospinning solutions of polyacrilonitrile (PAN) and dimethylformamide (DMF) followed by carbonization at 750 C in inert atmosphere. Gold nanoparticles were dispersed on the fibers to catalyze metal organic chemical vapor deposition (MOCVD) growth of InP nanowires. X-ray diffraction indicates that despite the graphite surface, InP nanowires adopt primarily zinc blende crystal structures. Geometrical parameters have been determined by scanning electron microscopy and elemental analysis has been carried out using energy dispersive spectroscopy. Optical properties of InP nanowires integrated on carbon fibers are also investigated. Our demonstration is a first step towards direct integration of semiconductors onto one of the important structural materials with the view toward a new class of material platform for solid-state devices.

8106-36, Session 8

Comparative study on nucleation and growth of InP nanowires on micro-crystalline- and single-crystalline-Si surfaces

C. W. Greene, A. J. Lohn, N. P. Kobayashi, Univ. of California, Santa Cruz (United States)

Increased capacity for strain relaxation in semiconductor nanowires allowing for heteroepitaxy on large-mismatch single-crystalline substrates has enabled unprecedented combinations of dissimilar crystalline materials. Through the use of a thin microcrystalline silicon (μc-Si) template layer, we have demonstrated that the concept of heteroepitaxy can be further extended to low-cost non-single crystalline substrates such as stainless steel or glass. Details of nucleation and growth of nanowires on the μc-Si surfaces, in contrast to those on single-crystalline surfaces, are still far from complete understanding. In this study, effects of the μc-Si layer on nucleation and growth of indium phosphide (InP) nanowires are investigated. Metal organic chemical vapor deposition was used to grow InP nanowires with diameter approximately 50 nm on μc-Si and single-crystalline Si surfaces. Growth time was varied between 1 and 20 minutes, resulting in samples quenched at various nucleation and growth stages. No nanowires were found on either substrate after 1 minute. Dense nanowires were observed on the single crystalline Si surface but only sparse growth was observed for the μc-Si surface after 5 minutes. Samples grown for 10 minutes and 20 minutes both showed dense nanowire growth. Nucleation and growth between crystalline (100) and μc-Si surfaces is further compared through x-ray diffraction and x-ray reflection. X-ray diffraction is also used to assess crystallographic changes in the μc-Si template layer occurring during the growth of nanowires. This study is a critical step towards understanding various stages of nanowire growth on non-single crystalline surfaces.

Conference 8107: Nano-Opto-Mechanical Systems (NOMS)

Sunday 21 August 2011 • Part of Proceedings of SPIE Vol. 8107 Nano-Opto-Mechanical Systems (NOMS)

8107-01, Session 1

Light-induced disorder in liquid-crystalline elastomers for actuation

A. Sanchez-Ferrer, ETH Zurich (Switzerland)

Liquid-Crystalline Elastomers (LCEs) are materials which combine the entropic properties of a crosslinked polymer melt with the enthalpic properties of a liquid-crystalline state of order. LCEs show unique characteristics: visco-elasticity and order at the same time in one system. The elastic and the viscosity properties come from the crosslinking and friction of the polymer chains, respectively, while the orientation comes from the mesophase which keeps the polymer backbone aligned.

LCEs behave as normal polymer networks or rubbers when no energy-storing mesophase is present. This state of disorder can be induced by means of temperature or light.

Thermally, the change in shape of LCEs can easily reach 300% when all the enthalpy stored by the mesophase is released and the crosslinked polymer chains are free to move and adopt a random coil conformation.

The light-induced local disorder can be achieved when shape-changing molecules are incorporated in the LCE matrix. These compounds are able to absorb light, rearrange themselves in a new shape and thus disturb the mesophase. This results in the molecules that are keeping the order no longer being able to sustain the retractive force from the polymer backbone, and the material contracts exerting an actuating force.

But, how does a light sensitive side-chain LCE elastomer behave? And a main-chain LCE? What about nematics or smectics? Is a different kind of actuation, besides the common retractive force possible? To answer this questions, new chemistry needs to be developed, together with new physics to understand the systems, and new applications need to be created.

8107-02, Session 1

In-situ control of shape and molecular order in liquid crystalline polymeric nanoparticles

S. Tsoi, J. Zhou, U.S. Naval Research Lab. (United States); S. Wu, Agilent Technologies, Inc. (United States); C. Spillmann, J. Naciri, N. Hashemi, U.S. Naval Research Lab. (United States); T. Ikeda, Tokyo Institute of Technology (Japan); B. Ratna, U.S. Naval Research Lab. (United States)

Two types of stable 100-nm liquid crystalline polymeric nanoparticles were synthesized and when immobilized on solid substrates, actuation of their shape and internal molecular order, respectively, experimentally demonstrated. The first type contains azo-benzene-based liquid crystals fused into an elastomeric network. The shape of the nanoparticles can be reversibly altered by illumination with light. AFM measurements reveal that exposure of the immobilized nanoparticles to UV radiation results in reduction of their height and concomitant increase of the lateral size. Conversely, exposure to visible light increases the height of the nanoparticles and decreases their lateral size. The amount of the strain achieved is controlled by the exposure dosage and can reach values as high as 20%. The second type of nanoparticles studied is gel-like and contains cyano-biphenyl liquid crystals 5CB and 8CB. The nanoparticles are immobilized on a metallic substrate and Scanning Kelvin Probe Microscopy is employed to probe effect of electrostatic field on them. Experimental data and finite element modeling suggest that exposure to the field induces collective mesogen re-orientation inside the nanoparticles without noticeable change in their shape.

8107-03, Session 1

Opto-mechanical parameters of liquid crystal elastomers with carbon nanotubes

N. Torras, K. E. Zinoviev, H. Campanella, C. J. Camargo, J. Esteve, Ctr. Nacional de Microelectrónica (Spain); E. M. Campo, Univ. of Pennsylvania (United States); J. E. Marshall, E. M. Terentjev, Univ. of Cambridge (United Kingdom)

Nematic liquid-crystal elastomers (LCE) have demonstrated great potential as actuators. Due to unidirectional orientation order of the mesogenic groups the material suffers uniaxial contraction when heated. The heat might be supplied from outside or generated inside the material and the latter gives additional functional capabilities for a range of applications. Energy generation inside the material can be provided by illumination of the material if the elastomer contains light absorption component. Liquid crystal elastomers enriched with the carbon nanotubes combine thermoelastic properties of nematic LCEs and the capability of carbon nanotubes (CNT) to absorb infrared and visible light and transform it into thermal energy.

The studies of photo induced actuation of LCE-CNTs present luck of phenomenological step despite intuitive simplicity and the existing theory of contraction mechanism. This work was aimed at experimental characterization of the material with the purpose of general understanding the macro properties of it and of behavior of the elastomer when illuminated by light and with the final objective to facilitate the design of optical actuators on the basis of LCE-CNTs. The parameters like absorption spectra and absorption coefficients of the material as a function of CNTs concentration have been studied. Temperature induced three dimensional deformations were compared with the photo-induced deformations monitored using SEM and conventional optical microscopy techniques combined with thermal imaging done with the IR camera. The basic test structures, cantilever beams and circular plates, have been applied for studies of thermal and mechanical properties of the material.

The work was done within the EU FP7 project (NMP 228916).

8107-04, Session 1

Light-responsive actuation materials based on the photodeformable liquid crystal polymers

Y. Yu, Fudan Univ. (China)

In recent years, photodeformable polymer materials have experienced a vigorous development due to their potential applications such as artificial muscles, photomobile actuators, Micro Opto Mechanical System (MOMS) and so on. On the other hand, as a combination of polymer networks and liquid crystals (LC), crosslinked LC polymers (CLCPs) exhibit such unique properties as elasticity, anisotropy, stimuli-responsiveness and molecular cooperation effect. In this work, a good method was developed to incorporate widely-used photodeformable trigger molecules, azobenzenes, into side chains of polymer networks, in which the azobenzene units are able to act as mesogens. Then the cooperative motion of liquid crystals was utilized to magnify the microscopic structural change of azobenzene units to a significant macroscopic deformation of the whole material upon irradiation of UV light. For example, photoinduced bending was successfully achieved by inducing an asymmetry contraction in the azobenzene CLCP films. Recently, such interesting motions as a motor rotation, an inchworm walk, and a robotic arm motion fully controlled by light have also been demonstrated with the use of CLCP/polyethylene laminated films. Most lately, azotolane-containing liquid crystal polymer networks have been developed whose deformations can be induced by visible light and even directly by sunlight. Furthermore, full-light-driven microrobots,

microvalves and micropumps have also been fabricated. With these modes of deformations and all plastic actuators, one can convert the light energy directly to mechanical energy, which leads to such applications as micro-or nano-mechanical machines.

8107-05, Session 1

Light-activated shape memory of glassy, azobenzene liquid crystalline polymer networks

K. Lee, H. Koerner, R. Vaia, T. J. Bunning, T. White, Air Force Research Lab. (United States)

We present a distinctive approach to generating reconfigurable light-activated shape memory behavior of glassy azobenzene liquid crystalline polymer network (azo-LCN). Linearly polarized, eye-safe 442 nm light is used to photo-fix temporary shapes in both cantilever and free-standing geometries. The original permanent shape is all-optically recovered with exposure to circularly polarized light. All-optical, isothermal shape memory cycles (photo-fixing and photo-recovery) will be discussed. Due to the glassy nature of the azo-LCN materials utilized here, the all-optical shape memory can be combined with thermal-shape fixing that is independent of the photo-fixing of the material, yielding substantial functionality in a single adaptive material.

8107-06, Session 1

Photoactuators on the base of polymeric elastomers and carbon nanotubes

I. Krupa, M. Omastová, J. Mosnácek, M. Micu?ík, K. Czaníková, M. Ilcíková, P. Kasák, Polymer Institute (Slovakia)

Carbon nanotubes (CNT) represent attractive and challenging structures for formation various, especially electro-conductive polymeric nanocomposites. Other interesting feature of polymer/CNT nanocomposites is their photoactuating behaviour. The main problem is that CNT do not spontaneously suspend in polymers, thus the chemistry and physics of filler dispersion is a major issue in actual research. One way to achieve a homogenous CNT dispersion is to decrease the surface energy of this filler via surface modification.

This work is focused on the non-covalent modification of CNT by various surfactants and their characterization.

Modified CNT were used for preparation of nanocomposites with an elastomeric matrix from solution. The orientation of CNT within a matrix was ensured by cross-linking

Acknowledgements.

Project NOMS which is funded by the European Commission under contract no. 228916

8107-07, Session 2

Nanotube micro- and nano-opto-mechanical systems

B. Panchapakesan, P. Xu, Univ. of Louisville (United States)

Ever since the discovery of carbon nanotubes, its electro-mechanical actuation has been well studied. However no such investigation has happened in the area of photomechanical actuation of nanotubes. When light is irradiated on nanotubes, they undergo stretching, relaxation, bending and actuation. Several attempts have been made in the past to combine nanotubes with polymeric materials to create photomechanical actuators that release the stored energy on infra-red trigger. However these polymers are neither compatible with MEMS process nor the actuation was reversible.

In this paper we discuss our efforts in the development of micro/nano-optomechanical actuators. Using a combination of SU8 patterning process and carbon nanotube films, we demonstrated micro-optomechanical actuators that exhibited a displacement of 24 microns for 400 micron long cantilever at 170 mW of laser power. Since then several new devices has been created using the same process. In one such study micro-grippers were shown to manipulate polystyrene microspheres and cells at about 240 micro-watts of laser power. In another study, we were able to demonstrate photomechanically actuated micro-mirrors about 500 microns in diameter with large rotational angles of 19 degrees at only 170 mW. Finally, we integrated optical filters on the rotational micro-mirrors to demonstrate 10:1 and 20:1 wavelength selectivity of the mirror using red and green filters and their corresponding wavelengths. All these studies show the potential for new area of optomechanical systems that can rival silicon based electrically driven MEMS technologies. Currently we are working on integrating our process with all silicon technologies. Further, integration of 50 nm nano-needles with both SU8 as well as silicon grippers creating the first opto-mechanically actuated nano-grippers for nano-positioning and manipulation. Such grippers have the potential for nano-manipulation of particles, nano-assembly and nano-lithography. We will discuss our efforts in all these new area of nano-opto-mechanical systems.

8107-08, Session 2

Microstamped opto-mechanical actuator for tactile displays

C. J. Camargo, N. Torras, H. Campanella, Ctr. Nacional de Microelectrónica (Spain); J. E. Marshall, Univ. of Cambridge (United Kingdom); K. E. Zinoviev, Ctr. Nacional de Microelectrónica (Spain); E. M. Campo, Univ. of Pennsylvania (United States); E. M. Terentjev, Univ. of Cambridge (United Kingdom); J. Esteve, Ctr. Nacional de Microelectrónica (Spain)

Over the last few years, several technologies have been adapted for use in tactile displays, such as thermo-pneumatic actuators, piezoelectric polymers and dielectric elastomers. None of these approaches offers high-performance for refreshable Braille display system (RBDS), due to considerations of weight, power efficiency and response speed. Optical actuation offers an attractive alternative to solve limitations of current-art technologies, allowing electromechanical decoupling, elimination of actuation circuits and remote controllability. Creating these optically-driven devices requires liquid crystal - carbon nanotube (LC-CNT) composites that show a reversible shape change in response to an applied light. This work thus reports on novel opto-actuated Braille dots based on LC-CNT composite and silicon mold microstamping.

The manufacturing approach succeeds on producing blisters according to the Braille standard for the visually impaired, by taking shear-aligned LC-CNT films and silicon stamps. For this application, we need to define specifically-shaped structures. Some technologies have succeeded on elastomer microstructuring. Nevertheless, they are not applicable for LC-CNT molding because they do not consider the stretching of the polymer which is required for LC-CNT fabrication. Our process demonstrates that composites micro-molding and their 3-D structuring is feasible by silicon-based stamping. Its work principle involves the mechanical stretching, allowing the CNTs alignment, which is an important aspect to act the LC-CNT due to the alignment-dependence of its actuation.

Our European Union FP7 NOMS (Nano Optical Mechanical Systems) Consortium aims at building a tactile tablet for the visually-impaired. This will be the main application of the microstamped optomechanical actuator concept presented in this work.

8107-09, Session 2

Opto-thermal actuation in double layer polymer microcantilevers

C. Martin-Olmos, L. G. Villaneva, A. Llobera, Ctr. Nacional de

Microelectrónica (Spain) and Instituto de Microelectrónica de Barcelona (Spain) and Consejo Superior de Investigaciones Científicas (Spain); A. Voigt, G. Gruetzner, Microresist Technology (Germany); M. Arroyo, M. Calleja, Ctr. Nacional de Microelectrónica (Spain) and Instituto de Microelectrónica de Madrid (Spain) and Consejo Superior de Investigaciones Científicas (Spain); F. Perez-Murano, Ctr. Nacional de Microelectrónica (Spain)

Actuation at the micro scale and nanoscale without direct contact is of high interest in different areas, as for example the manipulation of small objects for cell manipulation. We present a simple fabrication process of photo-thermal actuators using low-cost modified photosensitive materials.

The fabrication of these photo-thermal actuators was performed using two layers of polymers: one layer is epoxy-based resist with high optical transparency that allows the realization of high aspect ratio patterns for micromachining applications with high resolution. The second polymeric layer is obtained using the same resist but doped with polyaniline. Polyaniline is an organic dye that changes the absorbance spectrum of the bare epoxy based resist, providing the polymer with absorbance bands in the visible-infrared range. Absorbed photons undergo a phononic transition, resulting in localized thermal effects.

Cantilevers with dimensions in the following ranges have been fabricated: length: 200-450 µm; width: 50 µm and thickness: 4-6 µm. According to this, the elastic constant of these cantilevers range from 0.4 N/m to 0.05 N/m (assuming a Young's modulus value of 4,02 GPa).

Two sets of experiments have been performed, one at a constant temperature and measuring deflection (only thermal actuation) and the other locally applying a constant incident power by means of laser focused in the actuator, and measuring the deflection (opto-thermal actuation).

Using the theoretical calculations to analyze the experimental data, it has been possible to determine the coefficient of thermal expansion (CTE) and the thermal conductivity of the doped resist. These measurements show that systems fabricated with such technology will be valid as actuators, with a very low fabrication cost and high displacement.

8107-10, Session 2

In-situ TEM studies of thin film nanobatteries prepared by focused ion beam

T. McGilvray, S. Meng, Univ. of California, San Diego (United States)

Lithium ion battery electrodes are continuously improving, and it is becoming increasingly important to understand the complex dynamic processes that occur during electrochemical cycling. Li de-intercalation often proceeds as a two-phase process in complex oxides such as lithium nickel manganese spinel. Ex-situ methods fall short in describing the actual processes occurring during electrochemical cycling, such as, how does the lithiation front move within an electrode as a function of state of charge and charging rate? This study aims to observe these processes in-situ in a high resolution transmission electron microscope (TEM). In-situ capabilities exist in other analytical techniques such as XRD, XPS, and other beamline methods, but so far no group has observed a thin film battery in-situ in a TEM. equipped with chemical analytical tools such as energy dispersive X-ray spectroscopy (EDXS).

We prepare nanoscale batteries suitable for in situ TEM study by using a "DualBeam" Focused Ion Beam (FIB) paired with a Scanning Electron Microscope (SEM) to mill a cross section out of a thin-film microbattery. We then mount the nanoscale cross section to a custom grid capable of biasing in the TEM. Finally, we thin the sample to a thickness suitable for EELS characterization. We present the main challenges and corresponding solutions, since cross section milling requires high energy ions and the deposition of a protective layer on the battery surface. It is our goal that this work produces a standardized method of studying electrochemical thin film nanodevices in the TEM for applications beyond battery research.

8107-11, Session 3

Materials science: the key to revolutionary breakthroughs in micro-fluidic devices

M. Czugala, B. Ziolkowski, R. Byrne, D. Diamond, F. Benito-Lopez, Dublin City Univ. (Ireland)

Nowadays, precise flow control, provision of exact reagent amounts, contamination prevention between reagents, autonomy, disposability and low-cost manufacture are factors that can not be found together for micro-fluidic valves.

Valves made using photo-responsive materials are of great interest as functional materials within micro-fluidic systems since actuation can be controlled by simple light irradiation, without physical contact, offering improvements in versatility during manifold fabrication, and control of actuation. Nevertheless, their poor versatility, slow response times and limited robustness render them currently as scientific curiosities rather than ideally functioning devices.[1]

The incorporation of photo-responsive gels with ionic liquids (ILs) produces hybrid ionogels with many advantages over conventional materials. For example, through the tailoring of chemical and physical properties of ILs, robustness, acid/ base character, viscosity and other critical operational characteristics can be finely adjusted. Therefore, the characteristics of the ionogels can be tuned by simply changing the IL and so the actuation behaviour of micro-valves made from these novel materials can be more closely controlled.[2]

We have investigated the potential use of spiropyran-modified ionogels for controlling fluid within micro-fluidic channels. This remote ability could greatly simplify specific device design and cost. We have effectively incorporated ionic liquids into hydrogels to attain specific material contraction performance.[3] An advantage of using ionic liquids is the plethora of synthetic and material design options that can be used to design devices optimized for certain performance parameters or behaviours.

Polypyrrole/DBSA actuators sense working conditions and surrounding variables.

T. Fernández Otero, L. Valero, Y. A. Ismail, J. G. Martinez-Gil, Univ. Politécnica de Cartagena (Spain)

The electrochemical reactions of oxidation-reduction in a film of any conducting polymer (CP) with prevailing cation (C+) exchange with solution during reaction can be written in presence of an aqueous electrolyte in a simplified way as:

[CPa+(A-)a]s + n(C+) aq+ mH2O ↔ [(CP(n+a)+)(A-) a (C+)n (H2O)m]gel + (n e-)metal

This reaction supports both, electrochemical properties and the electrochemical applications of those non-stoichiometric [1], reactive and biomimicking materials. Driven by a constant current the electric potential of the film, followed versus a reference electrode, gives increasing anodic, or increasing cathode potentials along oxidation, or reduction processes, respectively. The reaction is influenced by ambient conditions: electrolyte concentration, temperature, mechanical conditions (when the reaction promotes a change of volume). Those influences follow the Ohms law applied to electrochemical reactions: E = IR. Driven by constant current (I) decreasing electrical energies (I ∫ E dt) will be consumed at increasing values of the variables favouring the reaction rate. Both, the potential evolution and the consumed electrical energy are sensors of the ambient variable during the reaction. Sensing abilities from oxidation and reduction reactions from films of different polypyrrole/ DBS films and bimorph actuators will be presented Polypyrrole/DBS films and devices were characterized for different variables: electrolyte

concentrations, temperature, weight of objects attached to the bottom of the muscle, or current flowing through the device will be presented. Lineal evolutions are obtained for the electrical energy consumed by the artificial muscles to move across a constant distance as a function of the studied experimental variable. Both signals, the actuating current and the sensing potential response, are included by the same two connecting wires, opening a new paradigm for those devices including chemical reactions.

8107-13, Session 3

Self-powered system for structural vibration sensing

P. Gaudenzi, F. Capece, S. Gabriele, Univ. degli Studi di Roma La Sapienza (Italy)

The problem of investigating the structural integrity is a critical aspect for a great number of complex system; an airplane, for instance, needs scheduled revisions to check the perfect status of each component. Many problems arose when a component to be inspected lies in a position requiring the disassembly and successive reassembly of many structural elements, and the consequent time during which the vehicle, or every other equipment which status needed to be checked, is not available due to maintenance, imply additional costs. Therefore, a system that can remotely monitor the components, without the need to physically inspect them, should constitute an advantageous mean for reducing costs and time.

Such a system could be a network of sensors, which sense the vibration stressing the structure, integrated with a system able to remotely transmit the data collected: this kind of system, known as WSNs (Wireless Sensor Networks) have drawn significant attention in monitoring plants, resources, and infrastructures. For the supply of energy needed to this system to work we propose to develop some energy harvesting form vibration sources, the same to be monitored. In fact the use of traditional source of stored energy, like electrochemical batteries, is not practical for small scales. Smart materials can come to the aid of solving this issue: integrating piezoelectric patches on the vibrating structures could be not only the way to monitor vibration but also to generate electric current capable to produce energy to charge a rechargeable battery, or to be stored in a supercapacitor, according to the energy needs.

A critical issue of the system is the evaluation of the level of power needed by the sensing system.

Furthermore, differently from some application, in which the inspections can be carried out only post-operation, i.e. with the vehicle or resources not working, such a system can continuously and on-line test and sense the structural behaviour of the under-investigation components.

8107-14, Session 3

Some electrical transport properties of PLA/MWCNT composites

S. Kumar, E. Marwah, R. Cardona, J. J. Santiago-Aviles, Univ. of Pennsylvania (United States)

Super-capacitors are becoming commonplace, which makes its environmental friendliness an important attribute. For high capacitance, we need suitable materials, formulations and electrodes. Super-capacitors can store energy as part of double layer capacitance (a purely physical effect) or through the charge and discharge of an electro-active polymer (Faradaic, or electro-chemical contribution). Of course, both schemes need a compliant and flexible packaging material with particular electrical and thermal properties. In this abstract we would like to briefly describe how the authors addressed some issues in these types of materials. For this work, we utilize commercially available biodegradable electrospun polymer fibers, In this case, Poly Lactic Acid (PLA) which is a popular corn derived material. It is synthesized by corn fermentation, which generates Lactic Acid. As received, PLA is a solid resin in pellet form. It is dissolved in dichloroethane as to achieve the proper electrospinning kinematic viscosity. Once in the liquid phase, the material is mixed with commercially available dispersed multiwall CNT at concentrations varying from 2 to 5 w/o. This mixture is then spun at room temperature using a home built electrospinning apparatus capable of depositing randomly oriented fiber mats or oriented fibers onto different substrates, ranging from oxidized Si wafers, Alumina squares or glass microscope slides. The fibers diameters and lengths are statistically distributed following a log-normal distribution and the mean and dispersion are controlled by spinning parameters. One of the challenges achieved in this work lies in obtaining fibers with a small as possible mean diameter, ideally, in the nano-scale range.

Once the fibers are obtained, they are compositionally, morphologically and structurally characterized using thermal analysis, EDX (Energy dispersive X-rays), SEM images, Raman scattering and XRD. The electronic transport properties as function of temperature were measured from 2K to room temperature on a computer controlled superconducting cryostat. Results point to the formation of a PLA / CNT composite with a conductive filler and insulating binder, and where the electronic transport properties strongly correlate with the filler to binder ratio. The room temperature photoconductivity using a visible / near IR monochromator points to a charge carriers photo-transport dominated by the CNT filler as expected.

8107-15, Session 3

The continuing quest for the ‘Holy Braille’ of tactile displays

D. B. Blazie, N. H. Runyan, National Braille Press, Inc. (United States)

The Boston-based National Braille Press has established a Center for Braille Innovation (CBI), whose mission is to research and develop affordable braille literacy products. The primary focus has been to facilitate the development of dramatically lower cost electronic braille display devices, and the much-sought-after “Holy Braille” of a full-page braille display.

The NBP specs include braille dot dimensions, spacing, displacement, lifting force, and response time requirements. In addition to summarizing the technical requirements and specifications for braille and other tactile displays. We discuss human factors issues, such as why multiplexing with only a single braille character display is not acceptable for most applications. Several of the common and repeated pitfalls and assumptions that have led many previous tactile display developments astray are reviewed. We briefly summarize past efforts to use optical actuation in tactile displays. Finally, we list what appear to be the remaining challenges to developing practical tactile displays employing Electro Active Polymer actuator materials.

8107-16, Session 3

Nano opto-mechanical systems (NOMS) as a proposal for tactile displays

B. Mamojka, Slovak Blind and Partially Sighted Union (Slovakia); J. Roig, Univ. Autònoma de Barcelona (Spain); B. Roeder, Univ. Hamburg (Germany); F. Crompvoets, Philips Research Nederland B.V. (Netherlands); N. Walker, Microsharp Corp. Ltd. (United Kingdom); D. Wenn, iXscient Ltd. (United Kingdom); E. M. Campo, Univ. of Pennsylvania (United States); M. Omastová, Polymer Institute (Slovakia); E. M. Terentjev, Univ. of Cambridge (United Kingdom); J. Esteve, Ctr. Nacional de Microelectrónica (Spain)

Nano-opto mechanical Systems (NOMS) based on the photoactuation of photoactive polymer actuators and devices is a much sought-after technology. In this scheme, light sources promote mechanical actuation producing a variety of nano-opto mechanical systems such as nano-

grippers. The European Union NOMS consortium is a multidisciplinary team assembled to build a tactile tablet for the visually-impaired. The consortium is formed by experts in materials, optics, microsystems, neuropsychology, as well as end users, and commercial partners. In this paper, we will provide a series of specifications that the NOMS team is targeting in the development of a tactile display using optically-activated smart materials. Indeed, tactile displays remain mainly mechanical, compromising reload speeds and resolution which inhibit 3D tactile representation of web interfaces, much needed by the visually impaired. We will also discuss how advantageous NOMS tactile displays could be for the general public. Tactile processing based on stimulation delivered through the NOMS tablet will be tested using psychophysics and neuroscience methods, in particular event-related brain potentials. Additionally, the NOMS tablet will be instrumental to complete basic neuroscience research.

8107-17, Session 4

A nonlinear model an actuator

P. V. Negron-Marrero, Univ. de Puerto Rico en Humacao (United States); E. M. Campo, Univ. of Pennsylvania (United States)

We consider a mixture of carbon nanotubes (CNT's) with a polymer matrix. Laboratory experiments have shown that this composite reacts mechanically to infrared irradiation (IR). Ahir and Terentjev (2005) proposed a model based on linear elasticity in which the mechanical behavior of the CNT is assumed to be that of an incompressible material. The mechanical properties of the polymer do not enter into their model. A stress vs strain test of an actual specimen of this composite shows that at approximately 10% applied pre-strain, there is a crossing of the corresponding stress responses with and without IR stimuli. Ahir and Terentjev's model predicts this crossing at a 20% compression or reduction of the CNT's while actual experimental data shows the crossing at a 1--2% compression. We propose to improve on this by including the mechanical response of the polymer into the model and by using more general models of material response. The actuator process is incorporated into the model as a constitutive equation for the CNT's which changes its behavior in response to an external stimuli. We use a variational model in which the potential energy function corresponds to one for a mixture of two phases. To compute approximate minimizers we use a finite element method which incorporates the requirement that the stresses within the composite are continuous, yet it allows for jump discontinuities in the deformation gradient across interfaces. We perform calculations both in two and three dimensions and compare our numerical results with previous experimental data.

8107-18, Session 4

Mechanical modeling of thermally actuated LC-CNT composite

C. J. Camargo, H. Campanella, K. E. Zinoviev, N. Torras, Instituto de Microelectrónica de Barcelona (Spain); E. M. Campo, Univ. of Pennsylvania (United States); J. E. Comrie, E. M. Terentjev, Univ. of Cambridge (United Kingdom); J. Esteve, Instituto de Microelectrónica de Barcelona (Spain)

Optoactive polymer actuators and devices (OAPAD) are, undoubtedly, promising technologies. Analytical and finite element models describing dynamics of photo-induced deformation in OAPADs have already been developed, particularly for liquid crystal elastomers (LCE). Advanced materials like LCE - Carbon Nanotube (CNT) composites, require a more complex physical analysis involving different coupled phenomena like photochemistry, photophysics and chemomechanical coupling. The need for rigorous modeling of such complex physics as well as the imminent implantation and development of ground-breaking practical OAPADs like tactile tablets, demand a fast way to model the light-induced deformation of the material.

Our European Union FP7 NOMS (Nano Optical Mechanical Systems) Consortium aims at building a tactile tablet for the visually-impaired. Hence, modeling of optoactive polymer blister - Braille dot - geometries is the basis of further tactile tablet design.

The purpose of this work is to build a finite element model serving as a bridge between basic elastomer physics and device engineering and design. We take advantage of experimental actuation data to build an empirical model describing the material deformation. The concept that sets the basis of the model is explained: the light irradiation provokes the heating of the material mainly thanks to the absorption properties of the CNTs. Thus, we can consider that CNTs behave as internal heat generators. Consequently, an opto-mechanical system based on LCE-CNT can be evaluated and the mechanical response optimized.

8107-19, Session 5

Education and dissemination strategies in photoactuation

E. M. Campo, Univ. of Pennsylvania (United States); D. Wenn, iXscient Ltd. (United Kingdom); I. Ramos, Univ. de Puerto Rico en Humacao (United States); J. Esteve, Ctr. Nacional de Microelectrónica (Spain); E. M. Terentjev, Univ. of Cambridge (United Kingdom)

Photoactuation is a novel property where a material system actuates upon light irradiation. Few material systems have shown this effect; such as carbon nanotubes (CNTs) and CNT-polymer composites. Recent efforts aim at promoting photoactuation to mainstream research and development. Indeed, these efforts span from developing a basic understanding of mechanisms behind photoactuation, to creating methods within microsystem technologies to integrate these smart materials into practical devices. Ultimately, we envision optical actuation in multiple environments such as intracellular motors, artificial muscles, and tactile displays for the general public.

In the current information age, scientists and educators are urged to disseminate scientific findings in a prompt manner for increased public acceptance later on in the market place. Customer acceptance of highly novel technologies is an education-driven effort that requires attention early-on during the stage of technology development, particularly where nanoparticles are employed. Another driving force to disseminate photoactuation is to generate interest and curiosity amongst the K-12 population that could eventually lead to increased enrollment of graduate students in the physical sciences.

In this paper, we present a work plan for the dissemination of photactuation to society at large; from K-12 to the general public. The work plan will be designed in accordance to the logic model and will include a thorough assessment plan to gauge the effectiveness of deploying these education programs. We also discuss the prompt integration of photoactuation on the academic curriculum, striving to emphasize the similarities amongst other smart systems such as electro and thermal actuators.

8107-20, Session 5

CNT dispersion and precursor synthesis for electrospinning of polymer-CNT composites

J. P. Crespo, S. Rosa, Univ. de Puerto Rico en Humacao (United States); L. Rotkina, J. J. Santiago-Aviles, Univ. of Pennsylvania (United States); I. Ramos, Univ. de Puerto Rico en Humacao (United States); E. M. Campo, Univ. of Pennsylvania (United States)

In electrospinning, the reported ease of use combined with the spatially controlled deposition of fibers in adequately patterned substrates, could open unexplored avenues in micro and nano-systems technology manufacturing. In the context of nanocomposites, electrospun fibres appear to yield well-aligned CNTs; critical to the advent of these

nanocomposites in practical applications. In fact, great effort is being dedicated to develop effective methods for dispersion and alignment of CNTs; for which some researchers have proposed electrospinning and pyrolysis. Following this trend, and combining the advantages of electrospinning with the promise of actuating nanocomposites, we study the suitability of electrospinning to synthesize photoactuators.

Dispersed MWCNTs were dissolved in a Poly(dimethylsilocaxe)/ Poly(methylmethacrylate) precursor solution which was then fed into a homemade electrospinning aparatus. Electrospun nanofibers were collected on a (25 x 25) cm cardboard with two strips of aluminum foil to improve alignment. The nanofibres were irradiated with a visible light source of 40W and a deformation of approximately 1mm was observed as discussed elsewhere. In this work, we study the effects of different filler concentrations on dispersion and in-matrix distribution, as well as the subsequent response of the composite to light.

8107-21, Session 5

Electrospun polymer-CNT actuators

S. Rosa, J. P. Crespo, D. M. Yates, J. J. Santiago-Aviles, I. Ramos, E. Campo, Univ. de Puerto Rico en Humacao (United States)

Electrospinning of technology-relevant compounds could offer a simple bottom-up solution to integrate one-dimensional nanostructures in practical devices. Electrospun nanocomposites present well-aligned CNTs; presumably a critical factor in actuation. Electrospun polymer-CNT fibers discussed here, exhibited faceted morphologies of 1μm width. In the physical properties space, polymer-CNT composites are known to have increased thermal, electrical, and mechanical properties. Contrary to their thin-film counterparts; little effort has been dedicated to examine the active behavior of electrospun polymer-CNT composites. In this work, we report evidence of photoactuation in electrospun PDMS/PMMA-CNT composites. In this scheme, micron-width fibers were collected in a mesh pattern and then weaved onto threads. When irradiated with a visible light source, the threads bent by 1mm. However, no deformation was observed when the composites were irradiated with a heat source; suggesting the actuation mechanism is of optical nature.

High and Low Concentrator Systems for Solar Electric Applications VI

8108-15, Poster Session

Compact solar concentrator designed by minilens and slab waveguide

S. Wan-Chieh, National Taiwan Univ. (Taiwan)

Solar power is a supplying inexhaustibly, causes no pollution, and requires slightly maintenance economic energy source. Currently, very high efficiency solar cells based on III-V semiconductors are available on the market. Since these solar cells are more expensive than silicon or thin film ones, they need to be used at high concentration ratio to reduce III-V multi-junction solar cell area. Concentrated photovoltaic (CPV) system is to collect light by using low-cost optical elements so that the total cost can be reduced. A common design uses Fresnel lens as a concentrator is bulky and the acceptance angle is very small that requires a high accurate stepper motor for tracking system.

This paper presents a new solar concentrator for III-V concentrated photovoltaic. Minilens array focus sunlight to triangular prisms causing traveling wave by total internal refraction in a waveguide. High efficiency solar cell is placed on the sidewall of the waveguide. The light and thin optical system can be fabricated by low-cost process and have the linear property for the tilt of the sun light. As the result, the sun tracker rotates nine times a day accompanying by linear-moving waveguide. It also reduces the cost by decreasing the electricity demand for tracking system. At 200X and 400X concentration ratio, the design system reached 92.35% and 90.02% optical efficiency, respectively. The accepting is +/- 10 degree at each rotate.

8108-16, Poster Session

Recent progress in high-concentration Photovoltaic Cavity Converter (PVCC) development for extreme high efficiencies

U. Ortabasi, United Innovations, Inc. (United States); J. Waszczak, S. Allen, Raytheon Missile Systems (United States)

A collaboration team supported by United Innovations, Raytheon, California Energy Commission, Science Foundation Arizona and the University of Arizona has designed, fabricated and tested a Photovoltaic Cavity Converter (PVCC)/Parabolic Dish system that efficiently converts the sun's energy into electricity. The down scaled (1/36) kaleidoscopic PVCC receiver (module) developed under this demonstration project uses EMCORE's CTJ cells optimized for the "Photon Re-cycling" process.

The re-cycling of photons benefits the performance of the PVCC particularly at high concentrations (e.g. 500 suns and above). The improvement of conversion efficiency occurs due to the following effects.

1. The reflected photons from cells (metal grid fingers and active cell areas) are reutilized

2. The contact grid fingers can be denser with no significant increase in shadowing losses (minimized series resistance losses)

3. The inevitable areas between the cells can be made reflective, thus the absorption losses are minimized

4.The photon-recycling allows the spectral splitting of the trapped solar spectrum inside the cavity by using Rugate filters. This allows to create a 6- bandgap system by using two types of available 3-j cells, each responding two half of the full solar spectrum.

The demonstration tests with photon re-cycling showed significant relative improvements of the electric output (53%) when compared to "one hit" mode of operation. Further tests gave the first indication of module efficiencies better than 35% with Photon Recycling. This result compares well when compared to the existing "one hit" HCPV systems that use advanced 3-j cells and operate at 500 suns.

8108-17, Poster Session

The package structure of solar photovoltaic module and method of manufacturing texture interface

C. Peng, C. Huang, Industrial Technology Research Institute (Taiwan)

A package structure of solar photovoltaic module and method of manufacturing the same are provided. The package structure of solar photovoltaic module includes a transparent substrate, a backsheet disposed opposite to the transparent substrate, a plurality of solar cells between the transparent substrate and the backsheet, and several encapsulants sandwiched in between the transparent substrate and the textured backsheet, wherein the encapsulants encapsulate the solar cells. There is at least one embossing interface (texture) between the encapsulants, and the encapsulant having the embossing interface is a thermosetting material.

The package structure is manufactured according to the texture interface with an embossing glass, which has a bottom width of about 0.1mm, a period of about 1mm, and a height of about 0.1mm. Then, a first fabrication process is performed to laminate a structure of the glass/ the EVA adhesive (the EVA adhesive having the embossing interface between the solar cells). Then, a second fabrication process is performed to complete laminating the module package, and fabrication parameters thereof are the same to that of the first lamination process. The EVA adhesive and the EVA adhesive have the same material, and according to the IEC61215 standard test conditions, the output power is tested according to the same method as that of the comparison example. By comparing the voltage-current output characteristics of the comparison example and the first experiment, it is discovered that the module power can be enhanced by 0.77%.

8108-18, Poster Session

The electricity enhancement of solar module through the optical sheet interlayer

C. Peng, F. Lin, Industrial Technology Research Institute (Taiwan)

One optical sheet is added between the glass plate and the solar cell of the general type package structure. The new laminate structure is designed as: (glass plate/encapsulant /optical sheet/encapsulant/ solar cell/encapsulant/highly reflective back sheet) (from the front to the back). According to the present pressing processes, the above laminate structure is placed into the laminator at 165.0 and a vacuum in 10-2 torr is drawn from the upper and lower chambers for 8 minutes in total. Next, the vacuum of the upper chamber is broken for 8 minutes and the solar module package structure is pressed and sealed. The above laminate structure can be fabricated by employing the pressing processes compatible with the currently used laminator machinery.

Under STC conditions, A-class flash simulator is used to test the power output of the above laminate structure, when compared with the control group (without the optical sheet), the power output of the above laminate structure is increased. When the surface textures of the optical sheet are serration structures, the cell maximum power of the above solar module package structure is increased about 0.25%. When the surface textures of the optical sheet are waved structures, the cell maximum power of the above solar module package structure is increased about 1.12%.

Reflectance optimization using thin film coating on concentrating photovoltaic optics

G. Butel, B. M. Coughenour, College of Optical Sciences, The Univ. of Arizona (United States); R. Angel, The Univ. of Arizona (United States)

High concentration photovoltaic systems require several reflections to achieve a concentration level of approximately 1000 suns in order to make triple junction cells cost efficient. In the system we develop, we use two cascaded concentration stages that reflect the sunlight onto triple junction cells. Optimization of the reflectance of those surfaces is critical to increase the efficiency of the whole system. In this paper we report the research being carried out in order to maximize the overall reflectance of the optical surfaces of the high concentration system. More specifically it presents the different results we obtained, using different thin films coatings on the first and second concentration stages, to optimize the global efficiency for the specific cells we are using. The primary mirror is a back-silvered glass which has a high reflectance over the range of useful wavelength, 350 nm to 1600 nm. In the region below 400 nm, silver reflectance requires a boost in order to collect a broader spectrum of the sun radiation. With this new thin film design, the mirror reflectance increases by 1 to 2 % from 350 nm to 550 nm. The secondary funnels were first made with nickel over coated with silver. This specific coating not has only the role of increasing the reflectance of silver at steep incident angles (70°) in the short wavelengths by about 1 %, but also to protect silver against tarnishing since it is the layer exposed to air.

8108-20, Poster Session

Closed-loop control for solar thermal heliostats

M. R. Convery, SLAC National Accelerator Lab. (United States)

In a large-scale solar thermal power plant, alignment and control of the heliostats constitutes one of the largest costs of both time and money. This is especially the case in systems where individual heliostats are small (~1m2). Widely used techniques for performing alignment and control are “open-loop” in which heliostat alignment constants are obtained offline and applied over time with little feedback. While some closed-loop techniques have been previously been proposed, they have not been widely adopted.

In this paper, I describe a system that generates the required feedback by inducing small mechanical vibrations in the heliostat reflector surface using piezoelectric actuators. These vibrations induce time-dependent changes in the reflected wavefront that can be detected by photosensors surrounding the thermal receiver target. Time and frequency encoding of the vibrations allows identification of a misaligned heliostat from among the thousands in the system. Corrections can then be applied to bring the reflected beam onto the receiver target.

Outdoor testing of a small-scale model of this system has confirmed that such a system is effective and can achieve milliradian tracking accuracy. Furthermore, the time series of required corrections can be used to calculate precise alignment constants that can be subsequently used in open loop tracking.

This work has been supported by a grant from the California Energy Commission EISG 56084A/08-20.

8108-01, Session 1

A profile of the Amonix 7700 CPV solar power system

A. P. Plesniak, Amonix Inc. (United States)

The Amonix 7700 CPV power system is a massive pedestal mounted, dual axis tracking photovoltaic generator and truly a sight to see. The fit, form and function of the system is one of a kind when compared to other products in the PV marketplace, but the features of the system are no accident. Discussed is the reasoning behind the profile of the Amonix 7700 CPV power system and why the Amonix 7700 product is the lowest cost CPV solution of today and the lowest cost energy solution of tomorrow.

8108-02, Session 1

>41% efficient lattice matched solar cells

M. Wiemer, V. Sabnis, H. Yuen, Solar Junction (United States)

The most common triple-junction solar cell design which has been commercially available to date utilizes a germanium bottom cell with an InGaAs and InGaP middle and top cell. This type of device has a well known efficiency limitation somewhere around 40% at 500 suns. Higher efficiencies can be obtained by changing the effective bandgaps of the three junctions, but the choice of materials and approaches to do so is very limited. Solar Junction has adopted the dilute nitride material system to obtain these new bandgaps, and break through the 40% efficiency barrier.

The unique advantage of the dilute nitrides is that the bandgap and lattice constant can be tuned independently, allowing Solar Junction to make bulk material lattice matched to Germanium or GaAs over a range of bandgaps. Our dilute nitride technology in our first commercial product has enabled us to maximize the efficiency of a triple junction solar cell by using the optimal set of bandgaps (including one around 1eV). Solar Junction concentrator cells with efficiencies in excess of 41.4% have been independently verified by NREL, and represent typical cells on a wafer. These higher efficiencies are generally the result of higher output voltage, not higher current, which keeps system-level resistive wiring losses in check.

8108-03, Session 1

Optics development for micro-cell based CPV modules

W. Wagner, E. Menard, M. Meitl, M. Samarskiy, K. Ghosal, Semprius, Inc. (United States)

Semprius’ two-stage pupil imaging CPV design incorporates optically imperfect but extremely cost-effective glass ball secondary lenses, in addition to standard primary lens arrays. Our secondary lens design process involves modeling the illumination uniformity of the primary aperture (the ‘pupil’) on the transfer-printed, multi-junction solar cell in response to the secondary lens index, diameter, surface quality, location, and tolerance offsets. We reconcile our theoretical model with experimental results from a single fully adjustable ‘concentrating unit’, and we thereby create a robust model for design updates, for tolerance and sensitivity modeling, and for prediction of full module and on-sun tracker performance based on receiver placement relative to our primary lens array.

In this presentation, we discuss the rationale behind our optics approach, our criteria for optimizing our optics, and our tolerancing approach. Then we discuss our experimental approach, including our universally adjustable ‘concentrating unit’ fixture, our light source, and our primary and secondary optics. We show sensitivity curves of our ‘concentrating unit’ towards receiver placement, receiver tilt, and ball lens size. We reconcile these with our ray-traced model, and, finally, we show predicted module performance based on receiver tolerance data and receiver wiring in the module. Finally, we compare data from our trackers with predicted module performance.

Optical properties and solar radiation durability of PV materials and solar mirrors

R. H. French, W. Lin, M. Murray, Case Western Reserve Univ. (United States); S. A. Brown, K. A. Shell, M. Schuetz, Replex Plastics (United States)

Solar and environmental durability of materials and components used in photovoltaic (PV) systems is a critically important issue, so as to ensure the reliability and ultimate bankability of PV systems. We have been developing quantitative optical properties and solar radiation durability methods and metrics for materials used in flat panel, and in low concentration PV (LCPV) systems. We'll discuss solar radiation durability of PV and LCPV materials such as frontsheet, encapsulant and back sheet materials, and of acrylic solar mirrors. Solar mirror durability is important for both mirror augmentation of flat panel PV, and other LCPV type systems.

A useful solar radiation durability metric is the induced absorbance rate (Incremental ΔAbs/cm per GJ/m2), which quantitates the wavelength dependent change in the absorbance/cm for a material exposed to a full spectrum AM1.5 solar radiation dose, in units of GJ/m2. The induced absorbance to dose, allows one to identify wavelengths and rates of photodarkening and photobleaching processes in materials. Since it is normalized to full spectrum dose, comparisons of rates at different irradiances (e.g. 1, 3.8, and 48.2 kW/m2) allow serve to check linearity and reciprocity of the observed photochemical degradation processes. We will discuss results from EVA, PMMA, PET and silicones.

8108-02, Session 2

Direct comparison of PMMA and silicone-on-glass

H. P. Annen, L. Fu, R. Leutz, L. González, Concentrator Optics GmbH (Germany)

The CPV community is still undecided on one critical issue: what material to use best for Fresnel lens parquets. Reliability and longevity are the most important, but all other properties play roles as well.

We have developed and manufactured Fresnel lenses with the two commonly used materials: PMMA and silicone on glass (SOG). Both lenses are designed for the same optical train for best comparability.

This allows for better understanding the pros and cons of the materials and making an informed choice for a specific CPV module.

Theory predicts a slight optical performance benefit for PMMA lenses due to the higher refractive index and only two instead of three optical transitions. This can be directly tested and compared under laboratory and outdoor conditions. While PMMA lenses are embossed from pre-fab sheets in a hot-cold process, the silicone lenses are cast from a heat-curing silicone rubber at moderate temperatures, reducing the energy consumption. PMMA allows for the inclusion of custom low-profile 3D (2.5D) structures for module assembly and mechanical alignment, a feature not possible in silicone due to its low rigidity.

SOG lenses are prone to delamination of the silicone film. The adhesive strength of the film to the glass can be measured using a modified blister test that we developed. The results show large difference with different materials and confirm the necessity of controlling this issue closely. While the small thermal expansion of the glass sheets allows for larger parquet sizes, the deformation of the prisms with temperature may cause a performance hit.

Failure modes for PMMA lenses include cracking and yellowing. Cracking is accelerated by internal stress, material and geometry. Also, PMMA lenses tend to global deformations and the thermal expansion limits the maximum usable parquet size.

Acknowledgment: This study is part of the Triple Primaries project, initiated as research project for various primary and secondary optics in combination with cells, by Concentrator Optics, Azur Space Solar and Isuzu Glass.

8108-04, Session 2

Field performance of concentrix CPV systems

A. Gombert, C. Crawford, T. Gerstmaier, S. van Riesen, M. Röttger, J. Wüllner, Concentrix Solar GmbH (Germany)

Concentrix Solar GmbH - a division of the Soitec Group - is manufacturing and installing concentrating photovoltaic (CPV) systems. Concentrix modules are based on III-V triple junction cells, a Fresnel lens array with a relatively small single lens aperture of 5 square inch, and a cover and bottom plate made out of glass. In case of this small primary lens, a simple heat spreader made out of a metal with a satisfying thermal conductance is sufficient for the thermal management. The first installations were conducted in 2008 in Europe, later installations followed in the US, in East Asia, in the Arabian Peninsula, and in Africa. This paper gives an overview of the performance of Concentrix Solar´s CPV systems with special focus on the different climatic conditions and their impact on the system performance. The seasonal distribution of the direct normal irradiation at the mentioned locations was found to be very different which enabled us to perform studies on the system performance depending on irradiation and ambient temperature. The first generation modules which were installed in 2008 had an average efficiency of 25%, resulting in a peak solar-to-grid system efficiency of 23% and an average AC system energy efficiency of > 20%. The system peak efficiencies of the second and third module generations reach maximum values of > 25% and average AC system efficiencies of > 22%. A detailed analysis of the performance of the different system generations will be presented.

8108-05, Session 2

Techniques, regression, and applications of glass strength measurements for concentrator photovoltaic (CPV) mirrors

D. Krevor, M. Milbourne, SolFocus, Inc. (United States)

A primary failure mode for glass failure in reflective CPV systems is the mechanical stress caused by a thermal gradient. To establish the necessary reflector specifications, it is essential to have both economic techniques to measure glass strength and an insight into the failure mechanisms. Due to the highly stochastic nature of glass fracture, large data sets are necessary for statistical validity and to provide meaningful estimates of field failure rates. This paper discusses experimental measurement techniques for both value-added reflectors and for non-value surrogate substrates which are generated as waste during the manufacturing process. Specialized tooling enables measurement by commercially available stress-strain equipment (e.g., "Instron" testers). The glass strength is calculated from the force-to-break data, sample thickness and a substrate shape dependence. These strength data are regressed using a two-parameter Weibull model, which enables calculation of the Weibull modulus, which is a measure of the distribution of flaws of a brittle material. Using a finite element analysis model of the thermal-mechanical stress to determine the critical stress, the Weibull analysis enables extrapolation of the data to predict field failure rates. The test and regression now comprise an On-going Reliability Test (ORT) that is inherently low-cost and appropriate for high-volume manufacture.

For fracture, the initiating flaws are the result of glass cutting and trimming operations. There can be low-strength outliers which result from bulk glass defects, though such flawed product should be culled during the manufacturing and inspection processes. As expected and commonly known, the as-cut glass strength is very sensitive to the cutting method and resulting quality.

Concentrating PV survey: an unbiased overview

J. Handy, Objective Analysis (United States)

Concentrating photovoltaics (CPV) technology is well positioned to contribute in an important way to utility-scale power generation. All CPV systems share certain attributes and certain shortcomings. This presentation is intended to help attendees understand the commonalities of all CPV systems and the differences between the leading technologies, and to present criteria to help understand which technologies are likely to succeed and which are less likely to survive.

The analysis is based upon the CPV technologies themselves along with arguments involving economics, insolation, and policy. It encompasses all aspects of CPV combined with its strengths and weaknesses to illustrate the likelihood that some of these technologies will participate in the power grid of tomorrow.

The author has reviewed all leading CPV technologies and has interviewed key CPV suppliers and important test sites to better understand the reasons that some CPV systems are more likely to succeed than are others.

8108-07, Session 3

A CPV thesis

S. Ghosh, D. S. Schultz, Banyan Energy Inc. (United States)

This decade is different for CPV because of optic innovations capable of delivering low to mid levels of concentration within a compact form factor, increases in mono-silicon cell efficiencies (complimentary increases in capacity) and the maturation of vertically integrated solar companies more focused on delivering system oriented solutions that minimize the levelized cost of energy. Monosilicon cells are well-suited for concentration because of their high cost structure and robust efficiency. This category of receiver achieves the greatest system capital efficiency benefit when paired with an appropriate module-integrated concentrator technology. The viability of a concentrator technology is determined by five interrelated factors: economic benefit, cell efficiency under concentration, thermal management, optical performance and manufacturability. These factors impose tradeoffs that dictate that the 5-10x concentration range is ideal for silicon-based receivers. This range of concentration provides substantial improvement in capital efficiency while mitigating technical risk. Below the 5x concentration level, the cost to integrate optics with receiver approximately equalizes with economic benefit. Above 10x, the vast majority of the capital efficiency benefit is achieved, but substantial threats to reliability arise. The combination of thermal management costs, reduced manufacturing yields (for cell and module) and increased degradation rate serve to erode any marginal economic benefit from increasing concentration significantly beyond 10x.

8108-08, Session 3

Design and performance of a low-cost, low-concentration PV module

K. A. Shell, S. A. Brown, M. Schuetz, Replex Plastics (United States); B. Davis, The Ohio State Univ. (United States); R. H. French, Case Western Reserve Univ. (United States)

Replex Plastics is developing a low-cost, low-concentration PV (LC2PV) module using Replex acrylic solar mirror. The module is designed for use in northern climates, where lower insolation and higher levels of atmospheric scattering result in system designs with wide acceptance angles and reduced tracking accuracy requirements. The first generation prototype uses silicon cells and a reflective compound parabolic concentrator (CPC) designed specifically for relatively low-accuracy (~1°) single axis tracking systems. The asymmetric CPC has a nominal geometric concentration factor of 10x, and acceptance angles of 12.1° in the tracking direction and 23.5° in the non-tracking direction to allow for seasonal variation of the sun.

The challenge of a low-concentration system is to minimize the additional cost from the reflector, heat dissipation, and additional electrical bus material so that it does not negate the benefits from using 1/10th the silicon content. Accordingly, three critical performance parameters are being addressed in the LC2PV design: (1) Maximizing the optical efficiency of the mirrored reflector, (2) Designing a low-cost, light-weight passive heat sink suitable for low-concentration heat dissipation, and (3) Minimizing electrical losses in the PV ribbon due to increased current.

The first LC2PV module prototype was installed on a tracker in Athens, OH in October 2010, and achieved a 7.1x concentration over a receiver with no concentration. The power output of the module is being monitored continuously, and has exhibited a peak output of 140W. Environmental monitoring is currently being installed at the test site so that module performance can accurately be compared to irradiance, temperature and wind-speed conditions. The next generation prototype is currently under development with an expected installation Summer 2011.

8108-09, Session 3

Significant cost reduction through new optical, thermal, and structural design for a medium-CPV system

M. A. Finot, B. MacDonald, Skyline Solar, Inc. (United States)

The design of cost-efficient medium-concentration CPV (MCPV) systems requires the analysis of dozens of engineering, manufacturing and financial trade-offs. In 2007, Skyline Solar designed its first system, HGS1000, based on a 7x concentration factor and 0.5 m aperture width. Due to the modular aspect of the Skyline Solar architecture, the system has been re-optimized for the current cost/performance roadmap of the critical components using a combination of field data and advanced performance modeling for lowest levelized cost of energy (LCOE). The key area is to design a system using high-volume, high quality commodity components. Use of efficient high volume Si cells, standard mirrors and tracking structure minimizes supply chain and reliability risk and ensures a fast ramp-up of a new architecture.

All CPV designs substitute optical and structural materials with lower area cost than the PV cells they are replacing. Design choices span many engineering disciplines including optical, thermal, structural, electrical, packaging - each of which has many parameters. Optimization requires deep understanding of system cost and performance under a variety of conditions. We used field performance data from multiple installations of the HGS1000 system and comprehensive design modeling tools to re-optimize our CPV design. The analysis led to a new design with cost reductions exceeding 40% with major changes in several design parameters - most notably 14x concentration and 1 meter aperture width. We will discuss optimization of thermal and structural designs in the context of peak power cost and energy cost. Early field performance data will be presented along with correlation to predicted results.

8108-10, Session 3

Bringing new technology to the solar market: low concentrating solar and trackers for maximum generation for PV installations

K. Gibson, Solaria Corp. (United States)

Solaria's photovoltaic silicon modules offer industry-leading costs with the reliability and performance of traditional crystalline solar modules. Solaria modules are manufactured with an efficient use of silicon that leads to the smallest carbon footprint and fastest energy payback of any silicon-based panel; the company is a leader in the solar industry in reducing the environmental impact of PV manufacturing.

Solaria delivers more energy and lower LCOE. The patented technology combines silicon solar cells with proprietary glass optics to reduce module costs without compromising performance. Solaria's proprietary flat-plate optical concentrator delivers maximum output.

The company uses only proven, UL-listed materials that are standard in the PV industry, thereby eliminating risks associated with new materials.

The modules are specifically designed and optimized for tracking systems, which yield additional cost savings in installation and balance of system costs, providing a low-cost, high-performance solution for developers of large-scale solar tracking systems. The form factor, mounting system and installation processes are also optimized for efficiency and reliability. Solaria provides large integrators and system developers with the most cost-effective and reliable module for large- and utility scale solar electric installations.

8108-11, Session 4

Comparison of tracking and non-tracking holographic planar concentrator systems

R. K. Kostuk, D. Zhang, J. M. Castro, J. M. Russo, S. D. Vorndran, The Univ. of Arizona (United States)

In this paper we review the properties of holographic planar concentrators (HPCs) with tracking as a design consideration. Static holographic concentrators have been shown to collect approximately 50% of the available solar illumination illuminating the hologram area and deliver it to the photovoltaic (PV) surface. Another feature of the static concentrator is that the composition of the spectrum varies as the sun moves in its daily and seasonal trajectory. This results in a variation in the PV cell output due to changes in the responsivity and the spectrum of the solar illumination. In addition the uniformity of the illumination can vary considerably as the sun moves resulting in effective shading effects which diminish the PV system output.

A variety of tracking systems have been developed to increase efficiency and energy yield of different photovoltaic systems. Tracking has primarily been developed for high concentration systems that use expensive multi junction cells and require high pointing accuracy. However tracking has also been shown to be near cost competitive by improving energy yield of one-sun systems with more expensive PV cells. For holographic planar concentrators tracking can be used to control the spectrum of the diffracted solar illumination directed to the photovoltaic cell surface and has important consequences on the performance of the overall solar concentrator system. In this presentation we examine the use of single axis tracking systems as a design parameter to optimize the energy yield of holographic planar concentrators. A levelized cost of energy analysis is also performed to determine the point at which tracking HPC systems become cost effective.

8108-12, Session 4

New luminescent materials and filters for luminescent solar concentrators

D. K. de Boer, C. R. Ronda, W. K. Keur, Philips Research Nederland B.V. (Netherlands); A. Meijerink, Utrecht Univ. (Netherlands)

In a Luminescent Solar Concentrator (LSC), short-wavelength light is converted by a luminescent material into long-wavelength light, which is light guided towards a photovoltaic cell. In principle, an LSC allows for high concentration, since the heat generated by the conversion process can be used to lower the entropy of light. In practice, however, this is prevented by less controlled loss mechanisms, like limited sunlight absorption, limited quantum efficiency and high self absorption. To tackle these problems, a suitable luminescent material is needed. Another important loss mechanism is the escape of luminescent radiation into directions that do not stay inside the light guide. To reduce this amount, wavelength-selective filters can be applied that reflect the luminescent radiation back into the light guide while transmitting the incident sunlight. In a previous paper [1], we used simulations to clarify the optimal luminescent and filter properties. In this paper, we discuss experiments and simulations of new luminescent and filter materials. We will introduce a phosphor with close-to-optimal luminescent properties. A problem for use in an LSC is the large scattering of this material; we will discuss possible solutions for this. Furthermore, we will discuss the use of broad-band cholesteric filters [2] in combination with this phosphor.

8108-13, Session 4

Efficient hybrid electric and thermal energy generation

X. Xia, A. Parfenov, T. Aye, M. Shih, T. Jannson, Physical Optics Corp. (United States)

Ideally, solar Photovoltaic (PV) panels should be efficient, lightweight, and more affordable to manufacture than they are today. Recently, power generation systems using Concentrated Solar Thermal (CST) energy have demonstrated conversion efficiency levels over 30% under optimal conditions. Multi-junction Concentrated Solar Photovoltaics (CSP) have demonstrated conversion efficiencies over 40%. In this paper, we demonstrate a novel hybrid electrical and thermal energy cogeneration system for combined solar photovoltaic electricity and heat conversion with much higher efficiency (reaching over 50%), at reduced overall weight and size compared with current solar power systems. The new system is based on highly efficient photovoltaic solar panels and tubular water thermal receivers, incorporating POC's proprietary holographic spectral beam light guide concentrators resulting in a more cost-effective solution. The holographic concentrator consists of a dual-film broadband holographic optical element device, so that the first hologram collects energy in the visible part of the spectrum (400 680 nm) for electricity generation via thin strips PV, and the second hologram collects infrared (680-2000 nm) radiation to cogenerate heat using tubular thermal receivers. The holographic structure is angularly, spectrally, and spatially multiplexed to accept incoming light from a range of incidence angles so that it can be mounted at an optimized angle tilted to south at latitude-15 degrees in a nontracking configuration, collecting both direct and diffuse light. Details of fabrication and experimental testing results will be presented.

8108-14, Session 4

Novel luminescent solar concentrators (LSCs) enabled by large-area microoptical sheets

P. H. Schmaelzle, Palo Alto Research Center, Inc. (United States)

Luminescent Solar Concentrators have not yet found broad commercial adoption despite their unique ability to concentrate direct and (!) diffuse light without any tracking.

A major impediment --besides fading lifetime and efficiency challenges-- originates from the dimensional coupling between the lightguide slab's thickness and the width of the receiving photovoltaic (PV) cells. While embodied energy and materials cost considerations mandate to minimize slab thickness, we explain how a thin slab requires the outcouplers to be small (in at least one dimension). If the consequently large number of outcouplers are conventionally realized as PV cells directly attached to the lightguide, then assembly cost, yield and efficiency issues of small cells become limiting. This leads to severe design compromises and prevents ultra-lowcost LSCs.

Instead, we propose a novel architecture using microoptical outcouplers as an intermediary between the lightguide and the receiving PV cells. The microoptical elements we have designed are on the 100um scale, finely spaced in arrays and partially collimate the light which they tap out. Film replicated sheets comprising large arrays of elements are simply laminated onto a luminescent slab and direct light to a few external, conveniently large PV cells.

We will discuss our designs based on raytracing studies and use Markov-chain models to predict efficiency. We will review the constraints which were observed to ensure processability with existing industrial roll-to-roll equipment for fabless manufacturability on a square-kilometer (photonic GW) scale.

Conference 8109: Solar Hydrogen and Nanotechnology VI

Tuesday-Thursday 23-25 August 2011 • Part of Proceedings of SPIE Vol. 8109 Solar Hydrogen and Nanotechnology VI

8109-01, Session 1

Charge photogeneration in nanostructured photoelectrodes for water oxidation

J. R. Durrant, Imperial College London (United Kingdom)

My lecture will focus upon the charge separation and recombination in photoelectrodes for solar water photolysis. I will focus upon dynamics in nanocrystalline TiO2 (1) and Fe2O3 (2) electrodes - but also consider dye sensitized and catalyst functionalised electrodes. My talk will discuss address in particular the role of recombination dynamics in limiting photoelectrode performance, and how these dynamics can be modulated both by electrical bias and surface functionalisation.

8109-02, Session 1

Interfacial charge separation and recombination dynamics in photocatalytic systems consisted of alpha-Fe2O3 and carbon-free water oxidation catalysts

T. T. Lian, Emory Univ. (United States)

Solar-driven photocatalytic water splitting (H2O + h H2 + ½ O2) is an attractive general approach to sustainable and environment-friendly energy. We have demonstrated that the carbon-free, stable and soluble polyoxometalate (POM) complexes, [{Ru4O4(OH)2(H2O)4} (-SiW10O36)2]10- (Ru4-POM) and [Co4(H2O)2(PW9O34)2]10- (Co4-POM), are highly effective homogeneous catalysts for light-driven water oxidation. To ultimately realize stable light-driven water splitting systems, we have successfully synthesized economic and robust photocatalyticanodes by grafting these POM catalysts onto nanoporous colored (narrow bandgap) iron oxide (hematite, -Fe2O3) films. The performance of these photocatalyticanodes was tested in a photoelectrochemical cell of water splitting. Co4-POM significantly enhanced the photocurrent of the Fe2O3 photoanode. The catalyst was shown to be stable under water oxidation conditions as confirmed by ATR-FTIR spectroscopy. We have also carried out transient absorption studies of interfacial charge separation and recombination dynamics in these materials in an effort to determine factors limiting the efficiency of photo-driven water oxidation in this system. In this talk, we will report recent progress in the characterization and optimization of this hybrid photocatalytic water oxidation system.

8109-03, Session 1

Transient absorption study on photogenerated carrier dynamics in visible light responsive photocatalysts GaN:ZnO

A. Furube, National Institute of Advanced Industrial Science and Technology (Japan); K. Maeda, K. Domen, The Univ. of Tokyo (Japan)

Transient absorption of visible light responsive powder photocatalysts, solid solution of GaN and ZnO (denoted as GaN:ZnO), and other related materials were measured by using femtosecond diffuse reflectance spectroscopy in order to evaluate the nature of photogenerated electrons and holes through spectral information in visible and near-infrared and kinetics from 100 fs to 1 ns. The GaN:ZnO is known to be one of successful photocatalysts which are able to split water into oxygen and hydrogen molecules under visible-light irradiation. Since photoexcitation generates electrons and holes in the conduction and valence bands, respectively, it is important to understand their trapping and recombination processes in details. Generally efficient and quick trapping and slow recombination of them are required to increase the chance of charge transfer of them to protons and water molecules. We have elucidated that the charge trapping was within time resolution (~200 fs) and recombination time was about 100 ps for 30% of carriers and much longer for 70%, clearly indicating that most of photogenerated carriers have long lifetime as we have previously reported for TiO2, where no recombination was observed until 1ns. Other photocatalysts with lower photocatalytic activity showed much shorter lifetimes. These results indicated that the long carrier lifetime in GaN:ZnO is one of the reasons for the efficient reactivity.

8109-04, Session 1

Solar hydrogen generation pathways investigated by static and transient x-ray absorption spectroscopy

L. X. Chen, Argonne National Lab. (United States) and Northwestern Univ. (United States)

Solar hydrogen generation, a process of splitting water, involves multiple step reactions using frequently multiple metal centered complexes. In spite of progress made in recent years, some reaction pathways are still unclear. The ambiguity arises from the identities of the catalyst intermediates along the reaction pathways. Using in-situ and pump-probe X-ray spectroscopy, we investigated different intermediate structures of photocatalysts used for solar hydrogen generation. In a di-iron complex mimicking the hydrogenase function, we carried out in-situ electrolysis combine with x-ray absorption spectroscopy where we identified two different intermediates with significant structural change from the starting materials. The intermediate structure provides an explanation about proton binding and then hydrogen generation. In a solar energy storage material of a di-ruthenium complex, the structural analysis from the results of pump-probe x-ray transient absorption (XTA) spectroscopy identified an intermediate that has severe distortion from what was perceived, suggesting new reaction pathways. These results suggest that static and pump-probe x-ray absorption spectroscopy is one of the ideal methods to clearly identify the structural details of the photocatalysts during the reactions. These studies will significantly help in catalyst design and reaction control.

This research is supported by the ANSER Center, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Award Number DE-SC0001059, and the Division of Chemical Sciences, Office of Basic Energy Sciences, the U. S. Department of Energy under contract DE-AC02-06CH11357. Work at the Advanced Photon Source was supported by the U. S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

8109-05, Session 2

Excited state dynamics in nanoscale materials for solar energy harvesting

O. V. Prezhdo, Univ. of Rochester (United States)

Solar energy applications require understanding of dynamical response of novel materials on nanometer scale. Our state-of-the-art non-adiabatic molecular dynamics techniques, implemented within time-dependent density functional theory, allow us to model such response at the atomistic level and in real time. The talk will focus on exciton generation, relaxation and fission in semiconductor quantum dots (QDs) and photoinitiated charge transfer at molecule/bulk interfaces.

QDs are quasi-zero dimensional structures with a unique combination of molecular and bulk properties. They exhibit new physical phenomena, including phonon bottleneck and multiple exciton generation, with the potential to increase solar cell efficiency. Photoinduced charge separation across molecular/bulk interfaces drives dye-sensitized semiconductor solar cells. It creates many challenges due to stark differences between molecular and periodic systems.

Our simulations provide a unifying description of quantum dynamics on nanometer scale, resolve highly debated issues, and generate theoretical guidelines for development of novel systems for energy harvesting and storage.

8109-06, Session 2

First principle calculation of the effects of doping on Sulfur-doped TiO2

S. Arab, R. Lake, Univ. of California, Riverside (United States)

TiO2 has proven to be one of the most stable photocatalytic materials for solar-hydrogen cells, but it has a wide band gap, absorbing in the UV and limiting its performance in the visible spectrum. We aim to design doped material that will enable highly-efficient production of hydrogen via electrolysis of water using the visible solar spectrum. In order to have an efficient solar-hydrogen cell, the electrode should have a band gap that falls within the visible solar spectrum while maintaining the potential for redox couples of water (1.23 eV). In pursuit of a reduced band gap material we focused on S-doped TiO2 in both the anatase and rutile phases. This study is based on Density Functional Theory (DFT) using Perdue Burke Ernzerhof (PBE) pseudopotentials which were implemented in Vienna ab initio simulator (VASP). Optoelectronic and molecular dynamic properties of doped supercells consisting of 24 and 48 atoms in rutile and anatase phases were calculated, and analyzed. The band gap reduction effect of sulfur doping as a function of dopant concentration is investigated, most stable substitution sites for sulfur are predicted based on theoretical calculation and electronic transport properties of the S-doped TiO2 are analyzed. Based on the previous experimental results and the theoretical calculations in this presentation we claim that S-doping is a promising and experimentally feasible approach for photocatalytic improvements of TiO2.

8109-07, Session 2

Derivative coupling constants and their relation to excited state dynamics in dye-sensitized solar cell applications

K. Yamashita, The Univ. of Tokyo (Japan)

Recombination in dye-sensitized solar cells with direct injection is cast as internal conversion in the dye-Ti(OH)2 complex. For catechol-thiophene dyes with 1, 2, or 3 thiophene units, the complex reproduces the previously observed dye-to-semiconductor bands. Based on ab initio calculations, we compare the decomposition of the internal conversion rate by vibrational mode and predict a trend in recombination with the extension of conjugation, which offers an explanation for the trend in DSSC efficiency. We employ a simple model for the vibrational factors and show that they are only important in the presence of vibrational modes with low frequencies (<=kT) and strong electronic factors. We also analyze derivative coupling constants in dyes NK1 (2E,4E-2-cyano-5-(4-dimethylaminophenyl) penta-2,4-dienoic acid) and NK7 (2E,4E-2-cyano-5-(4-diphenylaminophelyl) penta-2,4-dienoic acid) and relate them to the different dynamics that was observed for these dyes on TiO2. We compute vibronic coupling constants in the excited and cationic states obtained by the ionization of the excited state as well as the electronic part of the internal conversion rate. We discuss that derivative coupling analysis connects molecular structure to excited state dynamics and explains the slower injection from NK7 into TiO2. The analysis suggests this is not due to low-frequency motions of the benzene moieties in NK7.

8109-08, Session 2

Electronic structure study of nanostructured Co3O4 in artificial photosynthesis

J. Guo, Lawrence Berkeley National Lab. (United States); J. Chen, Lawrence Berkeley National Lab. (United States) and Tamkang Univ. (Taiwan); P. Glans, Lawrence Berkeley National Lab. (United States); W. Wang, Lawrence Berkeley National Lab. (United States) and Tamkang Univ. (Taiwan); F. Jiao, Lawrence Berkeley National Lab. (United States); C. Chang, Tamkang Univ. (Taiwan); H. M. Frei, Lawrence Berkeley National Lab. (United States)

Solar energy can be converted to chemical fuels for energy use and storage. However, the cost and conversion efficiency have been the biggest challenge for potential use of solar energy. There are the emerging technologies of using semiconductors for light harvesting assemblies. The ability to control the particle size, morphology of nanoparticles and the arrangement of atoms along the surface of nanostructured material will determine most of its physical properties.

In general, electronic structure ultimately determines the properties of matter. Soft x-ray absorption spectroscopy (XAS) and emission spectroscopy (XES) have some basic features that are important to consider. X-ray is originating from an electronic transition between a localized core state and a valence state. As a core state is involved, elemental selectivity is obtained because the core levels of different elements are well separated in energy, meaning that the involvement of the inner level makes this probe localized to one specific atomic site around which the electronic structure is reflected as a partial density-of-states contribution. The participation of valence electrons gives the method chemical state sensitivity and further, the dipole nature of the transitions gives particular symmetry information.

The high-resolution selectively excitation has opened a new field of study by disclosing many new possibilities of soft x-ray resonant inelastic scattering (RIXS). In this presentation, we show recent findings regarding XAS, XES, and RIXS studies of shows the charge transfer peak in Co3O4 nanoclusters grown in silica nanopores that act as efficient and robust catalysts for water oxidation.

8109-09, Session 3

Immobilization of stable, tunable, fast catalysts for solar-driven water oxidation

C. L. Hill, Emory Univ. (United States)

In both natural and artificial photosynthesis, dioxygen is the unavoidable by-product. The oxygen evolving center (OEC) in photosynthesis and technologically useful water oxidation catalysts (WOCs) alike must be fast and selective, but unlike the OEC, technologically viable WOCs must also be extremely stable.

Our team has developed oxidatively, hydrolytically and thermally stable WOCs based on polyoxometalate (POM) ligands. This new class of WOCs combine the stability and cost advantages of heterogeneous

catalysts with the many advantages of homogeneous catalysts. Thus far, we have developed 6 POM WOCs, including [{Ru4O4(OH)2(H2O)4}(γ-SiW10O36)2]10- (Ru4) and [Co4(H2O)2(PW9O34)2]10- (Co4) and characterized their structural, spectroscopic and redox properties using a range of physical methods. They are the fastest soluble WOCs to date for water oxidation in both the dark ([Ru(bpy)3]3+ oxidant) and light (S2O82- oxidant with [Ru(bpy)3]2+ as photosensitizer).

These WOCs can be immobilized on photoanodes and other surfaces by several approaches. The immobilized POM WOCs, like those in solution, exhibit encouraging O2 yields (or photocurrents) and quantum yields.

Acknowledgment: We thank the DOE BES for support.

8109-10, Session 3

A two-step photoexcitation system for photocatalytic water splitting into hydrogen and oxygen under visible light irradiation

R. Abe, Hokkaido Univ. (Japan)

Photocatalytic water splitting into H2 and O2 using a semiconductor photocatalyst has received much attention recently due to the potential of this method for the clean production of H2 from water utilizing solar energy. Although a number of metal oxides have been reported to be active photocatalysts for the water-splitting reaction, most only function under ultraviolet (UV) light owing to the large band gap energy of the materials. Because almost half of all incident solar energy at the Earth's surface falls in the visible region, the efficient utilization of visible light remains indispensable for realizing practical H2 production based on photocatalytic water splitting. We have recently developed a new type of photocatalytic water splitting system, mimicking the mechanism of photosynthesis in green plants. This system reduces the energy required to drive each photocatalysis process, allowing visible light to be utilized more efficiently than in conventional water splitting system. We have achieved overall water splitting using various visible light responsive photocatalysts, such as SrTiO3 doped with Cr, tantrum oxynitrides (TaON or BaTaO2N), and organic dyes, which work as a H2 evolution photocatalyst, combined with tungsten oxide (WO3) for O2 evolution in the presence of a shuttle redox mediator such as iodate/iodide (IO3-/I-). The use of BaTaO2N or coumarin organic dye was demonstrating to be photoactive at wavelength up to ca. 700 nm. These results demonstrate the potential of a two-step water-splitting system for utilizing a broader band of visible spectrum.

8109-12, Session 4

Nanonet-based heteronanostructures for solar water splitting

D. Wang, Boston College (United States)

We present our recent results on using a heteronanostructure design to solve a key challenge in semiconductor-based solar water splitting - the charge diffusion distances within oxide semiconductors (e.g., Fe2O3) are generally too short. A key enabling factor of our design is the TiSi2 nanonet, a unique two-dimensional nanomaterials that possess high conductivities and suitably high surface areas. By introducing TiSi2 nanonets to the semiconductors, we obtain a dedicated charge transport pathway that also works as a structural support. The semiconductor absorbs light to generate photoelectrons and photoholes; the holes are scavenged by the solution to oxidize H2O and to produce O2 while the electrons are transported away by the nanonets to be used for H2O reduction at the counter electrode. We found that the ability to effectively remove photoelectrons leads to improved charge separation and hence higher solar water splitting efficiencies. This design principle is significant because it makes it possible to alleviate the reliance on a material's intrinsic properties and allows for the measurement of high performance on materials with undesired electronic properties.

We demonstrate the nanonet-based design principle within the context of three transition metal oxides: TiO2, WO3 and Fe2O3. The results we obtained on Fe2O3 is particularly significant because the short charge diffusion within Fe2O3 represents a challenge that has prevented the widespread usage of this otherwise appealing material. By having a material component dedicated to charge transport, we measured the highest external quantum efficiencies on intrinsic Fe2O3. Further improvement should be possible when doping of Fe2O3 and co-catalysts are applied.

8109-13, Session 4

Polyoxometalate-based solar cells for water splitting

L. Cronin, Univ. of Glasgow (United Kingdom)

Metal oxide based materials are all-pervasive in the modern world. Utilized in microchips, hard disks, displays, glass coatings, sun screen, chemical catalysts and superconductors it is hard to think of a modern technology that does not require metal oxides of one form or another. In almost all instances the metal oxide based materials are comprised of 'solid-state' infinite materials which require high temperature processing and can be difficult to modify systematically or to dope with 'molecular' additives.

In this talk I will describe routes to 'programmed' or designed assembly of complex metal-oxides under non-equilibrium conditions using molecular precursors. The use of non-equilibrium conditions will allow us to trap new types of catalytically and electronically active materials with radically new structures and morphologies via a Universal Building Block (UBB) approach. The UBB approach offers a rational methodology for the isolation of transient intermediate molecular metal oxide cluster anions and allows unprecedented design in the self-assembly processes from atoms to nano- and meso-scale materials.

Thus, I will describe how this research allows the development of radical new material design and assembly paradigms using non-equilibrium approaches, and the applications will be placed in context by describing two possible technology areas (1) Metal oxide coatings for photochromic and electrochromic devices including solar cells and (2) Heterogeneous metal oxide integrated devices for photo and electro-catalytic processes including water splitting.

8109-35, Session 4

Advantages of nanoporous 'black silicon' for photoelectrochemical water splitting

J. Oh, T. G. Deutsch, H. Yuan, H. M. Branz, National Renewable Energy Lab. (United States)

We report that a nanoporous 'black silicon' hydrogen-evolving photocathode provides a significant improvement in the rate of hydrogen production and reduces the overpotential required for the water-splitting half-reaction, compared to a planar Si photocathode.

Photoelectrochemical production of H2 at a semiconductor/water interface has potential to convert solar energy directly to a clean and storable fuel. Together with an appropriate photoanode for O2 evolution and/or an external bias, a p-type Si photocathode can produce H2 from water. However, about 25% of incident solar photons reflect from the silicon-water interface and would not contribute to H2 production. Anti-reflection (AR) coatings, such as quarter-wavelength films of SiNx and indium tin oxide (ITO), are used to reduce the reflectance from solid-state photovoltaic devices. For H2 production by water splitting, however, an interference-based AR coating can impede charge transfer from Si to the electrolyte interface and/or corrode in the electrolyte.

Our nanoporous Si forms a density-graded surface layer that suppresses reflectance in air to below 2 % over the entire solar spectrum, without any AR coating layer and has been used in 16.8%-efficient PV devices. [Yuan et al., Appl. Phys. Lett., vol. 94, 123501, 2009] The p-type nanoporous Si photocathode is fabricated in less then 3 minutes by a one-step metal-assisted liquid etch technique. Our photoelectrochemical water splitting measurement under simulated 1-sun, AM1.5G, illumination

shows that the light-limited photoreduction current density under reverse bias at the nanoporous Si photocathode increased about 20%, from 30 mA/cm2 to 36 mA/cm2, due primarily to enhanced photon absorption in the silicon. In addition, the overpotential to create H2 was reduced by 70 to 200 mV, due to the large surface area for the reduction reaction. Finally, H2 gas bubbles released efficiently from the nanoporous Si electrode surface, even without the surfactant required on planar Si.

This work was supported by the SISGR program of the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences, Biosciences, and Geosciences, under DOE Contract No. DE-AC36-08-GO28308.

8109-14, Session 5

Bio-inspired approaches to solar hydrogen production

D. Gust, T. A. Moore, A. L. Moore, Arizona State Univ. (United States)

Fossil fuels represent solar energy captured and stored in fuel by photosynthetic organisms. Thus, photosynthesis can serve as inspiration for the design of artificial photosynthetic systems for production of hydrogen or other fuels. Photosynthetic antennas collect sunlight, transport excitation energy to reaction centers, and perform regulatory and photoprotective functions. Reaction centers are molecular-scale photovoltaics that convert excitation energy into electrochemical energy in the form of redox potential. Biological catalysts use the oxidation potential of reaction centers to oxidize water. The reduction potential of the reaction centers is used by other catalysts to produce fuels. Living organisms have developed catalysts for production of carbohydrate fuels, precursors of biodiesel, hydrogen gas, and other fuels.

Following the photosynthetic paradigm, it is possible to design and construct artificial antennas that efficiently harvest light throughout the visible spectral region, transfer the excitation to artificial reaction centers, and regulate the artificial photosynthetic process. Artificial reaction centers use excitation energy from the antennas to carry out photoinduced electron transfer reactions that store a large fraction of the photon energy as redox potential. Catalysts based on natural proteins that use earth-abundant elements to oxidize water and to produce hydrogen are being developed and functionally interfaced to reaction centers. Several examples of progress towards hydrogen production by artificial photosynthesis will be discussed.

8109-15, Session 5

How nature harnesses quantum mechanics for light harvesting in photosynthesis: what we can learn from it

J. Koehler, Univ. of Bayreuth (Germany)

Currently there is an enormous interest to develop new strategies for light-harvesting and solar energy conversion based on organic matter. Important issues that have to be considered in order to optimise the energy- and charge transfer properties of the supramolecular building blocks without loss in efficiency concern the character of the donor-acceptor materials, their chemical nature, their mutual arrangement (distance and orientation), their electronic couplings, their reorganisation energies, the influence of the surrounding matrix and the hierarchical organisation of individual components. By the evolution of photosynthesis, nature has proven that organic matter can be successfully exploited for this purpose on large scales. In this regard, the nanomachinery of photosynthetic purple bacteria has served as a cornerstone to elucidate the key principles of biophysics, biochemistry, and molecular biology that are at the basis of photosynthesis. This presentation provides an overview of the basic quantum mechanical principles that are exploited in the light-harvesting apparatus found in purple bacteria and discusses possible implications for novel manmade devices.

8109-16, Session 5

Light-induced charge accumulation in molecular systems

A. Harriman, A. C. Benniston, Newcastle Univ. (United Kingdom); F. Odobel, Univ. de Nantes (France)

The design of effective molecular systems capable of the sustained generation of solar fuels is a non-trivial operation and has yet to be realized at any level. The most promising systems have been built around a finely balanced cocktail of reagents, usually involving an enzyme-based catalyst, that quickly moves from the optimised position. In seeking to overcome this challenge, two critical problems can be identified. First, photo-induced electron transfer is an inherently one-electron process, unlike multi-electron fuel production, and second the excited state is quenched very effectively by radical species. This latter feature, whereby an excited reacts with an electron stored momentarily on the catalytic site before discharge, can be used to drive unusual electron-transfer reactions but not in a cyclic manner. The most logical solution, based on bio-inspired molecular chemistry, demands the synthesis of novel arrays of tailored co-factors able to form a one-directional electronic conduit. This approach uses several chromophores to push electrons along a short molecular wire under visible light illumination until trapped at the catalyst. Discharge of the catalyst via fuel generation has to be faster than reverse electron transfer along the wire but not so fast that charge accumulation is by-passed. The key feature becomes the arrangement and selection of the co-factors.

Several molecular arrays have been built that offer promise along the above lines. Each system is capable of directing electrons along a pathway in a one-directional manner. The mechanism, and rates of individual steps, can be probed by laser flash photolysis and used to optimise the system.

8109-17, Session 6

All-inorganic polynuclear assemblies for artificial photosynthesis

H. M. Frei, Lawrence Berkeley National Lab. (United States)

An artificial photosynthetic system for the conversion of carbon dioxide and water to liquid transportation fuel requires the arrangement and coupling of light absorption, charge separation and catalytic units in a nanostructured membrane. The function of the membrane is to provide a physical barrier for separating evolving fuel and oxygen molecules, thereby minimizing back reaction. With the goal of combining the advantages of molecular components with the robustness of inorganic matter, we have developed well defined inorganic polynuclear units for visible light water oxidation and carbon dioxide reduction in inert nanoporous silica scaffolds. The chromophore is an all-inorganic oxo-bridged binuclear unit such as ZrOMn(II) or TiOCr(III) covalently anchored on the silica nanopore surface. These chromophores, which have unusually long excited state lifetimes of microseconds under ambient conditions, act as photon-driven electron pumps. When coupled to oxygen evolving catalysts such as iridium oxide nanoclusters inside the nanopores, efficient oxidation of water is achieved under visible light in neutral aqueous solution. Structural characterization of the units is based on vibrational, EPR, and X-ray spectroscopic analysis, while transient Fourier-transform-infrared and time resolved optical spectroscopy provide dynamic and mechanistic insights into the functioning of the photocatalysts. The molecular nature of the chromophore allows for the precise tuning of the redox properties of the donor and acceptor center by selecting appropriate metals and oxidation states. Such control is the key for optimizing thermodynamic efficiency and directional charge flow within the artificial photosynthetic system. Focusing on Earth abundant materials for reasons of scalability, we have developed cobalt oxide and manganese oxide nanostructured catalysts on mesoporous silica supports that evolve oxygen from water at high rates. The clusters have sufficiently high catalytic activity for developing integrated systems that are able to keep up with the photon flux at high solar intensity. Coupling of the photocatalytic units across nanoscale silica walls with embedded

rectifying molecular wires for assuring directional charge flow and separation of evolving oxygen from the reductive catalysis is in progress.

8109-18, Session 6

Suplamolecular photocatalysts for CO2 reduction and hydrogen evolution

O. Ishitani, Tokyo Institute of Technology (Japan)

Both the problems of the global warming and shortage of the fossil fuels have brought about great interest in both photochemical utilization of CO2 and hydrogen evolution with solar energy. Efficient and visible-light driven photocatalysts must be necessary for development of such an important technology. We have synthesized suplamolecular photocatalysts constructed by connecting [Ru(diimine)3]2+ type photosensitizer and catalyst, which is a Re(I) or Ru(II) complex for CO2 reduction and a Rh(II) complex for hydrogen evolution, with an alkyl chain. These new photocatalytic systems are driven by visible-light irradiation with high efficiency, high durability, and high turnover frequency. The architecture of such photocatalytic systems will be discussed in the presentation.

8109-19, Session 6

Hydrogen production from ethanol: surface science and catalysis study

H. Idriss, Univ. of Aberdeen (United Kingdom)

Solar hydrogen production from renewables such ethanol and water is one of the promising methods for fuel generation either for direct combustion or to power fuel cells. The presentation will focus on the photoreactions of ethanol over rutile TiO2 single crystal and Au/TiO2 anatase and rutile catalysts. On rutile TiO2 (110) single crystal we focus on the first step of the reaction: ethanol dehydrogenation to acetaldehyde while on Au/TiO2 the focus is on the effect of both particle size of the support (TiO2) and Au on the production of hydrogen from ethanol. In addition the possible synergetic effect between the two main phases of TiO2 (anatase and rutile) on the production of ethanol is also studied.

8109-20, Session 6

A light-assisted biomass fuel cell for renewable electricity generation

F. E. Osterloh, R. L. Chamousis, Univ. of California, Davis (United States)

Approximately $25 Billion are spent annually in the US for the treatment of municipal waste water (sewage). This talk describes a photoelectrochemical device that converts organic waste components into H2O and CO2 while generating electrical energy. The device consists of a two-compartment cell that is separated by a proton conducting membrane. In one half cell compartment, a platinum-air electrode catalyzes the reduction of oxygen into water, while the other half cell contains a TiO2 photoelectrode in contact with the waste water. To demonstrate the function of the device, electrochemical and photoelectrochemical measurements on aqueous solutions of glucose were conducted at variable pH. The onset potentials for glucose oxidation and IPCE values recorded at various wavelengths provide an estimate of the efficiency of the device.

8109-21, Session 7

Ultrafast studies of charge carrier dynamics in nanomaterials and relevance to solar energy conversion

J. Z. Zhang, Univ. of California, Santa Cruz (United States)

Nanomaterials possess novel optical and electronic properties promising for solar energy conversion into electricity or chemical fuels such as hydrogen. In particular, metal oxide (MO) nanomaterials are attractive due to their high stability and low cost. Their typically large bandgap requires sensitization for visible light absorption. Strategies include dye or quantum dot sensitization, doping, or bandgap off-setting using composite structures. Charge carrier dynamics in these nanostructures play a critical role in their performance for light energy conversion. A better fundamental understanding of processes such as charge generation, separation, recombination, trapping, transfer, and transport will significantly aid the design of new nanostructures for various applications including solar energy conversion. In this presentation, we will review our recent efforts on using ultrafast laser techniques to probe charge carrier dynamics in a number of MO systems, including TiO2, WO3, and Fe2O3 nanoparticles and nanorods, to demonstrate the important correlation between charge carrier properties and structural characteristics of the nanomaterials.

8109-22, Session 7

Photo-induced electron transfer reactions at semiconductor quantum dot interfaces

Y. Tachibana, RMIT Univ. (Australia)

Solar fuel has recently received significant interests as an alternative to fossil fuel. Solar water splitting is an ultimate system to generate hydrogen and oxygen from water using sun light. Photoelectrochemical process is believed to be one of the most attractive systems for the water splitting reaction, and such reactions at TiO2 surface were first reported by Fujishima and Honda in 1972. However, unfortunately, the efficiency in this system has remained low.

Photoelectrochemical water splitting occurs through electron transfer reactions at material interfaces and catalytic reactions at material surface, following light absorption. Interfacial nanomaterial structural design in addition to material selection is vital to enhance both electron transfer and catalytic efficiency. Semiconductor quantum dot (QD) is an attractive nanomaterial to architect this type of system. By employing the most characteristic property known as “quantum size effect”, the potential energy levels of QD conduction and valence bands can be adjusted with the QD size. Thus, the light absorption onset can be tuned by adjusting the QD size. In contrast, fundamental understanding for the factors controlling the electron transfer reactions at the QD interfaces is still limited. In this presentation, we attempt to elucidate relationship of the QD nanostructures with the interfacial electron transfer rates and efficiency.

This work was financially supported by JST PRESTO program, Japan, and TEPCO Research Foundation, Japan. The Venture Business Laboratory, Osaka University is also acknowledged for the financial support.

8109-23, Session 7

Charge separation and recombination processes in bare and dye-sensitized nanocrystalline TiO2 films

R. Katoh, National Institute of Advanced Industrial Science and Technology (Japan)

TiO2 have been attracting much interest because they can be applied

to water splitting, degradation of environmental pollutants, solar energy conversion and so on. We have so far studied primary process in bare and dye-sensitized TiO2 by using wide-wavelength-range (400-2500 nm), highly sensitive transient absorption (TA) spectroscopy and time-resolved microwave conductivity (TRMC) technique. Following subjects will be presented.

Assignment of active species in bare-TiO2

We have studied optical absorption spectra of nanocrystalline TiO2 films through TA spectroscopy. Three active species, trapped hole and electron, and conducting electron in the spectra can be identified in the spectra. This assignment is very useful to study charge recombination and primary reactions.

Temperature dependence of recombination rate

We observed slow recombination kinetics in nanocrystalline TiO2 films, which occurred within microsecond time region. Recently, we have measured temperature dependence of TA and TRMC signals in bare and dye-sensitized nanocrystalline TiO2 films. Small temperature dependence was observed for bare-films, suggesting that tunneling-type recombination occurs effectively.

Sub-ns dynamics of electron injection from excited dyes into TiO2 nanoparticles

From absorbance of TA signal of both dye-cation and injected electron, efficiency of electron injection can be evaluated. TRMC is also useful technique because only conducting electrons can be detected. Using these techniques, we have studied the efficiency of electron injection under various conditions. Recently, we developed new TA spectrometer with sub-ns time resolution to observe slow injection dynamics from triplet state. The results suggest that the efficiency is controlled by ultrafast charge recombination.

8109-24, Session 8

Solar hydrogen production with disorder-engineered titanium dioxide nanocrystals

S. S. Mao, Lawrence Berkeley National Lab. (United States)

This presentation will provide an overview of recent progress in the development of disorder-engineered titanium dioxide nanocrystals as applied to solar-driven hydrogen production from water. Starting with a brief introduction of the literature on titanium dioxide modification aimed to increase solar absorption, the concept of disorder engineering will be introduced along with the electronic band structure resulted from disorder incorporation. Synthesis of disorder-engineered titanium dioxide nanocrystals will be presented, as well as measurements of their structural, electronic, and optical properties. Photocatalysis experiments based on solar-driven degradation of organic compounds in water will be discussed, followed by detailed measurements of hydrogen production using disorder-engineered titanium dioxide nanocrystals that can absorb solar energy in both visible and infrared wavelength regions. The talk will end with a brief discussion of the perspective of solar hydrogen production based on disorder-engineered nanocrystal photocatalysts.

8109-25, Session 8

Bio-inspired co-catalysts bonded to a silicon photocathode for solar hydrogen evolution

I. Chorkendorff, Technical Univ. of Denmark (Denmark)

A selection of incomplete cubane-like clusters (Mo3S4) and complete cubanes like (Mo3XS4) where X is a transition metal have been shown capable of efficiently catalyze the evolution of hydrogen as a cathode. It has been tested both on planar hydrogen-terminated p-type Si semiconductor and on Si pillars with high aspect ratios using a photo-lithographic method in order to further improve the photo-electrochemical by orthogonalize the light capture and charge-carrier collection in the photoelectrode. The samples have been illuminated with a simulated red part of the solar spectrum i.e. long wavelength (> 620 nm) part of simulated AM 1.5G radiation. The current densities at the reversible potential match the requirement of a photo-electrochemical hydrogen production system with a solar-to-hydrogen efficiency in excess of 10%. Assuming that the coverage of Mo3S4 clusters present on the pillar surface during operation is similar to that measured on the planar surface (the accurate working coverage on the pillared structure could not be measured by XPS), the calculated TOF of hydrogen evolution is 65 sec-1 for the Mo3S4 modified Si pillars. Of course, the TOF is quite dependent on the light intensity. With an increase in light intensity, the photocurrent increases. The system is known to be susceptible to oxygen and the stability of the system will be discussed. The experimental observations are supported by DFT calculations of the Mo3S4 cluster adsorbed on the hydrogen-terminated Si(100) surface providing insights into the nature of the active site.

8109-26, Session 8

New layered semiconductors for efficient photoelectrochemical hydrogen generation

L. Wang, The Univ. of Queensland (Australia)

The increasing concerns over climate change and exhausting fossil fuels have seen great efforts being directed toward the development of new energy generation /conversion systems. Innovative materials for energy conversion hold the key for renewable energy production. The ability to design these nanomaterials with tailored structures and functionalised properties is an important challenge that researchers strive to meet. Aimed at developing new nanostructures for efficient photocatalytic and electrochemical energy conversion, we have recently advanced the design, band-gap and structural modifications of several types of transition metal oxides including layered titanate, clays, tantalates and niobate-based pervoskites.1-3 The exfoliation of these layered structures led to the formation of colloidal suspensions containing exfoliated nanosheets. These unique nanosheets can be structural modified into ideal two-dimensional building blocks for new nano-architecture fabrication. The self-assembly and flocculation of nanosheets led to multilayer ultrathin films and restacked nanoporous structures, which exhibited excellent visible light photocatalytic and electrochemical performances.

8109-27, Session 9

Low cost quantum-confined metal oxide heteronanostructures for direct solar water splitting

L. Vayssieres, National Institute for Materials Science (Japan)

Changing the fundamental physics and chemistry of materials to overcome their theoretical bulk limitations has become a crucial challenge for scientists to improve the efficiency and capability of existing materials to create a new generation of multifunctional and more efficient devices. R&D exploiting chemical nanoscience and nanotechnology has the greatest potential to efficiently contribute to such challenging goals. Indeed, the creation of new materials with higher performance and improved stability achieved by atomic and molecular design and control using unique nanoscale phenomena such as quantum confinements is the key to succeed.

Our strategy to contribute to these drastic requirements is the ability to design clean metal oxide semiconductor based on vertically oriented anisotropic (hetero)nanostructures with quantized band structure such as quantum rods and dots to enable high absorption in the visible range as well as bandgap and band edges engineering by size dependent confinement effects. Such unique characteristics, combined with in-depth investigation and modeling of their electronic structure and large

scale and low cost fabrication methods provide a substantial advance and (r)evolutionary prospect in the field of materials for sustainable development.

Such ideas will be illustrated and demonstrated on the modeling, design and low cost fabrication of metal oxide quantum dots and quantum rods-based large band semiconductor structures, arrays and devices, the in-depth characterization of their size dependent electronic structure performed at synchrotron radiation facilities and their applications for visible light-active semiconductors for direct solar hydrogen generation.

8109-28, Session 9

Titania-based nano-photocatalysts with solar energy applications

S. E. Hunyadi Murph, Savannah River National Lab. (United States)

Energy is the vital force powering every aspect of our society from business, manufacturing, transportation of products, and services to serve the people and worlds economies. Nanotechnology has introduced new concepts for innovative technology applications in energy research, such as solar energy harvesting, storage and conversion, hydrogen production and storage, conversion and use of energy.

Titania has been considered the most appropriate candidate for photocatalytic processes due to its powerful oxidation capability, superior charge transport, and corrosion resistance. Despite these attributes, the efficiency of TiO2 for photovoltaic and photocatalytic applications is severely limited by its large bandgap (~3.2 eV) and rapid charge carrier recombination dynamics which means that anatase titania can use less than 1% of the solar spectrum. However, Au, Ag and Pt nanoparticles and CdS quantum dots can be utilized to sensitize TiO2 and extend its photo-response to the visible region of the solar spectrum. Gold and silver strongly absorb and scatter light in the visible region of the electromagnetic (EM) spectrum and are tunable as a function of nanoparticle size, shape, and local environment. Additionally, by coupling TiO2 with other oxides new nano-composite with enhanced photo-catalytic activity can be produced.

In this presentation we bring to light recent advances in our laboratory on synthesis, characterization, optical and physico-chemical properties of titania-based nano-materials with solar energy production applications. Nano-photocatalysts with various designs, geometries and compositions prepared by wet chemical synthesis approaches and electron-beam lithography will be described. We'll highlight work from the author's laboratory on photo-catalytic applications, using noble metallic nanoparticles (Au, Ag, Pt) and titania-based nanoparticles, including TiO2 and TiO2 coupled with various other oxides such as SiO2, MnOx, WO3. The catalytic activity of these nano-photocatalysts under visible and UV-light demonstrates their potential use for solar energy applications.

8109-29, Session 9

Laser ablation to fabricate high-efficiency photo anodes

R. Ghosh, M. K. Brennaman, R. Lopez, The Univ. of North Carolina at Chapel Hill (United States)

A significant challenge for dye-sensitized photo-electrochemical synthesis cells (DS-PECs) is to either oxidize H2O for H2 production or to simultaneously split H2O and reduce CO2 with visible light without application of an external voltage bias. Our efforts are focused on the metal oxide semiconductor material of the photoanode: TiO2 for reference, and Nb2O5 or Sr2TiO3 due to their suitable conduction band energies for both H2 production and artificial photosynthesis. We have used pulsed laser deposition (PLD) to coat the surface of an optically transparent electrode (Fluorine-doped Tin Oxide glass) with a mesoporous network of vertically aligned metal oxide (TiO2, Nb2O5 or Sr2TiO3) bundles which are formed only by controlling oxygen background pressure during deposition, film thickness, and annealing conditions. As a first step in characterizing the overall performance of these nanostructured metal oxides, dye-coated electrodes were used as photoanodes in a DSSC configuration. PLD-TiO2 DSSC IPCE values are comparable to 3x thicker sol-gel films and nearly 92% APCE values have been observed using optimized PLD-TiO2 structures. UV-Vis studies show that there is a factor of 1.4 enhancement of surface area for PLD-TiO2 photoanodes compared to the best sol-gel films. Taken together, these data show that our PLD-synthesized metal oxide nanostructure simultaneously optimizes both charge transport properties and surface area for facile dye loading. The chemical states, crystallinity, film structure, and optical constants of these films have been characterized using X-ray photo-electron spectroscopy (XPS), Raman spectroscopy, scanning electron microscopy (SEM) and ellipsometry.

8109-30, Session 10

Efficient synthesis of complex oxide-metal particle electrodes

G. Westin, Uppsala Univ. (Sweden)

Utilisation of photo-catalysts for solar energy harvesting, weather through production of fuels or electricity requires versatile and cost efficient synthesis routes capable of producing complex functional nano-materials. The wide spectrum of solution based processes probably provide the most important routes for this purpose, but the complexity and diversity of the reactions taking the precursor molecules in solution to gels or nano-particles and their further processing into ceramic purpose designed structures require much understanding. Therefore knowledge about the entire route from precursor to target oxide is needed to produce well controlled high quality materials and make choices of suitable techniques. The synthesis of complex materials systems will be described with an emphasis on the addition of metal nano-particle co-catalysts to doped and non doped oxide semi-conductors such as; TiO2, ZnO and WO3. The processes were studied by a wide array of techniques including; TGA, DSC/DTA, SEM, TEM, XRD, XAS, IR-, Raman and UV-Vis-NIR spectroscopy. The photo-catalytic properties of the prepared materials will be described.

8109-31, Session 10

Synthesis and characterization of titanium doped iron oxide for photoelectrochemical water splitting

H. W. Tang, National Renewable Energy Lab. (United States) and Univ. of Denver (United States); M. A. Matin, Univ. of Denver (United States); Y. Yan, M. M. Al-Jassim, J. A. Turner, National Renewable Energy Lab. (United States)

Iron Oxide is a potential candidate for hydrogen production by photoelectrochemical decomposition of water due to its good bad gap and excellent chemical stability. However, its poor conductivity limits its PEC performance. 3d transition metals are predicted to be a good choice of dopants to improve the conductivity. In this paper, we report our synthesis of titanium doped iron oxide thin films by RF magnetron co-sputtering of iron oxide and titanium targets at various conditions. Our work shows that the structure and morphology of iron oxide can be modified by controlling the doping concentration of titanium. Moreover, our results show that the PEC performance of titanium doped iron oxide is better than the undoped films.

8109-32, Session 10

Surface nitridation of p-GaInP2 for durable photoelectrochemical water splitting

H. Wang, T. G. Deutsch, J. A. Turner, National Renewable Energy

Lab. (United States)

High efficient III-V semiconductor materials have been successfully applied for photoelectrochemical (PEC) water splitting systems. Monolithic p-GaInP2/n/p-GaAs PEC-PV tandem cell device demonstrated a 12.4% solar-to-hydrogen (STH) conversion efficiency [1], however the lifetime of the device was limited due to the stability issue in aqueous solution.

To extend the lifetime of the device, thin films of p-GaInP2 were tested in different solutions (including 3M H2SO4 for comparison) at 1 sun for 24h, and different techniques were used to analyze the surfaces and the tested solutions. Samples tested in sulfuric acid experienced extensive corrosion and surface Ga was selectively dissolved. The surfaces and XPS depth profiles of samples tested in ammonium-bearing solutions were kept almost identical to that of an as-received one. SEM and EDX investigation also confirmed the significant reduced corrosion with samples tested in ammonium-bearing solutions. In other words, ammonium showed inhibitive effect for p-GaInP2, which is very promising to meet US DOE's 2013 goal of 8% STH efficiency for 1000h duration.

8109-33, Session 10

Nanostructured phosphides as photoelectrode materials for artificial photosynthesis

S. Maldonado, Univ. of Michigan (United States)

In this presentation I describe our recent efforts to enhance and augment the photoresponse of gallium phosphide (GaP) for the purposes of designing a fuel-forming photoelectrochemical system. GaP is a potentially useful material in artificial photosynthetic systems but is hampered by short minority carrier diffusion lengths relative to visible light penetration depths. In this work, I will show data on several types of nanostructured n-type and p-type GaP photoelectrodes with thicknesses ranging from 0 - 45 microns. Solar-to-electrical energy conversion properties in regenerative and photosynthetic photoelectrochemical cells are reported. Larger short-circuit photocurrents, increased internal quantum yields at long wavelengths, and decreased open-circuit photovoltages were observed for photoelectrodes with optimal doping-morphology combinations. For these materials, the short-circuit photocurrents, open circuit photovoltages, and fill factors collectively resulted in more than an order of magnitude improvement in the photoelectrode efficiency as compared to single-crystalline planar GaP photoelectrodes. Additional data are shown on that explore alloying GaP, in conjunction with high aspect ratio nanostructured morphologies, as a means to produce more active solar energy conversion materials. The data thus comprehensively detail strategies for overcoming the carrier-collection limitation of GaP and related phosphides in solar energy conversion applications.

8109-34, Session 10

Metal-doped hematite nanocrystalline films for photoelectrochemical water oxidation

A. Bak, S. K. Choi, T. H. Jeon, H. Park, Kyungpook National Univ. (Korea, Republic of)

Solar-light driven water splitting has attracted great attention over the past decades yet the solar-to-fuel conversion efficiencies are still very low. The water oxidation has been studied in a photoelectrochemical (PEC) cell with various metal-doped iron oxide films synthesized by electrodeposition. Despite its proper energetics for water oxidation, the iron oxide has showed disappointingly low PEC efficiency due to small optical absorption coefficients in the visible light region, short carrier diffusion lengths, and rapid chare pair recombination. Attempt have been made to improve the PEC efficiency by synthesizing iron oxide films doped with more than 10 elements (Cr, Co, Ni, Ru, Pd, Ag, Cd, Ir, Pt, Au, Sn, etc). Experimental results indicated that Pt improved the PEC efficiency by two times whereas Ru and Co decreased the efficiency as compared to undoped iron oxide. Detailed surface analyses (XPS, XRD, SEM, etc) were performed to investigate the role of dopants in affecting the PEC efficiencies.

Conference 8110: Thin Film Solar Technology III

Sunday-Monday 21-22 August 2011 • Part of Proceedings of SPIE Vol. 8110 Thin Film Solar Technology III

Progress and challenges in low-temperature, high-rate epitaxy for film silicon photovoltaics

C. W. Teplin, National Renewable Energy Lab. (United States)

Progress and challenges in low-temperature, high-rate epitaxy for film silicon photovoltaics

8110-02, Session 1

Microluminescence mapping of intragrain and grain boundary recombination in silicon film solar cells

M. J. Romero, National Renewable Energy Lab. (United States)

The expansion of the silicon production capacity will drive down the price of the feedstock but the costs associated to the fabrication of the wafers will continue at current levels at about half the cost of the final module. A wafer replacement approach, where crystalline silicon films are grown on inexpensive substrates, can provide high solar conversion efficiency and eliminate the expensive and energy-intensive wafer fabrication process.

There are numerous strategies for the fabrication of silicon film solar cells depending on the temperature compatibility of the supporting substrate. Hot-wire chemical vapor deposition (HWCVD) and electron- or ion-assisted deposition are compatible with inexpensive borosilicate glass substrates (requiring temperatures < 650 ºC), which is a more attractive approach to the production of solar cells.

The best projected efficiency of a silicon film solar cell is primarily determined by the collective effects of intragrain and grain boundary recombination. The diagnostics of the recombination (whether associated with grain boundaries, extended defects, or dissolved metallic impurities) is therefore critical to the progress of silicon film solar cells. In this contribution, we introduce the application of cathodoluminescence to the mapping of intragrain and grain boundary recombination in silicon films. The mutual contributions of these recombination processes can be differentiated by their effects on the local emission spectrum. Using this microluminescence mapping, the factors limiting the performance of silicon film solar cells are further discussed and guidelines to further improve efficiency are suggested.

8110-03, Session 1

Advanced light management for thin-film crystalline-silicon solar cells

I. Gordon, O. El Daif, F. Dross, IMEC (Belgium)

In order to decrease the cost of Silicon solar cells, presently the dominating technology on the market, there is a need to go towards cheaper fabrication techniques. A promising bottom-up approach is the fabrication of crystalline silicon (Si) on inexpensive substrates. Aluminium induced crystallisation (AIC) allows to obtain polycristalline Si with grains in the order of 10µm in diameter and a thickness of around 3 µm, 2 orders of magnitude lower than Si wafers used in photovoltaics. Efficiencies of 8.5% were obtained with such structures fabricated on alumina substrates. These thin film cells still suffer from important optical losses which decrease dramatically their short-circuit current (now 20mA/cm2), whereas their open-circuit voltage (530mV) has a value comparable to the state-of-the-art. Although plasma texturing of the front surface of the cells allows for a good light-in coupling, the low thickness and the absorption coefficient of silicon (low for wavelengths higher than 500nm) yield important losses.

We will show both experimental measurements and numerical simulations of the optical losses in thin Si solar cells on various substrates. We will then compare innovative light trapping techniques, showing that it is possible to to strongly enhance absorption and therefore efficiency. We will compare various back reflecting schemes: a simple metallic layer, a pigmented dielectric layer, a patterned dielectric, and metallic nanoparticles using plasmons modes. Experimental optical characterisation of these various features will be shown. We then performed optical simulations, showing that there is a great room for optimisation depending on topographical parameters. Optimal parameters and how to implement them in a solar cell fabrication chain from the material preparation through AIC until the light trapping features and the contacting will be presented. We show that thin film crystalline-silicon solar cells are a promising path to decreasing the cost of crystalline-Si solar cells. Beyond the absorption increase experimentally shown, modelling shows that efficiencies up to 14% can be reached through an increase of the short-circuit current.

8110-04, Session 2

Fabrication of copper zinc tin sulfide (C2ZTS4) solar cells using spray chemical vapor deposition

D. Lee, J. Seo, A. N. Cartwright, P. N. Prasad, Univ. at Buffalo (United States)

We investigated fabrication of Cu2ZnSnS4 (C2ZTS4) thin film solar cells using a spray chemical vapor deposition (CVD) technique. The devices studied are fabricated using the inverse stacking sequence of conventional CuInGaSe2 (CIGS2) solar cell structure (Glass/Mo/CIGS2/CdS/ZnO/Metal). The absorber layer of the device was deposited after the buffer layer deposition. This order of fabrication was necessary because the surface characteristic of the C2ZTS4 absorber layer is too rough to deposit further layers. Unlike other processes, these devices do not need the high temperature annealing above 400˚C. All layers are sprayed on the fluorine doped tin oxide (FTO) substrate at distinct temperatures. The spraying temperature for the In2S3 buffer layer and the C2ZTS4 absorber layer were systematically investigated. Devices fabricated under different spraying temperatures were investigated and characterized. The optimum temperature for In2S3 the buffer layer and the C2ZTS4 absorber layer were 360˚C and 380˚C, respectively. The C2ZTS4 layer sprayed at low temperature (340˚C) has a lower quality of crystallinity with secondary phases (ZnS and CuxS) and poor adhesion. The absorber layer sprayed at high temperature showed higher crystalline quality but the entire device performance was degraded due to poor fill factor (<25%). Moreover, the sheet resistance of the C2ZTS4 layer was drastically increased at high temperature spraying. The best cell shows power conversion efficiency (PCE) of 4.4%, open circuit voltage (VOC) of 410mV, short circuit current density (JSC) of 30.4mA/cm2 and fill factor (FF) of 35.3% under simulated AM 1.5G illumination condition.

8110-05, Session 2

Probing the defect physics of Cu2ZnSnS4 by luminescence spectrum imaging

M. J. Romero, H. Du, G. Teeter, Y. Yan, M. M. Al-Jassim, National Renewable Energy Lab. (United States)

Cu2ZnSnS4 (CZTS) is attracting considerable interest because it contains abundant elements Cu, Zn, Sn, and S and the reported bandgap is near the optimum for solar cells. First principle calculations predict that our understanding of the electronic structure and defect formation in CZTS can be partly extrapolated from CIGS, which will benefit the development of CZTS. CZTS shows a very limited region of stability in the Cu-Zn-Sn-S phase diagram and minor deviations from stoichiometry leads to the formation of secondary phases (ZnS, CuS, Cu2S, SnS).

The success of CIGS is based primarily on the exceptionality of its electronic structure which, in the regime of Cu deficiency, is dominated by the formation of Cu vacancies and their stabilization in defect

complexes. Under such conditions, the evidence suggests that (i) grain boundaries are non detrimental to efficiency, (ii) the surface electronics promotes the formation of the junction, and (iii) nanoscale fluctuations of the stoichiometry assist the transport of electrons and holes. These beneficial effects can be measured by luminescence spectrum imaging, which provides a direct correlation between the microstructure of the CIGS (or CZTS) and the electronic properties as revealed on the emission spectrum at cryogenic temperatures.

In this contribution, we apply this luminescence microscopy to the investigation of the defect physics, the electronic structure of grain boundaries, and the surface electronics of CZTS. When comparing these results to those obtained from CIGS, a strategy for the future development of CZTS solar cells will be presented.

8110-06, Session 3

Solution-based precursors in conjunction with rapid thermal processing for high-quality hybrid CIGS

P. A. Hersh, HelioVolt Corp. (United States); L. A. Eldada, SunEdison (United States); B. J. Stanbery, C. R. Martinez, HelioVolt Corp. (United States)

The use of liquid precursors offers potential benefits over traditional physical vapor deposition (PVD) methods, including better material utilization, higher throughput, and improved scalability. Rapid thermal processing (RTP) offers the potential to selectively heat the precursor films, allowing the substrate to remain relatively cool. This study shows that we are able to make high quality CIGS at ultra-high speeds, while keeping the substrate temperature below 350°C, reducing the risk of glass softening, warpage, and breakage, and enabling the potential use of alternative substrate materials.

In this study, we deposit metal-organic precursor inks on heated substrates using ultrasonic spray deposition to make precursor films that are subsequently rapid thermal processed into CIGS. To complete the devices, the CIGS film is covered with a chemical bath deposited CdS layer, which facilitates junction formation, and acts as a buffer to the transparent conducting oxide (TCO) based contact. The TCO consists of a bi-layer of insulating ZnO (100 nm) and conductive Al:ZnO (120 nm and 60 Ω/square). Device performance from liquid precursors and RTP has been on par with devices deposited via PVD methods and processed using the field assisted simultaneous synthesis and transfer (FASST®) method.

8110-07, Session 3

Characteristics of CIGS thin films prepared by RF sputtering employing CIGS single target

T. Kim, Y. Kim, S. Song, J. Lee, Korea Institute of Industrial Technology (Korea, Republic of)

Copper indium diselenide based materials including copper indium gallium deselenide (CIGS) have attracted much attention as a promising absorber layer for high conversion efficiency thin film solar cell due to their high absorption coefficient. Co-evaporation and selenization of metallic precursor film, which is so-called two-stage method, have been adopted as a conventional process to prepare CIGSe films. However, two-stage method is more promising from a commercialization perspective because the method is more favorable to produce high-quality CIGS film with good uniformity in large scale. Although the two-stage method possesses previous advantage, it is true that there are several problems such as agglomeration of Ga on the interface of CIGSe/Mo and formation of harmful gas phases during the process have been not still solved.

In this study, CIGS films were prepared by a RF sputtering system using a CIGS single target having a composition of CuIn0.75Ga0.25Se2. X-ray diffraction measurement confirmed that CIGS films grown on Mo-coated soda-lime glass at 350 exhibited polycrystalline structure with no compositional deviation. For the CIGS film treated at 550 by RTP the intensity of (112) diffraction increases 3 times more than that of the films grown at 350 , revealing crystal-quality of the film improved. Furthermore, SIMS analysis for the interface of CIGS/Mo revealed that heat treatment for Mo layer prior to CIGS film deposition suppresses the inter-diffusion of Cu,Ga, and Mo at the interface. These results demonstrate that RF sputtering of CIGS single target can be a promising method of high quality CIGS film and heat treatment of Mo layer is indispensible to control the interface of CIGS/Mo. In the presentation, we will give more details of our experimental results including the effects of heat treatment for Mo layer prior to CIGS film deposition and surface morphologies and optical properties of the CIGS films.

8110-08, Session 3

Synthesis and electrophoretic deposition of composite metal nanoparticles and non-vacuum fabrication of CuInSe2 solar cells

B. Liu, K. Hagedorn, W. Guo, IMRA America, Inc. (United States)

A method of non-vacuum synthesis of thin film solar absorbers is presented. The method is based on electrophoretic deposition (EPD) of elemental and composite nanoparticles onto conductive substrates (metal foils) in solvents. EPD is a traditional method for coating ceramic thin films with micron-sized particles. In this work, using Cu-In composite nanoparticles as an example, we demonstrate the feasibility of EPD as a low-cost route of producing thin film metal precursors for synthesis of CuInSe2 (CIS). Colloidal suspensions of Cu-In composite nanoparticles are prepared with pulsed laser ablation in solvents. Pulsed laser ablation is a fast way of producing high purity nanoparticles of various forms of materials, including elemental, alloy, and compound. We show that the nanoparticles acquire surface charges through electrochemical interaction with solvents, and the surface charge density is sufficient to enable migration of the metal nanoparticles in liquids under a moderate electric field. The success of deposition of nanoparticles on the electrode surfaces is also explained based on electrochemical charge transfer between the particles and the electrode. However, compared with the electroplating method of coating thin metal film, the EPD process has several advantages, including one-step deposition of multiple elements, compositional control through nanoparticle precursors, and high coating speed. After EPD coating, the thin films of metal nanoparticles are selenized in selenium vapor under atmospheric pressure. Solar cell devices have also been finished. This method provides a new choice of low-cost synthesis of thin film solar absorber materials on flexible substrates.

8110-09, Session 3

Characterization of intrinsic ZnO thin film deposited by sputtering and its effect on CuIn1-xGaxSe2 solar cells

M. Jiang, South Dakota State Univ. (United States) and Optorun Co. Ltd. (Japan); X. Yan, South Dakota State Univ. (United States); K. Tang, Optorun Co., Ltd. (Japan)

Intrinsic ZnO (i-ZnO) thin film is commonly used as a buffer layer between CdS layer and TCO layer for CuIn1-xGaxSe2 (CIGS) thin film solar cells. This film prevents the leakage current between the absorber layer and TCO layer due to its high resistivity. In general, i-ZnO thin film is deposited by RF sputtering. The electrical and optical properties of RF-sputtered i-ZnO thin films vary with the working gas pressure, the ratio of O2 to Ar partial pressure, sputtering power, substrate temperature, and thickness. However, most of these parameters were rarely reported in literatures concerning deposition of i-ZnO thin films for CIGS TFSCs except a thickness ranging from 50 to 100 nm was mentioned. Furthermore, the optimization of deposition of i-ZnO thin films has seldom been performed for the fabrication of CIGS TFSCs.

In this work, the correlation of the cell performance of CIGS TFSCs with i-ZnO thin films deposited under different conditions was studied. The substrates were heated to 250 or kept at 25. The deposition was carried out either using pure Ar as sputtering gas or under partial pressure of O2. It was found that the average conversion efficiency was significantly improved by 16% from 10.59% to 12.30% when i-ZnO thin film was coated at 25 without addition of O2 instead of 200 with addition of O2. This improvement was mainly attributed to the increase of fill factor and slight enhancement of short-circuit current density.

8110-10, Session 4

Nanophotonic light management in solar cells

S. Fan, Z. Yu, A. P. Raman, Stanford Univ. (United States)

We review some of the theoretical developments in understanding nanophotonic light trapping in solar cells, as well as in developing strategies for absorption enhancement over the entire solar spectrum.

8110-11, Session 4

Effects of metallic nanoparticle arrays in Si solar cell structures

T. Benkenstein, M. Flämmich, T. Harzendorf, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany); T. Käsebier, Friedrich-Schiller-Univ. Jena (Germany); D. Michaelis, M. Oliva, C. A. Wächter, U. D. Zeitner, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

Metallic inclusions in layered structures can have noticeable effects onto scattering and absorption due to the coupling of the external electromagnetic field and local charge oscillations. These effects are strongly related to both the geometry of the individual particle as well as to the array structure. Thus, sophisticated implementations of numerical methods like Rigorous Coupled Wave Analysis and Finite Element Methods are required in order to model the effects with adequate accuracy. To achieve a deeper understanding of peculiar scattering effects within the complete geometry it is helpful to consider the interplay of occurring individual plasmonic resonances, waveguide modes and Bloch modes, which depend on optical frequency, particle shape and array geometry, eventually. Based on that, and having in mind the efficiency improvement of silicon solar cells due to plasmonic effects, we report on the modeling, the fabrication and the characterization of periodic arrays of metallic nanoparticles on planar substrates. Special emphasis is placed on detailed parameter retrieval for non-ideal particle geometries. Since the very details of the individual particle at the one hand critically depend on the fabrication process and at the other hand reflection and transmission of the complete structure depend critically on the particle shape, corresponding optical measurements data contain precise information about processing induced geometry deviations. In combination with AFM characterization numerical modeling techniques are used to clarify corresponding implications which are due to non-perfect material removal as well as to material re-deposition during the etch-process.

8110-12, Session 4

Plasmonic effects and light-trapping in thin-film photovoltaics

E. A. Schiff, H. Zhao, B. Ozturk, Syracuse Univ. (United States); L. Sivec, J. Yang, S. Guha, United Solar Ovonic, LLC (United States)

Surface plasmons at metal-dielectric interfaces affect any solar cell that incorporates textured silver or other metallic reflectors. The effects can be deleterious, but recent research has explored possible plasmonic improvements in thin-film cells. In this paper we present our findings on three plasmonic effects. We show that optical phase shifts associated with surface plasmons substantially affect quantum efficiency measurements for silicon thin films; these results lead us to re-assess the early work indicating large plasmonic enhancements in photocurrents in silicon-on-insulator films. On the other hand, we show that plasmonic effects do contribute positively to the performance of some well-optimized back reflectors, essentially by enhancing the diffraction of light by the textured reflector. The experiments involve reflectance measurements of backreflectors with varying dielectric overlayers, and comparisons of silver and aluminum back reflectors with similar textures. Finally, we show that plasmonic effects can, in principle, lead to “supraclassical” light trapping beyond these diffraction effects. For cells based on crystalline silicon, 0.5 micron absorbers in plasmonically-enhanced cells should outperform 1.0 micron absorbers in fully optimized, conventional cells. We describe the experimental efforts to realize this improvement.

This research has been supported by the U.S. Department of Energy, by United Solar Ovonic LLC, and by the Empire State Development Corporation.

8110-13, Session 4

Enhanced absorbance of light due to multiple surface-plasmon-polariton waves

M. Faryad, A. Lakhtakia, The Pennsylvania State Univ. (United States)

Rigorous coupled wave analysis was used to compute the absorbance of a metal grating coated with a dielectric layer. The grating is formed by periodic bumps on an otherwise planar layer of a suitable metal. When the period of the grating is appropriate, the incident light excites a p-polarized surface-plasmon-polariton (SPP) wave at a certain incidence angle if the dielectric layer is homogeneous. However, if the dielectric layer is periodically non-homogeneous normal to the mean metal/dielectric interface, more than one p-polarized SPP waves with different phase speeds and attenuation rates are excited. In addition to p-polarized SPP waves, s-polarized SPP waves may be excited if the periodic non-homogeneity of the dielectric layer is sufficiently pronounced. The capability of periodically non-homogeneous dielectric layer to excite multiple SPP waves with different polarization states, phase speeds, and attenuation rates can help enhance light absorbance in thin-film solar cells.

8110-14, Session 5

Measurement and analysis of non-uniformities in CdTe solar cells

J. R. Sites, Colorado State Univ. (United States)

CdTe and other thin-film polycrystalline solar cells have potential spatial non-uniformities in their photovoltaic response that can both lower their performance and complicate the analysis of their current-voltage curves. Polycrystalline cells have inherent non-uniformities associated with their grain structure, but there are a variety of other possibilities including thickness variations, local shunts, and weak-diode areas. Additionally, there are possible issues associated with the fabrication process due to cleaning residues, scratches, thermal variations, and particulate inclusions.

The primary measurements used to map the non-uniformities of CdTe cells are light-beam-induced current (LBIC), which gives a direct measure of the local PV response, and electroluminescence (EL), which is the inverse of the PV effect. The former is attractive, because it can be used to deduce the local current-voltage curve, but data collection is time consuming. The latter though the use of modern CCD cameras takes only a few seconds and is compatible with production-line screening.

The presentation will show examples of several types of non-uniformity seen in LBIC and EL measurements, it will compare the current-voltage

curves of the cells with and without specific non-uniformities, and it will give the basic analysis strategies for connecting the uniformity measurements with cell performance.

8110-15, Session 5

Raman spectroscopy metrology for in-line quality control supporting high-throughput polycrystalline thin-film PV manufacturing

V. Bermudez, NEXCIS (France); V. Izquierdo, Univ. de Barcelona (Spain); E. Saucedo, A. Perez-Rodriguez, J. Morante, Institut de Recerca en Energia de Catalunya (Spain)

Raman scattering is an optical non destructive technique well suited for quality control and process monitoring in advanced chalcogenide PV thin film technologies. This includes state-of-the-art chalcopyrite absorber alloys as well as new emerging technologies based on kesterite absorbers. The Raman spectra from these compounds are strongly sensitive to defects, strain, chemical composition and secondary phases, being all these features determining for the performance of the cells. However, development of Raman scattering based process monitoring techniques is conditioned by the low efficiency of inelastic scattering processes in these materials which implies the need for high throughput optics in combination with very high sensitivity detectors, as well as the relative limited size of the measured surface in the layers and the integration time required for collection of spectra with good signal-to-noise ratio.

These experimental limitations can be solved by the the use of resonant or pre-resonant excitation conditions. This allows for a significant decrease of the measuring time to levels compatible with on-line process monitoring requirements. There is also the possibility for in-situ implementation which means that quasi-real time measurements can be achieved simultaneously to the process. Combination with suitable excitation and light collection optics allows for the analysis of phase, structure or composition inhomogeneities at both macroscopic and microscopic scales for the non destructive assessment of these complex absorbers at early process stages during the fabrication of the cells and modules.

8110-16, Session 5

Hall measurements on low-mobility, high-resistivity materials

J. R. Lindemuth, Lake Shore Cryotronics, Inc. (United States); S. Mizuta, Toyo Corp. (Japan)

Making Hall measurements of amorphous materials, organic materials or other low mobility materials is known to be very difficult1-3. There are two intertwined problems for Hall measurements on these materials. The first is an instrument problem. Experience has shown that instruments do not provide reliable results when making Hall measurements of materials with high resistivity and low mobility materials. In these materials, the true Hall voltage is often overwhelmed with large offset voltages.

To overcome these problems, first it is necessary to explicate and demonstrate a method that produces reliable, consistent results for Hall measurements of low mobility materials. With this knowledge, the researcher can then begin to confidently attribute “strange” results to the material, rather than to the instrument.

We propose a method using AC magnetic fields for measuring the Hall effect in low mobility materials. The Hall voltage is measured using phase sensitive detection. We have calculated the limits of the measurement method including sample shape effects and show measurements of amorphous and microcrystalline silicon which confirm these limits. AC field Hall can expand the limits of mobility that can be reliably measured by a factor of 100 or more.

8110-17, Session 5

First outdoor measurements on amorphous thin film photovoltaic panels performance embedded on curvilinear surfaces

A. Spena, G. D’Angiolini, C. Strati, S. Bartocci, Univ. degli Studi di Roma Tor Vergata (Italy)

The flexible thin film photovoltaic devices are finding a growing popularity as they offer very interesting prospects for building integrated together with a satisfactory electrical conversion efficiency especially in adverse weather conditions. The development of these technologies opens a new work range combining availability of energetic and environmental systems with the opportunity of original design shape going to realize embedded systems. The photovoltaic plant assumes the function of electricity producer and building element: curvilinear roof cover, cladding, architectonical accessories (i.e. shelters, parapets,...).

One of problems related to this photovoltaic system is the lack of data on energy producibility and photovoltaic components behavior when are embedded on surfaces unable to maximize solar radiation reception. Our research propose to analyze outdoor performances of thin film components on special surfaces, such as curvilinear. In this way it will be possible to have a more complete scenario of realistic performances to reach the best balance between architectonical needs and energetic performances. For this purpose a test section of thin film photovoltaic panels is been built going to integrate with existing appliances for outdoor monitoring of photovoltaic panels of Technical and Physics for Environment laboratories of University of Rome, Tor Vergata. The building, facing south, is composed of two pair of centering with radios of curvatures as 1.2 and 2.5 meters and of a pair of horizontal tubular enable to monitor panels also on horizontal plan. Measurements, data capture and transfer system is constituted of MPPT modules tracking maximum power point, of electronic compass, 3 RTD for each pair of centering to measure the temperature.

8110-18, Session 5

Correction methods and stabilisation of outdoor measurements of thin film modules

K. Weiss, K. Scharmach, J. Wirth, M. Koehl, Fraunhofer-Institut für Solare Energiesysteme (Germany)

Stabilised performance data are necessary to compare different types of modules in the emerging thin film PV market and as basic information for energy yield calculations. The test standard IEC 61646 ed. 2 describes demanding light soaking and repeated STC measurements to ensure stabilized values for thin-film modules.

Various types of CdTe, CI(G)S and a-Si modules were installed on a outdoor test facility in Freiburg, Germany, facing south in 45° inclination. IV-Curves of all these modules are measured every ten minutes. Between the measurements of IV-curves the modules are held in MPP conditions by electronic loads. Isc, Voc, efficiency and filling factor are determined automatically.

Measured irradiation, module temperature and air mass are used for analysis and comparison of the IV curves. The influence of the respective air mass was higher than expected and therefore regarded more intensely. Measured data were corrected to 1000 W/m² irradiation and 25°C module temperature according to IEC 60891 to make them comparable.

Different procedures of filtering and correction have been compared. The results show that the best results are achieved when the data are selected in a small range of air mass and module temperature and corrected to the same irradiation.

Modules of the same types like the outdoor exposed modules were stored without irradiation for some years. Afterwards, they were exposed at the test site with the other modules. Comparison of the module data of the same type allows the investigation of the stabilisation behaviour of the modules directly.

8110-21, Session 6

Application of nanostructured silicon for solar cells manufacturing

A. I. Luchenko, V. Lashkaryov Institute of Semiconductor Physics (Ukraine); T. Bilyk, M. M. Melnichenko, National Taras Shevchenko Univ. of Kyiv (Ukraine); O. Shmyryeva, National Technical Univ. of Ukraine (Ukraine); K. Svezhentsova, V. Lashkaryov Institute of Semiconductor Physics (Ukraine)

It is known, that a thin layer of nanostructured silicon on a textured substrate of single-crystal silicon considerably reduces reflection of light in comparison with usual textured substrates. However methods and mechanisms of formation of nanostructured silicon are ambiguous and are not yet completely investigated.

Therefore, detailed studying of mechanisms of formation and properties of the thin layers of nanostructured silicon is necessary for increasing efficiency of transformation of solar cells.

We studied the process of formation of nanostructured silicon, the influence of the formation technique type on its structural, photoluminescent and antireflecting properties. The layers of nanostructured silicon have been formed on the textured surface of solar cells. The layer of the nanostructured silicon was created by chemical etching in a mix of acids HF and HNO3. The thickness of a layer of the nanostructured silicon (3 - 60 nm) during chemical modification of textured surface of single-crystal silicon was supervised by preset parameters of technological process and was determined by a method of Auger electron spectroscopy.

It is shown, that the formation of contact systems on the nanostructured silicon on the textured substrate results in decrease of consecutive resistance, increase of a short circuit current, increase of shunting resistance, and increase of efficiency.

8110-22, Session 6

Conductive conformal thin film coatings for textured PV: ALD versus sputtering

T. Gennett, A. Dameron, S. Christensen, J. Perkins, J. Berry, D. T. Gillaspie, D. S. Ginley, National Renewable Energy Lab. (United States)

Physical vapor deposition techniques have been widely used for thin-film deposition in many photovoltaic applications. However, the conformal nature of films from conventional line of sight deposition processes are limited due to self-shadowing that can lead to poor step coverage on sidewalls and bottoms of trenches. These effects can lead to void formation when attempting to fill or coat a surface feature, which is especially important as one starts to apply TCO's to the up-and-coming realm of 3-D interdigitated solar devices. This preliminary work has taken a three-pronged approach to develop methods to deposit conductive materials conformally onto three-dimensional and textured supports.

While many materials with countless chemical compositions have been developed effectively for the the sputter depostions for planar applications, this line-of-sight process struggles to deposit these same materials with uniform-reproducible coverage over textured or shadowed surfaces. On the other hand, the self-limiting surface-gas phase reactions of atomic layer deposition (ALD) provide a means to generate extremely conformal thin films that are much improved compared to any other methodologies (both chemical vapor deposition and PVD). However, currently the materials reported for ALD coatings on PV relevant materials are limited because these ALD materials currently do not have the well-established physio-chemical properties of analogous sputtered films. Potential conformal materials developed by both these techniques can be further improved by development of a surface that promotes uniform growth.

This work will report on the preliminary findings associated with conformal metal oxides on structured substrates including: 1) Discovery of sputtering process conditions that can be made semi-conformal combined with in-situ techniques such as ion-beam milling for honing surface structures; 2) Development of relevant ALD chemistries that are materials-properties competitive with sputtered materials; 3) Evaluation of chemically-functionalized surface structures that maximize surface area but are structurally tailored for efficient gas flow and to minimize line-of sight shadowing.

The initial experiments have centered on combinations of amorphous and crystalline indium oxide, zinc oxide, aluminum zinc oxide, indium tin oxide, fluorinated tin oxide and indium zinc oxide. This presentation will describe these initial experiments and elucidate key physiochemical nature of the deposited thin films.

8110-23, Session 7

Colloidal quantum dot photovoltaics

S. M. Thon, E. H. Sargent, Univ. of Toronto (Canada)

Colloidal quantum dot solar cells offer to combine low-cost roll-to-roll solution-processing with efficient infrared as well as visible spectral harvesting. Their quantum size effect tunability offers a path to tandem and triple-junction cells. The first solution-processed infrared solar cells were reported in 2005; the latest devices offer greater than 5% AM1.5 PCE and many paths remain for further improvement to 10% and beyond. We will review the field and its prospects.

8110-24, Session 7

Low-cost fabrication of improved n-Si/p-AgGaSe2 heterojunction solar cells

K. C. Mandal, S. Das, Univ. of South Carolina (United States)

The fabrication of low-cost n-Si/p-AgGaSe2 heterojunction solar cells by controlled thermal evaporation method is reported. It is observed that in the case of p-AgGaSe2 films deposited on H-terminated n-Si (H-Si) substrates at higher temperature of 550K, the photovoltaic properties of the n-Si/p-AgGaSe2 junctions are considerably improved. The improved junction, under solar simulator AM1 illumination, demonstrated an efficiency of ~5.2% on an active area of 0.18 cm^2 without any antireflection coating whereas the AgGaSe2 films thermally evaporated at lower substrate temperature of 400K on H-Si substrates showed the efficiency ~2.7%.

8110-25, Session 7

Minority carrier transport length in electrodeposited Cu2O for heterojunction solar cells

Y. Liu, H. Turley, J. R. Tumbleston, R. Lopez, The Univ. of North Carolina at Chapel Hill (United States)

The minority carrier transport length (L) is a critical parameter limiting the performance of inexpensive Cu2O-ZnO photovoltaic devices. In this work, this length is determined for electrochemically deposited Cu2O by linking the optical carrier generation profile from back and front and incident photon conversion efficiency (IPCE) measurements to a one dimensional carrier transport model. A diffusion length of ~ 400 nm is estimated. This critical length explains the losses typically presented by these devices. The consequences of this L on device design with the aim of improving solar cell performance are described.

8110-26, Session 8

Application of electrochemical deposition techniques to thin film solar cell processing

B. Basol, EncoreSolar, Inc. (United States)

During the last eight years the manufacturing volume of thin film modules has grown at a compounded annualized rate of over 90%. Today the share of thin film products in the global PV market is in the range of 10-15%. Considering the fact that the wafer Si technologies have achieved impressive cost reductions during the last few years, any increase in thin film market share during the next decade will require these technologies to aggressively drive for cost reductions through device efficiency improvements and utilization of lower cost manufacturing techniques. Electrodeposition is an attractive low cost approach for the deposition of thin film coatings. Such coatings have already found large scale applications in circuit board fabrication and integrated circuit manufacturing. In these applications, the electroplated layers are mainly used as passive components that carry electrical current. Application of electrodeposition techniques to thin film solar cell fabrication involves formation of semiconductor absorber layers that actively participate in power generation. This requirement brings along certain challenges that need to be overcome. In this paper we will present a review of work carried out for the application of electrodeposition techniques to the fabrication of CdTe and CIGS based solar cells and modules.

8110-27, Session 8

CdTe, CIGS and a-Si thin film PV technologies: factors impacting LCOE

L. A. Eldada, SunEdison (United States)

We describe some of the most promising thin film photovoltaic (PV) technologies and contrast their attributes and how they impact the levelized cost of electricity (LCOE). The thin film PV technologies reviewed include cadmium telluride (CdTe), copper indium gallium selenide (CIGS), and amorphous silicon (a-Si), produced by a variety of methods. The factors studied include conversion efficiency and efficiency improvement potential, module lifetime, module cost and cost reduction potential, installation cost, operation cost, maintenance cost, and various factors affecting the internal rate of return (IRR), such as early-life annual degradation rate and energy yield under different lighting and environmental conditions. These thin film PV technologies are compared with crystalline silicon, the most widely deployed PV technology.

8110-28, Session 8

Novel concepts for low-cost and high-efficient thin film solar cells

D. Gomez, A. Menéndez, P. Sanchez, A. Martinez, L. Andrés, M. F. Menéndez, Fundación ITMA (Spain)

Although the development of different thin film solar technologies has represented an important advance along last years, further progresses are still required in order to reduce their manufacturing costs (below grid parity) and to increase their efficiency (closer to crystalline silicon cells). Among different approaches focused on overcoming these difficulties, the present work gives a short description of different concepts developed at ITMA Materials Technology in the framework of different industrial projects.

These novel concepts can be grouped in three categories:

(i) The development of surface treatment technology (low cost inorganic coatings by sol gel and tape casting) for the deposition of thin film solar cells on non transparent substrates (steel, ceramics, polymers)

(ii) The embedment of metal nanoparticles for light trapping following two different strategies: the increase of quantum efficiency width by electronic plasmon resonance of nanoparticles in the 10nm-range and the increase of light path by means of light scattering (in the 100-nm range)

(iii) The use of novel laser scribing and encapsulation methods in substrate configuration

It is important to point out that these advances are not directly related to any specific thin film solar technology and seem to be suitable for silicon based, CIGS and CdTe solar cells.

As an example, these progresses have been successfully demonstrated in single junction amorphous silicon solar cells in substrate configuration (n-i-p sequence) on different substrates. The work shows the individual improvements in cell efficiency according to the concepts previously described. As a second step, they have been joined together in a innovative cell structure with an increase of efficiency up to 2% (absolute). Moreover, the possibility to apply this cell concept on different rigid and flexible substrates opens their use on building materials for BIPV, as it will be shown for steel and ceramics.

All these facts represent a clear success. In addition, a detailed cost analysis is carried out and the decrease of the /W is estimated. An extrapolation of these results to other thin film technologies has also been evaluated.

Laser-induced localized strain and ultrafast absorption in the ablation of thin film solar cells

S. Buratin, E. Favero, P. Villoresi, Univ. degli Studi di Padova (Italy)

The selective removals of areas as well as the realization of narrow channels in the multilayer structure are central issues in thin film solar cell technology. The difference in optical absorption and the different mechanical parameters, including density, thermal conductivity, surface adhesion energy and stress-strain curve, allow for the exploitation of laser driven non contact removal processes based on different principles.

In this work we will address on the layer removal along channels for the serial connections of the cell by comparing two novel approaches. The two opposing cases of the ultrafast absorption and of the controlled thermal stress in microsecond timescale are investigated for their potentials in reaching a clean layer separation with sharp edges. The rationale for the investigation of the two processes in parallel is the different optimal removal required in the cell layer stack.

By using low energy and high repetition rate femtosecond laser pulses the ablation rate may be precisely controlled. The thermal effects are limited due to the short pulse duration and the threshold for the material ablation is beyond the Bloemberger square root law. We model and experimental observe the processing for different wavelengths and pulse parameters.

On a longer time scale, the exploitation of the temporal control of the laser pulse irradiance allows for the induction of mechanical strain of suitable amplitude and extension. We model the tridimensional distribution of the strains and its time evolutions as well as the experimental investigations of the induction of layer removal in a series of relevant cases for the thin film solar cells technology.

Our aim is to point out the optimal laser process for the different cell layers. We are convinced that these novel techniques are potentially superior with standard approaches.

8110-30, Session 9

Novel adhesion methods for solar cell assemblies using pressure sensitive adhesives

R. Thomaier, NuSil Technology LLC (United States)

Traditionally engineers and solar cell assemblers have used liquid silicone adhesives to bond solar cells to panel substrates and silicones with high light transmittance to bond cover glasses to cells. As advances are made in solar cell assemblies, innovative next generation silicone technology is used. Low outgassing silicone pressure sensitive adhesives (PSA) and thin film sheeting can serve the same purpose as liquid adhesives but eliminate the need to wait for a long room temperature cure or additional equipment such as ovens to heat accelerate the cure process. While both methods for manufacturing solar cell assemblies are viable they present different options for customers who are looking for flexibility in their application processes.

Solar cell assembly is made easier by using films and PSAs by controlling the bond line thickness between the cell and the cover glass though the PSA or film thickness. Design engineers have the ability to rework panels where PSAs are applied - cutting cost for components and time. The low outgassing PSAs and film adhesives have similar performance as liquid silicone adhesives without the need of mixing and deairing. Performance characteristics include: broad operating temperature ranges, maintain chemical stability, and offer stress release during thermal cycling. With dimethyl backbone chemistries, similar to traditional adhesives, the clear PSAs and thin films are resistant to yellowing and have light transmittance greater than 97% at 400 nm. This paper will demonstrate how the film adhesives and PSAs will perform similar to the liquid silicone adhesives in solar environments through optical transmission, optical transmission after heat and UV exposure, and adhesion at elevated temperatures.

Multilayer front-sheet with tuned color appearance

H. Rooms, TNO Science and Industry (Netherlands)

The acceptance of solar cells in the built environment is partly dependent on the appearance of the modules. One aspect is color. In most cases a solar cell itself reflects either blue or no color and will appear blackish. For the blue solar cells it is possible to tune the antireflection layer in such a way that a different color is reflected. We propose a front-sheet consisting of a multilayer stack of thin layers deposited from sol-gel onto PET foil such that only a particular wavelength range is reflected. We show through modeling that by alternating layers consisting of silicon dioxide (SiO2) and SiO2:TiO2 on PET foil such color reflection can be achieved In modeling exercises the influence of the number of layers, thickness variations and angle of incidence on the reflected color are predicted. We will show that with a four layer stack we can reach chroma values of 60 for green and 40 for red color in the CIELCH system. In experimental results we achieve a peak reflection at a desired wavelength of 40% with a band width of 100 nm while transmission is more than 90% for the other parts of the spectrum.

Fabrication and properties of mechanically grooved silicon solar cells with buried contact Cu electrode

P. Jang, C. Jung, S. Kyu, K. H. Kim, Cheongju Univ. (Korea, Republic of)

Due to larger shadowing area, higher contact resistivity and high intrinsic resistivity of screen printed Ag electrode, there is a limitation in the conversion efficiency of the cell. In order to solve the problem, buried contact solar cells have been developed. P-type Si wafer was successfully scribed by a home-made mechanical scriber which was composed of HDD 3 phase synchronous motor, 3-axis LM guide, phase shifter, audio amplifier, Labview, signal generator and etc. SiNx insulating films with a refraction index of 2.02 and an etching rate of 0.8 nm/min were successfully sputtered in an optimized sputtering condition, which is used to have Cu electrode selectively deposited in the scribed grooves. Uniform Ni films were successfully deposited in the scribed grooves with a conventional Ni electroless plating solution. After Cu plating, the buried contact solar cell was fabricated with a published condition and, however, the conversion efficiency was as small as 0.42 %. The reason was analyzed so that the contact resistance between Si wafer and electrodes was revealed to be much higher. With an optimized Ni annealing time of 30 min at 350oC the conversion efficiency was enhanced to 12.2 %. And when the electric potential difference was reduced to a voltage lower than 10 V, the conversion efficiency was further enhanced. Detail optimized conditions of the individual process will be reviewed in the conference site.

Physical properties of Al-doped MgZnO film grown by RF magnetron sputtering using ZnO/MgO/Al2O3 target

K. Hsueh, Y. Cheng, W. Lin, Vanung Univ. (Taiwan); H. Chiu, Chang Gung Univ. (Taiwan); Y. Huang, G. Chi, National Central Univ. (Taiwan); W. Liu, Yuan Ze Univ. (Taiwan)

In this work, we report on an investigation of the characteristics of Al-doped MgZnO (AMZO) films which were deposited on top of the sapphire by RF magnetron sputtering system using the ZnO/MgO/Al2O3 (76/19/5 wt%) 4 inch target. All AMZO films used in this study were grown by RF sputtering method (HELIX) on c-face sapphire substrates.

The XPS was performed by a Thermo VG-Scientific/ Sigma Probe instrument. The XPS results by varying the etching time were shown. The contents of AMZO were also estimated by varying the etching depth.

The transmittance spectrum of AMZO film is obtained. In this study, the AMZO film show high transparency with transmittances over 89.8 % in the visible region (400 ~ 700nm) and the sharp absorption edge is visible in UV region due to the Mg content. The absorption edges of AMZO shift toward the short wavelength compared with the previous report of ZnO, implying that band gaps can be tuned by changing the Mg content of AMZO layer.

We summarized the Hall measurement on the AMZO samples which were deposited at RF power of 150W and 200W, respectively. The results show that the Hall measurement of AMZO films which were deposited at lower RF power obtained the lower resistivity and higher mobility, but the doping concentration is not a strong function of the RF power and annealing temperatures.

Production of highly conductive copper doped ZnS thin films by dip-coating for solar energy technology

F. Ait medjane, R. Wendelbo, Abalonyx AS (Norway)

Thin cupper doped ZnS film is promising materials for the use in various application devices such as a photocatalyst or light-emitting diode in the blue to UV spectral region due to its wide band gap at room temperature.

Here we report a simple, low cost and very effective technique to prepare highly conductive copper doped ZnS thin films. The films were deposited on glass substrates by the dip-coating technique adopting the SILAR method. An automated high-throughput set-up was developed for the purpose, by using a commercial robotic arm to dip 24 substrates in parallel. The set-up includes in house made instrumentation for on-line measurement of conductivity and transmittance. X-ray diffraction (XRD), SEM, AFM and XPS techniques have been employed to investigate the structure and surface morphology of as-deposited films. It was found that, in narrow compositional range around Zn/Cu=100, semi-transparent films with sheet resistivity lower than 100 Ohms/sq were obtained. This is about 100 time higher conductivity than for materials previously reported. SEM-analysis indicated that the films were not uniform in early stages

of process. Elongated “islands” could be observed, which grows with increasing number of dipping cycles. However, after 90 dipping the SEM analysis shows continuous and homogeneous films.

The influence of active cell design on a monolithic organic photovoltaic module: fabrication and simulation

H. Lyu, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of) and Kyungpook National Univ. (Korea, Republic of); J. H. Sim, S. Jeong, S. Woo, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of); J. Shin, Kyungpook National Univ. (Korea, Republic of); Y. S. Han, Daegu Gyeongbuk Institute of Science & Technology (Korea, Republic of)

In this study, the influence of active cell design on the power conversion efficiency (PCE) of a monolithic organic photovoltaic (PV) module was investigated using experimental methods and circuit simulation. For computer simulation-based study, the organic PV cell was described by a circuit-based two-diode model and the modules were simulated under several conditions including shading effect, diode model parameters, series resistance and shunt resistance, etc. A unit organic PV cell as a reference device and four types of monolithic organic PV modules with different active cell length were fabricated together on a same glass substrate. The characteristics of the fabricated unit organic PV cell were measured and the electrical parameters were extracted to use it for simulation of the four types of monolithic organic PV modules. To analyze the influence of organic PV cell design on the PCE of monolithic organic PV modules, the I-V characteristic curves and the PCEs of the four type monolithic OPV modules with different active cell length were obtained and compared with the simulated results. The simulated I-V curves were matched well with the measured I-V curves for four types of monolithic organic PV modules with different active cell length. The highest PCE of the monolithic organic PV module was 2.86% with the active cell length of 11.6mm. This work is meaningful to enhance the performance of a monolithic organic PV module to a certain extent and offers a method to design a high-efficiency large-area monolithic organic PV module.

Effect of nanostructured FTO surface on photovoltaic characteristics of thin film solar cells

H. Chang, H. Wang, K. Lai, National Taiwan Univ. (Taiwan); P. Yang, AU Optronics Corp. (Taiwan); J. He, National Taiwan Univ. (Taiwan)

Nowadays, how to increase the optical paths of infrared light in uc-Si layer is the severe challenge in tandem thin film (TF) solar cells. In this study, we utilize nanostuctured FTO electrodes to enhance both the transmittance and haze in broadband wavelengths. The enhancement of optical transmittance in nanostuctured FTO films with the surface roughness could lower the reflectance between the FTO/a-Si interfaces. Furthermore, the high haze benefits from nanostructures could allow much incident light strongly scattering to increase not only optical paths but light absorption especially in the infrared region.

Upon the application of the nanostrucutured FTO surfaces, the current density of TF solar cell was increased from 10.01 to 11.05 mA/cm2, and the conversion efficiency could be improved from 8.82% to 9.74%. The concept and technique presented in this study should benefit the development of next generation of TF solar cells.

Preparation and properties of CdS film used in CIGS-based solar cell with CBD method and thermal treatments

T. Hsieh, W. Wu, C. Chuang, M. Chang, C. Liu, Yuan Ze Univ. (Taiwan)

Since CdS material has a direct and wide band-gap, it is very potential for fabricating photovoltaic devices. Due to its wide band-gap, CdS film can be acted as a window material to combine with Cu(In, Ga)Se2 film. Therefore, CdS film grown on ITO substrate is usually used to fabricate a high efficiency solar cell. To obtain a quite uniform, easily scaling-up, and inexpensive sample, the CdS thin film with a thickness of 50 nm was deposited by using chemical bath deposition (CBD) method. Through varying annealing temperatures and annealing times, the electrical and optical properties of CdS film could be obviously improved. From measurements, the transmittance of CdS sample annealed at 100°C with 5 min was increased from 80 to 90% in the wavelength range of 510-600 nm. The photoluminescence peak of CdS sample annealed at 150°C with 20 min is the maximum and its sheet resistance is the minimum. By using those data obtained at various annealing temperatures and times, we can find an optimum condition for growing CdS film application on Cu(In, Ga) Se2-based solar cell.

Effects of substrate temperature on the properties of MgF2 thin films and their applications on CuInGaSe2 solar cells

J. Chang, T. Hsieh, M. Yang, J. Guo, C. Chuang, Industrial Technology Research Institute (Taiwan)

Chalcopyrite CuInGaSe2 (CIGS) based thin-film solar cells are regarded as most promising candidates for film power modules due to high efficiencies and low cost. In order to increase cell efficiencies, anti-reflective (AR) coatings have been designed and applied to solar cells. MgF2 are usually utilized as an AR coating on CIGS solar cells and deposited on the surface of transparent-conductive oxides. In this study, MgF2 thin films were respectively formed on the 2 2 cm2 soda-lime glass (SLG) and SLG/ZnO/AZO substrates via e-beam evaporation at different substrate temperature. X-ray diffraction (XRD), scanning electron microscopy (SEM), transmittance and reflectance investigated characteristics of the films. Further, the AR coatings were also deposited on the CIGS cells at different substrate temperature.

Fig. 1 shows the XRD patterns of MgF2 thin films deposited on SLG substrate at different substrate temperature. The (110) peak intensity of MgF2 films clearly increases as the substrate temperature increases. High substrate temperature enhances the crystal growth. Fig. 2 shows the transmittance and reflectance of blank SLG and SLG/MgF2. The transmittance and reflectance of blank SLG are about 89.1% and 8.9%. Depositing MgF2 films on SLG substrates could increase the transmittance and decrease the reflectance. XRD patterns of MgF2 thin films deposited on SLG/ZnO/AZO substrate at different substrate temperature are shown in Fig. 3. The intensity of MgF2 peak at 27o increases with the substrate temperature. The peak appeared obviously at 200 oC. Fig. 4 shows the transmittance and reflectance of blank SLG/ZnO/AZO substrates and SLG/ZnO/AZO/MgF2. MgF2 AR-coatings sufficiently increase the transmittance and decrease the reflectance. SEM images of MgF2 thin films deposited on SLG/ZnO/AZO substrate are shown in Fig. 5. We have deposited 50 nm ZnO and 450 nm AZO films on SLG substrates. All of the MgF2 film thickness are ~100 nm. The surface looks much smooth. Fig. 6 shows the current-voltage characteristic of CuInGaSe2 solar cell without and with 100 nm MgF2 thin films. It could be find that the short-circuit current density of solar cell characteristics has been increased with adding AR coatings.

Laser scribing performance in thin-film silicon photovoltaic micromorph tandem modules using short pulse lasers

J. Cashmore, V. Cervetto, H. Chabane-Amat, S. Gardin, M. Lindic, S. Ristau, Oerlikon Mechatronics AG (Switzerland)

In thin-film silicon photovoltaic modules it is important to optimise the laser scribing processes to achieve low-loss performance of the segment interconnections and thereby obtain the highest module power outputs. The characterisation of the component scribes and the contribution of the complete interconnect structure to the module behaviour enable the optimisation of the laser scribing processes. Current laser patterning processes based on nanosecond (ns) pulse duration lasers are irradiated from the substrate side to enable high speed scribing. These through-the-glass processes require more than one laser wavelength for targeted removal of the different layers in the photovoltaic cell structure. Development of processes using lasers with picosecond (ps) pulse durations allow scribing from the deposition layer side of the module for all scribe processes using a single wavelength and at scribe speeds of up to 120 m/min. This approach has the advantage that the glass surface and bulk properties can be chosen to enhance the module performance unrestricted by the need for the laser to pass without absorption or scattering through the substrate (e.g. using an optimised glass transmission spectrum, an anti-reflection coating, or a scattering surface structure). In addition a single tool can efficiently process the complete interconnect structure. This allows improved flexibility of tool-routing and minimises the number of tools required within a fab. A comparison of ps-laser and ns-laser patterning results for Oerlikon Solar's Micromorph modules, together with process characterisation and optimisation methods will be presented.

Pulse-electrodeposition of lead sulfide thin films for PV applications

N. R. Mathews, E. F. E. Carrillo, Ctr. de Investigación en Energia (Mexico)

In this work we report the pulse electrodeposition of lead sulfide thin films on metallic and Tec 7 (Pilkington) glass substrates. For electrodeposition, the potential was fixed by the cyclic voltammetry studies. The deposition bath contained an aqueous solution of PbCl2 and Na2S2O3, the pH of which was adjusted to 2.5 by adding diluted HCl. It was observed that the deposition potential has an influence on the crystalline size. The films were deposited with potentials in the range of -0.9V to -0.5 V and was observed that the film deposited at 0.5V had the smallest crystalline size. The potential pulses applied was Von = -0.5V and Voff = +.1V. The obtained PbS thin films were characterized by XRD, Raman, AFM, and optical transmittance. The films were crystallized in cubic structure, with an average crystalline size of 10 nm. The band gap of the films was estimated at 0.7 eV and was found to vary with the crystalline size. The AFM analysis showed a uniform surface. The films exhibited photoresponse, and the resistivity in the dark was 4 x 104 Ohm-cm.

Effects of plasma enhancement on the Al:ZnO MOCVD

S. Kyu, Cheongju Univ. (Korea, Republic of)

Undoped ZnO and Al doped ZnO thin films were deposited on Si(100) and 7059 glass substrates by metal organic chemical vapor deposition (MOCVD) using diethyl zinc (DEZ) and N-methylpyrrolidine alane (MPA) precursors. Effects of substrate temperature, reaction pressure, feed ratio of Zn/O and Zn/Al on the growth rate, preferred orientation, resistivity and transparency were investigated. The growth rate showed a maximum value of 750 nm/min at the substrate temperature 350oC, reaction pressure 1.5 torr. From the Arrhenius plot of deposition rate vs. substrate temperature, it was found that the activation energy of surface reaction was 41.7 kJ/mole. Below 300oC, amorphous films were obtained, while (002) plane preferred oriented ZnO films were deposited above 300 oC. Optical transparency of the films deposited at various experimental conditions showed good quality above 80%, and band gap of the films decreased with the substrate temperature in the range of 3.93~4.14 eV. Especially, effects of plasma enhancement on the properties of film such as optimum substrate temperature, film quality were investigated. Surface morphology have been changed into faceting crystalline with plasma enhancement, especially in the direct plasma condition. XRD analyses show the positive effect of plasma enhancement. But at a high power conditions, diffraction intensity of the films decreased rapidly. Similar tendencies are observed in the growth rate and electrical resistivity of deposited films. It is assumed that mild energetic reactive radicals in the indirect plasma region are more effective for MOCVD process rather than highly energetic, aggressive ionic particles in the direct plasma region.

Advances in spectral conversion for photovoltaics

J. Marques Hueso, S. Ciorba, S. K. W. MacDougall, Heriot-Watt Univ. (United Kingdom); Y. Wang, D. Chen, Fujian Institute of Research on the Structure of Matter (China); B. S. Richards, Heriot-Watt Univ. (United Kingdom)

Up- and down-conversion constitutes two singular routes to achieve improved energy harvesting along the whole solar spectrum by changing the shape of this one rather than to change the absorption properties of the semiconductor layer. One of the materials more extensively studied for these propose have been lanthanides glasses, due to their stability and feasibility as real components of out-door solar panels. To obtain a significant conversion rate two main premises have to be accomplished. First, the excited ions have to emit efficiency, target that has been already achieved with efficiencies near 200%. Secondly, the absorption by the ions has to be significant, with large quantum yields to assure the harvesting at the wavelength to convert, thing that still constitutes a challenge, especially in up-conversion where the transformation has a non-linear dependence on the power.

In this paper we are going to review the materials used as spectral converters for PV, paying special attention to the up- and down-conversion processes in lanthanide glasses in fluoride matrices. We will discuss some strategies pursued to increase their quantum yield, and therefore their overall conversion efficiency. Finally, some methodologies form nanooptics are going to be discussed as possible candidates to overcome the low absorbance of the lanthanide ions.

8111-03, Session 1

Embedded metallic nanopattern for enhanced optical absorbance and photovoltaics

F. Ye, M. J. Burns, M. J. Naughton, Boston College (United States)

Novel metallic nanopatterns integrated with semiconductor films form optical metamaterials that can enable enhanced absorption. When employed in photovoltaics, such integrated nanostructures may facilitate a significant increase in power conversion efficiency. 3-D electromagnetic computer simulations in both time and frequency domains show that the absorbance of amorphous silicon can be enhanced by more than 3,000% for 1 to 30 nm-thick metal nanopatterns integrated with 30 to 100 nm thick a-Si films. Compared even to conventional thickness a-Si cells (e.g. 400 nm), a several 100% enhancement is observed in simulations. We show these calculated enhancements to be nanopattern shape- and material-dependent, with empirical dispersion relations for a-Si and the metals (Ag, Al, Au, Cu, In, Mg and Pt) employed. The role of plasmonics is investigated with respect to metal choice. Progress on experimental investigations into these effects will be discussed. Such metallic nanopattern integration represents a potential route to high efficiency solar power with ultrathin absorbers enhanced by optical metamedia.

8111-04, Session 1

Visible to infrared down conversion in rare-earth doped fluorides for luminescent solar converters

D. Serrano, A. Braud, Ecole Nationale Supérieure d'Ingenieurs de Caen et Ctr. de Recherche (France)

One of the well-known loss mechanisms in Si solar cells is the thermalization of charge carriers generated by the absorption of high-energy photons. These losses could be reduced by using a rare-earth based luminescent converter to realize multiple electron-hole pairs per incident photon. We present here results obtained in (Pr3+, Yb3+) codoped CaF2 and KY3F10 crystals showing absorption of blue light by Pr3+ ions, followed by an efficient energy transfer towards Yb3+ ions which subsequently emit around 1.2eV (1030 nm). Ytterbium ions are excellent candidates for the enhancement of Si solar cell efficiency since the Yb3+ emission around 1µm is adapted to the Silicon cell absorption.

Experimental results show an increase of the energy transfer efficiency from Pr3+ to Yb3+ when increasing the Yb3+ concentration. For the first Pr3+ to Yb3+ energy transfer, an efficiency of 97% is achieved in KY3F10: 0.5%Pr3+- 20%Yb3+. However, this promising result faces challenging issues since a high Yb3+ concentration induces energy migration between Yb3+ ions which impairs the Yb3+ luminescence. CaF2 appears then to be particularly interesting. A low Yb3+ concentration, only 2%, is sufficient to obtain a 97% energy transfer efficiency because of the creation of Pr3+/Yb3+ clusters. This clustering effect limits the need for a high Yb3+ concentration and therefore reduces the Yb3+ concentration quenching in CaF2. However, a detailed study of the CaF2 clustering process is required for a better understanding of the experimental results so as to asses precisely the potential of CaF2: Pr3+,Yb3+ as an effective luminescent converter.

8111-05, Session 1

Solar energy harvesting by 3D thin-slab photonic crystals

G. Demésy, S. John, Univ. of Toronto (Canada)

While silicon is a promising photovoltaic material, its limited absorption spectrum has rendered first generation photovoltaic devices with poor quantum efficiency in the near infrared spectral region. A light-trapping mechanism is required to harvest solar energy in thin films in this spectral range.

Earlier theoretical work showed that photonic crystals enable light harvesting in weakly absorbing semiconductors due to a broad band, wide angle, Parallel Interface Refraction (PIR) effect. Here light is trapped in slow group velocity modes in a region of enhanced electromagnetic density of states. We demonstrate that three-dimensional sculpting of silicon into cubic photonic crystals (e.g. cubic woodpiles, modulated nanoholes and nanowires) enables PIR based light trapping and strong absorption in the near-infrared with structured slabs of micron thickness.

We determine the optimum set of radii and lattice constants for 2D photonic crystals based on silicon nanowires at constant equivalent homogeneous slab thickness. A simple sinusoidal modulation of the rod radii along the propagation direction, resulting in a 3D cubic lattice is shown to offer an enhancement of 15% in absorption over the best 2D nano-rod array. These structures exhibit comparable performance to the most efficient silicon-based nanostructures proposed so far and offer more opportunities for optimization.

We describe mechanisms to further reduce reflection and transmission losses of light not captured by PIR resonances through anti-reflective surfaces, such as graded index layers and nano-cones. Back-reflectors made of different 3D photonic crystal architectures with targeted stop gaps are shown to be more effective than metallic mirror plates.

8111-06, Session 2

Plasmonic enhancement of thin-film solar cells using gold-black coatings

C. J. Fredricksen, LRC Engineering Inc. (United States); D. R. Panjwani, F. Khalilzadeh-Rezaie, R. E. Peale, K. Baillie, J. Colwell, Univ. of Central Florida (United States); S. Peppernick, A. G. Joly, K. M. Beck, Pacific Northwest National Lab. (United States)

Coatings of conducting gold-black nano-structures on commercial thin-film amorphous-silicon solar cells enhance the short-circuit current by 20% over a broad spectrum from 400 to 800 nm wavelength. The efficiency, i.e. the ratio of the maximum electrical output power to the incident solar power, is found to increase 7% for initial un-optimized coatings. Metal blacks are produced cheaply and quickly in a low-vacuum process requiring no lithographic patterning. The inherently broad particle-size distribution is responsible for the broad spectrum enhancement in comparison to what has been reported for mono-disperse lithographically deposited or self-assembled metal nano-particles. Photoemission electron microscopy reveals the spatial-spectral distribution of hot-spots for plasmon resonances, where scattering of normally-incident solar flux into the plane increases the effective optical path in the thin film to enhance light harvesting. Efficiency enhancement is correlated with percent coverage and particle size distribution, which are determined from histogram and wavelet analysis of scanning electron microscopy images. Electrodynamic simulations reveal how the gold-black particles scatter the radiation and locally enhance the field strength.

8111-07, Session 2

Plasmonic back contacts for light trapping in thin-film silicon solar cells

U. W. Paetzold, E. Moulin, B. E. Pieters, R. Carius, U. Rau, Forschungszentrum Jülich GmbH (Germany)

Light-trapping concepts are essential for high performance thin-film silicon solar cells made of amorphous (a-Si:H) or microcrystalline silicon (µc-Si:H). Conventional devices apply randomly textured TCO (e.g. ZnO) substrates serving as front contacts and reflective metal back contacts (e.g. Ag). In this contribution, a novel light-trapping concept based on Ag nanostructures at the back contact of a thin-film silicon solar cell is introduced. Plasmonic modes in the Ag nanostructures enable scattering of incident light to very large angles at low optical losses. This way, Ag nanostructures can serve as efficient sub-wavelength scattering components of solar cells which couple incident light into thin a-Si:H or µc-Si:H absorber layers. In addition, specific arrangements of Ag nanostructures offer ways to control the scattering angle distribution via diffraction orders.

Both, three-dimensional simulations and experimental results of thin-film silicon solar cells with Ag nanostructures at the Ag back contact will be shown. The interaction of electromagnetic waves and nanostructures on flat silver layers as well as complete solar cells is simulated with a numerical solver of Maxwell's equations. Spatial absorption profiles and photocurrents of solar cells as well as scattering profiles of Ag nanostructures are calculated from three-dimensional electromagnetic field distributions. To demonstrate the plasmon induced light-trapping effect of Ag nanostructures, state-of-the-art n-i-p substrate-type thin film silicon solar cells are fabricated on patterned substrates by conventional plasma-enhanced chemical vapour deposition (PECVD) and compared to those solar cells fabricated with the conventional light-management concept.

8111-08, Session 2

Self-assembly as a design tool for the integration of photonic structures into excitonic solar cells

S. Guldin, Univ. of Cambridge (United Kingdom); P. Docampo, Univ. of Oxford (United Kingdom); S. Hüttner, N. Yufa, P. Kohn, Univ. of Cambridge (United Kingdom); M. Stefik, Cornell Univ. (United States) and Ecole Polytechnique Federal de Lausanne (Switzerland); H. J. Snaith, Univ. of Oxford (United Kingdom); U. B. Wiesner, Cornell Univ. (United States); U. Steiner, Univ. of Cambridge (United Kingdom)

One way to successfully enhance light harvesting of excitonic solar cells is the integration of optical elements that increase the photon path length in the light absorbing layer. Device architectures which incorporate structural order in form of one- or three-dimensional refractive lattices can lead to the localisation of light in specific parts of the spectrum, while retaining the cell transparency.

In our work, we employ the self-assembly of soft matter to design inorganic material with photonic properties. We have previously shown the integration of a three dimensional photonic crystal into a dye-sensitised solar cell. [1] Recent efforts have now led to the incorporation of one dimensional photonic crystals - so called mesoporous Bragg reflectors (MDBR) - into the device architecture. Our new route relies on the use of the block copolymer PI-b-PEO in combination with sol-gel chemistry [2]. This allows unprecedented control to finely tune porosity and pore size in the resulting titania network, which is exploited to manipulate the refractive index within the photoanode. Deposition in a layer-by-layer fashion enables the stacking of alternating high and low refractive index layers. The result are bicontinuous, electron-conductive MDBRs made of TiO2 with an action spectrum which can be tuned over wide range of wavelengths.

Femtosecond laser doped silicon for photovoltaic applications

M. Sher, Y. Lin, Harvard Univ. (United States); M. T. Winkler, Massachusetts Institute of Technology (United States); E. Mazur, Harvard Univ. (United States)

Doping silicon to concentrations above the metal-insulator transition threshold yields a novel material that has potential for photovoltaic applications. By focusing femtosecond laser pulses on the surface of a silicon wafer in a sulfur hexafluoride (SF6) environment, silicon is doped with 1% atomic sulfur. This material exhibits near-unity, broadband absorption from the visible to the near infrared (< 0.5 eV, deep below the silicon bandgap), and metallic-like conduction. These unusual optical and electronic properties suggest the formation of an intermediate band. We report on the femtosecond laser doping techniques and material properties.

By changing the laser parameters and ambient environment we can control the dopant profiles, crystallinity, and surface morphology. We investigate mid-infrared absorption of femtosecond laser doped silicon.

In addition, we use temperature-dependent Hall measurements to investigate electron transport and to identify the energy states of the sulfur donors. These two techniques could shed light on energy levels of dopant states or bands. We will also discuss potential applications for intermediate-band photovoltaics.

8111-09, Session 3

Metamaterial-based photonic black-hole device for solar light energy harvesting

M. Gharghi, C. W. Gladden, Univ. of California, Berkeley (United States); J. G. Valentine, Vanderbilt Univ. (United States); X. Yin, X. Zhang, Univ. of California, Berkeley (United States)

One of the challenges in harvesting solar light is to control the flow of the optical energy inside the device. Ideally, a solar energy device would guide the optical energy in the desired direction to optimize the conversion process. Traditionally this was accomplished by simple light trapping in the optical ray regime. Recent advances in the understanding of sub-wavelength optical phenomena and in nanofabrication technology open new avenues to control and harvest light through stronger light matter interactions.

We have designed a photonic black-hole that is capable of attracting the propagating optical waves to a central spot. The device is based on a metamaterial structure with a radially increasing index of refraction toward the center, and a sudden steep decrease in the proximity of the center. The designed device is implemented in a two dimensional silicon-on-insulator (SOI) slab structure. The index modulation is achieved by a variable density of silicon pillars formed through electron beam lithography and reactive ion etching. The structure is designed to absorb to the center the infrared light propagating in arbitrary direction.

The strong concentration of the light by the photonic black-hole is useful for solar energy harvesting in several different schemes. The designed device is in principal spectrally wideband, the currently employed platform (SOI slab) is useful for frequencies below the silicon bandgap. A potential application is to enhance the density of the infrared light through concentrating at the center for up-conversion to visible light using rare-earth elements deposited at the center of the black-hole.

8111-10, Session 3

Light absorption enhancement in a high-efficiency Gallium Arsenide solar cell using a whispering gallery mode dielectric nanosphere array

J. Grandidier, D. M. Callahan, J. N. Munday, H. A. Atwater, California Institute of Technology (United States)

Light trapping is a critical requirement in thin film photovoltaics, and dielectric texturing is a viable method to induce light trapping, but thin film device quality often suffers upon direct texturing of the semiconductor active material. Thus it is desirable to develop a design method in which textured dielectric layers provide for light trapping on smooth planar thin film cells. We propose here an approach for coupling light into smooth untextured thin film solar cells of uniform thickness using periodic arrangements of resonant dielectric nanospheres deposited as a continuous film on top of a thin cell. Freely propagating sunlight can be diffractively coupled and transformed into several guided modes within the array of wavelength scale dielectric spheres. Incident optical power is then transferred to the thin film cell by leaky mode coupling into the cell thin absorber layer. It is shown that guided whispering gallery modes in the spheres can be coupled into particular modes of the solar cell and significantly enhance its efficiency by increasing the fraction of incident light absorbed. We numerically demonstrate this enhancement using full field finite difference time domain (FDTD) simulations of a SiO2 nanosphere array above a 1 μm thick Gallium arsenide (GaAs) solar cell structure featuring back reflector and double anti-reflection coating. In the case of a flat cell, the calculated current density is 27.6 mA/cm2. The incoupling element in this design has advantages over other schemes as it is a lossless dielectric material and its spherical symmetry naturally accepts a wide range of incidence angles. Moreover, analytical models show that for SiO2 nanospheres of a given dielectric material, a large number of resonant modes can be supported which can give rise to a 2.3% absorption enhancement in the GaAs absorber layer at several wavelength between 280nm and 900nm. Also, the SiO2 nanosphere array can be fabricated using simple, well developed self assembly methods and is easily scalable without the need for lithography or patterning. This concept can be easily extended to other thin film solar cell materials, such as silicon or copper indium gallium diselenide (CIGS), which are also considered.

8111-11, Session 3

Non-periodic plasmonic elements for broadband absorption in thin-film solar cells

R. Pala, J. Liu, E. S. Barnard, D. Askarov, M. L. Brongersma, Stanford Univ. (United States)

Choosing the optimum size and spatial arrangement of light trapping structures is essential for optically thin solar cells made of a semiconductor with a broadband absorption spectrum. Here we develop a simple model that describes the light trapping via waveguide coupling resonances in terms of the coupling response of individual scattering particles and the optical properties of the waveguide mode. We define a “Spectral Region of Interest” (SRI) where scattering will maximally contribute to the total absorption. An optimum distribution of particles with a coupling response matching with the spectral region of interest can easily be identified using this model. To test our model we analyze the increase in absorption induced by uniform periodic and non-periodic metallic nanostructures in an ultra-thin Si film. A simple system consisting of a 2-dimensional array of Ag strips with periodic, quasi-periodic, quasi-random and random patterns on a silica-coated Si film supported by a silica substrate is used in calculations. We find that non-periodic structures can offer a better performance with the tunability of coupling over the SRI as compared to uniform periodic structures in agreement with full-field simulations. We experimentally test our predictions on an ultra-thin (50nm) Si Schottky-Barrier photodetector platform and report a good agreement in between experimental and theoretical results. The model described here can serve as a useful tool in future ultra-thin solar cell designs incorporating 3-dimensional dielectric and metallic light trapping structures approaching the fundamental limit of light trapping.

8111-12, Session 3

Fundamental investigations of singlet fission and its potential in solar photoconversion

J. C. Johnson, National Renewable Energy Lab. (United States); J. Michl, A. Akdag, Univ. of Colorado at Boulder (United States); A. J. Nozik, National Renewable Energy Lab. (United States)

Singlet fission is a process by which a single photoexcited singlet exciton becomes two triplet excitons. If the process is efficient, there are a variety of situations in which singlet fission could result in greatly enhanced photovoltaic or photoelectrochemical yields. The fundamental photophysics that leads to the multiplication of excitons is poorly understood, and there are only a few cases in which singlet fission was found to be reasonably efficient. Our recent focus is to understand the molecular design criteria and the intermolecular interactions that give rise to a fast singlet fission rate. The regimes of weak, intermediate, and strong interchromophore coupling are considered in a class of model compounds that have appropriate singlet-triplet splitting. The interchromophore geometry is also explored and particular configurations discovered in polycrystalline solids yield extremely high efficiency (approaching 200%). Covalently bound dimers that mimic this geometry have been investigated spectroscopically and have the ability to inject multiple electrons per absorbed photon into nanocrystalline supports. The ultrafast photophysics of more commonly studied crystalline organic semiconductors (e.g., pentacene, tetracene) are also being explored and provide information about the mechanisms by which singlet fission occurs.

8111-13, Session 4

Highly efficient quantum dot sensitized solar cell

N. Park, J. Im, S. Park, C. Lee, Sungkyunkwan Univ. (Korea, Republic of)

Highly efficient quantum dot sensitized (QDS) solar cell is presented. Lead iodide based quantum dot was synthesized from methyl ammonium iodide and lead iodide and deposited on nanocrystalline TiO2 film. The synthesized organic-inorganic hybrid QD showed perovskite structure and was stable upto 300 oC in air. High resolution TEM confirmed that semi spherical QD with about 2 nm in diameter was covered on TiO2 surface. Surface and cross-sectional EDXS analysis also confirmed that QD sensitizer was homogeneously distributed in 3-dimensional TiO2 layer. From the detailed investigations on parameters affecting photovoltaic property of QD sensitized solar cell, we achieved the conversion efficiency of 5.7% at AM 1.5G full sun light intensity (100 mW/cm2). For the given thin TiO2 film (thickness is less than 4 um), the photocurrent density observed from external quantum efficiency (EQE) spectrum was 16.6 mA/cm2 that was two times higher than the conventional N719 dye. In addition, very high EQE of 61.3% was obtained even at long wavelength light of 700 nm, while N719 showed only 8.15% at the 700 nm. Moreover, QD sensitized TiO2 film exhibited charge collection efficiency being close to 100%. As far as we are concerned, the demonstrated conversion efficiency is the highest one among the reported QD sensitized solar cells.

8111-14, Session 4

Multiple chemical treatments for improved PbSe quantum dot solar cells

O. E. Semonin, Univ. of Colorado at Boulder (United States) and National Renewable Energy Lab. (United States); J. Gao, J. M. Luther, A. J. Nozik, M. C. Beard, National Renewable Energy Lab. (United States)

An essential component of third generation solar cells is the combination of a high-efficiency device with low cost materials and highly scalable manufacturing processes. This is generally considered essential for achieving the “dollar-a-watt” cost target for installed photovoltaic energy generation. Multiple exciton generation (MEG), where absorbed high energy photons generate more than one excitation at the band gap, has been proposed to be more efficient in quantum dots (QDs) than bulk materials, which would increase their theoretical solar cell efficiency. However, MEG has not been observed in a solar cell, leading to some debate about its effectiveness. Regardless, lead chalcogenide QD solar cells, with their relative precursor abundance, solutions-processing, and potential for increased theoretical device efficiencies, have seen significant research as a means to accelerate the cost of solar energy beyond the experience curve. In this work, we present progress with an improved ZnO/PbSe QD heterojunction solar cell that uses a second treatment layer to produce robust, stable, high current devices which nearly double the 1-sun efficiency from our previous work. Optical modeling, impedance analysis and additional progress towards measuring MEG in this solar cell will also be presented.

8111-15, Session 4

TiO2/PbS colloidal nanoparticle heterojunction solar cells and limiting factors on the performance

G. Zhai, Univ. of California, Santa Cruz (United States); A. J. Breeze, Solexant Corp. (United States); G. B. Alers, S. A. Carter, Univ. of California, Santa Cruz (United States)

In this work, we report on the fabrication and characterization of TiO2/PbS colloidal quantum dot (QD) solar cells, showing power conversion efficiencies above 4% under AM 1.5 illumination and peak external quantum efficiency over 80%. While our devices show record for short circuit current density of about 21mA/cm2 for PbS- based QD devices, low fill factor (~25%-~40%) impedes achievement of record power conversion efficiency. To understand the working mechanism and limiting factors of our solar cells, we studied the relationship between photocurrent and effective voltage applied on the devices as well as the light intensity dependence of the photocurrent and open circuit voltage, respectively. According to the physical model developed by Goodman and Rose for photoconductive layers, the results indicate that the mobility-lifetime product is responsible for the low fill factor of our devices. Moreover, trap-assisted recombination exists in our solar cells. These results give some insight into a potential limiting mechanism in QD solar cells and are valuable for the optimization and further improvement of QD solar cell performance.

8111-16, Session 4

High-efficiency quantum dot solar cells due to inter-dot n-doping

K. A. Sablon, U.S. Army Research Lab. (United States)

Similar to midgap impurities, quantum dots allow for harvesting the IR energy but at the same time increase the recombination losses. The tradeoff between harvesting and recombination processes in quantum dot solar cells is an ongoing problem studied in a number of theoretical and experimental investigations. Compared with the midgap impurities, the quantum dots offer substantially more flexibility for nano-engineering of electron processes via dot size, correlation of dot positions, and selective doping. We investigated effects of doping on the photovoltaic efficiency in GaAs reference cell, undoped, n-doped, and p-doped InAs/GaAs quantum dot solar cells (QDoSCs). We found that photovoltaic efficiency of the undoped QDoSC is almost the same as that of the reference cell. However, the efficiency improves monotonically with increasing inter-dot n-doping, while p-doping deteriorates the photovoltaic conversion. We observed a 50% increase in photovoltaic efficiency in the device n-doped to provide approximately six electrons per dot. In this QDoSC, the short circuit current density increases to 24.30 mA/cm2 compared with 15.07 mA/cm2 in undoped QDoSC without deterioration of the open circuit voltage. To identify the physical mechanisms that provide this improvement, we investigated the spectral characteristics of the photovoltaic response and photoluminescence of our QDoSCs. We found that the electron capture into QDs is substantially faster than the hole capture, which leads to an accumulation of electrons in QDs. The electrons trapped in dots enhance IR transitions. The built-in-dot electron charge together with charged dopants outside the dots creates the potential barriers, which suppress the fast electron capture processes and at the larger scale form the potential profile which precludes degradation of the open circuit voltage. All of these factors lead to the enhanced harvesting of IR energy and a radical improvement of the QDoSC efficiency. Higher efficiencies are anticipated with the further increase of doping levels and at higher radiation intensities. This makes the QDoSCs promising candidates for use with concentrators of solar radiation.

8111-17, Session 4

High-voltage quantum well waveguide solar cells

A. K. Sood, R. E. Welser, A. W. Sood, Magnolia Solar, Inc. (United States); E. F. Schubert, Rensselaer Polytechnic Institute (United States)

Quantum structured solar cells seek to harness a wide spectrum of photons at high voltages by embedding low energy-gap wells within a high energy-gap matrix in a single-junction device. Quantum well solar cells have the potential to deliver ultra-high power conversion efficiencies

in single junction devices, efficiencies that in theory can approach 45% in un-concentrated sunlight over a wide range of environmental conditions. In this paper, we review and summarize our recent experimental efforts to enhance the open circuit voltage of InGaAs quantum well waveguide solar cell structures.

Photon absorption, and thus current generation, is hindered in conventional thin film solar cell designs, including quantum well structures, by the limited path length of incident light passing vertically through the device structure. Optical scattering into lateral waveguide structures provides a physical mechanism to dramatically increase photocurrent generation through in-plane light trapping. However, the insertion of wells of high refractive index material with lower energy gap into the device structure often results in lower voltage operation, and hence lower photovoltaic power conversion efficiency. In this work, we demonstrate that the voltage output of an InGaAs quantum well waveguide photovoltaic device can be increased to over 1.05 V @ 25 mA/cm2 by employing a novel III-V material structure with an extended wide band gap emitter heterojunction. Analysis of the light IV characteristics from small area test devices reveals that both non-radiative and radiative recombination components of the underlying dark diode current have been suppressed.

8111-19, Session 5

Plasmon-enhanced photoelectrochemical cells

I. Thomann, B. Pinaud, R. Pala, Z. Chen, T. Jaramillo, M. L. Brongersma, Stanford Univ. (United States)

We will present progress towards the use of plasmonic metal nanostructures to enhance the efficiency of solar fuel generation. In the past, solar-to-fuel-efficiencies have been limited because of a large mismatch in the length scales for optical absorption and carrier extraction. Future generations of photoelectrodes must employ cheap, earth-abundant absorber materials in order to provide a large-scale source of clean energy. These materials will likely have relatively poor electrical properties requiring them to be thin to ensure efficient carrier extraction.

The central idea of this work is to employ plasmonic metal nanostructures to efficiently concentrate sunlight near the surface of such thin-film semiconductor electrodes. In this way, optical absorption close to the electrode surface is enhanced, precisely where the relevant chemical reactions are taking place.

We will present various device concepts under study. Full-field electromagnetic simulations were employed to identify suitable geometries for enhancing absorption close to the semiconductor-liquid interface. Thin-film electrodes made from cheap, earth-abundant semiconductors, such as iron oxide, were grown and their materials properties were characterized. Metal nanostructures were fabricated via e-beam lithography, as well as nanoparticle deposition methods. Photoelectrochemical characterization results clearly demonstrate that plasmonic effects are present, and I will discuss our progress towards a more systematic investigation of plasmonic enhancements, catalytic effects and charge recombination.

This project opens up an exciting new avenue for the use of plasmonic structures, exploiting the unique optical properties of metal nanostructures to direct electromagnetic energy precisely where it is needed to drive photoelectrochemical reactions.

8111-20, Session 5

Toward photonic fluorescent solar concentrators

J. Gutmann, M. Peters, B. Bläsi, M. Hermle, Fraunhofer-Institut für Solare Energiesysteme (Germany); H. Zappe, Albert-Ludwigs-Univ. Freiburg (Germany); J. C. Goldschmidt, Fraunhofer-Institut für Solare Energiesysteme (Germany)

Fluorescent concentrators concentrate both diffuse and direct solar radiation with no need for tracking. They consist of transparent plates doped with fluorescent materials such as organic dyes. These fluorescent materials absorb incident light and emit at longer wavelengths. Most of the emitted light is trapped inside the plate by total internal reflection and guided to the edges where solar cells convert the concentrated light.

We present a new concept for these concentrators that mitigates the two major loss mechanisms, namely the escape cone of total internal reflection and reabsorption of emitted light. Embedding the fluorescent material in a photonic structure enables highly efficient light guiding. The modification of both emission direction and spectrum by the surrounding structure can reduce path length dependant losses as well as reabsorption, thus enhancing system efficiency.

In 2D wave optical FDTD simulations we obtained a spectral light guiding efficiency of up to 97.7% for a multilayer system. That means that the loss is over 20 times smaller than in conventional fluorescent concentrators. We present how the photonic structure modifies the emission spectrum as the local density of states for photons inside the structure is different from the one in homogeneous media. In order to design suitable photonic structures, the angular characteristic has to be considered: We show for a Bragg filter, that optimum light guiding is obtained for wavelengths smaller than the design wavelength.

We further report on progress in device fabrication for experimental verification pursuing both a multilayer and a 3D photonic crystal design.

8111-21, Session 5

Many body effects in intervalence band thermophotovoltaic structures

M. Fernandes Pereira, Jr., Sheffield Hallam Univ. (United Kingdom)

In conventional single-energy-gap photovoltaic devices, only photons with energy close to the semiconductor bandgap are effectively absorbed and converted into current [1]. In contrast, intersubband - based Thermophotovoltaic (TPV) devices [2] are not limited by the bandgap. This study demonstrates that inter-valence band absorption structures may lead to devices that can potentially convert thermal photons to current efficiently in the far infrared, which is a range that remains to be further exploited. Absorption due to valence band transitions [3] allows simple perpendicular incidence in the TE mode without the need of prisms or other couplers that increase the complexity, cost, practicality and also the losses in a conduction-band-based TPV. Furthermore, the analysis demonstrates the relevance of many body effects, which are now routinely considered in laser and optoelectronic device simulators, but have been essentially overlooked for photo and thermophotovoltaic simulation and design considerations.

8111-22, Session 5

Theoretical analysis of nanostructured solar cells: opportunities, practical limitations, and results from bulkheterojunction inorganic devices

H. W. Hillhouse, Purdue Univ. (United States)

A basic feature of nanostructured solar cells is presence of increased interfacial area. Here, we define a simple model and several dimensionless groups that show how geometric factors and surface recombination interplay with bulk recombination (predominantly Shockley-Read-Hall recombination) to set practical efficiency limits and also illustrate opportunities for nanostructured photovoltaics. The model

is also extended to quantify the potential benefits of multiple exciton generation (MEG). We will also present recent experimental results on bulkheterojunction inorganic solar cells based on highly ordered "double-gyroid" arrays of PbS quantum wires. The wire segments that compose the ordered array are 4 nm in diameter and intersect at y-junctions every 12 nm. These unique nanomaterials are fabricated using self-assembled double-gyroid nanoporous films as the nanowire template. 2D grazing incidence small-angle x-ray scattering (GISAXS) patterns exhibit 96 diffraction peaks from the nanoscale order. The patterns are indexed with a (211) oriented cubic unit cell with Ia-3d symmetry and lattice constant equal to 18 nm. Thus, the PbS wire segments are interconnected with crystallographic periodicity. All-inorganic Schottky junction and interpenetrated p-n junction photovoltaic devices have been fabricated with a variety of contacts and device architectures.

8111-23, Session 6

Exceeding the limit in solar energy conversion

X. Zhu, The Univ. of Texas at Austin (United States)

The Shockley-Queisser (SQ) limit, i.e., the maximum power conversion efficiency of a conventional solar cell, results mainly from the loss of excess photon energy above a semiconductor band gap to the heat bath. The first approach to exceed this fundamental limit is to convert part of the excess photon energy to multiple electron-hole pairs in a process called exciton fission or multiple exciton generation (MEG). I will illustrate the harvesting of MEG via direct multi-electron transfer from the illusive "dark" multiexciton state. The second approach is to harvest the hot electrons/holes before they loss their excess energy. This must be a dynamic process occurring on ultrafast time scales to compete with hot carrier cooling. I will discuss challenges in implementing both approaches in solar cells with efficiency exceeding the SQ limit.

8111-24, Session 6

Plasmon-induced current rectification and power conversion through hot carrier tunneling

F. Wang, N. Melosh, Stanford Univ. (United States)

In spite of their high power conversion efficiency in the microwave regime, rectennas are facing fabrication challenges and parasitic capacitance at optical and infrared frequencies. We propose a new architecture of metal-insulator-metal (MIM) devices for solar energy harvesting at visible and infrared frequencies based on insulating barrier asymmetrical alignment relative to Femi level and spatial confinement of hot electrons excited through plasmon absorption. As plasmons excited in the upper metal are absorbed, they create a high concentration of hot electrons, which can tunnel through the thin insulating barrier, producing current. The theoretical efficiency enhancement by using surface plasmons can be greater than 75 times than direct illumination, and is effective for visible to IR wavelengths. Here we present both theoretical estimates of the power conversion efficiency and the first device measurements, which show clear rectification and power conversion behavior. Photocurrent enhanced by surface plasmons excited through high-index prism and grating structures will be discussed.

8111-25, Session 6

Ultrafast photocurrent in the nanotube PN junction: probing the interplay between electron-hole pair creation and annihilation

N. M. Gabor, Massachusetts Institute of Technology (United States); Z. Zhong, Univ. of Michigan (United States); K. Bosnick, National Research Council of Canada, Univ. of Edmonton (Canada); P. McEuen, Cornell Univ. (United States)

Understanding the efficent generation (creation) and recombination (annihilation) of electron-hole pairs in low-dimensional devices, as well as developing new optoelectronic nanotechnologies that incorporate efficient generation of multiple electron-hole pairs [1], will require the ability to measure individual device behavior at time scales comparable to electron motion. In individual carbon nanotubes (NTs), purely optical [2-6] and purely electronic [7] measurements have probed carrier dynamics at ultrafast (sub-picosecond) time scales by exploiting intrinsic nonlinear processes. In nanoscale optoelectronic devices, the microscopic details and characteristic time scales of nonlinear processes determine device performance limits for applications in ultrafast photodetectors, light emitting diodes (LEDs), lasers, and energy harvesting devices. Therefore, understanding the physical mechanisms that lead to nonlinear behavior is of paramount importance, yet no measurements have combined ultrafast optical and electronic techniques to probe the fundamental nonlinear processes in individual NTs at subpicosecond time scales.

Here, we present the first ultrafast photocurrent measurements of an individual NT optoelectronic device that explore the interplay between efficient creation and annihilation of electron-hole pairs. By using ultrafast lasers to excite photocurrent in a nanotube PN junction, we are able to probe optoelectronic device behavior at sub-picosecond time scales. Using this technique, we directly probe the transit of electrons and holes across the device in the time domain, finding that charge carriers escape the junction and travel to the device contacts within ~1 picosecond. The carrier escape time is found to result from an electric field-dependent velocity, in which carriers in the first subband (of effective mass m1*) escape the device in half the time as carriers in the second subband (m2* = 2m1*). Additionally, we observe strong photocurrent saturation at high optical powers that occurs more dramatically for carriers excited into the second subband $\varepsilon 2$. We attribute this strong saturation to the annihilation of electron-hole pairs by high-energy free carriers, a process that is more efficient for $\varepsilon 2$ carriers due to energy and momentum constraints.

8111-33, Poster Session

Efficiency enhancement of InGaN-based multiple quantum well solar cells via antireflective ZnO nanorod arrays

K. Lai, National Taiwan Univ. (Taiwan)

ZnO nanorod arrays (NRAs) were applied as the antireflection coating for InGaN-based multiple quantum well solar cells. The NRAs were obtained by a low-temperature (95 °C) hydrothermal method with two different process times: 105 minutes and 135 minutes, giving the average lengths of 1.0 μm and 2.4 μm, respectively. It was found that the 1-μm NRAs results in the enhanced external quantum efficiencies (EQE), fill factor (FF) and conversion efficiency (η) of the solar cell due to the suppressed surface reflections. However, the 2.4-μm NRAs, though exhibiting even lower reflections, led to decreased EQE, FF, and η. The deteriorated device performances were attributed to the absorption of ZnO at the wavelengths below 450 nm. This study indicates that the trade-off between optical transmission and absorption of wide-bandgap nanostructural ARCs should be considered when optimizing the morphology of nanostructures for solar applications.

8111-34, Poster Session

Embedded nanoparticles for absorption enhancement in Si-based photovoltaics

N. Kadakia, H. Bakhru, M. Huang, Univ. at Albany (United States)

Due to the low absorption of silicon, the majority of silicon-based photovoltaic cells are several hundred micrometers thick, limiting their economic feasibility. To achieve cost parity with conventional sources of energy, silicon-based photovoltaics have begun to move towards thinner substrates; such thinner cells necessitate the use of light-trapping

methods to increase the optical path length. We are investigating the use of metallic nanoparticles, which can increase the carrier transition rates, and therefore the absorbance, in the surrounding silicon by orders of magnitude. The enhancement however decreases exponentially with the radial distance from the particle and is virtually diminished by 10 nanometers from its surface. To exploit this phenomenon, therefore, such particles would need to be embedded into the silicon itself. To that end, we have developed a method to create subsurface silver nanospheres using a combination of implantation, thermal deposition, and thermal annealing. By adjusting the implantation parameters, we can localize the layer of nanospheres at specified depths. Through Rutherford backscattering characterization and secondary ion mass spectroscopy, we have found that the silver has indeed agglomerated into the desired location at high concentrations. Furthermore, through transmission electron microscopy bright field imaging and selected area diffraction patterns, we have ensured that the silver has formed bulk-phase nanoparticles, on the order of 30-50 nanometers in diameter. With further work, this method can help realize more efficient surface plasmon-enhanced silicon-based photovoltaics.

8111-36, Poster Session

Optical and electrical properties of crystalline silicon wire arrays

Y. Pai, B. J. Simonds, J. Fields, R. T. Collins, C. Taylor, Colorado School of Mines (United States)

Silicon wire arrays have been synthesized through two step Ag-assisted electrode-less etching from an n-type silicon wafer with (100) orientation. FESEM(Field Emission Scanning Electron Microscopy), UV-VIS-NIR(Ultra Violet-Visble-Near Infrared) spectrophotometer and RCPCD(Resonant-coupled photoconductivity decay) have been used to characterize the morphology, optical, and electrical properties of silicon wires at varying etching times. The reflectivity of the wire arrays decreased with increasing etching time because of light scattering from micro-roughness of the silicon wire surfaces.The effective carrier lifetime decreased with increasing wire length due to the increased surface area. We also created smoother wire surfaces by thermal oxidation followed by HF dipping. From FESEM cross sectional images and reflectivity results, this treatment remove the micro-roughness, but effective minority carrier lifetime is lower than the as-grown wire arrays. A photoluminescence peak observed only in the smoother wires suggests that the lower effective carrier lifetime is due to the diffusion of the residual Ag atoms from the wire surfaces into the bulk during the thermal oxidation process.

8111-37, Poster Session

Optical absorption in vertical silicon nanowires for solar cell applications

M. Foldyna, L. Yu, B. O'Donnell, P. Roca Cabarrocas, Ecole Polytechnique (France)

Photovoltaic research has moved from popular solar cells, based on crystalline silicon substrates with thicknesses of around 250 μm, to the thin film structures saving large amount of the active material. The next generation of solar cells requires substantial increase of the energy conversion efficiency, which can be achieved by enhancing of the optical trapping inside the cell. Light trapping can be improved either by texturing, using materials of different gap in multi-junction solar cells or by structuring the active materials and/or reflectors inside the solar cell.

In this work we study efficiency of the light trapping inside the silicon nanowire solar cells produced using cost-efficient PECVD plasma assisted growth process. The main focus is on the optical trapping inside the single vertical nanowires, which can enhance optical absorption far beyond capabilities of a thin film. A spectral optical absorption modelling together with an electro-magnetic field distribution analysis give insight into the light trapping inside the nanowires. The results provide a guide for the optimization of nanowires diameters, spectral absorptance as a function of nanowire length and optimal density maximizing absorption with minimal material demands. The effect of the regular (periodic) organization is also studied and compared with dense and sparse random structures.

8111-38, Poster Session

Improvement of solar cell efficiency using nano-scale top and bottom grating

X. Jin, A. Ellaboudy, G. Chavoor, California Polytechnic State Univ., San Luis Obispo (United States)

Solar cells are very critical for the energy conversion and they are irreplaceable energy sources. How to increase the efficiency of a solar cell is always an important research topic. We study solar-cell designs using nano-grating on both top (transmission) and bottom (reflection) of solar cells. First, we perform simulations based on rigorous coupled wave analysis (RCWA) to evaluate the diffraction top gratings. In the RCWA method, we calculate up to 20 harmonics, and sweep the launch angle of incident light from 0 to 90 degree. The incident light wavelength varies from 100nm to 1200nm weighted. The total efficiency is the summation of transmission powers of each harmonics, each incident angle, and each wavelength. Triangular gratings can achieve higher light absorption compared to rectangular gratings. The best top grating is around 200nm grating period, 100nm grating height, and 50% filling factor, which corresponds to 37% improvement for triangular grating and 23% for rectangular grating compared to the non-grating case. Then, we use Finite-Difference Time-Domain (FDTD) to simulate transmission/reflection double grating cases. Here the light source is placed on the top of solar cell. The time monitor is at the center of the cell to collect transmission power. We simulated triangular-triangular (top-bottom) grating cases and triangular-rectangular (top-bottom) grating cases. By varying the bottom reflection grating period from 100nm to 900nm and keep the top grating fixed as 200nm-period triangular grating, The solar cell efficiency improvement can reach about 42%. For the triangular-rectangular (top-bottom) grating case, the 20% efficiency improvement can be achieved.

Undamped collective surface plasmon oscillations in metallic nano-chains

W. A. Jacak, Wroclaw Univ. of Technology (Poland); J. Krasnyj, Odessa International Univ. (Ukraine); L. Jacak, Wroclaw Univ. of Technology (Poland)

We investigate utilization of nano-spheres organized in chain structures within the photo-voltaic setup to employ collective modes of surface plasmons, in order to aid plasmonic energy transport and enhance coupling to semiconductor medium for increased solar cells efficiency. The previously described [1] instability of collective surface plasmon oscillations in chains of metallic nanospheres with appropriately selected spheres radii and separation of particles is now discussed and analyzed within a nonlinear approach enabling description of undamped collective mode with appropriately adjusted amplitude, without instabilities. The nonlinear terms arise due to nonlinear contributions to Lorentz friction and effectively quench amplitude instability, thus resulting in stable undamped mode with strictly determined amplitude. This effect is helpful in theoretical interpretation of long range signals in metallic nano-chains observed experimentally by the group of Atwater [2], in terms of the near-field coupling with inclusion of retardation effects and beyond the extremely weak positive interference of the far-field radiation, as was already analyzed within the semi-numerical methods [3]. Considered nano-chain structures (possibly vertically oriented within the semiconductor layered solar cell setup) due to plasmonic undamped collective oscillation mode would enhance internal distribution of energy, providing a novel plasmon subsystem arrangement in layered cell setup, holding a potential for applications towards more efficient solar cells designs. With respect to the undamped collective modes, it is important

to consider nonlinear propagation model in order to remove instabilities and to determine optimal amplitude of the signal and geometry/size system parameters, and such nonlinear model for plasmon propagation is analyzed.

CNTs electric field enhancement of CIGS solar

S. Han, Hanyang Univ. (Korea, Republic of)

Compound semiconductor/CNTs composites have shown considerably improved efficiency improvement in photovoltaic devices, which is often attributed to two different factors. One is the formation of efficient electronic energy cascade structures. The other effect of CNTs on the performance of photovoltaic devices is the decrement of interfacial resistance. The interfacial resistances at n-type/p-type materials and/or n-type materials/TCO electrode are reduced by an outstanding electrical property of CNTs.

In addition to the effects of CNTs, we report the third reason for increment of efficiency in photovoltaic devices by CNT's well-known electrical field enhancement effects. The improved β values in reverse-FE currents of CIGS electrode with SWNTs layers indicate the enhancement of electrical field in photovoltaic devices, which implies the acceleration of the electron transfer rate in the cell. Due to the formation of an efficient electronic energy cascade structure and the decrease of the interfacial resistance as well as the improvement of the electrical field in the photovoltaic devices, the power conversion efficiency of electrochemically deposited superstrate-type CIGS solar cells was increased 24.3% in the presence of SWNTs and showed 10.40% conversion efficiency.

TiO2-nanotube-based dye-sensitized solar cells containing fluorescent material

W. Kim, Gangneung-Wonju National Univ. (Korea, Republic of); H. Park, KAIST (Korea, Republic of); W. Choi, Gangneung-Wonju National Univ. (Korea, Republic of)

Highly ordered TiO2 nanotube arrays were prepared by anodic oxidation of Ti foil in an application to dye-sensitized solar cells (DSCs). Vertical structure of TiO2 nanotube arrays is very attractive due to a high electron transfer from dye to electrode. To improve the power conversion efficiency, fluorescent material was inserted in a liquid electrolyte to use a light spectrum efficiently. Fluorescent material to emit the absorbed light energy provided an additional light for dye in DSCs and additional electrons was created. Thickness of TiO2 nanotube arrays grown by anodic oxidation was 15μm. N719 dye and I3-/I- electrolyte were used to fabricate the DSCs. DSCs containing fluorescent material show a higher short circuit current densities (Jsc) than DSCs without fluorescent material. Therefore the power conversion efficiency of DSCs was improved by fluorescent material. Electrochemical impedance spectroscopy (EIS) was observed to understand an electron transfer and life time.

A freestanding silicon nanowire array solar cell using plasmonic back reflection for broadband optical absorption

J. Jung, S. Jee, Z. Guo, K. Zhou, H. Um, K. Park, J. Lee, Hanyang Univ. (Korea, Republic of)

Si nanowire (SiNW) has been known to be one of the nanomaterials promising for future solar cell applications. Representative attractive features are low material consumption enabling the flexible design, and strong broadband optical absorption by multiple scattering [1]. Freestanding SiNW arrays without Si substrate show the superior absorption characteristics compared to a thin film at short wavelengths of incident light [2], in contrast to a poor light absorbance due to the insufficient thickness of absorbing material at long wavelengths. This paper demonstrates the additional light-trapping techniques for effective optical concentration of incident photon at a long wavelength region. Plasmonic nanostructures are focused as a promising technique for light trapping in high-efficiency solar cells [3].

A SiNW array is embedded in a PDMS matrix to make a flexible thin film in which the Ag plasmonic nanograting is formed at backside for solar cell applications. This metallic nanograting structure shows the plasmonic potential to enhance the absorption of incident light above the bandgap energy through the broadband and polarization insensitive absorption enhancements. This method yielded the light absorption of ~92.6% with only ~5% of silicon consumption in a conventional crystalline solar cell. Three major routes for light trapping such as back reflection, Surface Plasmon Polaritons (SPP), and SPP scattering have been introduced for absorption enhancement at a long wavelength range.

Fine-tuning the structure of unsymmetrical squaraine dyes towards the development of efficient dye-sensitized solar cells

S. S. Pandey, R. Watanabe, N. Fujikawa, Y. Ogomi, Kyushu Institute of Technology (Japan); Y. Yamaguchi, Nippon Steel Chemical Co., Ltd. (Japan); S. Hayase, Kyushu Institute of Technology (Japan)

In the recent past of development of sensitizer having effective light absorption and photon harvesting in NIR wavelength region has attracted a great deal of attention towards the fabrication of efficient dye-sensitized solar cells. Squaraine dyes exhibit strong and sharp absorption having very high molar extinction coefficient whose wavelength can be tailored from visible to IR wavelength region has a great potential toward the development of novel NIR sensitizers. Fabrication of dye-double layer dye sensitized solar cells (reported by our group recently) with efficient visible dye and novel NIR dyes are expected to open a window for the development of high efficiency dye sensitized solar cells. Recently it has been reported that unsymmetrical squarine dyes possess enhanced photon harvesting leading to increased photoconversion efficiency but no further insight has been proposed for the fine tuning of molecular structure of unsymmetrical dyes. We have synthesized a number of unsymmetrical indole bases squaraine dyes where carboxyl anchoring group was directly introduced in the indole ring. It has been found that relative length of alkyl groups and their positioning in the unsymmetrical dye molecular structure affects their photon harvesting behavior. Best efficiency 4.4 % (Jsc 10.86 mA/cm2, Voc 9.64 V and ff 0.61) was obtained when a long alkyl group was substituted in the ring bearing

carboxyl anchoring group while it was short chain length in the counter indole ring. The photovoltaic performances for different sensitizers will be discussed in detail in the light of structure property correlation.

Aluminum nanoparticles for improved OPV devices

V. Kochergin, L. A. Neely, MicroXact, Inc. (United States); H. D. Robinson, Virginia Polytechnic Institute and State Univ. (United States)

At present, the energy conversion efficiencies achievable with organic photovoltaic (OPV) technology are significantly below those in inorganic PV devices. The conversion efficiency of OPV devices is limited by the material properties: the high energy and narrow spectral range of the absorption band result in inefficient harvesting of solar radiation, while low charge carrier mobilities limits the possible active layer thickness. Utilization of plasmonic structures in or around the OPV active layer has been suggested as a way to improve the conversion efficiency of thin film photovoltaic devices. However, this promise remains unfulfilled, and the experimental results are often contradictory to theoretical predictions. We will present theoretical and experimental results indicating that the aluminum-based plasmonic nanostructures hold significant promise for conversion efficiency enhancement in OPV devices. The high plasma frequency of aluminum permits the use of particle concentrations close to the percolation threshold, which results in a wider band of enhanced absorbance and correspondingly better overlap between the plasmon resonance band and the intrinsic absorption bands of OPV materials than what is achievable with gold or silver plasmonic structures. While aluminum nanoparticles are prone to oxidation, the path toward stabilization of aluminum nanoparticles via proper surface functionalization is demonstrated, and we will present data demonstrating a significantly enhanced absorption across a broad frequency range in P3HT:PCBM layer with embedded functionalized aluminum nanoparticles.

Device properties of nanopore PN junction Si for photovoltaic application

H. R. Jin, G. L. Liu, Univ. of Illinois at Urbana-Champaign (United States)

Improvement of energy conversion efficiency of solar cells has led to innovative approaches, in particular the introduction of nanopillar photovoltaics. Previous work on nanopillar Si photovoltaic has shown broadband reduction in optical reflection and enhancement of absorption. Radial or axial PN junctions have been of high interest for improved photovoltaic devices. However, with the PN junction incorporated as part of the pillar, the discreteness of individual pillar requires additional conductive layer that would electrically short the top of each pillar for efficient carrier extraction. The fragile structure of the surface pillars would also require a protection layer for possible mechanical scratch to prevent pillars from breaking. Any additional layer that is applied, either for electrical contact or for mechanical properties may introduce additional recombination sites and also reduce the actual light absorption by the photovoltaic material.

In this paper, nanopore Si photovoltaics that not only provides the advantages but also addresses the challenges of nanopillers is demonstrated. PN junction substrate of 250 nm thick N-type polycrystalline Si on P-type Si wafer is prepared. The nanopore structure is formed by using anodized aluminum oxide (AAO) as an etching mask against deep reactive ionic etching (DRIE). The device consists of semi-ordered pores of ~70 nm diameter. Pore depths are studied in 4 distinct conditions compared to the 250 nm PN junction: 140 nm, 250 nm, 320nm, and 400 nm. IV characteristics of each condition is presented, with discussion on photovoltaic efficiency.

Nanoparticles for down-conversion: concept and theory

Z. R. Abrams, A. Niv, X. Zhang, Univ. of California, Berkeley (United States)

The Shockley-Queisser limit for solar cells assumes that each photon creates one electron, which is extracted at the band-gap of a semiconducting material. In this framework, all photons below the band-gap are lost to transparency, and higher energy photons lose their excess energy to the thermalization of electrons created above the band-gap. 3rd generation solar cells are aimed at surpassing these limitations and increasing efficiency.

From an energy conservation perspective, down-converting with energy larger than the band gap into two lower energy photons is one way to improve the overall efficiency. This is fundamentally different from a multi-exciton solar cell, where each high energy photon produces two electrons, despite the apparent similarities in their end result. However, currently no down-converting material system has been discovered with efficient quantum splitting characteristics.

We are inspecting the use of semiconducting nanoparticles as a possible material system that can be used to down-convert light. Since nanoparticles have large surface-to-volume ratios, the concentration of surface states per nanoparticle can reach a theoretical threshold beyond which they can become radiative with high quantum efficiencies. We analyze the efficiency gains for such a system, both with and without non-radiative losses, as well as describe the entropic processes of such a conversion system. Using direct band gap nano-materials, with high absorption properties, one can add a thin-film layer of nanoparticles and improve the overall efficiency of a cell by a few percentages, without the need to change the underlying solar cell.

Using oblique angle scatter depolarization as a metric of absorption for front surface nanoparticle enhanced solar collectors

T. M. Fitzgerald, Univ. of Dayton Research Institute (United States); M. A. Marciniak, Air Force Institute of Technology (United States); J. Vella, Jr., General Dynamics Information Technology (United States); A. M. Urbas, Air Force Research Lab. (United States)

The study of nanophotonic structures for advanced nanostructured solar cell concepts featuring enhanced light-to-energy conversion mechanisms is of significant interest to the solar energy harvesting community. A technique to augment the traditional integrating sphere method and provide precise angular quantification of enhanced absorption due to placement, composition, concentration, and geometry of nanoparticles on a solar cell surface is presented. The technique is based on the measured angular dependent depolarization of scattered light reflected from the nanoparticle-enhanced solar cell surface. The amount of depolarization, or loss of degree of total polarization, of obliquely scattered light from known incident polarization states is dependent on the degree of interaction of the light with the surface nanoparticles. Proper selection of nanoparticles increases surface scatter, increases the absorption of incident light energy, and increases the depolarization of the scattered light. The technique is model-based through the DDSCAT direct dipole approximation tool. This technique allows for the comparison of measured to modeled depolarization and permits selection of nanoparticle geometry for optimal light-to-energy conversion. Comparisons are presented for the oblique angle scatter depolarization to traditional absorption measurements for gold prism enhanced solar cells. The technique is based upon the measurement capabilities of the Air Force Institute of Technology (AFIT) Dual-Rotating-Retarder (DRR) full-Mueller-matrix (Mm) Complete Angle Scatter Polarimeter at 544nm wavelength. The technique is enabled by enhancements such

as automation, addition of multiple light sources, an improved sample positioning and orientation interface, and enhanced data-analysis software to a Schmitt Measurement Systems (SMS) Complete Angle Scatter Instrument (CASI®).

Fabrication and optical characterization of antireflective sub-lambda structures and nanotemplates of silicon nitride for photovoltaics

B. Sadeghimakki, M. Moradi, S. Sivoththaman, Univ. of Waterloo (Canada)

Antireflection coatings (ARCs) are keys to enhancing the photon collection in photovoltaic solar cells. One well-known and industrially applied but somewhat narrow-band ARC in silicon (Si) based solar cells is the silicon nitride (SixNy) thin film. However, if sub-wavelength structures of SixNy can be formed and deployed on Si, this will lead to much improved and broad-band antireflection properties. During the last decade, a great deal of work has been dedicated to show the potential of nanoscale structures on Si substrates in several application areas - from microelectronics to biological/chemical sensing. In this report, we demonstrate a simple and maskless process employing reactive ion etching (RIE) technique in a CF4 chemistry for the top-down fabrication of SixNy nanostructures on SixNy thin films pre-formed by plasma enhanced chemical vapor deposition (PECVD). The formation mechanism of SixNy nanopillars, the process controllability, and the dependence of their shape and size on plasma process conditions are discussed in detail. It is also shown that the fabricated nanopillar array can be used as a template to form nanostructures on the underlying Si substrate surface this time using a less aggressive different plasma etch chemistry (SF6). Spectroscopic measurements performed on the different types of nanostructure layers revealed a low reflectivity over a broad range of photon spectrum, as opposed to the thin film ARC. The spectral reflectance of the single/double layer with different nanostructure dimensions and pitches is compared to obtain the optimized ARC structure. Finally, we have analytically calculated the spectral reflectivity of the fabricated structures by assigning an effective refractive index to the sub-wavelength layer, as well as adopting experimentally obtained wavelength-dependent refractive indices for Si and SixNy. Excellent fits were obtained between the analytical calculations and experimental data. The simplicity, repeatability, and scalability of the developed process have strong potential for deployment on photovoltaic device architectures.

Comparison of graphene film thickness to power conversion efficiency in a graphene-based solar cell

I. Ruiz, Univ. of California, Riverside (United States)

Since the experimental extraction of graphene in 2004, one focus for its application has been as a window electrode in solar cells. Not only is graphene more plentiful and low cost compared to other materials used as window electrodes but it is also expected to have the right characteristics to make it a viable window electrode alternative. One of the important characteristics is the transparency of the window electrode. The transparency is determined by the thickness of the graphene sample, which affects the resistance of the solar cell. The resistance of the graphene film affects the power conversion efficiency (PCE) of the solar cell and in the following set of experiments the PCE is measured as functions of resistance due to varying graphene film thicknesses. The results of the PCE of graphene are then compared to the PCE of common materials used as window electrodes.

Properties of Si/SiOx quantum well structure for solar cells applications

K. H. Kim, Cheongju Univ. (Korea, Republic of)

By restricting the dimensions of silicon to less than Bohr radius of bulk crystalline silicon (~5 nm), quantum confinement cause its effective bandgap to increase. Therefore, silicon quantum wells (QWs) using these quantum phenomena could be a good candidate to achieve high performance silicon solar cells.

The SiOx/Si QW structures were fabricated by using the successive deposition technique, as quantum confinement device to increase the effective energy bandgap and passivation effect in Si surface for the 3rd generation solar cell applications. In Si/SiOx QWs, the thicknesses of Si layers and SiOx layers were varied between 1 to 5 nm, respectively.

The roughness of sputter-deposited Si on SiOx was less than 4 Å in the thickness of 2 nm.

By using the SiOx/Si QW structures on Si surfaces, the lifetime measured by u-PCD technique increased as a result of passivated surface effects.

The discussion about the other properties such as electrical, structural and optical properties of the QWs will be presented at the conference.

8111-26, Session 7

Silicon nanowire solar cells with a-Si heterojunction showing 7% efficiency

F. Falk, G. Jia, G. Andrä, I. Sill, Institut für Photonische Technologien e.V. (Germany)

Core-shell TCO/a-Si/Si nanowire (SiNW) heterojunction solar cells were fabricated on SiNW arrays. The nanowire arrays were prepared by metal-assisted electroless etching of an n-type silicon wafer (1015 cm-3 P). As etchant a AgNO3-HF mixture (HF 5 M:AgNO3 0.02 M = 1:1 by volume) was used in which Ag nanoparticles form acting as a catalyst for silicon etching. The silver catalyst was carefully removed after the etching by a three-step procedure. The nanowires are about 900 nm long with diameters in the 200 to 300 nm range. The distance between wires is in the range of several 10 nm to 500 nm. A stack of intrinsic and p-doped hydrogenated a-Si was deposited as a shell around the SiNWs by plasma enhanced chemical vapor deposition (PECVD). Finally, an about 200 nm thick TCO layer (aluminum doped zinc oxide) was deposited on top of the a-Si layer by atomic layer deposition (ALD) at 225°C substrate temperature. In a mesa-structured solar cell with contact area of 7 mm2, an open circuit voltage of 476 mV, short circuit current density of 27.03 mA/cm2, a fill factor of 0.562, and a power conversion efficiency of 7.29% were determined under AM 1.5 illumination. Electron beam induced current (EBIC) measurements show clear evidence that most of the current comes from the thin SiNW layer and not from the wafer beneath.

8111-27, Session 7

Comparison of novel 3D nanoarchitectures for solar cells

A. Wangperawong, S. F. Bent, Stanford Univ. (United States)

Several new solar cell device architectures utilizing vertical nanojunctions to decouple light absorption from charge carrier collection are presented. Using models we developed that for the first time describe the device performance of nanostructured solar cells in three dimensions, we have analyzed point-contact nanojunctions, extended nanojunctions, isolated radial nanopillars, and inverted grain boundaries. Our modeling shows that for CdTe solar cells using low quality materials, the power conversion efficiency of nanostructured solar cells is superior to the planar junction.

8111-28, Session 7

Modeling light trapping in silicon microwire arrays

E. D. Kosten, E. L. Warren, H. A. Atwater, California Institute of Technology (United States)

Silicon nanowire and microwire arrays have attracted significant interest as an alternative to traditional wafer-based technologies for solar cell applications. In addition to the device physics advantages of a radial junction, such arrays have been found to exhibit significant light trapping and absorption properties, and some recent experimental results suggest that these structures could exceed the ergodic light trapping limit.[1,2] In an attempt to understand this strong light trapping, we have developed a ray optics model of silicon microwire arrays. For an array on a Lambertian back reflector, this model shows asymptotic increase in the light trapping factor for low areal filling fractions. This asymptotic increase exceeds the ergodic limit for light trapping within the wires, as the back reflector acts like a concentrator with a large acceptance angle.[3] Comparing the ray optics model to experimental data, we find that it shows reasonable agreement with large (4 um radius) wires, but underpredicts the absorption in smaller (1 um radius) wires, suggesting wave optics effects are significant in the stronger absorption observed in wires on this scale.[3] Thus, in addition to the ray optics results, we will present a hybrid model that accounts for wave optics effects by combining a ray tracing multiple scattering model with cross sections derived from exact solutions to Maxwell's equations.

Spectroscopic studies of dopant incorporation in solution-grown Ga:ZnO nanostructures

R. J. Noriega-Manez, Stanford Univ. (United States); S. Misra, Stanford Synchrotron Radiation Lightsource (United States); S. Mehra, Stanford Univ. (United States); M. F. Toney, Stanford Synchrotron Radiation Lightsource (United States); A. Salleo, Stanford Univ. (United States)

ZnO nanostructures have the potential to become an alternative to ITO as transparent electrodes for photovoltaics by combining their light scattering properties with a suitable electrical performance, all in a low-cost solution-based approach. The observation of a dramatic decrease in the free charge density of gallium-doped ZnO nanostructures upon annealing in air at moderate temperatures (200-600 C) poses questions on the mechanisms that determine the defect chemistry in this material system. ZnO nanostructures of varying impurity concentrations, morphologies and sizes were synthesized in the presence of a high boiling point organic solvent and surfactant. Doping effectiveness depends on the incorporation of impurities into electrically active sites in the crystal lattice; in this case, Ga atoms in Zn substitutional sites. We probe the efficiency of solution-based doping using anomalous X-ray diffraction, monitoring the intensity of a set of diffraction peaks as the incoming radiation energy is scanned across the atomic absorption edge (Ga K-edge, 10370 eV). These types of experiments require the use of a synchrotron lightsource in order to tune the photon energy, achieve an excellent monochromaticity across a wide and continuous range of X-ray energies, and maintain a high brightness as well as the necessary angular resolution. The coordination power of the growth environment and the precursor/solvent molar ratio are critical variables in determining doping efficiency and nanostructure morphology. Complementary experiments are performed with photothermal deflection spectroscopy, studying the amplitude and shape of the free carrier absorption peak in the near infrared to calculate the mobility and density of free charges in the nanostructures using the Drude model.

8111-30, Session 7

Engineering optical absorption in aperiodic silicon nanostructures for photovoltaic applications

C. Lin, M. Povinelli, The Univ. of Southern California (United States)

We maximize the solar absorption within an aperiodic, vertically-aligned silicon nanowire structure by manipulating the positions of nanowires. We use a random walk optimization algorithm integrated with a rigorous electromagnetic forward solver based on the transfer matrix method (TMM). We found the configuration of the optimal structure to be highly non-intuitive and symmetry-broken. For a wire diameter of 65nm and initial spacing of 100nm, the optimal aperiodic structure showed a dramatic 2.35 times enhancement in ultimate efficiency compared to its periodic counterpart. Moreover, with only one third the absorbing material volume, the optimal structure can outperform a silicon bulk film of equal thickness with an optimal single layer Si3N4 anti-reflection coating. The significant absorption enhancement can be explained by examining the absorptance spectrum of the optimal aperiodic structure, which mimics that of a periodic array with a larger lattice constant. Specifically, we observe a large overall red shift of the absorption spectrum and numerous absorption enhancement peaks in the low absorption range of crystalline silicon. The absorption profile within the optimal structure exhibits highly localized strong absorption "hot spots" at resonance. These local resonance modes introduce a unique and effective light trapping mechanism that gives rise to resonantly-enhanced absorption at multiple wavelengths, in a similar fashion to that of guided resonance modes in periodic systems with larger lattice constants. We further investigate whether aperiodicity in a silicon nanowire array is in general beneficial for enhancing optical absorption. Interestingly, we found that one thousand randomly picked aperiodic structures invariably have higher ultimate efficiency than that of the corresponding periodic system.

Broadband absorption enhancement in organic photovoltaics based on nanopatterned ultra-thin metal films

Q. Gan, Univ. at Buffalo (United States); W. Bai, Institute of Semiconductors (China); Z. H. Kafafi, National Science Foundation (United States) and Lehigh Univ. (United States); F. J. Bartoli, Lehigh Univ. (United States)

Three-dimensional finite-difference time domain calculations have shown that plasmonic structures can significantly enhance the optical absorption of active layers in polymer- or molecular-based organic photovoltaics (OPVs).* A polarization-independent nanopatterned ultra-thin metallic structure supporting short-range surface plasmon polariton (SRSPP) modes is used to improve the performance of OPVs via broadband absorption resonances. The physical mechanism of the excited SRSPP modes is delineated and their distributions are analyzed. In this talk, we will demonstrate that the SRSPP-assisted broadband absorption enhancement could be spectroscopically tuned by carefully designing the OPV devices and tailoring the parameters of the nanopatterned metallic structure(s). These results are very promising for the development of OPVs with enhanced performance.

8111-10, Session 8

Towards fully printed organic solar cells: material aspects and process challenges

C. J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); M. Heyder, Bavarian Ctr. for Applied Energy Research E.V. (Germany); F. Jakubka, F. Machui, T. Stubhan, I. Litzow, J. Krantz, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Organic PV is rapidly gaining high attraction because of its simple production process and its potential for a true low cost solar technology. The compatibility with printing and coating requires a careful stack design - in the simplest scenario, functional solar modules consist of only three layers, while more advanced and efficient device concepts require the deposition of 5 layers. This is an outstanding simple production process compared to inorganic thin film PV technologies. However, the challenge is in the detail of the printing process and in the formulation of suitable inks.

In this contribution we introduce and discuss material aspects and process challenges towards fully printed solar cells, including the replacement of the ITO electrode. Various concepts were already discussed to develop a fully printed OPV stack, including lamination techniques, printing of CNT networks as well as deposition of highly conductive PEDOT. However, none of these material combinations and concepts currently does fulfill the specifications for highly performing solar modules.

In detail, we discuss the combination of printed metallic nanowire electrodes in combination with metal oxide interface layers as a viable process towards fully printed organic solar modules. Experimental data for fully printed cells will be combined with results from process simulation. The overall process will be evaluated by a cost estimations to give a realistic picture on the potential cost scenario for organic photovoltaics.

8111-11, Session 8

Transparent, non-TCO electrodes for organic photovoltaics

L. Müller-Meskamp, C. Sachse, Y. H. Kim, C. Häfner, A. Zakhidov, Technische Univ. Dresden (Germany); O. R. Hild, Fraunhofer-Institut für Photonische Mikrosysteme (Germany); K. Leo, Technische Univ. Dresden (Germany)

Transparent conducting oxides (TCO) are still the first choice for transparent electrode applications. However, for organic photovoltaics, strong demand for flexible and low-cost substrates led to several alternative technologies and ideas. Using our highly efficient OPV technology, based on the evaporation of small molecules, doped transport layers and bulk-heterojunction geometries, we have studied polymer electrodes (PEDOT:PSS), Ag-nanowire electrodes, and carbon nanotube based electrodes. For PEDOT:PSS, we could enhance the conductivity by optimized solvent treatment, resulting in a selective removal of PSS from the electrode film, as could be shown by XPS and optical spectroscopy. Using these materials, we could achieve the same cell performance than for ITO on small area. Nanowire based electrodes, using random networks of highly conductive material, such as silver or CNTs, are very promising candidates, with Ag-NWs achieving similar transmission and conductivity properties as ITO (ca. 85% Transmission, <10Ohm/sq.). We used different Ag-NWs (diameter, length) coated by dipping or spraying from solution, show the influence of different post-treatment methods, and examined the optical and electrical properties of the network layer. For integration into solar cells, these electrodes were combined with an additional polymer coating, to improve the surface roughness. Carbon nanotubes were used in form of free-standing membranes, as top electrodes in semitransparent solar cells. All systems are shown to yield decent solar cells, with every technology having certain benefits and specific issues, but certainly with huge potential to rival ITO in the future.

8111-12, Session 8

Efficient heterojunction photovoltaic cell utilizing nanocomposites of lead sulfide nanocrystals and a low-bandgap polymer

J. Seo, M. J. Cho, D. Lee, A. N. Cartwright, P. N. Prasad, Univ. at Buffalo (United States)

Hybrid polymer-inorganic nanocrystal (NC) solar cells consisting of a hole-conducting conjugated polymer and inorganic semiconducting quantum dots, like cadmium selenide (CdSe), lead sulfide (PbS) and lead selenide (PbSe), have attracted considerable research attention since the advantages of two classes of materials can be effectively combined. In this work, we demonstrate a facile approach to make an efficient hybrid bulk heterojunction photovoltaic device with PbS NCs and a polymer. Herein, we introduced a low band gap polymer as the electron donor host and fabricated a blended film of oleic acid (OA)-capped PbS NCs with a polymer. Direct post-deposition chemical treatment using a short length cross-linker molecule, 1,2-ethanedithiol, applied to the blend film on the PEDOT:PSS layer kept the bulk heterojunction intact by selectively solubilizing the OA ligand of the PbS NCs without affecting the polymer matrix during the process of ligand exchange. Subsequently, inspired by the use of a multifunctional buffer layer in organic polymer photovoltaic devices, we deposited a titanium dioxide (TiO2) thin layer (through non-hydrolytic sol-gel method) on the blend film to facilitate efficient electron transfer and extraction from the blend toward the metal and to prevent holes from reaching the metal. In addition, the effect of the PbS NC size, and thus excitonic energy, on the power conversion efficiency was studied. Power conversion efficiencies of 2~3% were observed in the resulting devices.

8111-13, Session 8

Polymer nanocomposite solar cells based on in-situ formed CuInS2

C. Fradler, T. Rath, M. Edler, A. Fischereder, S. Moscher, A. Pein, Technische Univ. Graz (Austria); R. Trattnig, E. J. W. List, JOANNEUM RESEARCH Forschungsgesellschaft mbH (Austria); W. Haas, F. Hofer, G. Trimmel, Technische Univ. Graz (Austria)

Inorganic-organic nanocomposite solar cells have become a research topic of great interest within the last decade as, by choosing a suitable inorganic compound as acceptor phase, e.g. CdSe, CuInS2, the amount of absorbed light can be enlarged. Such inorganic semiconductors have a bandgap matching the maximum of the solar spectrum quite well, and therefore significantly contribute to the light absorption in a solar cell.

We developed a CuInS2 in-situ formation process by using new metal xanthate precursor materials. We were able to prepare stable bulk solutions containing the mentioned metal xanthate precursor materials and photoactive polymers like PCDTBT (poly[[9-(1-octylnonyl)-9H-carbazole-2,7-diyl]-2,5-thiophenediyl-2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophenediyl]) or PSiF-DBT (poly[2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophenediyl(9,9-dioctyl-9H-9-silafluorene-2,7-diyl)-2,5-thiophenediyl]) from solvents like toluene or chlorobenzene. In order to prepare nanocomposite solar cells this precursor solution can be coated by spin coating or doctor blading on glass/ITO substrates that have been coated with a thin PEDOT:PSS layer first. The conversion of the precursor material to CuInS2-nanostructures is performed by an annealing step and takes place at a temperature below 200°C. The annealing leads to a homogenous network of the organic and the inorganic phase. In a final step a photocathode was put about the photoactive layer. This solar cell assembly led to efficiencies above 2% up to now.

The solar cells were analyzed by their I-V curves as well as by transmission electron microscopy, optical spectroscopy and IPCE measurements

This work was funded by the Austrian Ministry of Economy, Family and Youth and Isovoltaic AG.

GaAs nanowire/PEDOT:PSS hybrid solar cells: the relationship between nanowire morphology and device performance

J. Chao, S. Shiu, C. Lin, National Taiwan Univ. (Taiwan)

In this study, we demonstrate a new type of hybrid solar cell based on a heterojunction between poly(3,4-ethylenedioxythiophene):poly(styren esulfonate) (PEDOT:PSS) and vertically-aligned n-type GaAs nanowire. The GaAs nanowire arrays are fabricated by directly performing the nano-etching of GaAs wafer with spun-on SiO2 nanoparticles as the etch mask through inductively coupled plasma reactive ion etching. The use of vertically-aligned GaAs nanowire makes the interpenetrating heterojunction interface possible. Thus a large heterojunction interface and short collection paths of photo-generated carriers can be achieved. Moreover, vertically-aligned GaAs nanowire arrays with high aspect ratio can provide much smaller optical reflectance. The hybrid cells are prepared by attaching the GaAs nanowire arrays onto ITO glass substrates coated with PEDOT:PSS films. The PEDOT:PSS adheres to the surface of GaAs nanowrie arrays to form a p-n junction. Our study shows that the GaAs nanowire/PEDOT:PSS heterojunction clearly exhibits a solar cell behavior. The morphology of GaAs nanowire arrays strongly influences the characteristics of hybrid solar cells. The suppression of reflectance and the interpenetrating heterojunction interface of GaAs nanowrie arrays will offer great improvements in device performance. The reduction of reflectance is in agreement with the increase in Jsc of hybrid cells. On the other hand, a larger heterojunction interface between PEDOT:PSS and GaAs nanowire arrays results in a high Jsc. A good PEDOT:PSS coverage also provides improved Voc due to the reduction in shunts. The power conversion efficiency of GaAs nanowire/PEDOT:PSS cells under AM 1.5 global one sun illumination can achieve 5.8 %.

8111-32, Session 8

Silicon/silicon nanowire/poly(3,4-ethylen edioxythiophene):poly(styrenesulfonate) heterojunction solar cells

H. Syu, S. Shiu, C. Lin, National Taiwan Univ. (Taiwan)

Conventional manufacturing processes of solar cells, including epitaxy, diffusion, deposition and dry etching, are high cost and high power consumption. To save energy and reduce expenses, we use organic material, silicon nanostructure and solution process. The devices structure is n-type bulk Si (n-Si)/n-type silicon nanowires (n-SiNWs)/ poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) heterostructure. The active region includes n-Si and n-SiNW arrays, promising the property of ultra low reflection for high light absorption. In this work, SiNWs of only a-few hundred nanometers could lower the reflectance to below 5%. In addition, an organic material - PEDOT:PSS, instead of p-type doping, is introduced to form a p-n junction with n-Si/n-SiNWs for separating the electron-hole pairs. The use of PEDOT:PSS can also passivate the surface defects of n-SiNWs.

N-type SiNW arrays are made by aqueous etching process. The etchant contains Ag ions and HF etching vertically to the 1-10 Ω-cm Si (100) wafers. After etching and removing residual Ag and SiO2 by nitric acid and diluted HF successively, n-SiNW arrays existed on either surfaces of n-Si with very dark color; then Ti and Ag were evaporated on n-Si to be a cathode. Finally, nanowires of n-Si/n-SiNWs were stuck on the PEDOT:PSS that were spin-coated on the ITO coated glass to form a core-sheath heterojunction.

The performance and quantum efficiencies (QE) were measured. The short circuit current density and power conversion efficiency are 27.46 mA/cm2 and 8.05%, respectively, which are higher than other solar cells containing SiNWs. The external and internal QE are beyond 50% and 60% in visible range, respectively.

Conference 8112: Reliability of Photovoltaic Cells, Modules, Components, and Systems IV

Monday-Thursday 22-25 August 2011 • Part of Proceedings of SPIE Vol. 8112
Reliability of Photovoltaic Cells, Modules, Components, and Systems IV

8112-32, Poster Session

An LED-based solar simulator

L. L. Tobin, Univ. College Dublin (Ireland) and Science Foundation Ireland (Ireland); L. McManus, D. Zerulla, Univ. College Dublin (Ireland); J. T. Sheridan, Univ. College Dublin (Ireland) and Science Foundation Ireland (Ireland)

Solar simulators are used as an integral part of the standard testing conditions (STC) for solar cells. They provide a close spectral match to the solar spectrum without the natural variability of outdoor conditions. Typically xenon or sulphur lamps are used to produce this artificial light. However, the output differs considerably from the natural AM 1.5 global spectrum and consequently, filters and sophisticated spectral matching principles are necessary. These solar simulators are less than ideal as their lamps have short lifetimes (~1000 hours) that are expensive to replace and they produce a considerable amount of heat. One relatively inexpensive alternative to xenon and sulphur solar simulators is to replace the lamp with light emitting diodes (LEDs). The advantages of using LEDs are that they are cool, economical and highly energy efficient with extended lifetimes (~10,000 hours). By strategically placing LEDs with various appropriate wavelengths in difference planes and geometries and using suitable controls optical modulation, it is anticipated that the collective spectral output from the LEDs can be matched to the AM 1.5 global spectrum.

Automatic recognition of defects in solar cells and modules

A. Vesely, J. Vanek, R. Stojan, J. Dolensky, Brno Univ. of Technology (Czech Republic)

This paper deals with automatic computer analyze of LBIC images. The output data of defect detection method like LBIC or electroluminescence image contains lots of information about contacts structure and about the defects in the area of solar cell. This data can be analyzed by operator in image form or can be analyzed by computer system in row form.

Presumption of automatic computer analyze of LBIC image is knowledge of defects of silicon solar cells. Next necessary step is choosing right image processing method which convert raster image to the numeric values.

Whole processing of LBIC image has a following four steps:

- Scanning and digitalizing
- Pre-processing
- Segmentation
- Classification

Scanning and digitalizing which means conversion of the solar cell image to the digital matrix. Pre-processing is responsible for preparation of the images for highlighting of the defects. We use several different, filters that help us to separate defect from the rest of the solar cell. Segmentation then make themselves separated defect from the rest of the solar cell. And the last step of analysis is classification. It compares the image obtained with a database of defects and determine that the defect is.

We are present in this paper what kind of defects we are able to analyze and how correctly the defects is specified.

8112-34, Poster Session

Reverse bias test of c-Si single-cell PV modules

Y. Jin, K. Ikeda, T. Doi, National Institute of Advanced Industrial Science and Technology (Japan)

As a new method for the deterioration test, we have been trying reverse bias constant current test (RBCC test) and IV duty cycle test (IDC test). We have conducted the both kinds of tests to single-cell modules under different loading levels, input power to the cell. We observed finger electrodes discoloration, inflated back sheet, burnt back sheet in the modules, these are often observed in the field PV modules. We found the change ratio of series resistance Rs in the cell increased exponentially with loading level, and shunt resistance Rsh in RBCC test decayed exponentially with time, and than approached constant values. We also found that around 70 to 80 watt is a certain threshold level for whether the breakdown breakage occurs or not in our cells. Our results showed the possibility for applying the reverse bias test to deterioration test.

8112-36, Poster Session

The influence of different metal ions on light scattering properties of pattern microbial fuel cells' bacteria Desulfuromonas acetoxidans

O. M. Vasyliv, O. I. Bilyy, V. B. Getman, Y. P. Ferensovich, R. Y. Yaremyk, S. O. Hnatush, Ivan Franko National Univ. of L'viv (Ukraine)

Desulfuromonas acetoxidans are uncoloured gram-negative obligatory anaerobic sulfurreducing bacteria that are considered to be used as microbial-anode fuel cells with high electron recovery (>80%) from acetate oxidation to electric current. Microbial fuel cell (MFC) technologies represent the newest approach for generating electricity - bioelectricity generation from biomass using bacteria. The power generation by a pure culture of D. acetoxidans in MFC is approximately 15 mW/m2. The development of processes that can use bacteria to produce electricity represents a highly effective method for bioenergy production as the bacteria are self-replicating, and thus the catalysts for organic matter oxidation are self-sustaining. The influence of cooper sulfate, cadmium sulfate, lead nitrate and zinc sulfate on bacteria Desulfuromonas acetoxidans on the base of their cells' light scattering properties changes according to it's size distribution and relative content have been investigated by the new method of measurement. The most crucial changes of the cells' concentration dependences, comparable with other investigated metals, have been observed under the influence of copper ions. The distribution curve is in the range of 0,4 - 1,4 μm and with increase of the copper ions' concentration from 0.5 to 2.5 mM the size of the cells decreased. Distribution curves of the cell sizes under the influence of cadmium, zinc and lead are in the range 0,4 - 1,8 μm and have high similarity. Their maximum is 0,58 μm. The ability of sulfurrerducing bacteria D. acetoxidans to produce electric current under the influence of investigated metal ions has been shown.

8112-37, Poster Session

Design and implementation of a power management module for a UAV

H. H. Torres-Ortega, G. Garcia-Torales, J. L. Flores-Nuñez, R. Estrada-Marmolejo, Univ. de Guadalajara (Mexico)

The function of rotator-wing UAVs is to perform complex tasks for longer periods of time. The flight time is usually short and is limited by the battery, but for most cases is not enough, so the use of renewable energy sources is considered necessary. In this work, the results of the implementation of an array of solar cells and a module that manages the energy supplied by the cells are explained. The module provides a substantial improvement in the flight time and energetic autonomy of the UAV. This module consists of an electronic circuit which tracks the maximum power point of the cell; it offers a PWM controller with a high accuracy current and voltage regulation to charge a Lithium-ion battery. To make an efficient adjustment between electronics and the array of cells it is necessary the characterization and modeling of solar cells under different conditions of temperature and solar irradiance. It is also important to conduct a computer simulation to estimate several parameters such as the speed the battery charges and flight duration of the UAV. The increase in the energetic autonomy of the UAV is reflected in a more robust system which can perform tasks for longer periods of time.

8112-01, Session 1

Optical properties and solar radiation durability of PV materials and solar mirrors

R. H. French, W. Lin, M. Murray, Case Western Reserve Univ. (United States); S. A. Brown, K. A. Shell, M. Schuetz, Replex Plastics (United States)

Solar and environmental durability of materials and components used in photovoltaic (PV) systems is a critically important issue, so as to ensure the reliability and ultimate bankability of PV systems. We have been developing quantitative optical properties and solar radiation durability methods and metrics for materials used in flat panel, and in low concentration PV (LCPV) systems. We'll discuss solar radiation durability of PV and LCPV materials such as frontsheet, encapsulant and back sheet materials, and of acrylic solar mirrors. Solar mirror durability is important for both mirror augmentation of flat panel PV, and other LCPV type systems.

A useful solar radiation durability metric is the induced absorbance rate (Incremental ΔAbs/cm per GJ/m2), which quantitates the wavelength dependent change in the absorbance/cm for a material exposed to a full spectrum AM1.5 solar radiation dose, in units of GJ/m2. The induced absorbance to dose, allows one to identify wavelengths and rates of photodarkening and photobleaching processes in materials. Since it is normalized to full spectrum dose, comparisons of rates at different irradiances (e.g. 1, 3.8, and 48.2 kW/m2) allow serve to check linearity and reciprocity of the observed photochemical degradation processes. We will discuss results from EVA, PMMA, PET and silicones.

8112-02, Session 1

Direct comparison of PMMA and silicone-on-glass

H. P. Annen, L. Fu, R. Leutz, L. González, Concentrator Optics GmbH (Germany)

The CPV community is still undecided on one critical issue: what material to use best for Fresnel lens parquets. Reliability and longevity are the most important, but all other properties play roles as well.

We have developed and manufactured Fresnel lenses with the two commonly used materials: PMMA and silicone on glass (SOG). Both lenses are designed for the same optical train for best comparability.

This allows for better understanding the pros and cons of the materials and making an informed choice for a specific CPV module.

Theory predicts a slight optical performance benefit for PMMA lenses due to the higher refractive index and only two instead of three optical transitions. This can be directly tested and compared under laboratory and outdoor conditions. While PMMA lenses are embossed from pre-fab sheets in a hot-cold process, the silicone lenses are cast from a heat-curing silicone rubber at moderate temperatures, reducing the energy consumption. PMMA allows for the inclusion of custom low-profile 3D (2.5D) structures for module assembly and mechanical alignment, a feature not possible in silicone due to its low rigidity.

SOG lenses are prone to delamination of the silicone film. The adhesive strength of the film to the glass can be measured using a modified blister test that we developed. The results show large difference with different materials and confirm the necessity of controlling this issue closely. While the small thermal expansion of the glass sheets allows for larger parquet sizes, the deformation of the prisms with temperature may cause a performance hit.

Failure modes for PMMA lenses include cracking and yellowing. Cracking is accelerated by internal stress, material and geometry. Also, PMMA lenses tend to global deformations and the thermal expansion limits the maximum usable parquet size.

Acknowledgment: This study is part of the Triple Primaries project, initiated as research project for various primary and secondary optics in combination with cells, by Concentrator Optics, Azur Space Solar and Isuzu Glass.

8112-04, Session 1

Field performance of concentrix CPV systems

A. Gombert, C. Crawford, T. Gerstmaier, S. van Riesen, M. Röttger, J. Wüllner, Concentrix Solar GmbH (Germany)

Concentrix Solar GmbH - a division of the Soitec Group - is manufacturing and installing concentrating photovoltaic (CPV) systems. Concentrix modules are based on III-V triple junction cells, a Fresnel lens array with a relatively small single lens aperture of 5 square inch, and a cover and bottom plate made out of glass. In case of this small primary lens, a simple heat spreader made out of a metal with a satisfying thermal conductance is sufficient for the thermal management. The first installations were conducted in 2008 in Europe, later installations followed in the US, in East Asia, in the Arabian Peninsula, and in Africa. This paper gives an overview of the performance of Concentrix Solar´s CPV systems with special focus on the different climatic conditions and their impact on the system performance. The seasonal distribution of the direct normal irradiation at the mentioned locations was found to be very different which enabled us to perform studies on the system performance depending on irradiation and ambient temperature. The first generation modules which were installed in 2008 had an average efficiency of 25%, resulting in a peak solar-to-grid system efficiency of 23% and an average AC system energy efficiency of > 20%. The system peak efficiencies of the second and third module generations reach maximum values of > 25% and average AC system efficiencies of > 22%. A detailed analysis of the performance of the different system generations will be presented.

8112-05, Session 1

Techniques, regression, and applications of glass strength measurements for concentrator photovoltaic (CPV) mirrors

D. Krevor, M. Milbourne, SolFocus, Inc. (United States)

A primary failure mode for glass failure in reflective CPV systems is the mechanical stress caused by a thermal gradient. To establish the necessary reflector specifications, it is essential to have both economic techniques to measure glass strength and an insight into the failure mechanisms. Due to the highly stochastic nature of glass fracture, large data sets are necessary for statistical validity and to provide meaningful estimates of field failure rates. This paper discusses experimental measurement techniques for both value-added reflectors and for non-value surrogate substrates which are generated as waste during the manufacturing process. Specialized tooling enables measurement by commercially available stress-strain equipment (e.g., "Instron" testers). The glass strength is calculated from the force-to-break data, sample

thickness and a substrate shape dependence. These strength data are regressed using a two-parameter Weibull model, which enables calculation of the Weibull modulus, which is a measure of the distribution of flaws of a brittle material. Using a finite element analysis model of the thermal-mechanical stress to determine the critical stress, the Weibull analysis enables extrapolation of the data to predict field failure rates. The test and regression now comprise an On-going Reliability Test (ORT) that is inherently low-cost and appropriate for high-volume manufacture. For fracture, the initiating flaws are the result of glass cutting and trimming operations. There can be low-strength outliers which result from bulk glass defects, though such flawed product should be culled during the manufacturing and inspection processes. As expected and commonly known, the as-cut glass strength is very sensitive to the cutting method and resulting quality.

8112-06, Session 1

Concentrating PV survey: an unbiased overview

J. Handy, Objective Analysis (United States)

Concentrating photovoltaics (CPV) technology is well positioned to contribute in an important way to utility-scale power generation. All CPV systems share certain attributes and certain shortcomings. This presentation is intended to help attendees understand the commonalities of all CPV systems and the differences between the leading technologies, and to present criteria to help understand which technologies are likely to succeed and which are less likely to survive.

The analysis is based upon the CPV technologies themselves along with arguments involving economics, insolation, and policy. It encompasses all aspects of CPV combined with its strengths and weaknesses to illustrate the likelihood that some of these technologies will participate in the power grid of tomorrow.

The author has reviewed all leading CPV technologies and has interviewed key CPV suppliers and important test sites to better understand the reasons that some CPV systems are more likely to succeed than are others.

8112-14, Session 2

Toward bulk-heterojunction solar cells with stable morphology

S. Bertho, B. Conings, F. Piersimoni, D. F. Spoltore, J. D'Haen, L. J. Lutsen, H. Boyen, Univ. Hasselt (Belgium); B. Van Mele, G. Van Assche, Vrije Univ. Brussel (Belgium); D. J. Vanderzande, J. V. Manca, Univ. Hasselt (Belgium)

The nanomorphology of interpenetrating donor:acceptor networks is of crucial importance for state-of-the-art bulk heterojunction (BHJ) solar cells. For each combination of donor:acceptor materials, specific preparation procedures are developed and optimised in order to obtain the required 'ideal' morphology, which results in the highest photovoltaic energy conversion efficiency for the given material system. However, when these optimised solar cells with 'ideal' morphology are submitted to a prolonged storage or to a prolonged operation at elevated temperatures (e.g. solar cells in outdoor applications), a temperature induced disruption of this ideal morphology can occur and therefore also the corresponding photovoltaic performance will deteriorate. In this contribution the effect of temperature on morphology and photovoltaic properties is investigated for different sets of donor:acceptor materials by using a variety of analytical techniques (e.g. Transmission Electron Microscopy - TEM, Thermal Analysis Techniques,..) and electro-optical techniques (e.g Fourier Transform Photocurrent Spectroscopy - FTPS). This approach provides a better insight in the underlying mechanisms causing the temperature induced morphology changes. Complementary to this analytical and electro-optical characterisation, an accelerated ageing system is used to study in-situ the degradation kinetics of the BHJ solar cells at various temperatures in order to obtain an accelerated ageing model to predict lifetime. Solutions and concepts are proposed and investigated towards thermally stable morphologies and therefore towards next generation BHJ solar cells with an increased intrinsic thermal stability.

8112-15, Session 2

Understanding degradation in unencapsulated organic photovoltaics

M. T. Lloyd, A. Garcia, J. J. Berry, N. Kopidakis, M. O. Reese, D. S. Ginley, D. C. Olson, National Renewable Energy Lab. (United States)

We employed an automated combinatorial testing system to monitor the degradation rates for inverted geometry poly(3-hexylthiophene):fullerene bulk heterojunctions solar cells in air. These devices utilize ZnO and Ag for electron and hole contacts, respectively, the relative stability of which enables meaningful studies of unencapsulated device lifetimes. For inverted devices under constant illumination, we find oxygen and moisture ingress to be the primary cause for decay in power conversion efficiency (PCE) via decreased short-circuit current (while the fill factor and open-circuit voltage are unchanged). Consequently, we find that the contacts serve as a de facto encapsulation layer and the detailed method for contact preparation becomes the first order, rate-limiting factor in determining device lifetime. In an ex-situ experiment, we evaluate the water vapor transmission rate (WVTR) of commonly used electrode materials to show that the permeability of the metal electrode is determined by its thickness and composition (in multi-layer configurations). Parallel findings confirm the observed transmission rates in devices monitored under constant illumination, where electrodes of the lowest WVTR yield devices with lifetimes extending beyond 5000 hrs. End-of-life behavior consistently results in a catastrophic loss of photocurrent. We use high-resolution photocurrent mapping to reveal circular regions of zero photocurrent in the active area indicative of pinhole ingress and lateral diffusion of oxygen and water vapor. Using a modified form of the Avrami equation, which describes nucleation and island growth in two-dimensional systems, we are able to mathematically model photocurrent vs. time as the device experiences catastrophic failure.

8112-16, Session 2

Reliability of organic materials using photothermal deflection spectroscopy

A. Bezryadina, Univ. of California, Santa Cruz (United States) and NASA Ames Research Ctr, Advance Study Labs. (United States); J. Olson, APV Research (United States); C. France, S. Carter, G. Alers, Univ. of California, Santa Cruz (United States)

Degradation of organic materials used for solar energy collection was measured with photothermal deflection spectroscopy (PDS). PDS has the ability to measure absorption over a range of 5 decades and can detect the first signs of degradation in organic films. From the tail of the optical absorption trap states and defects are deduced to quantify light induced and temperature induced degradation due to photo-oxidation and polymer/dye decomposition. In this work we look at degradation of common solar energy polymer materials like P3HT and MEH-PPV and commercial dyes that are used for photon downconversion and luminescent solar concentrators.

Most polymers have inherently weak optical absorption in the visible-IR region and might exhibit scattering due to surface roughness. PDS measurements are independent of scattering and can detect slight changes in band-edge absorption after temperature or light soaking treatments. At the tail region non-radiative absorption processes for the material are present with no detectable photoluminesence emission. A commercial red luminescent material was tested and had strong degradation after 50 hours of light soaking at 35C under 100mW/cm2 illumination from a metal-halide lamp. Absorption increased by a factor

of 4 in the tail and the band-edge region. Another commercial material showed no changes in absorption after ~100 hours of light soaking. Highly sensitive PDS measurements can test optical absorption of organic films after long exposure under the sun, high humidity and/or high temperatures. Small changes in absorption can be extrapolated to quantify degradation behavior from 1000 hour measurements to predict 20-year lifetime and the long term efficiency of photovoltaic devices.

8112-17, Session 2

High-efficiency polymer-based OPV with lifetimes approaching 7 years

C. H. Peters, I. T. Sachs-Quintana, J. P. Kastrop, M. D. McGehee, Stanford Univ. (United States)

As efficiencies increase, the questions of lifetime and reliability of OPV gain importance. Current polymer-based OPV devices typically show lifetimes of 2-4 years when encapsulated. In this study we performed accelerated lifetime testing on poly(-heptadecanyl-2,7-carbazole-alt-5,5-(-di-2-thienyl--benzothadiazole) (PCDTBT). From the testing, we estimate a lifetime approaching 7 years which, to the best of our knowledge, is a record for reported polymer OPV devices.

PCDTBT has been used with PC(70)BM to achieve device efficiencies over 6.1%, making it one of the most efficient polymer-based OPV materials. 16 high-efficiency devices were encapsulated using state-of-the-art encapsulation techniques. The devices were held at the maximum power point, closely mimicking the actual conditions under which they would be operated in the field. The lamp intensity and temperature of each device were monitored in real-time. 16 P3HT:PCBM devices, encapsulated in an identical manner, were testing along with the 16 PCDTBT devices for comparison.

Results show an initial burn-in where the PCDTBT devices experience an exponential decay in efficiency, which lasts 500 hours. After this period the devices are incredibly stable, showing a linear decay for the remaining 4,000 hours of the test. Taking the initial value from the start of the linear decay period at 500 hours and extrapolating to where 20% of this initial value has been lost leads to a lifetime approaching 7 years.

The P3HT:PCBM devices show a more gradual burn-in lasting close to 1,300 hours which is also followed by a linear decay period but with a more severe slope. Performing the same lifetime analysis on these devices leads to an estimated lifetime of 3.3 years.

We will also introduce results of advanced optical and electrical characterization techniques that were used to understand degradation. This will provide the scientific community with greater insight into approaches to make more stable devices.

8112-18, Session 2

Luminescence imaging as characterization tool for polymer solar cells and modules

H. Hoppe, M. Seeland, R. Rösch, B. Muhsin, M. Bärenklau, G. Gobsch, Technische Univ. Ilmenau (Germany)

We demonstrate luminescence imaging to be a powerful tool for characterizing organic solar cells and modules with respect to deficiencies in the production process, local defects and degradation processes. As an example, the complementary use of photoluminescence and electroluminescence imaging has been employed to identify the cause and nature of polymer solar cell degradation stressed under different storage conditions. In this study we directly relate imaging results with solar cell parameters.

Furthermore we have developed a quantitative analysis for electroluminescence images obtained on organic solar cells. This approach is based on a complex device modeling employing a network of interconnected micro-diodes. The equivalent circuit network model takes interface and bulk resistances as well as the sheet resistance of the transparent electrode into account. The application of this model allows direct calculation of the lateral current and voltage distribution as well as determination of internal resistances and the sheet resistance of the higher resistive electrode. Furthermore, we have extended the micro-diode-model to also describe and predict current-voltage characteristics for devices under illumination. The local nature of this description enables important conclusions concerning the geometry dependent performance of thin film solar cells.

Finally the beneficial use of luminescence imaging as tool for quality control is shown for single devices and monolithically connected polymer solar cell modules.

8112-19, Session 2

Degradation of PCBM-P3HT organic photovoltaic cells and structure changes as determined by defect investigations

F. Reisdorffer, Univ. de Nantes (France); L. Wang, National Taiwan Univ. (Taiwan); T. Nguyen, Univ. de Nantes (France)

We present an investigation of the intrinsic degradation of organic photovoltaic cells using poly(3-hexylthiophene) (P3HT) and phenyl-C61-butyric acid methyl ester (PCBM) composite as an active layer. The encapsulated devices of structure ITO/PEDOT:PSS/P3HT-PCBM/Ca/Al were investigated using the Charge based Deep Level Transient Spectroscopy (Q-DLTS). An efficiency of ~ 4,0% and a fill factor of the IV characteristics of ~ 64% have been obtained in fresh devices. Trap density determined in these samples is ~ 1017 cm-3 and their levels are found in the range from 0.1 to 0.5 eV from the band edges. Comparing the defect spectra obtained in freshly fabricated devices and those degraded over 1000 hours under 1.5 AM conditions, we observed a strong increase in intensity of deep traps, which indicated an alteration of the blend structure. On the other hand, a noticeable decrease of the trap peak of relaxation time of ~ 1s after degradation has occurred. The corresponding traps have been identified as defects induced by the presence of PCBM in P3HT matrix, and their reduction suggests a modification of the PCBM structure organization. We discuss the possible modifications of the blend structure induced by degradation and we propose a mechanism involving the transformations of PCBM basing on the defect measurement results.

8112-03, Session 3

Which factors need to be improved for array models to correctly predict “real-world” performance?

B. von Roedern, National Renewable Energy Lab. (United States)

This paper poses the question how statistically varying data should be handled by models? It asks the question whether modeled data or real-world data are of greater importance, when the real-world data may also show significant variation. This question is asked in the context of what is more important, e.g., having a model that correctly predicts real-world energy generation of a PV array or the “typical” generation for such array. Sometimes, modeling can predict standard performance, but real-world performance can only be predicted within an uncertainty level. A good standard value is obtained when the standard predicts the real-world average as close as possible.

This realization has major impacts on the expectations. It is cumbersome that some variables (like solar cell efficiency) may depend on parameters that can be controlled and others that cannot be controlled. There is a tendency to either over-value factors that can be controlled, or by being of the (fatalistic) opinion that such control is entirely useless, because uncontrollable factors are also in control. In other words, if there is current knowledge that greater control will not always achieve greater precision, is there a point to improve the precision of a model’s input when it does not always predict the outcome more accurately? In other words, one should be open to the possibility that while

greater precision helps with the accuracy of the output, at under some circumstances little or nothing is to be gained by further improving such control. Medical science has acknowledged such variation, by defining acceptable numerical ranges for certain parameters, rather than optimum values. There is some agreement in the medical community that once a parameter falls within the acceptable range, there is little value to find a further improved value for such parameter. There is also the realization that persons with parameters falling within the acceptable range may be sick from an associated or unassociated disease, while certain individuals with parameter values falling outside the acceptable range may be healthy. The process of solar cell optimization hence poses the following question: Are best solar cell parameters achievable by optimizing numerical values alone? (e.g., better dialing in the knobs for an established deposition process), or should one look for improved processes, which may or may not exist? It is argued that whenever there is more than one important factor determining the outcome, the observations (rather than expectations) would be correct. Solar cell performance depends on more than one optimization skill (e.g., materials skills and device fabrication skills) hence an argument for interactive optimization can be made, rather than trying to find "a single best" optimum. In other words, is there "an" optimum process to achieve the greatest solar cell efficiency, or are there multiple approaches leading to high solar cell efficiency.

It has recently been reported that multiple approaches can deliver very high solar cell efficiencies, e.g., for GaAs based (III-V) cells, matamorphic, inverted metamorphic, Ge substrated and the "Spire" processed cells have all led to similar high solar cell efficiencies [1]. Similarly, for wafer Si PV cells, various "selective emitter" approaches have all yielded a similar performance improvement (often, much smaller than advertised) [2]. I ask myself the question whether or not such observations are coincidental, or if there could be a mechanism for explaining such observations?

Ultimately, modeling also has to ask the following question: When is greater modeling precision "only" a value and when will greater modeling precision allow better control? This issue is of importance when "champion value" solar cell efficiency values are to be "further improved or optimized" by applying better control to an established process. Champion cells are cells made with a high-efficiency cell process, such that

$$\eta_{champion} = \eta_{average} + \eta_{variation} \quad (1)$$

Solar cell champions are obtained by selecting a large average value having a large positive variation. Some in the PV community believe that a reduction of variation could increase the average efficiency. It is argued that this may or may not be the case. Only if a unique mechanism linking variation and average performance could be established would the foregoing claim be uniquely acceptable. According to equation (1) above, a reduction of variation could in fact decrease champion efficiency values. Reduction of variation for an established process may or may not lead to greater average solar cell efficiency. The question is to determine (not assume!) when greater precision will be of value and when such greater precision will also provide a greater means of control. For example, a more accurate weather forecast is of value, but will not change the weather pattern. The assumption that more precise control would automatically allow fabrication of solar cells with greater efficiency is challenged.

Solar and other energy generators show a significant noise level in energy output. Such variation questions the value of rankings if the difference between ranks is less than the uncertainty of the prediction. For PV arrays, the largest variation in energy production arises from the fluctuating solar radiation resource. Such variation, if averaged properly, decreases. Other factors for energy generation of a solar PV array are: the quality of the installation, shading, soiling, component choice and matching, transients in module performance, component breakdown, and maintenance diligence. Energy data today are typically acquired with great accuracy. Typical data are averaged and an average line is plotted, for example in plots showing solar irradiation and energy generation. I advocate that good models have to model the output determined by such line, not the outlying best or worst (real-world!) points of such curves, which might be picked by advocates or foes of a specific technology to make their point. There are also differences as to the purpose of a procedure or modeling exercise. For example, for an acceptance test for a new PV array, one may measure its output on a cloudless cool day. Such acceptance test data is helpful in improving the energy generation data for such PV array, but such test data will only reduce, not eliminate, variations observed in real-world system energy generation. For example, acceptance test data are only valid at the time of the observation, they do not allow to estimate the system's long-term degradation. The group a Sandia National Laboratory has done a great job to "verify" different models predicting PV system energy generation and the actual system generation in a few locations [3]. The question to be asked is: Is the current modeling precision good enough or can greater accuracy result in greater insight and control?

This paper makes a point that individual PV system component behavior may be different from average system behavior. On the scale that different energy generators are compared (say in terms of cost of electricity) it has to be realized that even average electricity or energy prices have a different averaged "willingness" for spending such monies. Such "willingness" is not controlled alone by technical factors. Borders for bins can be set be set at levels of low or high impact. An example of setting borders at high level of impact are the commercial module tables presented by Photon International [4]. A T-coefficient bin limit (border) for power is set at 0.48%/C, which falls in the uncertainty range for standard wafer Si T-coefficients -(0.46±0.05)%/C. It then depends on the accuracy of the data sheet and on currently unpredictable behavior into which T-coefficient bin a module really falls.

Often, it appears to me that the correct use of a less accurate but correct model would have to result in the same average prediction as a more accurate model, except for a greater variation being associated with a less accurate model. It remains to be seen when a more accurate model would result in greater control. Observations have shown that sometimes greater accuracy results in greater controllability, and sometimes not. When the real-world observations are variable, like the energy output of a PV array, judgment must be used when an acceptable modeling accuracy has been reached. The fact that greater precision leads to greater controllability has to be proved, it cannot be assumed as a given.

Correlation between mechanical properties and microstructure of copper-ribbons used for cell interconnection

R. Meier, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany); S. Klengel, Fraunhofer-Institut für Werkstoffmechanik (Germany); M. Pander, S. Dietrich, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany); J. Bagdahn, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany) and Anhalt Univ. of Applied Sciences (Germany)

Soldering of solar cell strings is a critical step in the production of photovoltaic modules. During the soldering process significant mechanical stresses are induced in the stringed cell assembly. Since silicon has a very small coefficient of thermal expansion it is compressed

by the copper-ribbon during the cooling phase. The resulting stresses generate micro-cracks in the silicon cell, which are responsible for a high amount of cell breakage within the production line and even may lead to a delayed failure of the solder interconnections or cell cracking in field. Therefore the manufacturer try to create very soft ribbon material, which tends to be rather plastically deformed than generating stresses such that the silicon is prevented from damage.

Nevertheless, the general tendency of using thinner and thinner cells - in order to save silicon stock - and the projected step towards the usage of lead-free solder increase the mechanical requirements on the cell interconnectors and make systematic scientific investigations inescapable.

The purpose of this work is to analyze the micro-structure of ribbon in detail and to correlate it with its mechanical material behavior. An electron backscatter diffraction method was used to evaluate grain sizes and orientations in various annealing steps of the ribbon. These results were compared to their mechanical properties, achieved by conventional mechanical testing. As a result of these investigations the annealing process of the ribbon was optimized on laboratory scale to achieve highly adjusted material properties. Finally the benefit was verified by numerically simulation of the soldering process.

Impact of heavy soiling on the power output of PV modules

K. Weiss, M. Koehl, M. Heck, S. Brachmann, C. Schill, Fraunhofer-Institut für Solare Energiesysteme (Germany)

Fraunhofer ISE is running a PV-module outdoor testing set-up at the Gran Canaria island. The performance of the modules is assessed by IV-curve monitoring every 10 minutes. The electronic set-up of the monitoring system consisting of individual electronic loads for each module, which goes into a MPP-tracking mode between the IV-measurements will be described in detail.

Soiling of the exposed modules happened because of building constructions nearby. We decided not to clean the modules, but the radiation sensors und recorded the decrease of the power output and the efficiency over time. The efficiency dropped to 20 % within 5 months before a heavy rain cleaned.

A smaller rain-fall in between washed the dust partly away and accumulated it at the lower part of the module, what could be concluded from the shape of the IV-curves, which were similar to partial shading by hot-spot-tests and by partial snow cover.

8112-07, Session 3

Antistatic effect of power-enhancement coating for photovoltaic modules

D. Narushima, Asahi Kasei Chemicals Corp. (Japan)

Photovoltaic (PV) modules are periodically cleaned, particularly in large grid-connect photovoltaic plants, in order to avoid losses caused by dust accumulation. However, this maintenance task is often expensive, especially in those areas with water shortage.

A hydrophilic coating on the surface of PV modules is one of typical methods to reduce the dust accumulation. But it is not commonly used yet, because the electrical performance of PV modules with conventional hydrophilic coating was slightly degraded by the decrease of transmittance.

We have already developed a new hydrophilic coating and reported its fundamental characters and results of several ISO/IEC standard tests in SPIE Solar Energy + Technology in 2010.

One of the important characters was antistatic effect. It was showed that the surface resistances of the coated glass and the uncoated glass were 1.3 x 1010Ω and 5.3 x 1014Ω, respectively. It would be understood that low surface resistance of the coated glass resulted in antistatic characteristics, which reduced dust attraction onto the coated glass.

With this surface resistance result, it could be elucidated that the 3% additional energy production resulted from the antistatic effect of the coating on PV modules in the exposure test after several months without rain in Spain.

In this paper, the durability of antistatic effect performed under several ISO/IEC tests will be discussed.

Investigations on crack development and crack growth in embedded solar cells

M. Sander, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany) and Fraunhofer-Institut für Werkstoffmechanik (Germany); S. Dietrich, M. Pander, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany); S. Schweizer, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany) and Ctr for Innovation Competence SiLi-nano® (Germany); M. Ebert, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany); J. Bagdahn, Fraunhofer-Ctr. für Silizium-Photovoltaik (Germany) and Anhalt Univ. of Applied Sciences (Germany)

Photovoltaic modules (PV modules) are supposed to have a lifetime of more than 20 years under various environmental conditions like temperature changes, mechanical loads, etc.

In recent investigations using various analysis methods it has been shown that loading of PV modules leads to mechanical stress in the module parts and especially in the solar cells. Cracks in crystalline solar cells are a characteristic defect and can lead to efficiency losses and lifetime reduction. They are mostly invisible for optical inspection but can be identified using electroluminescence. Thus they are often called “micro-cracks”.

The mechanisms of crack initiation and crack growth under thermal and mechanical loading have been investigated systematically using electroluminescence imaging. For this purpose laminated test specimens on smaller scales were produced using different cell types and module layouts.

The test specimens were analyzed after the production steps (cell delivery state, soldering and lamination) and several times during loading (thermal cycling or mechanical load steps). The crack origin and the crack length were identified and assessed manually. A statistical evaluation of all test specimens allows conclusions about crack propagation over module lifetime. This results in a basis for reliability and lifetime concepts.

The contribution presents new experiments under thermal and mechanical loading using different test specimen types. The experimental results are compared to results from investigations on full scale PV modules and to results from numerical simulations.

8112-09, Session 4

Developing standards for PV packaging materials

J. H. Wohlgemuth, M. D. Kempe, D. C. Miller, S. R. Kurtz, National Renewable Energy Lab. (United States)

The existing PV standards were designed to help develop safe PV modules, capable of reasonably long lifetimes when deployed in the field. To accomplish this, TC-82 of the International Electro-Technical Commission (IEC), published module qualification standards (IEC 61215 for crystalline Si, IEC 61646 for thin films and IEC 62108 for concentrators) and module safety standards (IEC 61730 -1 and 2). As PV has grown and the technology has become better understood, the properties of packaging materials used in the module have become increasing critical to the safety and long term durability of PV modules. It is recognized that certain basic properties of the material are required for

the module to be safe and able to survive in the field.

Working Group 2 of IEC TC-82 has recently begun work on developing characterization standards specifically designed for PV packaging materials. Standards are being developed for four specific classes of polymeric materials:

- Encapsulants
- Back Sheets
- Edge Seals
- Adhesives and Pottants

These standards will utilize existing standards (when available), modified for use with PV materials and modified to incorporate environmental conditions specific to PV applications. The goal is to provide a uniform approach to characterizing packaging materials, providing the necessary information to those selecting materials for use in PV module products as well as to those assessing the quality and safety of the products made from these materials. By standardizing the testing of materials, module manufacturers can more accurately evaluate products from different suppliers.

8112-10, Session 4

Qualification of polymeric components for use in PV modules

G. Oreski, Polymer Competence Ctr. Leoben GmbH (Austria); K. Möller, SP Technical Research Institute of Sweden (Sweden)

The aim of these investigations was to develop, implement and evaluate an appropriate procedure in order to qualify new polymeric components for the use in PV modules and to predict the lifetime of materials and modules. A test program concerning six accelerated artificial aging tests (varying UV, temperature and humidity levels) was set up and the degradation behavior of six polymers was investigated. Two main degradation indicators for chemical aging of the polymers were identified and evaluated. Both indicators (solar transmittance, strain-at-break), which are sensitive indicators for chemical aging, are related to PV-module performance and failure and were used as input data for lifetime modelling.

A suitable material specific material degradation model was obtained, where changes of the material properties are accurately related to the applied environmental stresses. Reaction rates and activation energies for the degradation processes caused by temperature, humidity and UV were calculated. For the modelling of service life time the micro-climate, to which the encapsulation materials are exposed in a PV-module, was considered and reasonable end-of-life criteria were defined.

The results of the lifetime modelling showed that the standard Damp Heat Test (85°C, 85%RH) seems to be sufficient for the qualification of most polymers. If the material properties do not exceed a certain limit within an appropriate time period, the material is qualified for PV module encapsulation for the use in a defined climate. If a certain limit is exceeded, a second damp heat test at a lower temperature is to be done in order to predict the lifetime.

8112-11, Session 5

Impact of polymer stabilization compounds in EVA encapsulation foils on long-term module performance

I. Sinicco, F. Roth, M. Gossla, T. Schuhmacher, Oerlikon Solar Ltd. (Switzerland); K. Proost, NovoPloymers NV (Belgium)

It is known that one of the main functions of an encapsulation foil is to protect the module against external aging factors. But, what about the lamination foil itself? The polymer will need to be protected from external factors such as moisture, UV light and possibly oxygen diffusion in glass - glass modules. Next to this EVA polymer foils have a very low melting point and high flow characteristics, making it necessary to cross-link the polymer to allow for long term durability. In this study we will focus on (standard) EVA based lamination foils and the impact of some chemicals contained in such foils on the module performance. Special attention will be devoted to impact of the degree of cross linking on long term module performance and on the effect of several standard HALS (hindered amine light stabilizer) components on reliability of thin film silicon modules. Due to the earlier mentioned environmental factors, free radicals can be formed that can induce degradation effects. The link between the ability to scavenge these radicals, cross-linking chemistry and reliability will be studied.

8112-12, Session 5

PV modules with optimized energy balance

J. Weixlberger, LiSEC Group of Companies (Austria); R. Bruckner, INOVA-LiSEC Technologiezentrum Gmbh (Austria)

Lisec Group as global player in glass processing equipment focuses on innovation and new technologies for advanced applications. Glass tempering for enhanced impact resistivity (like hail resistivity) along with reduced thicknesses thus minimized weight and raw material consumption is the key for a new PV-module encapsulation. 2 mm TVG-glass on front and backside, based on innovative frameless sealing and solar cell embedding can reduce raw material consumption - thus energy consumption for its preparation - for more than 50 % compared to todays conventional module setup with single side glass and backside Tedlar laminate. Several additional advantages appear as a side effect of this approach like less weight, reduced mounting costs through frameless approach, optimized light transmission efficiency and enhanced coating possibilities for anti-reflection, de-icing etc. Its rigidness in terms of hail resistivity and even bending robustness without cell breakage can be convincingly demonstrated.

8112-13, Session 5

Novel edge sealing getter tape: ultra long breakthrough time and high mechanical properties at high temperature

A. Bonucci, M. Amiotti, P. Gallina, SAES Getters S.p.A. (Italy); R. van der Wel, SAES Getters USA, Inc. (United States)

Long operational lifetime, reliability and stability of PV modules are still crucial topics in the PV world since both performance as well as economics may strongly be affected by these parameters. Thin Film PV modules are especially subjected to many discussions about their stability over long outdoor periods, due to degradation for moisture permeation.

On the other hand, mechanical stability is an important requirement for different ageing and hard environmental conditions.

In particular, the mounted panels must resist to temperature of about 60°C in the daily sunny hot weather also at mid-latitudes and peaks of about 100°C cannot be excluded. Stressed areas near the clamps are subjected to irreversible deformation.

The regulation EIC 61646 can partially ensure these requirements.

In this work, we will show the relations between the regulation EIC 61646 and real outdoor requirements.

Moreover, we will present an edge sealant, the B-Dry® that has been developed to ensure long breakthrough time not only in the damp heat test conditions, but also for the real operative ones, as it has been demonstrated from characterization both in dummy panels and in real photovoltaic modules.

B-Dry® expresses a good mechanical resistance in elastic behavior also at higher temperature due to the nature of its bulk matrix and the lap shear adhesion is resistant after prolonged Miami test and damp heat conditions.

8112-14, Session 5

Next-generation ionomer encapsulants for thin film technology

A. Smith, E.I. du Pont de Nemours & Co., Inc. (United States); R. Czyzewicz, Dupont CR&D (United States)

The characteristic properties of newly developed ionomer-based encapsulants are highlighted along with an in-depth analysis of moisture ingress and electrical properties. The mechanical properties of these encapsulants with their high stiffness and strength have been found to allow the use of thinner glass and a possible shift from tempered to annealed glass.

These new materials have improved melt flow properties when compared to other encapsulant families such as EVA or PVB. This characteristic allows for faster processing which reduces production cost by shortening the lamination cycle. During the lamination process the sheets show excellent dimensional stability and low shrinkage behavior; and, as there is no need for curing, the energy costs are lower due to lower lamination temperature. The high melt flow index also allows module makers to minimize the caliper of the new encapsulants while still ensuring integration of features like busbars and edge delete areas.

The superior electrical and moisture properties may allow removal of edge seal and possibly reduced edge delete width when compared to modules made with PVB or EVA. Finally, these new thermoplastic grades are easy to handle. They have an extended shelf life versus traditional EVA encapsulants and need no refrigeration or interleaving during storage.

The combination of high surface resistivity and low moisture ingress provides the potential to remove edge tape and/or frames while retaining the edge integrity of the module. By optimization of encapsulant properties, the module manufacturer can significantly reduce costs by shortening cycle time and/or eliminating process steps.

8112-15, Session 6

Interlaboratory comparison of UV-light sources for accelerated durability testing of PV modules

M. Koehl, K. Weiss, D. Philipp, Fraunhofer-Institut für Solare Energiesysteme (Germany)

Accelerated testing of the durability of materials exposed to natural weathering requires testing of the UV stability, especially for polymeric materials. The type approval testing of PV-modules according to the standards IEC 61215 and IEC 61646 includes a so-called UV-preconditioning test with a total UV dose of 15 kWh/m² . The testing according to the edition 1 and IEC 61215 ed. 2 needed a UV-B fraction of 5 kWh/m², while the IEC 61646 edition 2 reduced the requirements to 3-10%. There are no more specifications on the spectral distribution of the UV irradiation.

Fraunhofer ISE performed an Interlaboratory comparison of UV-light sources used for this durability testing of PV-modules in accredited test labs and in test centres of major PV module manufacturers. One topic was the spectral measurement of the used UV sources. Another main issue was the comparison of the integral measurements by the sensors used for control of the tests. Errors up to 180% were found.

The evaluation of the results include a consideration of the filtering of the spectral irradiation by the glazing of the modules resulting in a changed action spectra for the polymers inside the module and a comparison of the material degradation over testing time caused by different UV sources.

8112-16, Session 6

Reliability evaluation of a photovoltaic module using accelerated degradation models

R. Laronde, A. Charki, D. Bigaud, Univ. d'Angers (France); P. Excoffier, GINGER CEBTP (France)

Many photovoltaic modules are installed all around the world. However, the reliability of this product is not enough really known. The electrical power decreases in time due mainly to corrosion, encapsulation discoloration and solder bond failure. The failure of a photovoltaic module is obtained when the electrical power reaches a threshold value equal to 50% of the initial power. Accelerated life tests are used to estimate the reliability of the photovoltaic module. However, we have few values on the degradation of this product and the realisation of accelerated life testing is expensive. Thus, the degradation is simulated for each several condition of accelerated life testing using the accelerated degradation models, the Wiener process and the few values we have. The Wiener process permits to carry out many simulations and to determine the time distribution when the threshold value is reached. So, the lifetime distribution can be obtained for each several condition and parameter of the acceleration model can be determined. Thus, the proposal modal allows us evaluating the reliability of a photovoltaic module taking into account stochastic conditions.

8112-17, Session 6

UV-accelerated test based on analysis of field-exposed PV modules

T. Shioda, Mitsui Chemical Analysis & Consulting Service, Inc. (Japan)

We proposed the UV accelerated test with low UV irradiation, based on analysis of long term field exposed photovoltaic (PV) modules.

Transmittance spectra of the EVA encapsulant sheets with discoloration in over 20 years field exposed PV modules have been obtained.

We found that absorbance due to UV absorber formulated in EVA in the transmittance spectrum still remained for long term exposed one.

In addition, we have carried out UV accelerated test using xenon weather-o-meter (XWOM) for the EVA encapsulant with the same old grade as that for long term field exposed.

Absorbance for UV accelerated test with high irradiation was disappeared, even though that with low irradiation correspond to 1SUN still remained as same as that for field exposed one.

This indicates that strong UV irradiation into EVA encapsulant leads to the fast decomposition of UV absorber, which has never seen in the field exposed PV modules.

Furthermore we observed the strong temperature dependence of change in transmittance spectrum for UV accelerated test.

As a result, we confirmed that low UV irradiation intensity and high temperature were suitable as UV accelerated test condition from viewpoint of lifetime prediction of PV modules and encapsulant.

8112-18, Session 6

Optical and opto-electronic equipment for testing solar cells and modules

A. Feldman, Oriel® Instruments, a Newport Corp. Brand (United States)

Newport Corp, ORIEL products Div, developed new line of devices for testing Solar cells, encapsulants and modules. It includes Solar simulators, concentrators, and PV-IV measuring systems. Improvements include superior uniformity of illumination, higher energy concentration, variable irradiance and dose control and feedback for energy stability.

Also available are Quantum Efficiency measuring systems which allow testing spectral stability and aging of cells and modules.

Paper provides specifications and capabilities of instruments, such as power, field and uniformity of illumination, spectral range and stability of irradiance, PV-IV measuring capability.

8112-19, Session 7

"PVRessQ!": a research activity on reliability of PV systems from an user's viewpoint in Japan

K. Kato, National Institute of Advanced Industrial Science and Technology (Japan)

Recent government policy successfully has brought about over 500 thousand residential PV systems in Japan. Because both the government and PV industries have not been interested in operation and maintenance of PV system, however, almost all the PV users never knows troubles and/or risks which may happen to their PV systems during long-term operation.

Since 2006, I have been carrying out nation-wide field survey of existing residential PV systems in order to find troubles/failures and develop practical techniques to detect these troubles/failures. I have been also doing statistical analysis on reliability of PV modules and power conditioners by collecting operation records from PV users. I call these activities "PVRessQ! (PV - Reliable, Safe and Sustainable Quality!) ".

I visited 28 residential PV systems so far and found about 2/3 of them had PV modules failures. Though these PV modules must have been replaced according to 10-year warranty provided by PV manufacturers, nobody could not find them due to following reasons: 1)it is impossible for users to be aware of PV module failure, 2)PV manufacturers and installers have no legal obligation to check PV systems, and 3)the maintenance and inspection guideline for residential PV systems prepared by PV industries is not effective against detecting PV module failures. In addition, present statistical analysis showed that 69 PV users out of 483 have replaced PV modules within 10-year operation.

In this paper, I will introduce recent topics obtained from the PVRessQ! activity and point out reliability issues to be solved.

8112-20, Session 7

Failure modes effects and criticality analysis (FMECA) approach to the crystalline silicon photovoltaic module reliability assessment

J. M. Kuitche, G. M. Tamizh-Mani, Arizona State Univ. (United States) and TUV Rheinland PTL (United States); R. M. Pan, Arizona State Univ. (United States)

Traditional degradation or reliability analysis of photovoltaic (PV) modules has historically consisted of some combination of accelerated stress and field testing, including field deployment and monitoring of modules over long time periods, and analyzing commercial warranty returns. This has been effective in identifying failure mechanisms and developing stress tests that accelerate those failures. For example, BP Solar assessed the long term reliability of modules deployed outdoor and modules returned from the field in 2003; and presented the types of failures observed. Out of about 2 million modules, the total number of returns over nine year period was only 0.13%. An analysis on these returns resulted that 86% of the field failures were due to corrosion and cell or interconnect break. These failures were eliminated through extended thermal cycling and damp heat tests. Considering that these failures are observed even on modules that have successfully gone through conventional qualification tests, it is possible that known failure modes and mechanisms are not well understood. Moreover, when a defect is not readily identifiable or for unknown failures, the existing accelerated tests might no longer be sufficient. Thus, a detailed study with more extensive statistical tools is essential. In this paper, we combine the physics of failure analysis with traditional approach to develop a statistical FMECA model that allows a more conclusive identification of root cause. This technique examines the failure of individual components of fielded modules to statistically determine its critical impact on the module reliability.

8112-21, Session 7

PV system reliability: lessons learned from a fleet of 400 systems

A. Kaushik, MEMC India (India); T. Golnas, SunEdison (United States)

The levelized cost of energy (LCOE) from PV systems can be reduced by maximizing the energy production of existing/future PV plants through increased availability. This can be achieved by detailed study of root cause and failure analysis of component failures leading to a systematic progress towards improving the reliability of various sub-systems.

SunEdison owns/operates ~400 sites across the world and systematically collects field failure data in addition to power output and weather data. Analysis of this information allows following-up on corrective actions to eliminate/minimize the re-occurrence of failures and leads to continuous improvements. This paper will analyze some of the key findings from the system failures as follows:

1) Inverter failures not only cause most of the system outages, but also result in substantial energy losses. Component failures in PCBs and inverter software/firmware bugs are the most common root cause of system outages

2) From a systemic root cause perspective, lack of robust quality systems at multiple levels of the supply chain is quite evident, which points toward the need for collectively inculcating the quality culture at every stage of the supply chain

3) This paper will try to establish the need for "Continuous Improvement Process" (CIP) where systemic issues are confronted and solutions are internalized in the operating procedures as the only path to improving component reliability

4) For a given level of reliability, cost associated with servicing the plant becomes critical. This paper highlights the importance of using "cost of ownership" metrics for making procurement decisions

8112-22, Session 7

Normalization technique for two matching solar arrays of the same size

A. A. Dubhashi, J. Wood, Xandex, Inc. (United States)

The power output of two solar arrays with same configuration and same type of solar modules is not equal due to module mismatch and array wiring. In addition, differences in ambiance can create difficulty in side-by-side comparison tests.

Tests performed on solar arrays require a data normalization method to account for differences in array power output and ambiance. This is done by swapping the location of the Units Under Test on the two arrays in order to cancel the differences between the arrays.

This paper illustrates and describes two experiments performed at the Xandex Solar Lab and demonstrates how normalization was performed using two arrays of the same system size. It is to be noted that the normalization technique presented in this paper is valid if only the Units Under Test are swapped between the arrays.

It is critical that the array modules, wiring and inverter are not swapped during the experiments. The normalization technique presented in the two experiments is an effective way to eliminate the difference in array power. This makes it possible to compare the performance of DC Power Optimizers when they are placed on the two arrays over a span of multiple days.

8112-23, Session 7

Methods for high-voltage bias testing of PV modules in hot and humid climate

N. G. Dhere, A. Kaul, Univ. of Central Florida (United States)

High voltage bias testing of PV modules is a very useful testing technique to estimate the reliability of PV modules. This paper describes and compares the methods for carrying out the high voltage bias testing of PV modules and provides recommended procedures and guidelines. Currently there are two approaches to carry out such a study. In the first method, the individual modules are connected in an array string to build a maximum voltage based upon the location of up to ±600 V in USA or higher e.g. 1000 V in Europe and elsewhere. This method although time intensive is desirable in a way that it duplicates the actual conditions the PV modules will be subjected to in the field. Over the years at the Florida Solar Energy Center many PV systems have been deployed and are being studied for over a dozen years.

The second method includes individually biasing the PV modules and measuring the leakage currents from the module frames to ground. A study of leakage currents in Photovoltaic (PV) modules has been shown to be effective in early detection of design, material, as well as process flaws. The modules have been biased to ±150 V, ±300 V, ±600 V and even ±1500 V and higher since higher voltage systems are being built across the world especially in Europe. The necessary high voltage test bed has been built complying with the NEC codes to test the modules up to ±3000 V. Since the modules are biased even during night, it enables calculation of the acceleration factors while calculating the degradation rates.

8112-24, Session 7

Long-term performance degradation of grid-tied photovoltaic modules in a hot and dry climatic condition

A. Suleske, J. M. Kuitche, J. M. Singh, G. M. Tamizh-Mani, Arizona State Univ. (United States)

Individual crystalline silicon photovoltaic (PV) modules typically degrade at a rate of about 0.5% per year. However, it is suspected that the modules in an array level may degrade at higher rates because of higher string voltage and increasing module mismatch over the years of operation in the field. This paper compares and analyzes the degradation rates of grid-tied photovoltaic modules operating over 10-17 years in a desert climatic condition of Arizona. The nameplate open-circuit voltage of the strings ranged between 400 and 450 V. Six different types/models of crystalline silicon modules with glass/glass and glass/polymer constructions were evaluated. About 1900 modules were inspected using an extended visual inspection checklist and infrared (IR) scanning. The visual inspection checklist included encapsulant discoloration, cell/interconnect cracks, delamination and corrosion. Based on the visual inspection and IR studies, a large fraction of these modules were identified as allegedly healthy and unhealthy modules and they were electrically isolated from the system for current-voltage (I-V) measurements of individual modules. The annual degradation rate for each module type is determined based on the I-V measurements. Finally, the paper attempts to correlate the performance degradation with observed visual defects and IR test results.

8112-25, Session 7

Fire hazard and other safety concerns of PV systems

N. G. Dhere, Univ. of Central Florida (United States)

With the exponentially increase of PV installations, there are serious concerns regarding fire hazard and other safety issues. There are several instances of solar systems on fire. Unfortunately, there is very little data from systematic studies of long-term liability and durability of PV modules, inverters and connectors, etc. In the absence of extensive systematic study on long-term exposure of PV systems, there is tendency to rely on accelerated testing. However, the essential acceleration factors have not been determined for the various failure modes and mechanisms. The problem is compounded by new and inexperienced manufacturers who are trying to cut corners and installers who have not received adequate hands-on training. This paper describes the instances of PV modules and inverters on fire; summarizes current practices of emergency response and provides recommendations for minimizing these concerns.

8112-26, Session 8

Long-term performance analysis of CIGS thin film PV modules

N. G. Dhere, S. V. Pethe, A. Kaul, Univ. of Central Florida (United States)

Current accelerated tests of photovoltaic (PV) modules mostly prevent infant mortality but cannot duplicate changes occurring in the field nor can predict useful lifetime. A clear correlation between indoor, accelerated testing and outdoor performance is still being sought. The long term outdoor testing of PV modules aids in determining the approximate degradation rate of PV modules, thus, providing means to approximately forecast the amount of degradation in PV modules under actual operating conditions. Moreover, it is helpful in detecting long term degradation, if any, and understanding the correlation of PV performance and the meteorological parameters. As a rule of thumb, each three-year study will increasingly assure approximately nine-year segments of useful life time. Hence to guarantee a US DOE goal of 30 years useful lifetime it is necessary to continue the outdoor testing of CIGS PV modules. Therefore, monitoring of field-deployed PV modules was undertaken at FSEC with goals to assess their performance in hot and humid climate under high voltage operation and to correlate the PV performance with the meteorological parameters. This paper presents performance analysis of commercially available CIGS PV modules. Statistical data analysis of PV parameters along with meteorological parameters, monitored continuously, is carried out on regular basis with PVUSA type regression analysis. Current-voltage (I-V) characteristic of module arrays that are obtained periodically complement the continuous data monitoring. One difficulty with the outdoor testing is that due to seasonal changes, several complete cycles are required in order to obtain reasonably accurate degradation rates.

8112-27, Session 8

Using PV module certification standards tests as evaluation tools for product development

M. Reinhout, T. Brehmer, S. Lim, A. Brown, T. Macrina, R. Adkar, K. Doering, C. Shetty, J. Jalbert, P. Mehra, T. Nguyen, A. Srivatsa, K. Ramanathan, S. Goyal, L. Dounas, K. Zak, R. G. Pethe, A. Tandon, B. Wieting, L. Rios, Stion Corp. (United States)

Standards used for certification testing of photovoltaic modules contain a comprehensive group of tests that, when successfully completed, attest to the safety and performance of a module. These tests can also be used as a guideline when developing internal reliability tests as a company moves from module design to evaluation, and eventually into production. Using the accepted certification standards as a guideline, some common photovoltaic module failures may be discovered during in-house testing that could later present themselves in the field. In this talk we will discuss the importance of reliability testing from the early stages of module design, material selection, and final product. Also, we will cover some key reliability testing methodologies, derived from the certification standards, which can be implemented as the module proceeds through these various stages. Some common photovoltaic module failures like

interconnect failures and material delamination can be identified in their infancy when widely accepted environmental testing is followed. Evaluating components by certain tests enable informed decisions on component selection for module design. The goal is to develop a product with all possible speed but also with sufficient preliminary knowledge of the module reliability so that the confidence level in the product lifetime is high.

8112-28, Session 8

Metastable behavior of the electrical characteristics of CIGS photovoltaic modules upon exposure and stabilization

C. A. Deline, D. S. Albin, S. R. Rummel, National Renewable Energy Lab. (United States)

We report on our studies to devise practical procedures to stabilize the measured performance of polycrystalline thin-film photovoltaic modules. We subjected 11 older and newer modules from three manufacturers through various steps and measured performance (current-voltage) and capacitance-voltage (C-V) characteristics as a function of a sequence of exposures: short outdoor preconditioning, 48-hour dark thermal (85°C) anneal, indoor light- and dark current-soaks at 65°C, final longer-term outdoor exposures.

For all modules, preconditioning shifts performance parameters to within a few percent of baseline values, carrier densities shift slightly. The dark thermal anneal diminishes performance by 5% to 12%, largely through losses in fill factor (FF) and open-circuit voltage (Voc), with declines in Voc or FF more prominent in the newer or older modules, respectively. Concurrently, carrier concentrations suffer large drops by factors of 5-10 while depletion widths double in size. Subsequent incremental chamber exposures-light-soaking and dark current-soaking in forward bias-restore performance and carrier profiles after 120-200 hours.

Long periods of dark storage following chamber exposures alter performance parameters more prominently for higher efficiency newer modules. The final outdoor exposure (300 kW-h/m2) recovers performance levels closer to those after indoor exposures thus validating our stabilization plan: dark current-soaking in forward bias and light soaking are equivalent stabilization procedures. Albeit, a conundrum appears in subsequent dark storage for the higher performing modules: Voc and carrier densities relax toward levels similar to those measured after dark thermal anneal, which are lower than at baseline. This suggests our procedures have altered some device properties.

8112-29, Session 8

Automated shading for cell-level failure detection in solar modules using differential IV analysis

G. B. Alers, Univ. of California, Santa Cruz (United States); J. Olson, N. Green, APV Research (United States)

Rigorous testing of photovoltaic modules is critical to maintaining high lifetime projections and thus a small number of dollars per watt. Although accelerated lifetime tests provide a useful method for quality assurance, there is no better test-bed for expected lifetime than already deployed modules. Unfortunately, monitoring the parameters of the individual cells in a module is challenging. Infrared and electroluminescence images are the dominate method for identifying degradation in a solar module.

Here we present a method by which critical parameters of each cell within a module can be measured quickly using an automated shading screen and differential IV analysis. By shading each cell individually with a flat-spectrum shading device, we can use differential I-V analysis to extract shunt resistance, power output, and short-circuit current of the shaded cell. Automated shading reduces both time for the measurement and opportunities for technician error. Problematic cells are pin-pointed within the module, and module statistics are improved by orders of magnitude. This technique provides a quick method to monitor the parameters of individual cells in the field or determine the best and worst cells for hot-spot testing. The results from this test would help detect failures and guide R&D in the development of new procedures and materials.

8112-30, Session 8

Characterization of damp heat degradation of CuInGaSe2 solar cell components and devices by (electrochemical) impedance spectroscopy

F. J. Pern, R. N. Noufi, National Renewable Energy Lab. (United States)

This work investigated the suitability of (electrochemical) impedance spectroscopy (ECIS) to monitor in early stage the damp heat (DH) susceptibility of CIGS solar cell contact materials, components and devices. A sample set was prepared with the conducting silver epoxy or Ag paste applied to different substrates and CIGS solar cells, with Au wires soldered at ~177oC onto the heat-dried paste spots. The sample set was exposed in an ESPEC environmental chamber, and characterized by ECIS, 4-probe, optical micro-imaging, I-V and QE measurements. The results show that, within first 50~100 h of DH exposure, ECIS was sensitive to detect notable changes on the contact resistance that allowed us to determine that (1) the conducting Ag paste was more stable and preferred over the Ag-epoxy, (2) the Al/Ni on glass and on BZO rapidly degraded (corroded) while Ni was very stable, (3) the Mo/SLG corrosion occurred with pinhole-like features, resulting in localized high resistance, and (4) the moisture-absorbed BZO showed a “transient” behavior of high resistance that was not detected by 4-probe. The ECIS results also showed the CIGS solar cells could be modeled essentially by a simple circuit of a series resistance with a parallel capacitor and resistor, while shorted or degraded devices, either initially or by short DH exposure, could be readily detected.

8112-31, Session 8

A novel approach for correlating capacitance data with performance during thin-film device stress studies

R. Graham, D. S. Albin, National Renewable Energy Lab. (United States)

A new data mining technique was applied to capacitance and performance measurement data to systematically identify the strongest correlations between these two sets of data during stress testing of CdS/CdTe solar cells. Instead of starting with a physical model (like the one-sided, abrupt junction model), this method scans the data for all possible correlations between 1st and 2nd level metrics (efficiency, Voc, Jsc, FF, resistance terms) and capacitance-derived data (carrier density, depletion width, conductance) collected during stress testing. The correlation coefficient, R2, for all combinations of these parameters is then determined, thus identifying where the best correlations exist. In doing so, we commonly observe that the best correlations exist when using higher, positive voltages. At these voltages, the data appear to fit quite accurately, the one-sided abrupt junction model, which is useful for determining junction built-in voltage, Vbi. The ability to uncover these hidden correlations is important from a practical perspective since it allows more insight into why devices degrade from a mechanistic perspective than measuring 1st and 2nd level metrics alone. The results of this approach will be demonstrated for a recent case involving CdTe devices where Vbi was observed to increase with degradation.

8113-01, Session 1

Recent advances in photorefractive polymers

J. Thomas, College of Optical Sciences, The Univ. of Arizona (United States) and UCF NanoScience Technology Ctr. (United States); C. Christenson, P. Blanche, R. Voorakaranam, College of Optical Sciences, The Univ. of Arizona (United States); M. Yamamoto, Nitto Denko Technical Corp. (United States); R. A. Norwood, N. N. Peyghambarian, College of Optical Sciences, The Univ. of Arizona (United States)

Photorefractive composites derived from conducting polymers offer the advantage of dynamically recording holograms without the need for processing of any kind. Thus, they are the material of choice for many cutting edge applications, such as updatable three-dimensional (3D) displays and 3D telepresence. Using photorefractive polymers, 3D images or holograms can be seen with the unassisted eye and are very similar to how humans see the actual environment surrounding them. Absence of a large-area and dynamically updatable holographic recording medium has prevented realization of the concept. We will discuss the development of a novel nonlinear optical chromophore doped photoconductive polymer composite as the recording medium for a refreshable holographic display which led to the development of a quasi-real time proof-of-principle 3D telepresence without the need for special eyewear. Further improvements in the polymer composites could bring applications in telemedicine, advertising, updatable 3D maps and entertainment.

8113-02, Session 1

Thermally stable hybrid organic/inorganic resonant cavities

H. S. Choi, A. M. Armani, The Univ. of Southern California (United States)

Whispering gallery mode (WGM) optical microresonators, such as microspheres, toroids, disks and rings, have been used in a wide range of applications including fundamental physics, bio/chem sensors, narrow linewidth lasers, and add/drop filters. The silica microtoroid resonator is an ideal platform because of its high quality factor (Q), small mode volume and straightforward on-chip fabrication. Also, it is easy to incorporate additional functionalities, such as frequency tuning and lasing, by adding gain material into the silica or coating the device. However, the resonant frequency position of these devices is very unstable because the large build-up intensities inside the cavity change the refractive index of the medium, also known as the thermo-optic effect. By balancing the thermo-optic coefficient of silica with that of a second material, it is possible to design a device which is thermally neutral. To demonstrate a thermally stable resonant cavity, we coat two distinctly different polymers, polydimethylmethacrylate (PMMA) and polystyrene (PS) on the surface of silica microtoroid resonant cavities, forming hybrid optical cavities. It is important to note that the thermo-optic coefficient of silica and the two polymeric materials have opposite signs. The hybrid microcavity's resonant wavelength is temperature stabilized, while maintaining a Q factor above 1 million. The distribution of the optical field in the polymer layers and in the silica was predicted through a series of finite element method simulations. The predicted optimal polymer film thickness agrees very well with the experimentally demonstrated one.

8113-03, Session 1

An electro-optic silicon-polymer hybrid modulator

R. Himmelhuber, College of Optical Sciences, The Univ. of Arizona (United States); L. Li, Tipd, LLC (United States); A. M. Jones, O. Herrera, R. A. Norwood, N. N. Peyghambarian, College of Optical Sciences, The Univ. of Arizona (United States)

We present the concept and design of a silicon/polymer hybrid modulator that is suitable for integration with silicon photonic components, exhibiting high optical confinement in the electro-optic (EO) polymer, while providing a much simpler fabrication process than existing hybrid Si/polymer approaches. EO polymers have been shown to have very high Pockel's coefficients and low optical losses, as well as enabling modulators with sub-volt $V\pi$ and > 100 GHz operation. Because of their outstanding properties, it is desirable to integrate EO polymers with silicon photonic components and benefit from state-of-the-art CMOS fabrication technology. One major challenge is that because of the large refractive index contract between silicon and the polymer, it is difficult to arrange for sufficient light to be in the low index EO polymer for effective interaction. One approach to address this issue has been the use of nano-slotted silicon waveguides, where part of the light is confined in the slot region into which the EO polymer is infiltrated. However, these slotted structures are very challenging to fabricate and, at the same time, suffer from high coupling and propagation losses. Here we present a novel approach to taper down a regular 500-nm-wide silicon waveguide to a width of 100 nm, resulting in more than 90% of the light being in the EO polymer overclad; meanwhile, an inverse silicon taper facilitates the coupling of light from fiber, which dramatically reduces the loss. We show that this design will be extremely useful towards achieving realistic integrated EO modulators built on silicon platforms.

8113-04, Session 1

Microcavity polariton electroluminescence via radiative pumping from a weakly coupled organic semiconductor

G. H. Lodden, R. J. Holmes, Univ. of Minnesota, Twin Cities (United States)

The strongly coupled regime is defined by a reversible and periodic energy exchange between the excitonic resonance of a semiconductor and the resonant photon mode of an optical microcavity. The eigenfunctions of this system are referred to as microcavity polaritons. Organic semiconductors have garnered significant interest as the active medium in strongly coupled optical microcavities due to their large exciton oscillator strengths and binding energies that permit the study of strong coupling at room temperature under both optical and electrical excitation. In these systems, the population of microcavity polariton states typically occurs via an uncoupled exciton reservoir. This results in the inefficient excitation of the upper polariton branch, and a significant population of uncoupled excitons in the active material. Here, an alternate excitation approach is demonstrated that permits the direct population of microcavity polariton states in tetraphenylporphyrin under both optical and electrical excitation without first forming an exciton reservoir. This is realized by introducing a weakly coupled emitter into an optical microcavity that also contains an organic semiconductor suitable for strong exciton-photon coupling. In contrast to previous work on organic microcavity polariton luminescence, angle-resolved measurements of the photo- and electroluminescence show variations in upper and lower branch emission intensity consistent with the branch photon character. This observation confirms that the excitation of the microcavity polariton states is by radiative pumping from the weakly

coupled emitter. This alternate approach for microcavity polariton excitation may ultimately permit the development of new architectures for the study of polariton luminescence.

8113-05, Session 2

Quantum dots, low bandgap polymers and C60 derivatives for photonic applications

K. Lee, Hannam Univ. (Korea, Republic of)

This presentation engrosses on the development of highly efficient organic and inorganic materials for photonic applications such as photodetectors, field effect transistors (FET), photovoltaic (PV) cells, light emitting diodes, and other display materials. Various issues addressed involves the development of new materials, study of device architecture and improving it to suit the materials by developing a fundamental understanding of transport mechanism in devices. Developing new materials including photopatternable quantum dots (QDs) to form patterned bulk heterojunctions (BHJ), synthesis of new low bang-gap polymers for light harvesting and designing fullerene derivatives to act as electron acceptors during excitonic transport are the strategies adapted to achieve these goals.

Modified C60 derivatives were synthesized as acceptor materials to get improved open circuit voltage in bulk heterojunction solar cells and high mobility in field effect transistors. Different low band gap polymers were synthesized to utilize as efficient materials for organic FET and PV cells. Some polymers were found with interesting photovoltaic and ambipolar transfer characteristics. Effect of ligand in a QD-polymer solar cells using PbS and PDTPBDT polymer is summarized. Ligand exchange between oleic acid (OA) and 1,2-ethanethiol (EDT) on the surface of the QD in a solar cell were found with increase in device efficiency. CdSe/ZnS QDs were functionalized with photoacid cleavable surface ligands as well as, polymerizable surface ligands. They were found to produce a large enhancement in photoluminescence. The effects of these modifications on the electronic and optical properties of devices employing these materials were studied extensively.

8113-06, Session 2

Investigation of highly nonlinear composite of Co3O4 nanoparticles and poly(vinylalcohol) in the nanosecond regime

X. Zhu, D. T. Nguyen, J. Thomas, R. A. Norwood, N. N. Peyghambarian, College of Optical Sciences, The Univ. of Arizona (United States)

Nonlinear properties of thin films made of a composite of Co3O4 nanoparticles and poly(vinylalcohol) (PVA) have been investigated using nanosecond lasers in the visible. Thin films with thicknesses of hundreds of nanometers were fabricated by spin coating. Extremely high nonlinearities have been found in these composites. Nonlinear refractive index (n2) of ~ 10-10 cm2/W and nonlinear absorption ( ) of ~ 103 cm/GW have been measured from 425 nm to 675 nm; the films also exhibit exceptional optical damage thresholds. The experimental results show that the Co3O4 nanoparticle/PVA composite is a promising material for nonlinear optical devices in the visible, since it takes advantages of the high optical nonlinearities of transition metal oxides and the superior mechanical properties and convenient fabrication properties of polymers.

8113-07, Session 2

Influence of aggregation on the optical properties of dye-doped porous, plasma polymerized titanium oxide films

R. Jakubiak, Air Force Research Lab. (United States); H. Jiang, W. Su, L. Sun, General Dynamics Information Technology (United States)

Solid host materials with functional materials have potential use in a variety of optical and photonic applications. An ongoing challenge is to get the dopant loading as high as possible without causing aggregation or phase separation. In particular, aggregation of dye molecules within thin films can lead to changes in the optical absorption and performance degradation. For this study porphyrin and phthalocyanine dyes were doped within porous plasma polymerized (PP-) TiOxCy films. By varying the processing conditions, including plasma reaction chamber pressure and carrier gas ratio (O2/Ar), we were able to control the porosity of the PP-TiOxCy films and, hence the degree of dye aggregation. Using UV-Vis, XPS, FTIR and Raman spectroscopy along with morphological studies including SEM, AFM and X-ray diffraction we were able to establish structure-property relationships to gain insight in how to decrease the deleterious effect of dye aggregation in titania derivatives that have potential use in photocatalysis.

8113-08, Session 3

Nonlinear photochemistry and 3D microfabrication by with Q-switched Nd:YAG microchip lasers

P. L. Baldeck, M. Bouriau, O. Stephan, Univ. Grenoble 1 (France) and Ctr. National de la Recherche Scientifique (France); G. Vitrant, IMEP-LAHC (France); V. Dewaele, O. Poizat, Univ. Lille 1 (France); J. Malval, Univ. Haute Alsace (France)

We review our recent advances in two-photon induced photochemistry to fabricate tri-dimensional micro-objects made in polymers, proteins and noble metals using Q-switched Nd:YAG microchip lasers. Such sub-nanosecond lasers have recently appeared to be more efficient than femtosecond lasers for such processes. Their longer pulse duration allows not only for the initiating two-photon absorption step but also for an additional energy deposition through excited-state absorption that is more favorable for photochemistry processes.

The 532-nm laser wavelength is particularly convenient to fabricate polymer 3D micro-objects that are transparent in the visible region. The two-photon resonance is at 266 nm. Thus, photoinitiators can be transparent at daylight wavelengths, that facilitates the sample preparation and fabrication process. Typical lasers parameters are 0.1 mW average powers and tens of millisecond exposure times to obtain sub- 200 nm lateral resolutions. We will report on recent results using new commercial resins including epoxyacrylate, PDMS, and electroactive hydrogels, that have been polymerized with new photoinitiators including photo-acid generators. The fabricated 3D micro-objects concern mainly new functionalities for microfluidic microchannels.

The 532-nm laser wavelength is also very suitable to fabricate micro-objects based on biomaterials. We will report on the cross-linking of collagen proteins to fabricate artificial extracellular matrix. We will also report on the fabrication of three-dimensional enzymatic microreactors within PDMS microfluidic channels, and demonstrate that the fabricated trypsin microstructures maintain their catalytic activity.

The 1064-nm wavelength is more adapted for metallic microfabrication. 3D gold and silver microstructures are obtained by the photo-precipitation that follows the two-photon induced reduction of soluble metallic cations at the laser focal point. We will particularly report on new plasmonic microlenses and Raman sensors that we have fabricated with different silver nanowire architectures.

8113-09, Session 3

New directions in nonlinear plasmonics

P. G. Kik, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

The use of surface plasmons for the enhancement of nonlinear optical effects is gaining momentum due to the promise of enhanced performance in ever smaller nonlinear optical devices. By designing structured metal-dielectric composites, one can obtain nonlinear metamaterials (NLM) that exhibit vastly enhanced nonlinear susceptibilities at specific design frequencies. These enhancements follow from the resonantly enhanced electric fields associated with surface plasmon resonances of the structures, resulting in a composite nonlinear optical response that is radically different from that of the constituent materials. In order to use these NLMs in applications, the improvement in nonlinear optical response must be achieved at acceptable linear optical absorption levels. This leads to application specific requirements and figures of merit (FOM). Here we summarize recent work on nonlinear optical refraction and absorption in a variety of metal dielectric composites with a focus on the figure of merit for nonlinear absorption. Based on 3D electromagnetic simulations it is shown that the presence of plasmon resonances in these composites results in complex enhancement factors related to the frequency dependent phase of the plasmon response. It is demonstrated that geometry optimization using only particle placement at a fixed amount of metal in the composite can be used to improve the FOM for nonlinear absorption by over an order of magnitude. We show that the use of coupled plasmon resonances can lead to an additional enhancement by at least an order of magnitude. Methods to extend the presented approach, as well as suggested fabrication approaches will be discussed.

8113-10, Session 3

Realizing metal and quantum dot containing patterns by two-photon lithography

P. Prabhakaran, K. Lee, K. K. Jang, Hannam Univ. (Korea, Republic of); D. Yang, Y. Son, KAIST (Korea, Republic of)

In this presentation are results from the design of materials and processes suited for two-photon lithographic microfabrication of : metal coated polymeric structures, metal nanoparticle embedded polymeric structures, quantum dot (QD) embedded polymeric structures and direct writing of metal structures.

For silver coated structures we have developed a simple strategy to incorporate amino groups on polymeric microstructures. These amino groups are then used as templates for generation of gold seeds by reduction of gold solutions by amino groups. The gold seeds further aid reduction of silver onto them through electroless coating. For silver nanoparticle embedded systems we developed a combination of photocuring and thermal curing techniques for a resin containing a metal precursor. Using this curing scheme we could successfully fabricated nanoparticle embedded three-dimensional microstructures. For achieving QD embedded microstructures, we designed and synthesized QDs stabilized with photopatternable ligands. These QDs could easily be doped into photopattenable resins to fabricate quantum dot embedded microstructures. Silver patterns were directly reduced from silver salts dispersed in poly electrolytes or amphiphilic block-co-polymers.

8113-11, Session 3

Metal plasmon enhanced luminescence of organic dyes

F. Liu, S. Rao, G. Aldea, J. Nunzi, Queen's Univ. (Canada)

Plasmons are known as collective vibrations of the electron gas surrounding the atomic lattice sites of a metal. When plasmons couple with a photon, a polariton is generated, it propagates along the surface of metal until it decays, either by absorption, whereupon the energy is converted into phonons, or by a far filed radiative transition into a photon. As regard to surface plasmon (SP), it is referred to fluctuation in the electron density at the boundary of two materials, while when the surface plasmon is excited by light, a surface plasmon resonance (SPR) was generated, which usually occurs at the interface of a material with a positive dielectric constant with that of a negative dielectric constant (such as a metal). Now SPR is attracting increasing interest for their broad application in Surface Enhanced Raman Spectroscopy (SERS), Surface Plasmon Resonance Spectroscopy (SPRS) etc. [1-2]. In SERS, a rough metal surface can enhance the Raman scattering signals as high as 14 to 15 orders, which allows the technique to be sensitive enough to detect single molecules [3]. That's because when the light is incident on a rough metal surface, the SP was excited and the localized electronic filed is enhanced by SP. As a results, the intensity of incident light was magnified, which therefore increases the signal of Raman scattering. For SPRS, one of its most common applications is the measurement of the adsorbed self-assembled molecule on metallic substrate [4], since the SPR frequency sensitively depends on the permittivity of both the metal and dielectric, thus, along the deposition of molecule on metallic surface, the SPR peak wavelength changes gradually.

Along with the surge of interests in micro-scale phenomena, the investigation of plasmon is also extended to nano-scale combined with nanotechnology. Due to the strong coupling between light and surface plasmons in nanostructures, there are novel phenomena emerging in plasmonics such as optical force enhancement, transport, storage, localization and guiding of light energy in nanoaggregates [5-9]. Besides, the investigation of Metal Enhanced Fluorescence (MEF) phenomenon in last decade breaks a new path to apply SP into the field of chromophore luminescence, and now more or less SP has found its application in the field of medical and biological imaging [10]. In this paper, we will focus on the application of surface plasmons to metal enhanced fluorescence; we discuss the interaction mechanism based on time resolved luminescence experiments and propose future developments.

Record-high intrinsic hyperpolarysabilities in conjugated polymers: a counterintuitive result

I. Asselberghs, K. Clays, T. Verbiest, G. Koeckelberghs, Katholieke Univ. Leuven (Belgium)

We present a new approach for attaining record-high intrinsic second-order nonlinear optical properties for a set of conjugated polymers, leaving the classical paradigms in second-order nonlinear optics unexplored. We will be focusing on the modulated conjugation present in a series of conjugated polymers. Moreover, we will demonstrated the influence of polaron formation on the second-order nonlinear optical response in the polythiophene derivatives.

8113-13, Session 4

Measurement of stress and strain applied to electrochemically aligned collagen fibres by second-harmonic generation microscopy

N. Goami, K. Yoshiki, T. Namazu, S. Inoue, Univ. of Hyogo (Japan)

Collagen fibres provide mechanical strength to biological tissues. When mechanical stress is applied, a cell enzymatically degrades and restructures the collagen fibres to relieve the stress in the extracellular matrix around the cell. For quantitative research of this mechanism, visualization of stress distribution in collagen fibres is essential. We demonstrated quantitative measurement of stress in collagen fibres by second-harmonic generation (SHG) microscopy and a tensile test. The collagen molecule is an ampholyte and forms bundles spontaneously under the conditions of pH 7. Based on this behaviour, electrochemically aligned collagen fibres were fabricated under a pH gradient generated between parallel electrodes after application of DC voltage in the collagen solution.

Both ends of the fibre were bonded to a tensile tester consisting of one pair of translation arms, and tensile stress was applied in the longitudinal direction of the fibre. Simultaneously, the intensity of SHG light emitted from the collagen fibre excited by a femtosecond pulsed laser was measured at the transmission and reflection sides. SHG intensities on both sides increased with the strain applied on the fibre. This result suggests that the alignment homogeneity of the collagen molecules in the fibre was improved by the strain. On the other hand, the transmission to reflection ratio of SHG intensity decreased with an increase in the strain because of an increase in reflectance due to a change in the degree of organization in the collagen fibrils.

The dependence of SHG intensity on stress and strain provides us with a non-contact probe to visualize stress and strain distribution in the extracellular matrix in the living body.

8113-14, Session 4

Spontaneous chirality in discotic liquid crystals: a linear and nonlinear optical spectroscopic investigation

S. J. Van Cleuvenbergen, K. Clays, T. Verbiest, Katholieke Univ. Leuven (Belgium); G. Hennrich, Univ. Autónoma de Madrid (Spain)

The unusual linear and nonlinear optical behaviour of a new family of discotic, octupolar 1,3,5-trisalkynylbenzenes is described. These molecules organize themselves in various crystalline and liquid crystalline (meso)phases that show great potential for nonlinear optical applications. Surprisingly, some of these phases consisting of clearly achiral molecules, exhibit strong circular dichroism in the linear and the second-order nonlinear regime. This seems to be indicative of a spontaneous chiral supramolecular ordering. A novel technique using polarized second harmonic generation microscopy was used as a tool to map this nonlinear circular dichroism effect and to study the symmetry properties of these materials, amongst other techniques such as X-ray diffraction and polarized optical microscopy.

8113-15, Session 4

Optimizing the second-order nonlinear optical response in some indoline-based chromophores at the molecular and macroscopic levels

A. Teshome, Katholieke Univ. Leuven (Belgium); D. Bhuiyan, M. Ashraf, G. J. Gainsford, A. J. Kay, Industrial Research Ltd. (New Zealand); I. Asselberghs, K. Clays, Katholieke Univ. Leuven (Belgium)

The effect of extending the conjugation length, the deployment of various substituents and configurational locking of the polyene backbone on the second-order nonlinear optical (NLO) response of a series of indoline based compounds has been investigated by Hyper-Rayleigh scattering (HRS). All of the compounds were found to have high molecular hyperpolarizabilities with values up to 1485 x 10E-30 esu. At the macroscopic level - for poled polymer thin-films - a strong second-order NLO signal has been detected by using relative second-harmonic generation (SHG) techniques. A femtosecond operating system at 1300 nm fundamental wavelength was used for both the HRS and SHG experiments. X-ray crystallographic studies were performed on three of the compounds and bond length alternation (BLA) values obtained. These were then related back to the observed NLO responses.

Nonreciprocal silicon-organic nanophotonic structures

M. Eich, Technische Univ. Hamburg-Harburg (Germany)

No abstract available.

8113-17, Session 5

The origin of SRG formation: a cage breaking mechanism at the nanoscale

J. Nunzi, Queen's Univ. (Canada); V. Teboul, Univ. d'Angers (France) and MOLTECH GmbH (France); J. Accary, Univ. d'Angers (France)

Illuminating thin polymer films doped with azo-dyes Rochon et al. [1] and Kim et al. [2] observed the formation of surface relief gratings (SRG) corresponding to a massive photoinduced mass transport well below the glass transition temperature of the material. An increase of the local diffusion has been suggested as a possible cause for SRG formation. Indeed a local diffusion increase has been observed experimentally [3]. This result suggests that the isomerization-induced massive mass transport that leads to surface relief gratings formation in these materials, is induced by this huge increase of the matrix diffusion coefficient around the probe. In order to investigate the microscopic origin of this amazing controlled local modification of the dynamical properties of the matrix, we use molecular dynamics simulations of the photo-isomerization of probe DR1 molecules dispersed inside a glassy molecular matrix. The simulations confirm that the probe isomerization modifies locally the diffusion coefficient of the matrix leading to liquid like diffusion properties below the glass transition temperature. Results show that the increased diffusion is due to an isomerization-induced cage breaking process. A process that explains the induced cooperative motions recently observed in these photoactive materials [4].

Optical nonlinearity and power limiting in organic molecules and nanocomposites

R. Philip, Raman Research Institute (India)

Nonlinear optical transmission in materials has several applications including laser mode-locking, pulse shaping, optical bistability, optical switching, and optical power limiting. Chemically stable organic molecules which are easily processable and suitable for functionalization have been extensively investigated for their third order nonlinearities employing different experimental methods. We have measured the optical nonlinearity of different novel organic and composite systems including nanocomposite polymer films of Au, Ag and Pt, Organic ionic crystals (pyridinium and quinolinium salts), Au-alkanethiol clusters, thiophene based polymers, and Schiff base complexes, using the z-scan and degenerate four wave mixing techniques, employing laser pulses of nanosecond and femtosecond durations respectively. It is found that most of these materials are efficient optical power limiters (except a few showing saturable absorption) under our excitation conditions. Their nonlinear extinction coefficients have been calculated. From degenerate four wave mixing experiments, the third order nonlinear susceptibility and figure of merit / also have been determined. A passive all-optical diode action of high contrast ratio, observed in a porphyrin-semiconductor nanocrystal device, is discussed. It is shown that enhancement in the optical nonlinearity can often be obtained even by simple actions like mechanical mixing of two organic media. The above experiments conducted in a large number of organic and composite materials unravel the potential of these media for diverse photonic applications.

8113-19, Session 5

Assessing limitations to the two-level approximation in nonlinear optics for organic chromophores by ab initio methods

M. M. Coles, J. N. Peck, V. S. Oganesyan, D. L. Andrews, Univ. of East Anglia Norwich (United Kingdom)

The use of a two-level approximation to simply characterize the nonlinear optical properties of organic materials is well known. Usually only electronic ground states are significantly populated; higher levels are engaged only in the capacity of virtual states, and it is frequently assumed that just one such state dominates in determining the response. Calculating nonlinear optical susceptibilities on this basis, excluding all but the ground and one excited state in a sum-over-states formulation, is a technique widely deployed in the calculation and analysis of nonlinear optical properties. However, the necessity for such an approach is diminishing as, particularly within the last decade, the accuracy of ab initio calculations has reached unprecedented levels. This offers new opportunities for a vigorous test of existing models using real molecular structures. Here we report the results of our recent work on testing the general validity of two-level calculations in nonlinear optics. Firstly, through the extension of approximation to a three-level model we demonstrate that the neglect of additional excited states can lead to substantially erroneous results for the hyperpolarizability elements. Secondly, using high levels of theory and basis set we report the results of ab initio calculations for both ground and electronically excited states of the optimised structures, for selected merocyanine dyes. The results are used for the calculation of hyperpolarizabilities by a rigorous sum-over-states formulation. A systematic comparison with the two-level approach provides a means for identifying the limits of the model and the criteria for its validity.

8113-20, Session 5

Why do we need three levels to understand the molecular optical response?

J. Pérez-Moreno, K. Clays, Katholieke Univ. Leuven (Belgium); M. G. Kuzyk, Washington State Univ. (United States)

Traditionally, the nonlinear optical response at the molecular level has been modeled using the two-level approximation, under the assumption that the behavior of the exact sum-over-states (SOS) expressions for the molecular polarizabilities is well represented by the contribution of only two levels. However, a rigorous application of the Thomas-Kuhn sum-rules over the SOS expression for the diagonal component of the first-hyperpolarziability proves that the two-level approximation is unphysical. We show how the contributions of potentially infinite number of states to the SOS expressions for the first-hyperpolarizability are well represented by the contributions of a generic three-level system. This explains why the analysis of the three-level model in conjugation with the sum rules has lead to successful paradigms for the optimization of organic chromophores.

8113-21, Session 5

The nonlinear optical response of quantum graphs

S. Shafei, M. G. Kuzyk, Washington State Univ. (United States)

The study of nonlinear optical properties of materials and their applications is a well-established area in science and technology. The nonlinear susceptibilities have found applications in 3-D nanophotolithography, telecommunications, and designing new materials for cancer therapies, to name a few. These activities have required tremendous experimental and theoretical efforts to discover and design materials with better nonlinear response as well as finding general characteristics of systems for which the nonlinear response is optimized.

A network of nanowires can form a quantum graph. Semiconductor nanowires are known for their potential as the building blocks of future optical devices. During their synthesis, key parameters such as the chemical composition, diameter and length, can be controlled enabling a wide range of devices and applications such as LED's, transistors and nano-scale lasers, the generation of single-cycle pulses and optical processing with sub-mW powers.

In the present work, we will show how the theory of fundamental limits of the first and second hyperpolarizabilities can be used to optimize the nonlinear optical properties of quantum graphs. The nonlinear response of three- and four-segment quantum graphs will be studied in detail. We discuss the geometries that provide the largest nonlinear response for each class of quantum graphs. The work extends our techniques to quantum wires, which will allow scientists and engineers to reduce to practice our theoretical work.

8113-22, Session 6

Single, two-, and multi-photon driven molecular motion and nanofabrication in azo-polymer films

Z. Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

Polymers contatining azobenzene derivatives have been the subject of intensive research for two decades owing to their unique "smartness", i.e., the ability to tailor and/or control materials properties by photoisomerization. In particular, it was shown that photoisomerization creates optical anisotropy by nonpolar orientation, and poling by polar optical excitation (all optical poling), and it triggers molecular movement far below the glass transition temperature (Tg) of the polymer

(photo-assisted poling), and polymer mass movement proceeds in spatial gradients of the excitation light (surface relief gratings). In solid polymers, photoisomerization of azobenzene derivatives creates free volume and drives efficient chromophore and polymer segmental and chain motion far below the polymer's Tg; an effect which is at the origin of photo-assisted and all optical poling and surface relief gratings. Most of the studies reported to date on azo-polymers used single photon isomerization, and it is of critical importance to investigate two- or multiphoton isomerization of azobenzene derivatives in polymers since it would trigger additional studies and applications of azobenzenes containing polymers at the interface of nonlinear optics and photochemistry, in that all of the effects that have been demonstrated in azo-polymers by one-photon isomerization may be reproduced by two- or multi-photon isomerization with potential applications in nanophotonics. In two-photon absorption, the photoreaction can be induced by tightly focused lasers into confined volumes - a resolution of 120 nm has been achieved for three dimensional nanofabrication in photopolymerizable resins. In this presentation, I will discuss our recent work on light induced molecular movement and induced plasticity in azo-polymers by one and two-photon isomerization. Nanoscale polymer movement is induced by a tightly focused laser beam in an azo-polymer film just at the diffraction limit of light both by one- and two-photon isomerization. The deformation pattern which is produced by photoisomerization of the azo dye is strongly dependent on the incident laser polarization and the longitudinal focus position of the laser beam along the optical axis. The anisotropic nanofluidity of the polymer film and the optical gradient force played important roles in the light induced polymer movement. The limits of the size of the photo-induced deformation were explored, and it was found that the deformation depends on the laser intensity and the exposure time. The smallest deformation size achieved was 200 nm in full width of half maximum; a value which is nearly equal to the size of the diffraction limited laser spot. Beyond the limit of light diffraction, a nano protrusion was optically induced on the surface of the films by metal tip enhanced near-filed illumination. A silver coated tip was located inside the diffraction limited spot of a focused laser beam (460 nm), and an enhanced near-field, with 30 nm light spot, was generated in the vicinity of the tip due to localized surface plasmons. A nano protrusion with 47 nm full width of half maximum and 7 nm height was induced with a resolution beyond the diffraction limit of the light.

Useful nonlinear optical properties of multi-chromophore materials

T. G. Goodson III, Univ. of Michigan (United States)

Organic conjugated macromolecules have received great attention due to their use in optical and electronic applications. Certain molecular assemblies have shown enhanced nonlinear optical properties by virtue of strong excitonic coupling in the multi-chromophore system. Organic dendrimers, two-dimensional networks, and circular macromolecular aggregates have shown properties of strong intra-molecular interactions which have been utilized in light harvesting processes, photovoltaic (solar) devices, dielectric effects, as well as for enhanced nonlinear optical effects. This talk will discuss our basic results and conclusions over the past years utilizing these systems. The excitation mechanism in these systems depends on the nature of the branching center, the geometrical orientation of covalently attached chromophores, and the extent of delocalization. Through steady-state and time-resolved spectroscopy, we have characterized the mechanism of energy transport and the relative strength of intra-molecular interactions. In this presentation the photo-physical properties and applications in optical and electronic devices will be described. For particular assemblies the processes of efficient energy transfer, fast energy re-distribution, and enhanced two-photon absorption cross-sections will be discussed.

8113-24, Session 6

Linkage dependence of nonlinear optical properties of porphyrin-appended mixed (porphyrinato)(phthalocyaninato) yttrium(III) double-decker complexes

Y. Li, South Dakota State Univ. (United States); X. Zhang, Univ. of Science and Technology Beijing (China); M. Yan, X. Yan, South Dakota State Univ. (United States); J. Jiang, Univ. of Science and Technology Beijing (China)

Nonlinear optical (NLO) materials have drawn considerable attention worldwide in the last few decades due to their potential applications in the field of optoelectronics and photonics. These include passive optical power limiting, optical switching, and the design of logic gates. In this report, the nonlinear optical properties of three mixed (porphyrinato) (phthalocyaninato) yttrium double-decker complexes appended with one metal free porphyrin chromophore at the para, meta, and ortho position, respectively, of one meso-phenyl group of the porphyrin ligand in the double-decker unit through ester linkage, 2-4, have been comparatively investigated along with a model complex, mixed [1,4,8,11,15,18,22,25-octa(butyloxyl)phthalocyaninato][tetra(4-butyl)-porphyrinato] yttrium double-decker complex YH(TBPP)[Pc(α-OC4H9)8] (1) by using the Z-scan technique with the fundamental (800 nm) laser emission from a Ti:sapphire femtosecond laser system. The nonlinear optical absorption and refraction have been measured with different incident laser power. Both the open-aperture and close-aperture results have shown significant dependence on the position of the porphyrin-substituent of the triads.

8113-25, Session 7

Monte Carlo simulations of the photomechanical effect in polymeric fibers

A. C. Mitus, P. Wrobel, G. Pawlik, Wroclaw Univ. of Technology (Poland); M. G. Kuzyk, Washington State Univ. (United States)

We formulate the kinetic Monte Carlo (MC) model for the study of physical phenomena underlying the photomechanical effect in polymeric fibers pumped with a linearly polarized laser beam, which propagates off-axis along the fiber, and causes its reversible bending [1,2]. The present model constitutes a generalization of the MC kinetic model used for the study of diffraction grating inscription [3]. The model fiber is a host - guest system consisting of the polymeric matrix (simulated using the bond fluctuating MC method [4]) and azodye chromophores, which undergo multiple trans - cis -trans cycles when illuminated by linearly polarized light. Special attention is focused on the characterization of the spatial distribution of local voids and on the calculation of void - void correlation functions, which play the central role in the hypothetical cooperative mechanism of stress relaxation in the photomechanical effect [1]. The model assumes that the translational movements of the monomers are stimulated in the vicinity of the voids as the result of laser light driven local kinetics of the chromophores. The Monte Carlo kinetic model correctly reproduces the elongation of the fiber along the direction of laser light propagation.

Photomolecular motions on azopolymer nano-objects: toward new applications for photonics and biology

R. Barillé, Univ. d'Angers (France)

Advance in the fabrication of nano-objects becomes more and more important. In this direction, assembly of nanometer-scaled building blocks into device configurations and functionalization is an intensively investigated research field in nanotechnology. Azopolymer has been emphasized in the past few years because of the ability to photoswitch. This ability comes from the trans-cis photoisomerization where molecules induce motions when they relax from cis to trans.

We show in this work how the structure properties of polymer nanofilms, nanotubes, nanospheres or nanowires containing azobenzene can be controlled by light for new photonics applications. Spatially confined excitation of unidirectional motions could make it possible the local control of mechanical properties of the material and its structuration.

In this goal the production of uniform-sized nano-objects is important. We review the possibilities given by these nano-size objets in view of future application in photonics and biology.

i) We show the possibility to inscribe a nanostructure on the surface of azopolymer nanotubes with laser illumination. These patterns on the surface of nanometer objects open new possibilities as a means of optical processing on a nanoscale. ii) Using a white light we photoinduce a deformation effect of azopolymer nanospheres. A modification of the diameter can reach 35 % of the initial diameter. This experiment allows modifying the curvature of a nano-object without a shape change. iii) We induced structuration with a laser beam of nanowires made by electrospinning. iv) we show the possibility of using patterned nanofilms for applications in the growth of neuronal cells.

8113-27, Session 7

Photochromic polymers as a versatile tool for devices based on switchable absorption and other optical properties

C. Bertarelli, Politecnico di Milano (Italy) and IIT@PoliMI (Italy); R. Castagna, IIT@PoliMI (Italy) and Politecnico di Milano (Italy); G. Pariani, Politecnico di Milano (Italy) and INAF - Osservatorio Astronomico di Brera (Italy); A. Bianco, INAF - Osservatorio Astronomico di Brera (Italy)

The ability to reversibly change colour upon irradiation with suitable wavelength is the peculiar property of photochromic materials. In organic photochromic switches, the chromic effect is a consequence of the reversible modification of the chemical structure (photoisomerization) and this feature finds application in smart sunglasses and inks. We exploited the light-triggered change in colour of suitably designed diarylethene-based photochromic polymers to develop multi-object focal plane masks for astronomical instrumentation (1) and holographic optical elements for interferometric optical testing (2). With a proper molecular approach it was also possible to enable a light-induced modulation of properties such as light emission, refractive index, dipole moment, nonlinear properties or conductivity, thus opening the way to many other applications into technology. Photochromic polyurethane with a high content of diarylethene units in the main chain has been designed to develop volume phase holographic gratings (3) and rewritable multistate optical memories with stored data to be read with a non-destructive method. Finally, a highly sensitive reversible quenching of amplified spontaneous emission (ASE) and photocurrent of a polyfluorene was achieved through an energy/charge transfer to the photochromic switching unit(4).

8113-28, Session 7

Role of symmetry and planarization in one- and two-photon properties of conjugated compounds based on arylamine donors and arylborane acceptors

N. S. Makarov, J. W. Perry, Georgia Institute of Technology (United States); A. Pron, M. Kivala, K. Müllen, Max-Planck-Institut für Polymerforschung (Germany)

Triarylamine donors and triarylborane acceptors are playing an important role in organic photonics and electronics as chromophores, luminescent compounds and charge-transport materials. The triarylborane group acts as relatively strong electron acceptor comparable to the nitro group. Even though the structure-property relations for two-photon absorption (2PA) of dipolar compounds are well studied, the 2PA properties of systems combining D-A groups in various geometries, such as bent dipolar or octupolar compounds, are not fully understood.

We have examined six triarylamino-triarylborane compounds with one, two or three arms to investigate the role of symmetry, as well as the effect of planarization. We performed studies of 2PA, excited-state absorption (ESA), linear spectroscopy, and fluorescence lifetimes of these systems. We find that the higher degree of symmetry and higher planarity yields larger peak 2PA cross sections. Experimentally determined permanent and transition dipole moments were used with essential states models (two- and three-levels), as well as an excitonic model, for description of 2PA for the low energy transitions.

We have compared the experimental 2PA cross sections with the results of the simple models listed above. Generally, we observe that exciton model explains reasonably the frequencies of the transitions in the multi-arm compounds, and the 2PA cross sections for the lowest-energy transition of three-arm compounds, but it fails in the case of the higher energy band, which may result from further electronic state interactions.

8113-29, Session 8

Optical nonlinearities of triphenylamine substituted tridentate pyridyl ruthenium complexes

X. Yan, M. Yan, P. Lu, South Dakota State Univ. (United States); H. Zeng, East China Normal Univ. (China)

Nonlinear refractive index n2 of four new polypyridyl ruthenium complexes (labeled as 1, 2, 3, and 4) was measured by using Z-scan techniques with femtosecond laser pulses. As a result, large nonlinear refractive indexes of 2.27×10^(-4) cm^2/GW, 11.4×10^(-4) cm^2/GW, 44.8×10^(-4) cm^2/GW and 199×10^(-4) cm^2/GW were measured for the ruthenium complexes 1, 2, 3 and 4, respectively at a wavelength of 800 nm. Time-resolved fluorescence spectroscopy provided interesting behavior which is related to their nonlinear optical response. It was found that the symmetry and coplanarity of ruthenium complex was quite important for obtaining high nonlinear optical refractivity. Meanwhile, no clear nonlinear absorption behavior was found for the four complexes at 800 nm, which indicated that the ruthenium complexes had a large real part of third-order susceptibilities but a very small imaginary part. This will highly extends their potential applications in nonlinear optical fields.

8113-30, Session 8

Hyperpolarizability dispersion in the wavelength domain: prediction using TKS-SOS and verification at long wavelengths using HRS

K. De Mey, Katholieke Univ. Leuven (Belgium)

The search for new non-linear optical (NLO) molecular materials has been one of the main focuses of the organic materials research field for the past decades. The screening of viable candidates for NLO applications has been a tedious work, much helped by the advent of the hyper-Rayleigh scattering (HRS) technique. The downside of this technique is the low efficiency, which usually means that measurements have to be performed at wavelengths that are close to the molecular resonances, in the visible area. This means generally that one has to extrapolate the results from HRS characterization to the longer wavelengths that are useful for applications. Such extrapolation is far from trivial and the 2-level model can only be used for the most straightforward single charge-transfer chromophores. An alternative is the TKS-SOS technique, which uses a few input-hyperpolarizabilities and UV-Vis absorption data to calculate the entire hyperpolarizability spectrum. We have applied this TKS-SOS technique on a set of porphyrines to calculate the hyperpolarizability dispersion. We have also build a tunable HRS set up, capable of determining hyperpolarizabilities in the near infrared (up to 1600 nm). This has allowed us to directly confirm the results predicted in the application region. Due to the very sharp transitions in the hyperpolarizability dispersion, the calculation is subjected to a very precise calibration with respect to the input-hyperpolarizabilities, resulting in very accurate predictions for long wavelength hyperpolarizabilities.

Our results not only underscribe the aforementioned technique, but also confirm the use of porphyrines as powerfull moieties in NLO applications.

8113-31, Session 8

Investigation of nonlinear optical properties of mixed (porphyrinato)(phthalocyaninato) rare-earth double-decker complexes by Z-san technique

Y. Li, M. Yan, M. Jiang, X. Yan, South Dakota State Univ. (United States); J. Jiang, Univ. of Science and Technology Beijing (China)

Nonlinear optical (NLO) materials can provide efficient suppression or extinction of potentially damaging light to human eyes or other delicate elements under conditions of intense irradiation, while allow efficient transmission of low photonic energy under ambient conditions. Among the large number of organic materials, tetrapyrrole compounds, including phthalocyanines, porphyrins, and their analogues, are promising candidates for NLO applications, due to their extensively delocalized π-electron systems, extraordinary stability, tailor-ability, and processability. Due to the strong intramolecular π-π interactions and intrinsic nature of the metal centers, sandwich-type rare-earth tetrapyrrole complexes show extraordinary optical, electronic, thermodynamic and magnetic properties, which have enabled them to be versatile materials such as novel molecular conductors, molecular magnets, molecular electronics, and sensing materials. NLO studies on some sandwich-type rare-earth phthalocyaninato double-decker complexes have been carried out recently. They were found to exhibit reverse saturable absorption, which makes them to be optical limiting materials. However, the results reported thus far on the NLO properties of sandwich-type mixed (porphyrinato)(phthalocyaninato) rare-earth complexes still remain extremely rare.

In this paper, the nonlinear optical properties of a series of mixed (porphyrinato)(phthalocayninato) rare-earth double-decker complexes MH(TClPP)[Pc(α-OC4H9)8] (1-7; M = Sm, Eu, Tb, Dy, Y, Ho, Lu; TClPP = meso-tetrakis(4-chlorophenyl)porphyrinate; Pc(α-OC4H9)8 = 1,4,8,11,15,18,22,25-octakis(1-butyloxy)phthalocyaninate) in dichloromethane have firstly been investigated by using the Z-scan technique with the fundamental (800 nm) laser emission from a Ti:sapphire femtosecond laser system. The nonlinear optical absorption and refraction have been measured with different incident laser power, both of which have shown significant dependence on the metal centers.

8113-32, Session 8

Multi-wavelength top-hat nanosecond Z scans to determine excited-state absorption cross sections of a platinum bipyridyl complex in the visible

W. M. Shensky III, T. Pritchett, U.S. Army Research Lab. (United States); R. Liu, Z. Li, W. Sun, North Dakota State Univ. (United States); M. J. Ferry, U.S. Army Research Lab. (United States)

We report the results of measurements performed on a particular platinum(II) 4,4′-bis[3-ethyl-1-(2-ethylhexyl)heptyl]-2,2′-bipyridyl complex bearing 2-(benzothiazol-2′-yl)-7-ethynyl-9,9-dihexadecyl-fluorenyl units. A similar complex, identical except for the presence of ethyl groups at the 9-position of the fluorenes and tert-butyl groups at the 4- and 4′-positions of the bipyridine, was recently reported to possess a very high ratio of triplet excited-state absorption to ground-state absorption, a quantity that has long been used as a figure of merit for reverse saturable absorbers; in addition, femtosecond transient difference absorption experiments and picosecond open-aperture Z scans have shown it to display broad nonlinear absorption throughout the visible spectrum. In this work, we measured the triplet excited-state absorption cross section at several representative wavelengths between 450 nanometers and 660 nanometers in an open-aperture top-hat Z-scan experiment employing a nanosecond-pulsed tunable optical parametric oscillator (OPO). The open-aperture Z scan is a highly sensitive single-beam experiment used to measure nonlinear absorption. Since the spatial profile of the OPO beam resembled a cross-pattern, we closed an adjustable iris on the beam to create a top-hat profile. A dynamic five-level model was used to fit the Z-scan data.

8113-33, Session 8

Nonreciprocal phase shift enabled by magnetite core-polymer shell nanoparticles embedded in SU-8 cladding on direct laser written polymer waveguide Mach-Zehnder interferometer

A. Lopez Santiago, P. Gangopadhyay, R. Voorakaranam, College of Optical Sciences, The Univ. of Arizona (United States); A. Bablumyan, Tipd, LLC (United States); J. Thomas, R. A. Norwood, N. N. Peyghambarian, College of Optical Sciences, The Univ. of Arizona (United States)

Faraday rotation measurements of magnetite core-polymer shell nanoparticles embedded in SU-8 and their application in direct laser written polymer waveguide Mach-Zehnder interferometers (MZI) are presented. This type of nanocomposite material demonstrates enhanced Verdet constant values due to the long range magnetic coupling between neighboring nanoparticles and is strongly related to the size and concentration of nanoparticles in the polymer matrix host. This exceptional magneto-optic response can be exploited to fabricate integrated waveguide devices such as optical isolators and circulators, magnetic field modulators, and switches by using the magneto-optic nanocomposite as a cladding material and carefully controlling the film thickness to induce a low loss non-reciprocal phase shift via evanescent field effect when a DC magnetic field is applied in the vicinity of the nanocomposite. The losses introduced by the nanocomposite scattering are minimized by employing virtually symmetric and polarization independent polymer waveguides fabricated with a direct laser writing system thus confining the propagating mode in a polymer core with

intrinsic propagation losses of ~0.3dB/cm. A thin film of 120nm of the nanocomposite was deposited on the MZI devices showing a power transfer in the output ports of nearly 23%, while it was negligible in the absence of magnetic field, indicating that the interface refractive index change did not induce birefringence due to nanocomposite deposition.

8113-35, Poster Session

Synthesis and nonlinear optical properties of novel N,N-dihydroxyethyl based molecular organic glasses using triaryl substitutes as amorphous phase formation enhancers

K. Traskovskis, Riga Technical Univ. (Latvia); I. Mihailovs, A. Tokmakovs, Univ. of Latvia (Latvia); V. Kokars, V. Kampars, Riga Technical Univ. (Latvia); M. Rutkis, Univ. of Latvia (Latvia)

Organic materials exhibiting nonlinear optical (NLO) properties are increasing object of interest as an active media in designing of novel optoelectronic devices. Such material together with high NLO activity should meet several other standards. Among them is formation of stable amorphous phase, good optical quality, thermal and chemical resistance. Different material design architectures regarding placement of a NLO active chromophore have been applied to meet those standards: covalent boding to polymer main chain, guest-host systems, dendrimeric compounds and amorphous small-molecular organic glasses. Compared to other approaches small-molecular compounds have several advantages as relatively easy synthesis, well-defined structure, higher purity and increased concentration of active chromophore. Nevertheless, by contrast these compounds have been less explored. To create NLO active material chromophores containing N,N-dihydroxyethyl building block are widely used as polymer precursors. We present series of novel small-molecular materials based on the same building block, with further introduction of triphenylmethyl and triphenylsilyl groups. Presence of these bulky and non-polar substitutes ensures amorphous phase formation of given molecular organic glasses. As NLO chromophores, series of well-known azobenzenes with different electron accepting groups and benzylidene 1,3-indandione derivatives, were used. Results of quantum chemical calculations, synthesis, chemical characterization and experimentally obtained linear and nonlinear optical properties of materials will be presented.

8113-36, Poster Session

Time-resolved optical writing on a photosensitive and fluorescent polymer film

Z. Pan, R. Akrobetu, Fisk Univ. (United States); C. Ryan, A. Saini, J. Shan, Case Western Reserve Univ. (United States); R. Mu, S. H. Morgan, Fisk Univ. (United States)

We have performed time-resolved optical writing experiments on a melt-processed blend of polyethylene terephthalate glycol (PETG) and 1.1 % w/w of 1,4-bis(α-cyano-4-octadecyloxystyryl)-2,5-dimethoxybenzene (C18-RG) film. The C18-RG/PETG can be used for 3D optical data storage, which relies on the laser-induced switching of the aggregation state of an excimer-forming fluorescence dye in the inert host polymer. The optical writing here is realized by the localized excimer to monomer conversion and characterized by the fluorescence change. We obtained time-resolved writing results of excimer to monomer conversion. Our results indicate that the conversion time of excimer to monomer is in the order of 10 ms.

Design and fabrication of a chitosan-based integrated optical device for humidity sensing

A. Mironenko, Institute of Chemistry (Russian Federation)

Recently, polymers and polymer/inorganic hybrids have become of great interest for development of optical waveguides with tailored optical properties. Due to high availability, relatively low cost and good film-forming properties of some of the natural polymers, their use can be considered as an alternative to molecular design of synthetic polymers for optoelectronic applications. Aminopolysaccharide chitosan is one of the most promising biopolymer-candidates for development of optical waveguides and sensor [1, 2]. Advantages of chitosan are not limited to its easy processability. Refractive index of chitosan film can be tailored via metal ions binding, in-situ reduction and stabilization of metal nanoparticles [3] or incorporation of optically active inorganic nanocrystals into the polymer thin film. Moreover, interactions of chitosan, as a hydrophilic polybase, with organic solvents, water vapor, mineral and organic acids change level of polymer hydration and/or protonation degree, and thus, optical properties of the film that is beneficial for sensing application.

Here we report on preparation of optical waveguides and humidity sensors based on chitosan in different salt forms, chitosan/gold nanoparticles and chitosan/gold nanoparticles/silica hybrides with layered structure. Chitosan-based optical waveguides were obtained on quartz, glass and MgF2 substrates by spin-coating and dip-coating. For investigation of optical properties, the light (wavelength 632 or 532 nm) was coupled into the planar waveguide via the flint glass prism using goniometer. A number of modes, effective refractive index, waveguide propagation losses were determined for all samples in the range of relative humidity 10-99%. It was demonstrated that chitosan-based thin films could be used as humidity sensors with fast response time (0.3-1 s), and highest sensitivity was found for chitosan/gold nanoparticles/silica hybrids with layered structure.

Stable frequency doubling by all-optical poling in dye-doped polymer optical fibres

R. Barille, Univ. d'Angers (France); J. Nunzi, Queen's Univ. (Canada); B. Luther-Davies, A. Samoc, The Australian National Univ. (Australia); M. Samoc, Wroclaw Univ. of Technology (Poland)

We present experimental studies of all-optical poling in large-core dye doped poly-methylmethacrylate plastic optical fibres. We show that the confinement of light within the fibre core permits to reach the upper limit of second harmonic generation achievable by all-optical poling using repeated trans-cis isomery. Quantification of the output power provides clear demonstration that self-seeding can counteract relaxation of the orientation during readout of the induced nonlinearity.

Strong intramolecular coupling in organic cyclic aggregates

J. Donehue, O. Varnavski, T. G. Goodson III, Univ. of Michigan (United States)

A series of π-extended cyclic thiophene oligomers of 12, 18, 24, and 30 repeat units have been studied using methods of ultrafast time-resolved absorption, fluorescence up-conversion, and three-pulse photon echo. Previous study of these molecules showed evidence of cooperative enhancement in their nonlinear optical responses, and the ultrafast measurements were conducted in order to examine the structure-function relationships that may affect the coherence between chromophores within the organic macrocycles. Our results indicated an initial delocalized state can be seen upon excitation of the cyclic thiophenes. Anisotropy measurements show this delocalized state decays on an ultrafast timescale and is followed by the presence of incoherent hopping. Using theoretical models, we concluded our ultrafast anisotropy decay measurements suggest the system does not reside in the Förster regime and coherence within the system must be considered. Three-pulse photon echo peak shift experiments reveal a clear dependence of initial peak shift with ring size, indicating a weaker coupling to the bath (and stronger intramolecular interactions) as the ring size is increased. Our results suggest that the initial delocalized state increases with ring size to distances (and number of chromophores) comparable to the natural light harvesting system.

Ultrafast energy transfer in Pt-containing macromolecules at low temperature

D. Flynn, T. G. Goodson III, Univ. of Michigan (United States)

Platinum containing macromolecular structures are important for the development of novel optical, electrical, and energy related applications. These materials are potentially promising for optical limiting and other nonlinear absorption applications. Previous experiments have detailed the nonlinear optical properties of these materials. And in this poster we present information regarding the fundamental excitations in these systems utilizing ultra-fast pulses. In these studies we utilize fluorescence upconversion to probe the relaxation process with very fast time resolution. We also investigate the materials in neat samples where the concentration is particularly high to offer investigation of the inter-molecular interactions as well. We have carried out low-temperature measurements to probe the fundamental excitations and dynamics of the energy transfer and molecular dynamics of these interesting materials. The ultrafast dynamics of aggregated platinum acetylide complex has been investigated by femtosecond fluorescence upconversion down to 4.2 Kelvin. The results of this study are used to describe the mechanism for the enhanced nonlinear properties of platinum acetylide.

Synthsis of the novel beta-cyclodextrin-chromophore inclusion compound and research on the electro-optic activity of its systems

S. Bo, Z. Chen, Z. Zhen, X. Liu, Technical Institute of Physics and Chemistry (China)

Cyclodextrins (CDx's) have been the subject of many studies in the field of supramolecular chemistry due to their ability to bind a variety of organic compounds within their hydrophobic cavities via noncovalent interactions. In this work, we formed β-cyclodextrin-chromophore inclusion compounds by embedding dumb-bell shape chromophores in the β-cyclodextrin. β-cyclodextin-chromophore inclusion compound was calculated to have a binding energy of 16.1 kcal/mol, which meant the compound was steady. Since it is inconvenient to purify the inclusion and spin coat in polymers. A donor-β-cyclodextin inclusion compound was formed firstly, and then bonded to the accepter. The NLO chromophore and the inclusion compound were characterized by UV-Vis, FT-IR, MALDI-TOF, and 1HNMR. Thermal properties of the inclusion compounds were characterized by DSC and TGA. The highest EO coefficient (r33) of the β-cyclodextrin-chromophore inclusion compound in the polymer is about three or four times than the NLO chromophores in the polymer at 1310 nm. So, there results show this inclusion compound could reduce electrostatic interactions between the NLO chromophores and improve polarization efficiency because of the big distance between any chromophore in β-cyclodextrin inclusion compound. Highly stable NLO properties have been achieved through inclusion compound, and the EO coefficients values of the polymer films could keep 90% of the original ones even after 500 hours under 80 . We provides a convenient method to reduce the aggregation of chromophores and enhance the electro-optic activity in different polymer systems for technical bottleneck of the nonlinear optical materials.

Synthesis and nonlinear optical properties of a novel crosslinkable system containing TCF-based chromophores

Z. Chen, S. Bo, Z. Zhen, X. Liu, Technical Institute of Physics and Chemistry (China)

In the crosslinkable system, poling process generally goes with crosslinking progress, and then the rigid polymer chains would limit the movement of the chromophores, thus the poling efficiency and the EO coefficient of the crosslinked polymer may be lower than the guest-host polymer system and uncrosslinked polymer system. For this reason, only a relatively small number of thermal crosslinking reactions have been reported in the field of organic second order nonlinear materials, just like Huisgen reaction and Diels-Alder cycloaddition. In this work, a novel crosslinkable polymer with side-chain system was investigated to increase the content of NLO chromophores and to improve the stability of oriented chromophores in second order nonlinear optical materials. A series of crosslinkable copolymers which bear different concentrations of strong push-pull type chromophores with the tricyanofurane (TCF) acceptor were successfully synthesized. The NLO monomer and the copolymers were characterized by 1HNMR, MS and GPC. Thermal properties and EO coefficients (r33) of the uncrosslinked and the crosslinked NLO copolymers were also characterized and discussed. For our synthesized copolymer system, the similar EO coefficients can be achieved in the uncrosslinked and crosslinked NLO copolymer films, since the crosslinking temperature (Tc) has to be above to the glass transition temperature (Tg) to ensure an efficient poling of the chromophores before the crosslinking reaction starts. Higher stable NLO properties occur in the crosslinked copolymer, such as the EO coefficient values of crosslinked NLO copolymer films could keep 83% of the original ones even after 500 hours at 80 degrees Celcius.

Non-linear optical time-resolved studies on dendritic oligothiophene-perylene bisimide hybrids

J. Zhang, Univ. of Michigan (United States); M. K. R. Fischer, P. Bäuerle, Univ. Ulm (Germany); T. G. Goodson III, Univ. of Michigan (United States)

A series of novel dendritic oligothiophene-perylene bisimide hybrid (DOTPBI) system, as novel dendritic p-n heterojunction materials, up to the second generation (G0, G1, G2) was investigated using non-linear optical time-resolved measurements. Results of these measurements reveal the ability of these molecules to undergo intramolecular

fluorescence resonance energy transfer (FRET) from the DOT to the PBI moiety. In addition, the existence of delocalization of the excited state in the DOTPBIs was discovered. The photoinduced electron transfer (PET) process is facilitated by increasing the DOT generation and donor strength, and increasing the distance between the donor and acceptor. Although both thiophene dendrons and PBIs have extremely rigid structures, in the higher generation, a high degree of structural conformational flexibility of the perylene exists. This distorted structure and the energy migration time scale explains the decreased lifetime of the fluorescence and the ultrafast excited state relaxation dynamics.

Conference 8114: Liquid Crystals XV

Sunday-Monday 21-22 August 2011 • Part of Proceedings of SPIE Vol. 8114 Liquid Crystals XV

8114-01, Session 1

A combined study of mesomorphism, optical, and electronic properties of donor-acceptor columnar liquid crystals

S. H. Eichhorn, M. Ahmida, H. Kayal, S. Chen, Univ. of Windsor (Canada); B. R. Kaafarani, American Univ. of Beirut (Lebanon)

Donor-acceptor structures are commonly found in polymeric semiconductors but have been little studied in columnar liquid crystals. [1] Presented here are two new types of donor-acceptor liquid crystals that both form columnar mesophases. All compounds show rich polymesomorphism (different columnar and nematic mesophases) that affect their alignment, optical and electronic properties. Charge carrier mobility of discotic compounds based on extended hexaazatrinaphthalene cores, for example, sharply increases at the transition from a Col(r) to a Col(h), which is reasoned with the associated change in charge transfer integrals of occupied and empty frontier orbitals. Interestingly, electron and hole mobility are not equally affected and derivatives that show electron but no hole mobility will be presented. Board-shaped liquid crystals based on a quinoxalino[2',3':9,10] phenanthro[4,5-abc]phenazine core form rectangular and hexagonal columnar mesophases despite their large aspect ratios of 1:5-6. All compounds are highly fluorescent in solution and in their mesophases but, more importantly, their fluorescence intensity reversibly decreases with increasing temperature within one mesophase. Computational studies confirm that these changes in fluorescence intensity correlate with changes in molecular mobility and intracolumnar packing.

Confined blue phases: trapping of colloidal particles in new disclination superstructures

S. Zumer, Univ. of Ljubljana (Slovenia); M. Ravnik, Univ. of Oxford (United Kingdom); J. Fukuda, National Institute of Advanced Industrial Science and Technology (Japan)

Following revival of interest in blue phases stimulated by the new broad temperature range materials [1] we have recently examined stable colloidal blue phases [2,3]. The Landau - de Gennes description and topological theory has proven to be extremely useful in dealing with nematic and blue phase colloids [4,2,3]. Here we use our experience with bulk blue phase colloids to focus on confined blue phases. Recently we have found that confinement to thin layers yields numerous disclination networks not present in bulk blue phases. In case of homeotropic anchoring at certain layer thickness we have found that double twist cylinders are accompanied by disclinations forming double helices [5]. In case of planar anchoring a 2D lattice of disclination rings have been found [6]. Such networks represent complex effective trapping potentials that mediate the attraction of particles to disclinations. This process allow for a self-assembling of superstructures in confined blue phases. Here we examine effects of particle properties and sizes. Such assemblies can lead to colloidal crystals that can be manipulated via affecting the liquid crystal matrix and/or colloidal particles by external stimuli. We expect that some of these assemblies will open new ways to photonic applications. [1] F. Castles et al. PRL 2010, [2] S. umer et al., Proc. SPIE 77750H 2010, [3] M. Photomobile polymer materials: from nano to macro

T. Ikeda, Tokyo Institute of Technology (Japan)

An actuator is an energy transducer that can convert input energies of a variety of forms into mechanical work. Many actuators that respond to various external stimuli have been developed. Crosslinked liquid-crystalline (LC) polymers show a strong coupling between the alignment of mesogens and the conformation of polymer chain, which gives rise to the characteristic properties of the crosslinked LC polymers. If the crosslinked LC polymer is heated toward LC-isotropic phase transition temperature, the order of the mesogens decreases, and the mesogens become disordered when the temperature exceeds the phase transition temperature. With this phase transition, the crosslinked LC polymers in general show contraction along the alignment direction of mesogens. If photochromic molecules such as azobenzene are incorporated into crosslinked LC polymers, the LC-isotropic phase transition can be induced isothermally and reversibly by photoirradiation. Then a variety of three-dimensional movements of the polymers can be brought about just by photoirradiation. Light-driven polymer actuators are promising in a wide range of micro- and macroscale devices. We will show some recent examples of the three-dimensional movements of crosslinked LC polymers in response to light.

Nanoparticle-doped isotropic liquid crystal for sensor protection

A. V. Parfenov, X. Xia, A. Shapoury, E. A. DeHoog, F. Zhang, S. Pradhan, T. M. Aye, M. Shih, Physical Optics Corp. (United States)

Advances in protecting the eye or optical sensors and visual devices from laser radiation are particularly important with operations in intelligence, surveillance, and reconnaissance (ISR) becoming increasingly critical, not only in the military and law enforcement communities, but also in other commercial fields where imaging using intense light is required. Various nonlinear optical materials and devices have been investigated and developed to meet the challenge of protecting the sensing devices from laser radiation of wide spectral and temporal ranges. In most devices, the nonlinear absorption mechanism at a specific wavelength has been used for optical limiting; and the material has to be placed in the focal plane of the optical system in order to utilize the increased laser energy fluence to achieve the desired limiting performance characteristics. In this paper, we demonstrate a novel high-speed, multiple-notch broadband passive optical switching material to selectively discriminate bands of electromagnetic radiation in ISR systems. This new material is composed of isotropic liquid crystal (ILC) blended with semiconductor nanoparticles, and has demonstrated fast response (~1 ns), high nonlinear 3rd order optical Kerr coefficients (light-induced refractive index change, n2 = ~4E-9 esu) exceeding 200 300 times of classic nonlinear material CS2 with n2 = 1.2E-11 esu. Unlike conventional absorptive notch switches, our device is based on passive "notched-out" reflection resulting in negligible heating that is in particular desired by the close-by near or short-wave IR imaging sensors when applied in day/night and all inclement weather conditions. Details of fabrication and experimental results will be presented.

8114-05, Session 2

Spatial optical soliton used as a spectral probe in colloids of liquids crystals and nanoparticles

J. Henninot, J. Blach, M. Warenghem, Univ. d'Artois (France)

Since 10 years, Spatial Optical Solitons (SOS) have been widely studied in Nematic Liquid Crystal (NLC) for their potential application in optical routing or switching devices. In this work, we describe another use of spatial optical solitons: the recovery of a spectral signal escaping from a soliton propagating into a nanoparticles/NLC colloid. As a dye is mixed

with the colloidal suspension, the induced fluorescence is trapped within the soliton, collected by a fiber and analysed in a spectrometer. To the best of our knowledge, this is the first time that a spectral analysis is performed through a spatial soliton. We demonstrate first the enhancement of the fluorescence intensity recovery by comparing the collected fluorescence signal of quinizarin in a NLC host (5CB), excited either by a spatial soliton or by a freely propagating beam induced between two optical fibers. The enhancement factor is in the order of 4. Next, we collected a set of spectra, for different inter-fiber distances d, from 125 to 500 microns, at constant input pump power. The main result is that the signal of fluorescence is quite constant whatever the d values. A model based on the waveguide properties of the soliton will be presented and confirms such a behavior. Finally we will give recent results concerning the localization of polystyrene particles inserted in NLC host by spectral analysis during the scanning of the sample by a soliton.

8114-06, Session 2

Spatial light modulators: a tool to image multiple-scattering media

S. Gigan, S. Popoff, P. Bondareff, N. Curry, S. Farahi, F. Ramaz, G. Lerosey, S. Grésillon, M. Fink, A. C. Boccara, Ecole Supérieure de Physique et de Chimie Industrielles (France)

Scattering of coherent light in heterogeneous biological media and tissues, leads to strong scattering and interferences phenomena which destroy both the spatial amplitude and phase information of any laser illumination. At the spatial level, it gives rise to the well-known “speckle” interference patterns. At the temporal (or spectral) level, a short pulse entering a scattering medium will be stretched due to the multiplicity of path lengths in the propagating medium. Consequently this greatly limits the imaging of an object through a scattering medium.

Multiple scattering is a highly complex but nonetheless deterministic process: it is therefore reversible, in the absence of absorption. Speckle can be coherently controlled. By « shaping » or « adapting » the incident wavefront, it is in principle possible to control the propagation and to overcome the scattering process.

Liquid crystal spatial light modulator (SLM) is a tool of choice to shape a laser beam over a very large number of modes, in order to match the high complexity of a multiple scattering medium. I will show how, using a SLM, one can measure the transmission matrix which links the input - output modes of the scattering medium. We present our original approach of solving the inverse problem for the reconstruction of an arbitrary image through the scattering media. I will detail our recent experiments with phase SLMs applied to, spatial -temporal focusing, imaging and phase conjugation through a thick opaque multiple scattering media. These experimental results confirm that phase-only SLMs are well suited to control laser light propagation in scattering media.

8114-08, Session 2

Graded-subdomain diffraction grating based on a nematic liquid crystal with semi-radial alignment

J. Kim, J. Na, S. Lee, Seoul National Univ. (Korea, Republic of)

Liquid crystals (LCs) are widely used for optical devices due to the large electro-optic modulation resulting from the high optical anisotropy, the electrically tuning capability at low voltages, and the design flexibility on various substrates. Among a number of the LC devices, the LC grating elements play an important role in many optical systems such as 3-dimentional displays and optical data storages through the modification of the phase or the polarization of light. In typical LC gratings, the uniform alignment of the LC molecules has been employed for obtaining the constant phase retardation from one domain to the other. Recently, for certain applications, graded types of the LC gratings have been fabricated using a micro-rubbing method, a graded-electrode patterning method, and a photo-alignment method based on either multiple laser beams or the optical interference but they suffer from the continuity in the graded phase retardation within each domain. In this work, we demonstrate a new type of the LC grating device exhibiting the continuously graded phase retardation where the semi-radial alignment of a nematic LC is spontaneously produced on a microgrooved surface constructed by imprinting. Our graded LC grating device with the semi-radial LC alignment provides the high diffraction efficiency with the continuity in the phase retardation.

8114-45, Session 2

Liquid crystal-coil block copolymers: from hierarchal micelles to responsive monolayers

P. Pirogovsky, Z. Kurji, R. Hule, J. A. Kornfield, California Institute of Technology (United States)

The spontaneous anisotropy of side-group liquid-crystal polymers (SGLCPs) in a nematic solvent leads to ordering on multiple length scales when an SGLCP block is covalently linked to a random coil polymer. Micelles that form in a nematic solvent can have anisotropy at the level of the SGLCP chains in the corona that is orthogonal to the anisotropy of the micelle core that is, in turn, orthogonal to the anisotropy of the assembly as a whole. The orientational coupling between the SGLCP-block and the nematic liquid can be used to “transduce” changes in the conformation of the coil domain when it resides that the interface between an LC and an aqueous solution. Structural characterization by neutron scattering will be presented, along with examples of potential applications of LC-coil block copolymers.

8114-09, Session 3

Molecularly oriented surface relief formation and multi-directionally oriented crossed gratings in photoreactive liquid crystalline copolymer films

N. Kawatsuki, A. Tashima, Univ. of Hyogo (Japan); H. Ono, Nagaoka Univ. of Technology (Japan)

Photo-control of the molecular reorientation has received much attention in fabricating of polarization-sensitive and polarization-controllable optical devices. In this contribution, we demonstrate surface relief (SR) gratings and crossed SR gratings with molecularly oriented structure using photo-cross-linkable liquid crystalline copolymer films. For intensity holography, SR gratings were formed after annealing the exposed films, where the molecular migration to the higher-exposed region occurred. The reorientational direction and SR height were dependent on the degree of the photoreaction. When the exposure doses were low, molecular reorientation at the convex region was generated. In contrast, higher exposing doses resulted in the molecular reorientation at the concave area. Additionally, molecular reorientation was not generated for the much higher doses, although SR structure was formed. The generated SR height reached up to 300 nm for a 1μm-intial film, and the resulting gratings showed polarization sensitivity for diffraction efficiencies of the probe light beam according to the molecularly reorientation direction. Furthermore, combining the multi-holographic exposure and the unidirectional linearly polarized UV light exposing yield multi-directionally oriented film structure. Surface topology, molecular orientation and diffraction properties of the fabricated gratings were discussed.

8114-10, Session 3

Measuring Sagnac effect using liquid crystal adaptive holography

S. Residori, U. Bortolozzo, J. Rubin, Institut Non Linéaire de Nice Sophia Antipolis (France); J. Huignard, Jphopto (France)

Sagnac effect, due to different optical paths of counterpropagating waves in a rotating system, attracts a lot of attention both for its fundamental interest and its important applications in rotation sensing. For enhancing Sagnac detection different systems have been proposed, such as ring laser gyroscopes [1], fiber gyroscopes [2], nonlinear interferometers [3-5] and, recently, slow and fast light interferometers [6-7]. Here, we show the first realization of nonlinear Sagnac detection, which is made by inserting a liquid crystal light-valve, LCLV, in a Mach-Zehnder interferometer. The detection is based on slow-light effects [8] and adaptive holography [9] in the LCLV.

Two-wave mixing between the beams traveling clockwise, respectively, counterclockwise, in the interferometer is performed, while the whole experiment is mounted on a rotating platform. Before interfering in the LCLV the two beams acquire a differential phase shift due to the Sagnac effect. The refractive index grating induced in the liquid crystals is highly sensitive to instantaneous phase changes, therefore, by measuring the intensity of the diffracted orders we can obtain direct information on the Sagnac effect.

The liquid crystal response time [10] provides a frequency bandwidth determining two detection regimes: at low variation rate of the rotation speed, the LCLV operates in the slow-light regime providing a direct measurement of the angular acceleration [11]. For fast variation rate of the rotation speed, the interferometer detects, instead, the amplitude of the Sagnac phase shift. In both case, the adaptive character of the wave-mixing in the liquid crystals fixes automatically the optimum detection condition.

Anchoring strength of o-, m-, and p-methyl red-dye-doped nematics on rubbed and unrubbed polyimide surfaces

D. Statman, Allegheny College (United States)

It is demonstrated that the photoinduced gliding of the easy axis for nematics doped with various azo dyes on rubbed polyimide involves the formation of a second easy axis on the polyimide surface. While some azo dyes, such as disperse orange 3, do not exhibit large surface induced nonlinear effects, other dyes, such as methyl red, do. The amount of gliding on rubbed polyimide is determined by the relative anchoring strengths of the easy axis formed from adsorbed dye and that formed from rubbing. One question of interest is what is the source of the anchoring strength? In this presentation, I will discuss the formation of easy axes via the photo-induced adsorption of azo dye. Using the results of optical measurements, I compare the anchoring strengths between dyed nematic liquid crystals and the easy axes formed by photoinduced adsorption of three isomers of the methyl red azo dye, ortho, meta, and para. I will also discuss the impact of the carboxyl group position in the dye molecule on the anchoring strength.

8114-12, Session 3

Monitoring anchoring energy in LC-based sensors

R. G. Lindquist, Y. Zou, D. Ke, The Univ. of Alabama in Huntsville (United States)

Liquid crystal (LC) based sensors have been investigated over the past decades in an effort to develop low cost, portable, field-deployable, highly selective chemical and biological sensors. Due to the collective behavior and the highly anisotropic properties of liquid crystal molecules, detection of very low levels (ppbs) of chemical and biological agents is possible. However, present LC sensors rely on a threshold concentration of a targeted analyte to cause a surface driven molecular reorientation of the LC molecules. At a lower concentration, a molecular reorientation will not be induced and thus undetected by passive transduction. The surface anchoring energy maintaining the initial molecular alignment will, however, weaken. By forcing a reorientation of LC molecules near the surface with an applied electric field and then tracking the deformation via capacitive transduction, the anchoring energy can be monitored. In this paper, we present a technique to significantly improve the sensitivity of LC - based sensor by monitoring changes in anchoring energy via capacitive transduction.

Theoretical and experimental results indicated a minimum of 10-fold and potentially 1000-fold improvement can be achieved. Several electrode structures have been investigated with preliminary experimental results closely matching the simulations. By incorporating these techniques with microfluidic systems, portable, compact and highly sensitive chemical and biological sensors can be achieved for either gas or liquid environments. Preliminary experimental results with LC in microfluidics channels will be presented.

8114-03, Session 4

Metallic subentities embedded in micro-periodic composite structures for the realization of metamaterials

L. De Sio, R. Caputo, U. Cataldi, Univ. della Calabria (Italy); J. Dintinger, H. Sellame, T. Scharf, Ecole Polytechnique Fédérale de Lausanne (Switzerland); C. Umeton, Univ. della Calabria (Italy)

We report on the fabrication and characterization of a micro periodic structure realized in soft-composite materials containing metallic nanoparticles. These are used to infiltrate a passive polymer template realized by combining an optical holographic curing setup and a microfluidic etching process. In experiments, a small amount of nanoparticles are dissolved in the original mixture normally utilized for the realization of polymer-liquid-crystal-polymer-slices gratings (POLICRYPS) in order to fabricate POLICRYPS-like structures showing novel electromagnetic (metamaterial) properties. Obtained structures are characterized towards the impinging probe light polarization in the UV/visible range. Correlation between the optical response and external perturbations (electric field, temperature) is also reported. First attempts are oriented to the fabrication of devices with tuneable metamaterial properties.

8114-13, Session 4

Nanoparticle-dispersed cholesteric blue phase and its electro-optic and photonic applications

M. Ozaki, H. Yoshida, S. Yabu, Y. Tanaka, Y. Ogawa, A. Fujii, Osaka Univ. (Japan); N. Uehara, Santec Corp. (Japan); H. Kikuchi, Kyushu Univ. (Japan)

Cholesteric blue phases (BPs) appear in very narrow temperature range because of the inevitable existence of disclinations. We have proposed the BP stabilization by introducing nano-scale particles into BP LC. With doping spherical gold nanoparticles (NPs) with a mean diameter of 3 nm in a BP-exhibiting LC using a unique technique without having to chemically modify NPs' surfaces, the temperature range of the BPs expanded from 0.5 to 5 oC. We tentatively interpret that the NP localization in the lattice disclinations stabilizes the BP structure, which is similar to that of polymer-stabilized BPs. We also discuss about not only phase transition characteristics but also electro-optic and photonic behaviors in NP-doped BP LC. Using the stabilized BP LC, polarization independent refractive index modulation was demonstrated, which is expected to use in a telecommunication application. The light propagation and emission characteristics in BP and NP-doped BP LCs have also been investigated using both a numerical calculation and experimental approaches.

Novel photorefractive CdSe/CdS nanorods liquid crystal nanocomposites

L. L. Petti, M. Rippa, Consiglio Nazionale delle Ricerche (Italy); M. Zanella, L. Manna, Istituto Italiano di Tecnologia (Italy); P. Mormile, Consiglio Nazionale delle Ricerche (Italy)

Nematic liquid crystals (NLCs)-based photorefractive materials are very attractive for photonic applications such as dynamic hologram, optical information processing, phase coniugation and optical switching because of their large optical anisotropy, low driving voltage, and large electro optic effects.

Multimaterial nanocrystal heterostructures that contain two or more different functionalities are attractive candidates for enabling the bottom-up fabrication of unprecedented materials. CdSe/CdS nanorods present the appealing characteristics of strong and tunable light emission from green to red, are highly fluorescent and show linearly polarized emission.

These characteristics open the way to a new class of nanocomposite devices based on LCs and colloidal NRs in which the unique optical properties of the inorganic moiety are combined with the electro-optical and the large optical anisotropy of the host system to develop new high performing optical and photonic devices/systems. In the present contribution we designed and fabricated novel nanocomposites devices prepared by incorporating CdSe/CdS core/shell nanorods into a NLC to realize homeotropically aligned cells. We studied the photorefractive and the orientational responses of these samples by both asymmetric two- beam coupling to measure two beam coupling gain and diffraction efficiency under the influence of an applied electric field, and forced light scattering technique. Nanorods alignment with the orientation of the LC molecules has been also investigated. A refractive index grating was written in the device in a holographic tilted configuration by two p-polarized laser beams at 514 nm. Self-diffraction of the writing beams and diffraction of a probe beam at 633 nm were measured. A high TBC gain coefficient of 270 cm−1 was achieved at a DC field applied of 3.4V/μm. First-order diffraction efficiencies were evaluated with a maximum efficiency of 7% in the dynamic grating with a nonlinear refractive index, n2, 4 × 10−2 cm2/W for E0 = 3V/μm.

8114-15, Session 4

Toward cloaking in nanosphere dispersed liquid crystal (NDLC) metamaterial: Monte Carlo studies

G. Pawlik, W. Salejda, K. Tarnowski, W. T. Walasik, A. C. Mitus, Wroclaw Univ. of Technology (Poland); I. C. Khoo, The Pennsylvania State Univ. (United States)

We discuss cloaking at infrared frequencies in NDLC metamaterial [1] using Monte Carlo and FEM methods. It requires a design of an inhomogeneous configuration of liquid crystal molecules which corresponds to the spatial inhomogeneity of effective permittivity and permeability resulting from optical transformation. Recently, we have shown that external electric field and anchoring forces [2,3] as well as filling factor and size of coated nanospheres [4] constitute relevant parameters for tuning of the magnitude and gradients of local optical properties of NDLC. We present first results for cloaking in NDLC at chosen infrared frequencies.

8114-16, Session 4

Nanomaterials dispersed in liquid crystals: how they change LC-properties

W. Haase, Technische Univ. Darmstadt (Germany)

It is well known small amount of nanomaterials dispersed in Liquid Crystals can change their physical properties remarkably. This allows for practical application, although the so far reported properties are in part wide spreading.

Within this Invited Talk our recent results on Nanodispersions of Carbon Nanotubes, of metallic functionalized particles like gold and silber and of dipolar particles like Bariumtitanate in Nematic and Ferroelectric Liquid Crystals will be presented and discussed.

8114-18, Session 5

Photochemical on-off switching of structural color of a multi-bilayered film consisting of azobenzene-polymer liquid crystal and polyvinylalcohol

S. Kurihara, M. Moritsugu, Y. Kuwahara, T. Ogata, Kumamoto Univ. (Japan)

We have found that some side chain type polymer liquid crystals having an azobenzene group as a side chain group showed thermally spontaneous out-of-plane molecular orientation by annealing at a smectic phase. We prepared a multi-bilayered film consisting of PA6Az1, which is one of the azobenzene polymer liquid crystals, and polyvinylalcohol (PVA) on a glass substrate by spin coating of the polymer solutions alternately. The multi-bilayered film reflected light of a wavelength depending on the layer thickness as well as refractive index of the polymers. The reflectivity of the multi-bilayered film disappeared by annealing at 80 °C. The disappearance of the reflection by the annealing was related to the thermal out-of-plane molecular orientation of PA6Az1 in the multi-bilayered film, leading to very small difference in refractive

indices between PA6Az1 and PVA. The reflectance of the multi-bilayered film was increased again by UV irradiation because of the transformation from the out-of-plane orientation to the in-plane random orientation. The on-off switching of the reflection was achieved by the combination of the thermally spontaneous out-of-plane molecular orientation and following photoisomerization of PA6Az1.

8114-19, Session 5

Optofluidics based on liquid crystal microflows

A. E. Vasdekis, J. G. Cuennet, L. De Sio, D. Psaltis, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Optofluidics emerged in early 2000 as the fusion between integrated optics and microfluidics, focusing primarily on novel photonic devices and analytical methods [1, 2]. Typical examples involve light sources [3] and waveguides [4], but also miniaturized microscopes [5] and adaptive imaging components. Optofluidics has also significantly impacted the field of molecular manipulation and sensing, with the recent demonstration of sub-100 nm particle trapping [6], and the manipulation of fluids via laser radiation [7].

In this presentation, we will discuss our recent efforts in optofluidics based on anisotropic fluids. To this end, we replaced common microfluidic buffers with nematic liquid crystals in microfluidic channels and controlled the director orientation via flow. Rapid pulsatile flows were possible via micro-flow engineering and integrated micro-pumps. We will present the steady state analysis of liquid crystal molecules inside the channels and present the results of our recent efforts in developing optical modulators operating in the kHz regime [8].

8114-20, Session 5

Photodriven, multidimensional oscillation of glassy azobenzene liquid crystalline polymer networks

K. Lee, M. L. Smith, H. Koerner, Air Force Research Lab. (United States); N. Tabiryan, BEAM Engineering for Advanced Measurements Co. (United States); R. A. Vaia, T. J. Bunning, T. J. White, Air Force Research Lab. (United States)

Glassy, photoresponsive monodomain azobenzene liquid crystalline polymer networks (azo-LCN) are prepared by photo-polymerization, and show large amplitude, high frequency in-plane oscillation (~ 50 Hz) when exposed with a 442 nm coherent-wave (CW) laser. In addition to the in-plane oscillation, multidimensional out-of-plane twisting behaviors are observed by adjusting the orientation of the nematic director to the long axis of the azo-LCN cantilever. The frequency of photodirected oscillations is strongly correlated to the length of the cantilever (width/length ratio), while the amplitude and threshold laser intensity for oscillation are strongly correlated to temperature. The effect of cantilever aspect ratio, laser intensity, and temperature on the photoresponsive bending, twisting and oscillation behaviors of azo-LCN will be discussed.

8114-21, Session 5

Simple and functional photonic devices from printable liquid crystal lasers

D. J. Gardiner, P. J. W. Hands, S. M. Morris, T. D. Wilkinson, H. J. Coles, Univ. of Cambridge (United Kingdom)

We report on printable laser sources formed by the emulsification of dye-doped chiral nematic liquid crystals within a polymeric binder. Such lasers can be easily formed on single substrates with no alignment layers. The system comprises the self-organizing periodic structure of chiral nematic liquid crystals with the simplicity of the emulsion procedure so as to produce a material that retains the emission characteristics of band-edge lasers yet can be readily coated. [1]

Under optical excitation, it is shown that it is possible to generate both single-mode photonic band edge [2] and random lasing [3] depending upon the droplet morphology. Specifically, the laser output is determined by the size and number density of the droplets. Band-edge lasing is observed for large droplets (tens of μm) and low number densities. On the other hand, small droplets (< 10μm) and high number densities, promotes random lasing via a diffuse scattering feedback mechanism. The preparation, characterization and optical output of both types of emulsion-based sources are discussed in detail. Finally, sequential and stacked layers demonstrate simultaneous multi-wavelength (white) laser output from glass, metallic and flexible substrates, permitting new application areas into mass manufacturable, flexible and conformable laser devices.

8114-22, Session 5

Broadband ultrafast all-optical processing with nematic liquid crystals

K. Hong, S. Zhao, I. C. Khoo, The Pennsylvania State Univ. (United States)

We present a critical review of the nonlinear optical responses of transparent as well as plasmonic- or dye-doped nematic liquid crystals. Experimental studies have demonstrated the feasibility of sub-microseconds - nanoseconds all-optical one-way switching of nanoseconds pulsed lasers spanning the entire visible - near infrared regime (488nm, 532 nm, 750 nm, 1060 nm, 1550 nm). These effects will be useful for developing tunable metamaterials and to realize faster-response version of many coherent optical image processing applications demonstrated previously with slower mechanisms.

8114-23, Session 6

Diffuse cone behavior and microscopic structure of the de Vries smectic-A and smectic-C phases

S. Kumar, Kent State Univ. (United States)

In the smectic-A (SmA) and smectic-C (SmC) liquid crystal phases, calamitic molecules are arranged in layers. In the uniaxial SmA phase, the director is parallel to the layer normal but tilted at a polar angle α(T) in the SmC phase. In conventional cases, the director tilt occurs in a well defined azimuthal direction and the corresponding layers shrinkage is can be as high as ~11%. In 1979, deVries discovered materials in which the layer shrinkage was about an order or magnitude smaller, and yet the system transformed from uniaxial to biaxial smectic phase. He proposed that the local director is already tilted in the SmA phase, but without any coordination in the azimuthal direction. In the SmC phase, the aximuthal tilt becomes increasingly coordinated with decreasing temperature rendering the phase biaxial. This “diffuse cone model” has been investigated by various groups, but the evidence obtained has mostly been indirect. In our x-ray experiments, we directly measured the molecular tilt, director orientation, and find differetn values of the nematic order parameters for the siloxane and hydrocarbon parts of the molecules. Specifically, the results show that exponent of the tilt order parameter β agrees with tricritical behavior. Among other results, we also show that linear extrapolation of the thermal evolution of SmA layer spacing into the SmC region requires modification. These results provide a quantitative picture of the structure of the two deVries phases and the transition between them which changes from second order to first order for different homologs.

8114-24, Session 6

Liquid crystal beam shaping devices employing patterned photoalignment layers for high-peak-power laser applications

K. L. Marshall, S. K. H. Wei, K. Wegman, M. Vargas, C. Dorrer, P. Leung, J. Boule, Z. Zhao, S. Chen, Univ. of Rochester (United States)

Optical elements with spatially varying transmission are required for laser engineering and imaging systems. Although refractive systems can transform the Gaussian energy distribution of a laser beam into a “top-hat” distribution, they lack the versatility to produce the more complex and precise intensity distributions required for high-peak-power laser systems such as the OMEGA land OMEGA EP laser systems at the University of Rochester’s Laboratory for Laser Energetics and the National Ignition Facility at Lawrence Livermore National Laboratory. Previously, distributions of opaque metal pixels on a transparent glass substrate have been used for such beam-shaping efforts, but the laser damage thresholds of the order of 0.2 J/cm2 in the nanosecond regime limits their applicability. By applying the process of photolithographic patterning of either cinnamate-based or coumarin-based photoalignment layers using polarized UV light to generate spatially-varying molecular orientation in a nematic liquid crystal device, we have developed and demonstrated high-resolution beam shaper devices optimized for such high peak power laser applications in the near IR region. Operating at 1054 nm, these devices demonstrated a contrast ratio of 430:1, a pixel size of 10 µm with inter-pixel resolution of 1.7 µm, and laser damage resistance ranging between 20-40 J/cm2 at 1054 nm (1 ns pulse width) using a 10 µm layer of commercially available nematic LC materials. Coupled with the ability to generate almost an infinite variety of binary and grey-scale apodization and beam-shaping profiles by the photoalignment process, the high laser damage threshold of these devices makes them attractive and useful tools for a multitude of laser applications.

8114-25, Session 6

Liquid crystal lasers: from basics to practical holographic systems

H. J. Coles, Univ. of Cambridge (United Kingdom)

We briefly describe the background to Microscopic Liquid Crystal lasers and then consider the key properties of the liquid crystal host & cavity design that lead to high slope efficiency (~70%), low laser thresholds (~100nJ/pulse), narrow line widths (<0.01nm) and quasi-continuous working 53kHz pulse rate) giving average powers of 5mW per pixel or laser spot. The birefringence, the elastic constants and the orientational order parameters of the liquid crystals and the dye (as well as the spectral absorption coefficient and peak absorption wavelength), were the key parameters that influenced markedly the performance of such LC lasers. Further, through cavity design/construction and using 2-D lenslet arrays of up to 100 by 100 spots we can optimize the gain to give a quasi- continuous working wide color gamut RGB laser output with powers of Watts in the far field. We will show how the narrow band output from these microscopic cavity lasers may be continuously wavelength tuned through the application of in-plane electric and we will describe a multi-wavelength prototype, continuously tunable from the ultraviolet to near infrared, with an 8inch by 5inch footprint and 2inches high used for projection through computer generated holograms and medical applications. We will consider new Blue Phase systems, stable over a 100ºC temperature range, in which an electric field is used to switch the photonic band gap from red to green. Finally we will describe new paintable lasers, that have been coated on flexible plastic and foil substrates that have been used for holographic projection displays.

8114-26, Session 6

Polymer stabilization of phototunable cholesteric liquid crystals

L. V. Natarajan, SAIC (United States); T. J. White, Air Force Research Lab. (United States); Q. Li, Kent State Univ. (United States); T. J. Bunning, Air Force Research Lab. (United States)

We have recently demonstrated phototuning of more than 2000 nm in an azobenzene-based cholesteric liquid crystal (CLC) composed of a nematic liquid crystal and a high helical-twisting power chiral bis(azo) molecule. Phototuning range and rate were dependent on azo dopant concentration, light intensity, and cell thickness. The time for restoration of the original spectral properties in the absence of light source was long, lasting for several hours. Polymer stabilization of the CLC by LC monomers reduced the relaxation time to less than an hour. In this work, we present the results of a systematic study of the effect of polymer stabilization on the kinetics of phototuning and dark relaxation of the bis(azo) based CLC. The impact of varying LC monomer structure, polymer concentration, cross linker concentration, curing power, and cell thickness on the optical performance of these photoresponsive CLCs will be discussed.

8114-27, Session 7

Liquid crystal molecular orientation properties of microrubbing cells and its application to electrically tunable gratings

M. Honma, W. Toyoshima, T. Nose, Akita Prefectural Univ. (Japan)

Liquid crystal (LC) gratings consisting of twisted nematic orientation domains have been demonstrated. The LC grating cells were fabricated by the microrubbing, which is microscale rubbing technique using a tiny stylus. Fabricated LC cells exhibited multistable LC molecular orientation state, which could be divided into two types of twist orientation states; that is, ±90 and ±180 degrees twist orientation states. After the LC

grating cells were heated and cooled so that the nematic-isotropic phase transition was induced, the mixed orientation state of ±90 and ±180 degrees twist domains was observed. The entire microrubbing area was covered with the ±90 degrees twist domains by inducing LC flow in an appropriate direction in the LC grating cells. Furthermore, the ±180 degrees twist domain spreading over the entire microrubbing area could be obtained after a suitable voltage application. Diffraction properties of the LC grating cells under the voltage application were also investigated. The LC grating cells exhibited symmetric diffraction properties with the same light intensities of positive and negative order diffractions when the incident light was linearly polarized. However, for the circularly-polarized incident light, asymmetric diffraction properties were revealed. Namely, the diffraction efficiency of the positive order diffraction exceeded 70%, while that of the negative order diffraction was quite low (less than 10%).

8114-28, Session 7

Wavelength-tuneable liquid crystal lasers from the visible to the near-infrared

P. J. W. Hands, C. A. Dobson, S. M. Morris, Q. M. Malik, D. J. Gardiner, T. D. Wilkinson, H. J. Coles, Univ. of Cambridge (United Kingdom)

Photonic band-edge lasers made from dye-doped chiral nematic liquid crystals have been a subject of detailed academic interest in recent years [1]. Their periodic micro-molecular structure is self-organising, allowing mirror-free lasing with low thresholds and high slope efficiencies in simple device architectures. Thus far, liquid crystal lasing has been restricted to wavelengths within the ultra-violet and visible spectrum. Extending emission into the near-infrared offers the opportunity of developing a new range of low-cost optical sources, with applications including sub-dermal medical imaging, point-of-care medical diagnostics tools, telecommunications, and unique optical signatures for security coatings.

In this paper, a wide range of commercially available organic dyes are examined for their suitability within a liquid crystal host as light emitters in the near-infrared [2]. Problems such as poor dye solubility and reduced quantum efficiencies are overcome, and successful band-edge lasing is demonstrated up to 850 nm, using the dyes LD800, HITC-P and DOTC-P. Despite reduced quantum efficiencies, near-infrared lasing slope efficiencies are comparable to their visible counterparts. A discussion of the mechanisms behind these results and other important factors in their fabrication is presented.

By combining both visible and near-infrared lasing mixtures, array-based gradient-pitch systems can be produced [3], capable of outputting multiple simultaneous band-edge laser emissions that are arbitrarily selectable across the visible and near-infrared spectrum (460-850 nm). Forster transfer enables such polychromatic emission to be achieved whilst pumping the device with a single-wavelength optical source.

8114-29, Session 7

Dynamic selective reflection properties in cholesteric liquid crystals

T. J. Bunning, M. E. McConney, J. Hurtubise, M. Duning, Air Force Research Lab. (United States); L. V. Natarajan, V. P. Tondiglia, SAIC (United States); T. J. White, Air Force Research Lab. (United States)

We discuss the development of spatially templated polymer networks formed from a templated cholesteric liquid crystal fluid. By controlling the nuances of the anisotropic photopolymerization conditions employed and the nature of the monomer mixture used, liquid crystal films with a variety of dynamic electro-optic, photo-optic, and thermo-optic responses can be formed.

8114-30, Session 7

Waveguides with liquid crystals

K. Neyts, J. Beeckman, W. De Cort, P. Vanbrabant, Univ. Gent (Belgium)

The orientation of liquid crystal near an optical waveguide determines the propagation speed and the losses in that waveguide. This principle can be exploited for tuning the resonance frequency of a ring resonator or for sensing the presence of molecules at the interface between water and liquid crystal. In this work, experimental evidence and qualitative explanations are provided for the case of silicon-on-insulator high index-contrast waveguides with liquid crystal and for the case of liquid crystal in a section of a low index contrast doped glass waveguide.

8114-07, Session 8

Universal soft matter template: from photonic to metamaterial applications

C. Umeton, L. De Sio, R. Caputo, S. Ferjani, G. Strangi, R. Bartolino, Univ. della Calabria (Italy)

We report on the realization and characterization of a polymeric template sculptured in photosensitive material, on a chemical inert surface. The structure is devoted to micro/nano-confinement and stabilization of a wide range of organic and nano-particle components with self-arrangement properties at the nanoscale [1]. High quality morphology of a polymeric, micro-patterned, arrays is obtained by combining a nano-precision level optical holographic setup and a multi-step chemical-physical process. The “universal” template represents the basic platform to be filled with different organic materials, which can also include metallic nano-particles. The long range self-organization is induced without making use of any kind of surface chemistry. Due to their capability of exhibiting self organization, light responsive Liquid Crystals (LC) [2], short pitch cholesterics LC [3] and ferroelectrics LC have been exploited, and experimental studies have been carried out in order to investigate the photo-optical and elecro-optical response of obtained composite structures for the realization of photonic devices. Finally, the possibility of including metallic nano-particles has been also investigated, with the aim of inducing a “metamaterial” behavior of the realized structure.

8114-31, Session 8

Design of SmAPF mesogens

E. D. Korblova, D. M. Walba, T. Gong, Univ. of Colorado at Boulder (United States); A. Reddy, VVI Bright, Inc. (United States); C. Zhu, R. Shao, Y. Shen, J. E. MacLennan, M. A. Glaser, N. A. Clark, Univ. of Colorado at Boulder (United States)

Smectics with both tilted and/or untilted phases are quite commonly

found in mesogens with linear cores, but untilted (orthogonal) phases are very rare among known bent-core materials, these systems usually transition directly from the isotropic melt to SmCP phases, smectics with tilted molecules and polar layers.

SmAPF phases although rare are very desirable for applications due to an interesting set of unique features, including fast analog switching, phase-only modulation, and electro-optic latching. A disadvantage of existing SmAPF mesogens is relatively small maximum modulation depth ($\Delta\Delta n$).

One class of known SmAP mesogens possesses a bent molecular core with a single flexible tail, which stabilizes fluid smectic layers with untilted molecules and in-plane polar ordering. In single tail wedge systems SmAP phase may occur, but the antiferro arrangement is the only arrangement seen.

Our design approach uses the principle of nanosegregation of the layers. We used carbosilane units in conjuction with a single tail to get a prototypical SmAPF material W586. Modification of the core bite angle, ester unit reversal and other features will be presented and discussed in the context of controlling the spontaneous polarization, birefringence change ($\Delta\Delta n$) and other electro-optics properties.

8114-32, Session 8

Liquid crystal homo and alternating (co) polymers based on pi-conjugated backbone

F. Mathevet, I. Tahar-Djebbar, D. Zeng, Univ. Pierre et Marie Curie (France); B. Heinrich, B. Donnio, D. Guillon, Univ. de Strasbourg (France); D. Kreher, A. Attias, Univ. Pierre et Marie Curie (France)

The self-organization of pi-conjugated organic materials forming highly ordered supramolecular architectures has been extensively investigated in the last two decades in view of optoelectronic applications. Indeed, the control of both the mesoscopic and nanoscale organization within thin semiconducting films is the key issue for the improvement of charge transport properties and achievement of high charge carrier mobilities. These well-ordered materials are currently either self-organized semiconducting polymers or liquid crystals.

In this context, we endeavored to investigate the self-organization of a side-chain liquid crystal (SCLC) semiconducting polymer where (i) the backbone is a pi-conjugated polymer and (ii) the side groups are pi-conjugated discotic mesogens.

Here we describe the design and synthesis of columnar side-chain liquid crystal homo and alternating (co)polymers with triphenylene mesogens as side groups, and well-defined regioregular polythiophene as backbone.

These different kinds of architectures prepared following the Grignard methathesis (GRIM), allow the control of the triphenylene side group ratio along of the polymer chains, and lead to tunable electronic properties and nanostructures.

In this work, we will give the details on the synthesis and structural characterization studied by Polarized-light Optical Microscopy (POM), Differential Scanning Calorimetry (DSC) and Temperature-dependent, small-angle X-ray diffraction. Moreover, their photophysical properties and the preliminary charge transport results will also be depicted in view of applications for organic optoelectronics.

8114-33, Session 8

Polymer-stabilized isotropic liquid crystal and display

D. Yang, Kent State Univ. (United States)

We constructed a polymer-stabilized isotropic liquid crystal by polymerizing monomers in the isotropic phase of liquid crystal materials at elevated temperatures. The system exhibits an optically isotropic state under zero field at room temperature, and becomes optical birefringent when externally applied electric fields are applied. We studied the field-induced birefringence as a function of applied field and temperature. We also developed a simple theory to explain the experimental results. We used the material to make flat panel display with in-plane-switch cell, which has large view angle and sub-million second response time.

8114-34, Session 8

Phototropic liquid crystals

B. Taheri, T. Kosa, L. Sukhomlinova, AlphaMicron, Inc. (United States); T. J. White, T. J. Bunning, Air Force Research Lab. (United States); A. Munoz, AlphaMicron, Inc. (United States)

Analogous to the melting of a crystalline solid into a liquid melt, heating liquid crystals transitions the mixture from crystalline solid, to liquid crystal, to isotropic liquid. In general, liquid crystals are classified into thermotropic, lyotropic, and polymeric liquid crystals based on the stimulus that is responsible for the phase transition. Within each liquid crystal regime, a number of well-known mesophases are observed including nematic, cholesteric, and many variations of smectic. Here, we present a new class of liquid crystal material wherein light induces the phase transition. In contrast to previous examinations of photoresponsive liquid crystal systems, this work presents a system in which light exposure increases the order parameter of the mixture, allowing for “phototropic” phase transitions. In particular, light illumination can increase the order of the mixture and induce phase transition from isotropic to nematic, isotropic to cholesteric, or nematic to smectic phases. This system is based on series of novel photodichroic dyes that are disruptive to liquid crystallinity in the ground state and favorable to liquid crystallinity in the open form. The increase in order with light exposure has profound implications in dynamic optics, photonics, lasing, and displays.

8114-35, Session 8

Plasmonics-enhanced optical fields and nonlinearities in liquid crystals

I. C. Khoo, J. Huang, Y. Ma, The Pennsylvania State Univ. (United States)

Optically induced localized plasmonic fields of Au- and Ag- nano-spheres and nano-strips embedded in liquid crystals are calculated. Results for uniform distribution of the nano-spheres show large resonant peaks shift with nematic index change. For paired nano-strips, we have quantitatively examined the dependence of these field enhancement effects on the separation distance, periodicity, aspect ratio and the size of the nanostrip. Complex third order ultrafast electronic nonlinearities due to the laser-induced plasmonic local fields are also ‘observed’, theoretically and experimentally using short-pulsed lasers. These effects will be useful for tunable optical sensor, all-optical switching, tunable filters and nonlinear transmission applications. References: I. C. Tunable retarder made of pentaprisms and liquid crystal

M. Saito, K. Hayashi, Ryukoku Univ. (Japan)

Nematic LC (no=1.53, ne=1.82) was sandwiched between two Si pentaprisms (n=3.4) with its director being oriented perpendicular to the Si surface (homeotropic alignment). When an angle of incidence was 28° (Brewster’s angle), p-polarized light passed through the LC layer, while s-polarized light, which took the smaller index (no), suffered total internal reflection. Consequently, this LC layer acted as a polarization

beam splitter. The reflected light beam (s polarization) propagated in the Si prism and reached the opposite surface of the pentagon. A gold mirror was adhered to this surface for creating a gap (5-15 μm) between them. This gap was filled with the nematic LC, which was aligned parallel to the Si surface with its director being rotated by 45° from the direction of s polarization. Since this LC layer acted as a retarder, the beam that was reflected at this surface took different polarization state depending on wavelength. Consequently, when the beam returned to the beam splitter, it was reflected or transmitted at the Si-LC boundary depending on its polarization state. The transmitted beam (selected wavelength) passed through the LC layer and emerged from the other Si prism. The transmission wavelengths could be tuned by applying an electric voltage between the gold mirror and the Si prism. Since this device was symmetrical with respect to the beam-splitting LC layer, the similar phenomenon took place for p polarization in the opposite Si prism. This wavelength tuning function was confirmed by measuring infrared transmission spectrum of the device.

Cost-efficient manufacturing process of switchable glazing based on twisted nematic LC cells

E. Kurz, L. Rau, N. Fruehauf, M. Prskalo, W. Haase, W. Sobek, Univ. Stuttgart (Germany)

Large-area glass facades are widely spread in contemporary architecture. They meet demands for natural light illumination of rooms and satisfy esthetic requirements of modern architecture. However, larger glass facades increase transfer of energy into the building. Since this has to be compensated by the intense use of air condition, modulation of the energy passing through the glazing is essential.

The authors have been developing a system for modulation of penetrating sunlight. It consists of a modified twisted nematic (TN) liquid crystal (LC) cell which is embedded in a double glazing. The materials used in the TN-LC cell must withstand certain environmental conditions, primarily UV radiation, moisture and heat. In particular, this applies to the polarizer. Since a conventional outside film polarizer is susceptible to heat, the authors substituted this component for an inside coatable polarizer. Long term outdoor weathering tests demonstrated that the concept is viable. Part of the current research is the integration of the TN-LC cell into double-glazing focusing on increased stability towards external loads and a reduction of energy transferred into the building.

A further demand for such a system is a cost-efficient manufacturing process. It has been investigated to use the coatable polarizer at the same time as an alignment layer for the liquid crystal. Aluminum zinc oxide (AZO) is to be used for the electrode material substituting conventionally used indium tin oxide (ITO) which is expensive.

Currently the authors are looking into the coating process for the inside polarizer. The polarizer consists of lyotropic liquid crystal and has to be aligned linearly during its application defining the polarizing direction.

Waveguide display using polymer-dispersed liquid crystal

Y. Cheng, G. J. Su, National Taiwan Univ. (Taiwan)

In this paper, we demonstrate two promising novel displays: light waveguide display and arrayed waveguide display. In the light waveguide display, light emitted from commercial LEDs propagates in a glass planar waveguide with a polymer dispersed liquid crystal (PDLC) upper layer. When the voltage is off, light would be partially scattered via PDLC and that pixel becomes bright and opaque. When the voltage is on, PDLC is properly aligned so that light would not be scattered, showing a transparent pixel. By electrically controlling the PDLC, a counting seven-segment pattern is clearly displayed. Arrayed waveguide display has been theoretically proposed to be a full color display with high light-use efficiency. Light of three primary colors from an emitter array is coupled into a waveguide array upon which is the PDLC switches. In our design, the core of the waveguide is made of SU-8 photoresist while the side and under cladding is polymethyl methacrylate (PMMA). The upper cladding PDLC is controlled pixel by pixel such that the light can be selectively scattered. Both displays are well patterned and packaged with their driving circuits so that finalized products can be shown. Furthermore, since most materials are transparent, the displays are applicable for head-mounted displays (HMD).

Slope efficiency characteristics of mode-hop driven tunable single-mode cholesteric liquid crystal laser

Y. Inoue, H. Yoshida, K. Inoue, Y. Shiozaki, H. Kubo, A. Fujii, M. Ozaki, Osaka Univ. (Japan)

Cholesteric liquid crystals (ChLCs) are known to self-organize into helical structures with periodicities of a few hundred nanometers and thus possess a reflection band attributed to their periodicity p and birefringence dn. By introducing a gain medium (usually dyes) with appropriate fluorescence properties, lasing can be realized in these materials. Consequently, ChLCs lasers have attracted a large amount of interest as compact, low-threshold and tunable coherent light sources.

In this study, we report the improvement in the slope efficiency of tunable single-mode ChLC lasers with a three-layered structure. The device consists of one photo-polymerized ChLC layer with a wide reflection band, another ChLC layer with a notch reflection band and a Rhodamine6G doped ionic liquid layer acting as the gain medium. Single-mode lasing is obtained from this device structure because the ChLC layer with the notch reflection band strongly reflects only one of the Fabry-perot cavity modes, and mode-hop driven tuning of the lasing wavelength is possible because the reflection band of the notch ChLC can be tuned by external stimuli, such as heat. Our device showed a maximum slope efficiency of 16% (considering emission only in the foreword direction), and was found to be approximately 1.5 times larger than ordinary DFB-type ChLC lasers doped with the Pyrromethene597 laser dye.

Degradation of liquid crystals device performance due to ionic adsorptions: issues and solutions

L. Lu, Kent State Univ. (United States); A. Alagh, Okaya Electric America, Inc. (United States); P. J. Bos, Kent State Univ. (United States)

In this paper, we first investigated the degradation of the performance of liquid crystals display (LCD) units after driving by a DC bias. Missed segments were found in the test LCD units. By carefully investigating the alignment layer and ITO layer separately, an explanation of the ITO failure is proposed: voltages applied to the liquid crystal cell causes accumulation of charged impurities or ions, resulting in a decomposition reaction of ITO in regions where segment and common planes overlap and there are scratches on the PI layer. Consequent, missing segments in the corresponding regions is generated.

To prevent this kind of degradation, we studied the correlation between the alignment layer and ions adsorption. Both organic alignment layer (PI2555, SE1211, and FPI) and inorganic alignment layer (SiOx, SiO2, and Al203) are analyzed by residual DC and voltage holding ratio measurement. A correlation between ion adsorption and the dielectric constant of the alignment layer is demonstrated. Alignment layer with a smaller dielectric constant is good for reducing ion adsorption in the alignment layer. Alignment layer with a bigger dielectric constant is good

for reducing mobile ions in the LC device, and could be used in non-active areas of the liquid crystal device to remove ion from the active area.

Polarization twisted nematic gratings: a study of the far-field diffraction patterns

D. Statman, R. Pettit, S. Bottini, A. Jockers, Allegheny College (United States)

When left and right circularly polarized beams of light from a pump laser interfere in a nematic liquid crystal doped with azo dye, a polarization twisted nematic (PTN) grating is formed in the sample. The same is true if two beams of light linearly polarized perpendicular to the rubbing direction of the sample interfere. In the first case the easy axis is rotated toward the polarization direction of interfering beams. In the latter case rotation toward the polarization only occurs at the bright regions. The absorption of the pump beam by the dye is strong enough so that there is no reorientation of the easy axis on the opposite side of the sample. However, photoinduced gliding measurements demonstrate that the reoriented easy axis is not parallel to the polarization of the interfering pump beams. The far-field diffraction pattern of a probe beam entering the sample from the opposite side consists of elliptically polarized spots. Fourier analysis of the far-field pattern determines how the easy axis of the nematic has been reoriented. In this presentation, we compare the PTN ratings formed by interfering circularly polarized light and linearly polarized light.

Study of cholesteric liquid crystal: rhodamine 6G doped polymer thin film, cholesteric liquid crystal system

T. Dadalyan, R. Alaverdyan, N. Hayrapetyan, Yerevan State Univ. (Armenia)

The creation of compact, easy processible, low threshold and tunable optical components and laser sources is in great demand in science and industry. One of the strategies for solving this problem are multilayer structures consisting of laser dye-doped polymer thin films, as solid active element and Cholesteric Liquid Crystals (CLC)-s as resonators.

In this work we have experimentally investigated optical properties of multilayered structure, consisting of two right handed CLC with the same pitch and Rhodamine 6G doped polymethyl metacrilate (PMMA) 10nm micrometer thin film.The CLC was a compound of commercial NLC E7 and the ciral agent. The transmission and luminescence spectra and their temperature dependeces for this system were measured, for visible wavelength light. About 10 nm temperature tunability of selective reflection band is observed. The experiments are in process, now we are working on achieving efficient lasing from this system.

Optically switchable photoluminescence using liquid-crystal dispersed quantum dots

M. Cheng, W. Chang, V. K. S. Hsiao, National Chi Nan Univ. (Taiwan)

In the conference, we will show the suggested mechanism formatting liquid-crystal (LCs) dispersed quantum dot (QDs) and achieve the reversible optical switching of photoluminescence (PL) intensity of QDs. By mixing QDs into azobenzene-doped cholesteric LCs, it is possible to switch the PL of QDs into two different states, switching between high intensity at optical field-off state and low intensity at optical field-on state. At the field-off state, the QD-dispersed LC cell presents highly scattering and the excitation photons (from 514 nm pumping laser) undergoes multiple scattering before the pumping laser getting out off the LC cell that the situation increases the possibility for pumping laser hitting and be absorbed by the dispersed QDs. At the field-on state (from 405 nm laser irradiation), the trans-to-cis photoisomerization of azobenzene makes the QD-dispersed LC cell presenting highly transparent, most pumping photons go straight through the LC cell, reducing the possibility for the QDs being excited. The PL intensity can be modulated by controlling the light intensity from laser irradiation. In view of the considerable interests in PL of QDs for photonic applications, our study on optically switchable PL from azobenzene doped LC-dispersed QDs introduces a new approach of controlling emission of QDs by means of light. This may open the door to new exploitation for applications of QD such as light switchable, emission based liquid-crystal display (LCD).

Polymer hosts for efficient electrophosphorescence

H. Yang, SAMSUNG Electronics Co., Ltd. (Korea, Republic of)

New series of printable novel polymer host materials for electrophosphorescent organic light emitting devices (PhOLEDs) was developed, which exhibited starburstic core monomer connected by linker units. Moreover, the hole mobilities were controlled by the number of carbazole of linker units. Development of high efficient host materials for electrophosphorescent device could improve quantum efficiency of light output intrinsically, which is a real challenge. Our materials could be summarized following: i) The linkage mode of para position of polymer should be prohibited by synthetic modification. ii) By introducing the linker units, the HOMO levels are finely tunned and the contribution portion of HOMOs could be shifted to the linker units, which resulted in hole injection and transporting property could be controlled. iii) When looking at the results of current density vs voltage, it is tendency to be increased as increasing the number of carbazole units, which means that the hole mobility tends to increase. iv) These host materials shows wide bandgaps (Eg>3.0 eV) and high triplet energies (ET>2.4 eV). The present work provides a new route for designing host materials with wide bandgap and high triplet energy, and for controlling hole transporting property simultaneously.

Recent advances in materials for efficient green and blue electrophosphorescent light emitting diodes

B. Kippelen, S. Kim, D. Cai, W. Haske, E. M. Najafabadi, C. Fuentes-Hernandez, J. Leroy, C. Zuniga, Y. Zhang, L. Zhu, J. S. Sears, S. Barlow, J. Brédas, S. R. Marder, Georgia Institute of Technology (United States)

(Invited talk)

In recent years, significant progress has been made towards the development of organic-based semiconductors for display and lighting applications. However, the search for new materials for blue organic light-emitting devices (OLEDs) remains of importance for the development of satisfactory full-color flat-panel displays and of efficient and stable white-light devices. Furthermore, materials should preferably be processed from solution to further lower the fabrication cost.

In the first part of this talk, we will discuss the use of a bis-sulfone small molecule, 4,4'-bis(phenylsulfonyl)biphenyl, as a host for the phosphor iridium(III) bis(2-(4,6-difluorophenyl)pyridinato-N,C2')picolinate in blue-green organic light-emitting devices. In addition, we will report on the use of a new poly(norbornene)-based polymer functionalized with a 3,6-bis(carbazol-9-yl)carbazole moiety as a side group as a solution-processible hole-transport layer. Comparison will be made to the widely-used hole-transport polymer poly(N-vinylcarbazole) (PVK). At 100 cd/m2, the highest efficiency device incorporating the new polymer achieved an external quantum efficiency (EQE) of 6.9 % (12.9 cd/A) with a turn-on voltage of 4.3 V. In the second part of the talk we will report on high-efficiency organic light-emitting devices (OLEDs) fabricated with solution-processed blends of hole- and electron-transport side-chain polymer hosts doped with a green-emitting iridium complex. The ambipolar host blends consist of blends of bis-oxadiazole-functionalized poly(norbornene) electron-transport materials and poly(N-vinylcarbazole). For the best device examined, an external quantum efficiency of 13.6% and a maximum luminous efficiency of 44.6 cd/A at 1000 cd/m2 with a turn-on voltage of 5.9 V were obtained.

8115-03, Session 1

Materials design concepts for efficient blue OLEDs: a joint theoretical and experimental study

A. B. Padmaperuma, L. Cosimbescu, J. S. Swensen, E. Polikarpov, P. K. Koech, L. Wang, D. J. Gaspar, Pacific Northwest National Lab. (United States)

Organic light emitting devices (OLEDs) have great potential for lighting, displays and TVs. One remaining technical challenge for very high efficiency OLEDs for solid-state lighting applications is the blue component. Optimization of not only blue emitters, but also host matrices and transport layers is necessary to achieve efficiency and lifetime targets. Charge balance and exciton confinement are key factors in achieving high quantum efficiency in OLED devices. It is a commonly held view that the host material for a phosphorescent emitter in an organic light emitting device (OLED) must have a triplet energy higher than that of the phosphorescent emitter in order to obtain high quantum efficiencies. We show that a combination of HTL, ETL and host with appropriate energy levels can provide high external quantum efficiency (EQE), even with a host triplet energy lower than that of the emitter. Specifically, we report results demonstrating improved OLED performance for a new host material, 4-(di-p-tolylamino)phenyl) diphenylphosphine oxide, with a triplet energy lower than FIrpic. Our results suggest modified design rules for the development of new, high performance host materials. Molecular design strategies, device design and OLED data will be discussed.

8115-04, Session 1

Highly efficient new hole injection materials for OLEDs based on phenothiazine and phenoxazine derivatives

J. Park, Y. Park, B. Kim, The Catholic Univ. of Korea (Korea, Republic of)

New hole injection layer (HIL) materials for organic light-emitting diodes (OLEDs) based on phenothiazine and phenoxazine were synthesized, and the electro-optical properties of the synthesized materials were examined by UV-vis and photoluminescence (PL) spectroscopy, and by cyclic voltammetry (CV). 1-PNA-BPBPOX showed glass transition temperatures (Tg) of 161°C, which was higher than that (110°C) of Tris(N-(naphthalen-2-yl)-N-phenyl-amino) triphenylamine (2-TNATA), a commercial HIL material. The HOMO levels of the synthesized materials were 4.9-4.8 eV, indicating a good match between the HOMO of indium tin oxide (ITO) (4.8 eV) and the HOMO of N,N'-bis(naphthalen-1-yl)-N,N'-bis(phenyl)benzidine (NPB) (5.4 eV), a common hole transfer layer (HTL) material. Because the synthesized materials showed minimal absorption at wavelengths shorter than 450 nm, they have good potential for use as effective HIL materials. The synthesized materials were used as the HIL in OLED devices, yielding power efficiencies of 2.8 lm/W (1-PNA-BPBPOX) and 2.1 lm/W (2-TNATA). These results indicate that 1-PNA-BPBPOX yields a higher power efficiency, by a factor of 33%, than the 2-TNATA commercial HIL material. Also, 1-PNA-BPBPOX exhibited longer device life-time than 2-TNATA.

8115-05, Session 1

Novel hole transport materials for blue phosphorescent OLEDs: synthesis, properties, and performance

L. Cosimbescu, E. Polikarpov, J. S. Swensen, L. Wang, D. J. Gaspar, A. B. Padmaperuma, Pacific Northwest National Lab. (United States)

We report the development of novel hole transport (HTm) and host materials, to achieve a stable and efficient blue phosphorescent OLED system. Developing compatible HTms for blue phosphorescent devices remains a challenge, due to the fact that their triplet energies have to be higher than the dopant for maximum efficiency as well as maintaining a good charge transport into the emissive layer analogous to state of the art HTMs. The new HTms contain known moieties such as triphenyl amine or phenyl carbazole, but linked through bulky or inert spacers, and the design is based on the well known HTms, TAPC and DTASi. A thorough computational analysis of all HTm structures was performed to determine the relative HOMO/LUMO energetic and excited state properties. Excited state calculations using TD-DFT-B3LYP/6-31G* as implemented in NWChem was conducted and was used to select the best set of candidates for synthesis and then further evaluation in blue OLEDs. The novel compounds have photophysical properties such as EHOMO, ELUMO and ET values, similar to their analogs, TAPC and DTASi. Based on the estimated values from CV and emission, the new molecules are perfectly suitable for use as high bandgap, hole transport materials. The new molecular design provided materials with good morphological properties, which is expected to add to the overall stability of the OLED system. The work presented herein will encompass the design and synthesis of a series of hole transport materials, their electronic and photophysical properties and their performance in an OLED device.

8115-06, Session 1

Exploration of highly luminescent exciplexes and their application to OLEDs

K. Yoshida, K. Goushi, K. Sato, C. Adachi, Kyushu Univ. (Japan)

The external electroluminescence (EL) quantum efficiency (hext) based on fluorescent materials as an emission center is limited to only 5%. Recently, without phosphorescent materials we proposed the novel EL mechanism to enable the hext of 5% by using up-conversion from triplet (T1) to singlet (S1) excited states. In this mechanism, in order to realize the high up-conversion efficiency, the energy gap between S1 and T1 (dEST) should be close to zero. dEST is determined by the exchange energy between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). Therefore, the separation of the HOMO from the LUMO can enhance the reverse intersystem crossing from T1 to S1 (RISC). More recently, we reported that organic donor and acceptor interfaces give rise to a small dEST; dEST for exciplexes is expected to be very small, due to the separation of the positive and negative charges located mainly in donor and acceptor molecules, respectively. Our observations showed that a high RISC efficiency can be realized using exciplexes, which lead to high efficiency for radiative-exciton production. By taking advantage of the highly efficient ISC, we demonstrated a pronounced enhancement of electroluminescence efficiency under electrical excitation. The observed EL efficiency is, however, still at a low level. In order to highly EL efficiency, high PL efficiency of exciplexes is a key factor. In this paper, we demonstrate the external EL quantum efficiency over 5% by using highly luminescent exciplexes as emitter layers.

8115-07, Session 1

Asymmetric molecular design for high-efficiency in blue phosphorescent organic light emitting diodes

J. Y. Lee, Dankook Univ. (Korea, Republic of)

Asymmetric organic materials were synthesized as the host materials for blue phosphorescent organic light emitting diodes. The design of asymmetric high triplet energy host material was effective to reduce the driving voltage and improve the quantum efficiency of blue phosphorescent organic light emitting diodes. A high quantum efficiency over 20% was achieved in the blue phosphorescent organic light emitting diodes using the asymmetric high triplet energy host materials.

8115-08, Session 1

High-efficient yellow-emitting materials based on thieno-pyridine framework for yellow and white OLEDs

H. Huang, T. Chao, Industrial Technology Research Institute (Taiwan); V. Van Elsbergen, Philips Technologie GmbH (Germany); M. Tseng, Industrial Technology Research Institute (Taiwan)

High efficient yellow light-emitting materials based on thieno-pyridine framework have been synthesized for organic-light emitting diodes (OLEDs). We investigated and synthesized different orientation and substituted group of the thieno-pyridine framework organo-iridium complexes (PO-01 series materials). These materials exhibited yellow light. Fabrication of these emissive phosphorescent dopants with conventional materials and the device configuration of ITO/ HTL/ CBP: yellow Ir-complex emitters (4-6%) /BCP/Alq3/LiF/Al showed the EL emitting peak of 560 nm. The electroluminescent efficiencies of the devices were from 35.1 lm/W (51.6 cd/A) to 37.1 lm/W (62.8 cd/A) under the brightness of 1000 cd/m2 and external quantum efficiencies were all above 16.9% to 18.5%. With some advanced materials applied on the yellow devices, we also can obtain efficiencies of the devices were from 84.4 lm/W (76.7 cd/A) to 97.7 lm/W (88.9 cd/A) under the brightness of 1000 cd/m2 and external quantum efficiencies were all above 19.3% to 20.4%. Besides, we also apply the PO-01 series materials on WOLED and obtain good power efficiency of 44 lm/W under 1000 cd/m2. We demonstrated high-efficiency, high-brightness and saturated yellow Ir-complex phosphorescent materials for yellow and white OLEDs.

8115-09, Session 1

Theoretical design for carrier-transporting molecules in view of vibronic couplings

T. Sato, K. Shizu, K. Tanaka, H. Kaji, Kyoto Univ. (Japan)

Novel carrier-transporting materials are proposed in view of vibronic, or electron-phonon couplings.

To design for highly efficient organic-light-emitting diodes (OLED), it is necessary to develop a carrier-transporting molecule with a high carrier mobility and low power loss. The mobility of available electron-transporting molecules in OLED is smaller than that of hole-transporting molecules. This gives rise to carrier unbalance which result in low efficiency. Therefore an electron-transporting molecule with a high mobility is necessary.

Vibronic couplings cause a decrease of the carrier mobility and a energy dissipation.

Therefore a vibronic coupling is an important interaction in designing for such a molecule as well as frontier levels. We have recently proposed a concept of vibronic coupling density which enable us to control vibronic couplings in a molecule (Sato et al, “Vibronic coupling constant and vibronic coupling density”, in “The Jahn-Teller Effect: Fundamentals and

Implications for Physics and Chemistry" , Springer Series in Chemical Physics 97 (Springer-Verlag, Heidelberg and Berlin, 2009)).Based on the concept, we can design a novel carrier-transporting molecule with small vibronic couplings which can result in high mobility and low power consumption.

A vibronic coupling is small if the electron-density difference between the neutral and ionic state is localized not on bonds but on atoms. In addition, if the electron-density difference is equivalently delocalized over the molecule, the vibronic couplings are small due to the selection rule.

We design organoborane compounds as an electron-transporting molecule based on these guiding principles.

We also discuss the effect of asymmetric perturbations on the electronic-density difference.

8115-10, Session 1

Models of excited states of Ir(III) complexes for optoelectronic applications

B. J. Powell, A. R. G. Smith, M. J. Riley, S. Lo, P. L. Burn, I. R. Gentle, The Univ. of Queensland (Australia)

Realistic accurate predictions spectra of organometallic complexes have remained difficult, this has hampered the rational design of new complexes for optoelectronic applications. We show that relativistic effects cause important changes in the spectra of phosphorescent Ir(III) complexes. This is achieved by comparing high field magnetic circular dichroism (MCD), absorption and photoluminescence (PL) spectra with time-dependent density functional theory (TDDFT) calculations for a series of blue phosphorescent Ir(III) complexes. By gradually turning on the relativistic effects we identify several distinct relativistic effects in the spectra of these complexes. We show that both spin-free (scalar) relativistic and spin-orbit coupling must be included to accurately predict the observed spectra. Further, we use this combined theoretical and experimental methodology to investigate the changes in spectra as electron withdrawing groups are added to the organic ligand: tuning the emission towards a deeper blue, but also leading to a decrease in the observed photo luminescent quantum yield (PLQY). This leads to new insights into the low-lying excitations responsible for the observed phosphorescence, and suggests new avenues to improve the performance of organic light-emitting diodes (OLEDs).

8115-11, Session 2

Correlating hole injection layer film morphology and composition to the performance of single carrier and OLED devices

N. Chopra, S. B. Li, V. Seshadri, C. McGuiness, E. Scott, R. Mitchell, M. K. Mathai, Plextronics Inc. (United States); L. Scipioni, C. T. Huynh, Carl Zeiss SMT Inc. (United States)

In the space of organic light emitting diodes (both vapor and solution processed devices), most of the devices with low operating voltages and long lifetimes are obtained using doped charge injection layers. We focus our research on Plexcore® OC, a conducting polymer, aqueous based hole injection layer (HIL). The present study explores factors limiting the current state of the art HIL technology which will pave the way to realization of low power consumption OLEDs. We will present a detailed study outlining the effect of HIL composition, conductive polymer, resistivity and work function of hole injection layer on performance and stability of organic devices. The HILs were characterized using helium ion microscopy (HeIM), conductive AFM film conductivity uniformity, AFM for morphology and roughness, AC2 for work function measurements and elliposmetery for optical characterization. HeIM is emerging as one of most effective new microscopy technique for imaging nanostructured organic materials. Analysis of HeIM images reveal similar nanostructure to conducting AFM current map. Also, He ion beam modified surface of our HIL was clearly able to reveal the morphology of underlying structure hidden below the conducting polymer network. Hence, a combination of HeIM images with conducting AFM can help us to understand how different composition and processing conditions affect the nanomorphology of the polymer composite film. Finally the understanding from film characterization is correlated with the device data to investigate the effect of modulating HIL properties on device performance and voltage stability under operation.

8115-12, Session 2

Water/alcohol-soluble conjugated polymers for interface engineering of optoelectronic devices

F. Huang, South China Univ. of Technology (China)

The applications of water/alcohol soluble conjugated polymers in optoelectronic devices have attracted more and more attentions due to their unique characteristics different from the traditional conjugated polymers as interfacial modification/active materials in devices. The polar pendant groups of them not only render the materials good solubility in water and other polar solvents, which can overcome the challenge interfacial mixing problems in multilayer optoelectronic devices fabrication, but also can dramatically improve charge injection from metallic electrodes into organic active layers to greatly improve the device performance. Different from the traditional electron transporting/injection materials, this kind of materials can effectively enhance electron injection from high work-function metals (such as Al, Ag, Au). As a result, high-efficiency printable polymer light-emitting diodes (PLEDs) with Ag-paste as cathode have been realized. Moreover, the newly developed materials and protocols has led to significant improvements on the performance of PLEDs. By using a doped water/alcohol soluble conjugated polymer as electron transporting/injection, the resulting solution-processed white-emitting PLEDs showed a maximum forward viewing luminance efficiency of 36.1 cd/A (61.4 cd/A for total viewing) and a power efficiency of 23.4 lm/W (39.8 lm/W for total viewing), which is comparable to those reported from the state-of-the-art vacuum deposited small molecule white-emitting OLEDs.

Highly efficient and spectral stable blue light emitting polyfluorenes containing dibenzothiophene-S, S-dioxide unit

W. Yang, South China Univ. of Technology (China)

Polymer light-emitting diodes (PLEDs) have attracted great attention because of their potential applications in large-area, flat-panel displays. high-efficiency and stable blue light-emitting polymers with good color purity remain as a great challenge. Polyfluorene derivatives are a very attractive class of blue materials, however, a major drawback is their excimer and/or aggregate formation upon thermal annealing or the passage of current, leading to red-shifted emission. We present a detailed study on the 9,9-bis(2-ethylhexyl)fluorene-co-benzothiophene-S,S-dioxide copolymers (PF-FSO). The substantial improvements in PF-FSO device performances can be achieved by employing hole transport/electron block layer (HTL/EBL), as well as by performing an appropriate cathode buffer (CB). In particular, the simultaneously utilizing the aforementioned steps bring about a significant performance improvement.

8115-14, Session 3

Top-emitting OLED for mobile display: the comparison between inverted and normal top-emitting OLED

J. Lee, K. Lee, M. Kim, J. Kim, C. Yoo, J. Yoon, S. Yoon, C. Kim, LG Display (Korea, Republic of)

Top emitting OLEDs (TOLEDs) are implemented into mobile products with the great advantages of high filling factors and color gamut. The most commercialized AMOLEDs are consisted of TOLED using thin metal microcavity structure. However, thin metal TOLED has very little thickness tolerance in the manufacturing process. Due to the strong microcavity effects of thin metal TOLED, only 5nm thickness off of total organic layers alters CIE coordinate, which is one of crucial criteria in the display standard. This gives the big challenge on increasing productivity of OLED display panel. Therefore, inverted OLED are studied as one of options with less sensitive to thickness variation. The inverted configuration allows for integration of OLEDs with preferentially used n-channel TFTs for driver backplanes in active matrix OLED displays. Recently, Face Target Sputtering (FTS) system is introduced without sputtering damage to organic layers.

In this talk, thin metal TOLED and inverted structure TOLED are compared in electrical and optical performances. Capacitance-Voltage (CV) measurements as a powerful technique to analyze electric properties of Top emitting OLED (TOLED) devices are introduced. After comparing CV characteristics between inverted TOLED and conventional TOLED with thin metal, it is found that inverted OLED struggles charge injections, electron and hole injections both. Here Current-Voltage-Luminance (IVL) and CV characteristics are carefully analyzed for single carrier devices and dual carrier devices systematically. Thin metal TOLED shows more efficient electron injection and higher efficiency than that of inverted TOLED, which is attributed to the order of thermal deposition of organic/metal layers.

8115-15, Session 3

Effect of excited state interactions on the efficiency and lifetime in PLED

N. Akino, T. Yamada, Y. Tsubata, C. Sekine, Sumitomo Chemical Co., Ltd. (Japan)

Polymer light emitting diode (PLED) has been attracting considerable attention due to their potential for commercial applications such as flat panel displays and solid-state lighting. In the course of improving PLED performance, it has been realized that the interactions between singlet excitons, triplet excitons, and polarons play an important role in the efficiency and degradation in the devices, however their influences are not fully understood. Actually, part of singlet excitons is considered to be originated from the triplet-triplet annihilation process. Thus, a device with the use of triplet-triplet annihilation process would be able to have more fluorescent singlet exitons than a device without that process, thus leading to higher efficiency. On the other hand, the quenching of triplet excitons in the device degradation seems a major factor of the rapid initial decay in the device lifetime, suggesting the importance of the control of triplet excitons for better device stability.

In this presentation, we will present an efficiency and degradation analysis of PLED, and demonstrate that the triplet exciton transfer and triplet-triplet annihilation processes are of crucial importance in realizing the efficiencies and device stabilities required for commercialization of the technology.

8115-16, Session 3

Improvement of device efficiency in PIN-OLEDs by controlling the charge carrier balance and intrinsic outcoupling methods

F. Löser, T. Romainczyk, C. Rothe, D. Pavicic, A. Haldi, M. Hofmann, S. Murano, T. Canzler, J. Birnstock, Novaled AG (Germany)

For both display and lighting applications, OLEDs with high power efficiency are desirable. A prerequisite for high power efficiency is the achievement of a low driving voltage, which can be done via charge carrier doping of the transport layers in PIN OLEDs. However the reduction of the driving voltage may in some cases give rise to a reduction in current efficiency and device lifetime.

The reason for this is not the PIN structure and its material sets as such, but the change in charge carrier balance inside the device that is caused mainly by the greatly enhanced conductivity of the n-ETL.

We have looked for ways of how to combine low voltage with high current efficiency and long lifetime and have therefore investigated different ways of changing the charge carrier balance in PIN-OLEDs.

We demonstrated that good lifetime and efficiency in low-voltage OLEDs depend crucially on a well balanced charge carrier supply of electrons and holes to the emitting layer.

In further investigations we have developed highly efficient and stable white PIN top and bottom emission OLED devices using novel evaporation processable outcoupling enhancement materials inside the PIN OLED stack. In white bottom emission OLED structures the use of this outcoupling enhancement material in combination with a standard MLA outcoupling film can yield an efficiency enhancement of up to 1.8. A Power efficiency of 50.2 lm/W and color coordinates of 0.46/0.41 at a brightness of 1000 cd/m² has been demonstrated.

8115-17, Session 3

Low voltage, low power, organic light emitting transistors for AMOLED displays

M. A. McCarthy, B. Liu, E. P. Donoghue, I. Kravchenko, D. Y. Kim, F. So, A. G. Rinzler, Univ. of Florida (United States)

No abstract available

8115-18, Session 3

Efficient spin-coated small-molecule OLEDs

M. Cai, E. Hellerich, T. Xiao, R. Shinar, J. Shinar, Iowa State Univ. (United States)

Efficient fluorescent and phosphorescent spin-coated small molecule OLEDs are described. The structure of the fluorescent devices is ITO/PEDOT:PSS/spin-coated NPB:Alq3/thermally evaporated BPhen or BCP/CsF/Al. The structure of the phosphorescent devices is ITO/PEDOT:PSS/spin-coated Ir(ppy)3:CBP/thermally evaporated BPhen or BCP/CsF/Al. The fluorescent devices exhibited a peak luminous efficiency exceeding 10 Cd/A at low current, which gradually decreased to 8 Cd/A at 400 mA/cm2. The phosphorescent devices exhibited peak power efficiencies exceeding 60 lm/W or > 120 lm/W with outcoupling enhancement. The nature of the high efficiency and initial results on device stability will be discussed.

8115-19, Session 3

Fluorescent OLEDs with unusually high external quantum efficiency around 8%

Y. Pu, G. Nakata, J. Hu, Y. Yamashita, K. Kobayashi, D. Yokoyama, H. Sasabe, J. Kido, Yamagata Univ. (Japan)

Upper limit of external quantum efficiency (EQE) in fluorescent OLEDs has been considered to be 5%, which is introduced as the product of the following factors: charge balance of holes and electrons (~100%), fraction of singlet and triplet excitons in recombination (25%), photoluminescent quantum efficiency (~100%), and optical outcoupling (20%). However, recently, there are some reports on highly efficient fluorescent OLEDs showing the EQE over 5%.[1] First of all, we focused on making the charge balance as high as possible because it is a prerequisite to achieve an high EQE. Coumalin C545T and DPAVBi were used as an emitting dopant for green and blue emission, respectively. 2-Methyl-9,10-di(2-naphthyl)anthracene (MADN) was used a host. Several types of hole-transporting and electron-transporting materials were used to control energy levels to improve injection of charges to the emitting layer. When TAPC and 3,5,3”,5”-tetra-3-pyridyl-[1,1’;3’,1’]terphenyl (B3PyPB)[2] were used in a hole-transporting layer and electron-transporting layer, respectively, 7.5% of EQE at 100 cd/m2 and 7.2% at 1000 cd/m2 were achieved in green emission, and 8.1% at 100 cd/m2 and 7.7% at 1000 cd/m2 were achieved in blue emission. Those efficiencies were estimated from front luminance and spectrum with Lambertian assumption, which was supported by angular dependence of radiance measurement. Microsecond order of delayed emission from the device after pulse voltage application was observed and indicated that these unusually high EQEs could be resulted from triplet-triplet annihilation process.

8115-20, Session 3

Organic light emitting diodes with roll-up character

J. Jou, Y. Wang, C. Lin, P. Chen, M. Tang, National Tsing Hua Univ. (Taiwan); S. Chen, C. Chen, C. Wang, Industrial Technology Research Institute (Taiwan)

Highly efficient organic light-emitting diodes (OLEDs) are strongly demanded for both display and illumination applications. High efficiency would also help prolong the device lifespan. However, many OLEDs encounter significant roll-off problem, leading to undesired low device efficiency at high luminance, unfavorable to their commercial realization for lighting. OLED devices with mild or even little roll-off are hence highly expected. We have, nevertheless, observed some OLEDs to exhibit roll-up phenomenon; i.e. that their external quantum efficiency (EQE) or current efficiency increases as the applied voltage or brightness is increased. By taking such advantage in device architecture design, OLEDs with an approaching or even above the theoretical limit EQE are obtained at high luminance. We will present how this works for a monochromatic yellow OLED having a record-high power efficiency among reported fluorescent yellow OLEDs, and an OLED with very-low color temperature with a record-breaking efficacy based on the same color-temperature. The plausible mechanism regarding why roll-up occurs in some certain structure systems will also be reported.

8115-21, Session 3

Polymeric hole injection layers for highly efficient and stable organic light emitting diodes

M. Choi, T. Han, Pohang Univ. of Science and Technology (Korea, Republic of); D. H. Huh, Cheil Industries Inc. (Korea, Republic of); T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of); K. Shin, J. Jang, Seoul National Univ. (Korea, Republic of)

We introduced conducting polymer compositions based on water-dispersible polyaniline:poly(styrene sulfonate) (PANI:PSS) and water-soluble self-doped conducting polymer (PSS-g-PANI) as hole injection layers (HILs) in small molecule organic light-emitting diodes (SM-OLEDs). The luminous efficiencies of SM-OLEDs remarkably increased using our compositions, blended with perfluorinated ionomer (PFI) as HILs. Because the PFI was self-organized at the surface and, thereby, caused a high work function, we can tune work functions of HILs and make nearly ohmic hole-injection contact. Due to improved injection efficiency and electron blocking ability, we achieved very high luminous efficiencies (PANI:PSS/PFI : ~ 17 cd/A, PSS-g-PANI/PFI : ~20 cd/A), compared with a conventional small molecule HIL (2TNATA : ~12cd/A) and a commonly-used water-dispersed polymeric HIL (PEDOT:PSS : ~15 cd/A). Device half-lifetimes at 2000 cd/m2 using our water-dispersible compositions were remarkably improved because of the diffusion blocking capability of the PFI surface layer. (PANI:PSS/PFI : ~ 95 hrs, PEDOT:PSS : ~ 7.6 hrs). In the case of self-doped conducting polymer compositions (PSS-g-PANI/PFI), the maximum lifetime of the device reached ~ 290 hrs, which can be attributed to high doping stability as well as the PFI surface layer effect. PANI-based conducting polymer compositions can be good candidates for reliable HILs in SM-OLEDs.

8115-22, Session 3

High-work-function indium tin oxide for simplified high-performance organic light emitting diodes

M. G. Helander, Z. Wang, J. Qiu, M. T. Greiner, Z. Lu, Univ. of Toronto (Canada)

Transparent conducting oxides (TCOs), such as tin-doped indium oxide (ITO), are the electrode materials of choice in state-of-the-art organic photovoltaics (OPVs), organic light emitting diodes (OLEDs) and flat-panel displays due to their unique combination of high electrical conductivity and high optical transparency across the visible spectrum. Controlling the interface properties between ITO and organic materials is of great importance for device engineering since the performance, stability and lifetime of organic devices are greatly influenced by the electrode/organic contacts. Organic electronic devices fabricated on bare ITO electrodes are problematic due to insufficient charge injection and poor operational stability caused by the large mismatch between the low work function of ITO (~ 4.7 eV) and the highest occupied molecular orbital (HOMO) of the organic. We report a simple method for tuning the work function of TCO thin films using a novel halogenation technique. Using this facile technique we achieve an unprecedented high work function of > 6.1 eV for ITO. The application of the high work function ITO in organic electronic devices allows efficient charge injection into organic materials without the need for additional injection layers, greatly simplifying device design and fabrication.

8115-23, Session 3

High-performance green fluorescent host materials with high-thermal stability

T. H. Kim, Doosan Corp. (Korea, Republic of)

We demonstrate high efficiency green fluorescent Indenoanthracene-host material for OLED. Many derivatives of Indenoanthracene show high efficiency, but they have an issue of thermal stability for mass production. Most of melting typed Indenoanthracene host materials showed the low thermal stability. To increase thermal stability of a lot of derivatives in mass production evaporation system, we searched the sublimation typed Indenoanthracene host materials. Two approaches to the goal were available for us. One was to make the structure of product simple for low evaporation temperature. Another was to introduce some

bulky substituent in molecule for reducing the interaction between the molecules. Most of sublimation typed molecules kept their purity for quiet long time, compared to melting typed materials.

8115-24, Session 4

Solution-processed organic light emitting transistors

E. B. Namdas, The Univ. of Queensland (Australia)

Light emitting field effect transistors (LEFETs) are a new class of devices that combine the electrical properties of a transistor with light emitting capability in a single device architecture. One of the key problems with LEFET is their low brightness which limits their application. So far the gate dielectric has been viewed as a passive electronic component of the LEFET. Here we introduce a new strategy of an optoelectronic gate dielectric to improve, simultaneously, the brightness and efficiency of the LEFET. The optoelectronic gate dielectric (OEG) consists of three pairs of alternating high and low refractive index layers of quarter wave thickness and gives an LEFET with excellent electrical characteristics, very high brightness of 4500cd/m2, and an efficiency at this brightness of 0.9 cd/A. This is the highest brightness obtained so far from the LEFET device architecture. The efficiency was improved by a factor of 4.5 compared to the control device on SiNx gate dielectric.

8115-25, Session 4

Self-organized polymeric anodes for high-performance organic light emitting diodes with simplified structures

S. Woo, T. Han, M. Choi, T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Most of research on flexible transparent electrode materials has been focused on the improvement of conductivity at a fixed transmittance. However, all the reported flexible transparent anode materials suffer from poor charge injection due to low work function and thus an additional organic layer is necessary to facilitate hole injection/extraction in organic electronics. Here, we report a new material concept of flexible polymeric anode (we call “AnoHIL”) which has easy work-function tunability and thus makes ohmic-contact between the anode and organic layer even with high ionization potential up to 5.8 eV. In this manner, the device structure is simplified. We demonstrate highly efficient green organic light-emitting diodes (OLEDs) (~22 cd/A) and solution processed phosphorescent white OLEDs (~34 cd/A) using our AnoHILs without a hole-injection layer. This proves promising replacement of conventional brittle electrodes with even greatly improved performance toward flexible solid-state lighting sources and full-color displays.

8115-26, Session 4

Polarizer-free high-contrast organic light emitting diodes

S. Yoo, H. Cho, KAIST (Korea, Republic of)

We present our study on polarizer-free high-contrast organic light-emitting diodes (OLEDs) that are considered better positioned in terms of cost effectiveness and compatibility with highly flexible displays. A particular emphasis is placed on those compatible with inverted top-emitting (ITE) geometry in consideration of the growing importance of n-type thin-film transistors based on oxide semiconductors. As an introduction, the definition of contrast ratio (CR) and its practical implications are briefly discussed, and then the prior arts are reviewed and compared in an effort to find a strategy toward the best possible configuration for high-CR OLEDs. Promising high-CR OLED structures compatible with ITE geometry are then proposed that are based on (i) partially reflecting bottom electrodes and (ii) damage-free top electrodes consisting of dielectric-metal-dielectric multilayer structure. A particular attention is paid first to the bottom electrode configuration from both electrical and optical perspectives and then to the top electrode configuration from optical perspectives that consider the overall cavity structure. An exemplary ITE-OLED under the proposed scheme is demonstrated to exhibit luminous reflectance of ~2% with the current efficacy comparable to or higher than that of conventional high-CR OLEDs relying on circular polarizing films. A choice of outer dielectric layers is shown to play an important role in reducing reflectance in the wide range of the visible spectrum for truly “black” appearance. General optimization strategies to realize ITE-OLEDs striking a good balance between CR and performance are discussed as a conclusion.

8115-27, Session 4

Channel-wide illumination and angular emission profile in tri-layer organic light emitting transistors

S. Toffanin, W. Koopman, G. Generali, R. Capelli, M. Muccini, Istituto per lo Studio dei Materiali Nanostrutturati (Italy)

Organic light-emitting field-effect transistors (OLETs) are emerging as an innovative class of multifunctional devices that integrates the electronic properties of a transistor, the light generation capability and the full potential of organic photonics. OLETs can provide both a novel device architecture to investigate fundamental optoelectronic properties and can be used in applications as diverse as optical communications system, simplified flat panel displays and solid-state lightening [1].

We recently reported [2] a trilayer heterostructure OLET with a device external quantum efficiency of 5% in which not only the electrode-induced photon losses and exciton-metal interaction, but also the charge-induced exciton absorption were simultaneously controlled.

Apart from the potential advantage of the OLETs related to the higher EQE and brightness [1], the limited width of the recombination zone in the device channel might be a limitation for a number of application such as OLET-based active matrix displays and lab-on-a chip photonic detection. Moreover, optical and photonic investigations on light extraction from OLETs are mandatory to locate resonators and waveguides into field-effect planar structure for the realization of highly integrated optoelectronic multifunctional devices.

Here, we implement high performance trilayer heterostructures for realizing for the first time an OLET in which the emission area extends over the entire channel length in ambipolar conditions.

Moreover, we measure directly the angular emission profiles on trilayer OLETs in different bias conditions. Indeed, we correlate the lateral extension of the emitting zone and the bias-invariant angular emission profiles in trilayer OLETs with the device characteristics of charge transport and exciton formation processes.

[1] M. Muccini Nat. Mater. 5, 605 (2006).

[2] R. Capelli, S. Toffanin, G. Generali, H. Usta, A. Facchetti, M. Muccini Nat. Mater. 9, 496 (2010).

8115-28, Session 4

Phosphorescent organic light emitting diode with >60% external quantum efficiency at >10,000 cd/m2

Z. Wang, M. G. Helander, J. Qiu, D. P. Puzzo, M. T. Greiner, Z. Lu, Univ. of Toronto (Canada)

Phosphorescent organic light emitting diodes (PHOLEDs) attracted considerable research interest due to their potential to reach 100% internal quantum efficiency. However, two major factors limit the external quantum efficiency (EQE) for PHOLEDs, i.e. the light out-coupling factor and the efficiency roll-off. In this work, a novel out-coupling enhancement

method is presented. Using this new enhancement, a green PHOLED with up to 63 % EQE is realized. Moreover, the efficiency remains as high as 60% at 10,000 cd/m2. The peak value of power efficiency reaches 290 lm/W without using electrical doping.

8115-29, Session 4

Photostability of the organic/metal cathode interface in organic light emitting devices

Q. Wang, H. Aziz, Univ. of Waterloo (Canada)

We have studied the photo-stability of two types of organic/metal contacts widely used in organic light-emitting devices (OLEDs), namely, organic/Mg:Ag and organic/LiF/Al interfaces. Irradiating OLEDs which contain these contacts by external illumination is found to result in a gradual increase in driving voltage (Vd) and decrease in electroluminescence (EL) efficiency. This photo-induced degradation in device performance is found to be caused by changes at the organic/metal interface, possibly due to photochemical processes, that lead to a deterioration in electron injection. Evidence of interface photo-degradation, inherently, by device own EL, during electrical driving is investigated by means of removing the cathode and re-depositing a new one. The correlation between the density of excited states in the organic material adjacent to the organic/metal interface and the rate of the photo-degradation in device performance is also investigated. The results uncover an important degradation mechanism in OLEDs and shed the light on a phenomenon that might limit the stability of other organic optoelectronic devices.

8115-30, Session 5

Color tunable light sources based on organic light emitting diodes

J. Lee, J. Han, J. Huh, J. Shin, D. Cho, H. Chu, Electronics and Telecommunications Research Institute (Korea, Republic of)

We have fabricated color tunable white light sources by combining a transparent and a bottom emission organic light emitting diodes (OLEDs). White spectra could be obtained by mixing up two different light emissions from two OLEDs. To improve light extractions in color tunable OLEDs, we have taken advantage of micro-cavity effect and a transparent anode containing thin metal layer (about 1 nm of Ag) was used in the bottom emission OLED. Optical lengths could be optimized by controlling the thickness of a hole transporting layer (HTL) and 40% of light extraction could be enhanced in a blue bottom emission OLED. Although the thickness of the HTL was thicker than conventional HTL thicknesses, similar operating voltages could be obtained due to the special layer structure and therefore luminous efficacy could be also improved according to the enhancement of light extraction. As for transparent OLEDs, yellow and red emitting OLED was fabricated. In this case, we have used conventional ITO transparent anodes and tried to improve transmittance and light extraction. The transmittance of the transparent OLED was strongly correlated with the transmittance of the cathode as well as the optical thicknesses of each layers in the OLED. Light extractions could be engineered by optimizing the structure and thickness of the capping layer on the transparent cathode. Optimized transparent OLEDs showed 70 % of transmittance at 550 nm with a common glass encapsulation and about 80-90 % of external efficiencies of the corresponding bottom emission OLEDs. Finally, color tunable OLEDs could be demonstrated by combining the two OLEDs and the detailed results will be revealed in this presentation.

8115-31, Session 5

Stretchable polymer LEDs fabricated on silver nanowire polymer composite electrodes

Z. Yu, L. Li, Q. Zhang, J. Liu, Q. Pei, Univ. of California, Los Angeles (United States)

Various new transparent electrodes have been investigated to replace indium tin oxide (ITO). We report a new transparent electrode based on silver nanowires (AgNW) using a simple fabrication process. The AgNW-polyacylate composite electrodes have sheet resistances tunable in the range of 8-100 Ohm/sq with transmission of 80-95%. The surface roughness is <5 nm. Polymer LEDs fabricated on the new composite electrodes show similar performance as controls on ITO/glass. Some of the devices could be stretched by greater than 10%, repeatedly and reversibly.

8115-32, Session 5

Light emitting diodes based on quantum dot nanohybrid active layers

K. Char, Seoul National Univ. (Korea, Republic of)

Dispersion of colloidal quantum dots (QDs), which are considered quite useful for LEDs due to emitting visible light with narrow spectral bandwidth, within unconventional block copolymer (BCP) thin films was investigated and its effect on LED performance was studied. Unconventional BCP composed of either thiol (SH) anchoring groups or fluorinated (F) phenyl groups in the minor block (11 repeat units) and poly(triphenylamide) in the major block (60 repeat units) were synthesized through the Reversible Addition Fragmentation chain Transfer (RAFT) polymerization method. QDs (diameter ~ 8 nm) encapsulated with alkyl hydrocarbon (~ 1 nm) were mixed with both types of BCPs and deposited on substrates to create hybrid thin film (less than 100 nm). With combined techniques of TEM, AFM and Kelvin Probe Microscopy (KPM), we confirmed that QDs are evenly distributed within the BCP matrix with thiol (SH) anchor block as a result of enthalpic attraction between QD and BCP, while QDs are phase-separated from the BCP matrix with fluorinated phenyl block either to the top surface or bottom surface and laterally segregated to form QD clusters in order to minimize the interfacial energies between QD and BCPs during the deposition (solvent evaporation) steps. On the basis of this experiment, we realized electrically driven QD based light-emitting diodes with organic-inorganic hybrid active layers of evenly distributed QDs within conducting host thin films, demonstrating that QD hybrid active layers are quite useful in LED applications due to the combination of emission and hole/electron transport layers as well as the ease of film deposition.

8115-33, Session 5

Micro-optical beam-shaping concept for tailored light-emission patterns from OLEDs

C. A. Wächter, D. Michaelis, M. Flämmich, N. Danz, P. Dannberg, A. Bräuer, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

The OLED technology introduces thin, large area light sources. Any application that desires a shaped OLED emission pattern inevitably needs thin micro-optical systems in order to retain the OLEDs features of slimness and light-weight. In this contribution we will show that micro-optical arrays are well suited to fully open up the potential of OLED lights.

An OLED beam-shaping scheme utilizing thin micro-optical arrays will be demonstrated. Each array channel consists of a micro lens and a proper reflective/absorptive aperture. This approach combines two effects for OLED pattern shaping: (a) light recycling due to multiple reflections between the OLED and the beam-shaper, (b) distorted and arrayed Fourier imaging, where the aperture induced spatial light pattern

is transformed into a distinct angular light distribution. It may be applied with OLEDs readily comprising substrate outcoupling structures or OLEDs with planar substrates. In either way the light emission pattern of large area OLEDs can be tailored efficiently.

By means of such a beam-shaping concept several different illumination patterns (e.g. circles, triangles or letters) with divergence angles up to ~± 40° will be demonstrated. Furthermore, a reduction of the divergence angle down to about ± 10° accompanied by a stray-light level minimization to <1% at larger angles will be presented. In either case intensity enhancements by a factor of 2 can be realized with the thickness of the optics remaining below 2 mm.

8115-95, Session 5

Continuous-wave organic semiconductor lasing

Y. Zhang, S. R. Forrest, Univ. of Michigan (United States)

Optically pumped organic semiconductor lasers (OSLs) have, up until now, only operate in pulsed mode with a maximum duration of several tens of nanoseconds. This limitation is imposed by triplets generation along with radiative singlets. Triplet absorption typically overlaps the singlet emission spectrum, leading to losses at high triplet densities that accumulate over time during the pumping pulse, thereby prohibiting OSLs from achieving continuous-wave (CW) operation. In this work, we introduce “triplet manager” molecules into the emissive region of an OSL that prevent triplets from interacting with the singlet exciton or photon populations. Using this approach, we observe lasing time increase to 100 µs, limited only by device degradation. Theoretical analysis suggests that the devices have exceeded the CW lasing threshold that is higher than the pulse threshold. This result changes a fundamental understanding of OSL dynamics and opens a new route to electrically pumped organic lasers.

8115-34, Session 6

Organic semiconductor lasers: materials, photophysics, and fabrication

G. Tsiminis, Y. Wang, N. A. Montgomery, Univ. of St. Andrews (United Kingdom); S. Schumacher, J. Denis, I. Galbraith, Heriot-Watt Univ. (United Kingdom); A. Kanibolotsky, Univ. of Strathclyde (United Kingdom); I. Perepichka, Bangor Univ. (United Kingdom); P. J. Skabara, Univ. of Strathclyde (United Kingdom); I. D. W. Samuel, G. A. Turnbull, Univ. of St. Andrews (United Kingdom)

Organic semiconductors have considerable potential for compact, tunable, visible lasers. A particular advantage of these materials is their scope for simple fabrication. We show that nanoimprint lithography is a powerful technique for fabricating distributed feedback lasers and report the factors affecting the quality of replication and laser threshold. The choice of lasing material is also a key factor and we will report a systematic study of the photophysical and lasing properties of a family of star-shaped molecules consisting of a truxene core and fluorene oligomers arms. A combined experimental and theoretical study was performed, exploring the effect of the length of the arms on the transition dipole for absorption and emission. It is found that although the entire molecule absorbs, the excitation quickly localises on a single arm. Very good laser performance is obtained. For example the materials with 3 fluorene units in each arm gives an exceptionally broad tuning range for a deep blue material from 422 to 473 nm, high gain (38 cm-1), loss loss (3.5 cm-1) and a low threshold for lasing of 515 W/cm2.

8115-35, Session 6

Last advances in optimizing organic solid-state lasers based on photostable materials and high-quality resonators

M. A. Diaz-Garcia, E. M. Calzado, M. G. Ramirez, V. Navarro-Fuster, P. Boj, I. Vragovic, J. M. Villalvilla, J. A. Quintana, Univ. de Alicante (Spain); I. Alonso, A. Juarros, A. Retolaza, S. Merino, Tekniker (Spain)

In this presentation we will discuss the last advances achieved in our group in relation to the development of efficient and photostable organic solid-state lasers, including advances in improving both, the active material and the resonator.

From the material´s point of view, we have focused our efforts on searching for photostable and low-threshold materials in waveguide configuration. For such purpose we have investigaded small organic molecules doped into different types of inert polymers, searching for high index-contrast between the active film and the substrate. We have also studied organic single crystals, as model systems to advance understanding of the mechanisms involved in laser emission.

Concerning the resonator, we have designed, fabricated and characterized second-order distributed feedback (DFB) lasers by holographic lithography (HL) and by nanoimprint lithography (NIL). HL, a versatile method that allows the design to be easily changed and large samples to be prepared, has been used to test new designs. In these devices the photoresist has been used directly as the substrate, in order to symplify the fabrication process. NIL has been used to fabricate high-performing and low-cost DFB devices. Detail studies of the influence of several parameters, i.e. grating depth, film thickness, index contrast between film and substrate and location of the grating (over the substrate or over the active film), have allowed us to control the emission characteristics of the devices.

8115-36, Session 6

Electrically pumped organic laser device with a coupled microcavity structure

X. Liu, Y. Li, J. Lin, S. Qu, Changchun Institute of Optics, Fine Mechanics and Physics (China)

As laser gain media, organic materials are intrinsically quasi-four-level systems. They are materials that have high fluorescent quantum efficiencies, low absorption losses, and can be easily prepared in a film configuration. Although optically pumped laser action has been observed in a broad range of organic materials including polymers or small molecules with lasing wavelengths spanning the visible spectrum, the compact, low cost and practical organic laser devices (OLDs) should be electrically pumped. Obstacles are still in the way of realizing electrically pumped organic lasers in waveguide, distributed feedback (DFB), and light-emitting TFT structures. Recently, significant progress has been made in electrically pumped organic lasers with a microcavity structure. In this work, we will show some further results in this respect.

An electrically pumped OLD has been developed with a coupled microcavity (CMC) structure: Glass/bottom mirror/SiO2/middle mirror/ ITO/MoO3/2T-NATA/NPB/NPB:DCM/Alq:DCM/Alq /LiF/Al/top mirror. The OLD shows a single longitudinal cavity mode at 618 nm with a threshold current density of about 600 mA/cm2 under room temperature CW operation. The OLD has an active light emitting area of 1×1 mm2, and the output light beam shows apparent coherence. The design of device structure has been illustrated. Furthermore, we will show that the electrically pumped green light OLDs based on Alq:C545T gain layer has reached a maximum output power density of 1 mW/cm2.

8115-37, Session 6

Transparent electrodes for plastic electronics

J. C. de Mello, Imperial College London (United Kingdom)

Organic semiconductors are attracting widespread interest due to their potential applications in lighting, displays and solar cells. A key obstacle to successful commercialisation, however, is the absence of high performance flexible electrodes that can be processed at plastic-compatible temperatures. For rigid applications, indium tin oxide (ITO) is the transparent conductor of choice, but its high cost, tendency to crack when flexed, and need for high temperature processing are problematic for large area applications. Here we investigate the use of conducting polymers, single wall carbon nanotubes, and silver nanowires as ambient processable transparent electrodes for organic light-emitting diodes and solar cells.

Key issues that will be discussed include: ITO-free OLEDs based on vapour phase polymerised PEDOT; organic field-effect transistors utilising PEDOT:PSS and graphene source and drain electrodes; and efficient organic solar cells using solution processed single wall carbon nanotubes and silver nanowires for the transparent electrode.

8115-38, Session 6

Resonant optical antenna effects in organic photonic devices

D. M. O'Carroll, Rutgers, The State Univ. of New Jersey (United States)

Nanoscale optical antennas can modify the direction, decay rate and luminescence quantum efficiency (QE) of excitonic emission from organic semiconductors by concentrating optical modes into nanometer-scale volumes. Here, the emission properties of heterostructured optical antennas (fabricated by template-directed sequential electrodeposition [1]) consisting of plasmonic (noble metal) nanowire antennas coupled to poly(3-hexylthiophene), P3HT, conjugated polymer disks (20 nm high; 60 nm diameter) are presented. The radiative decay rate (Tr) of P3HT in the presence of a single gold nanoantenna is determined to be 440 x 10^6 s^(-1) from photoluminescence lifetime measurements - an increase by a factor of 31 over P3HT in the absence of antennas. Both Tr and QE enhancements of up to 135 and 55 are shown to be possible in theory (full-field electromagnetic simulations), for plasmonic nanowire antennas with optimized length and diameter (180 and 40 nm, respectively) that resonate at the emission wavelength of P3HT. Work is underway to characterize arrays of plasmonic nanoantennas coupled to 20 nm-thick P3HT films to demonstrate large-area enhancements in Tr and QE. Benefits to the absorption characteristics of P3HT thin films using silver nanoantennas with resonances tuned to the polymer absorption band will also be discussed. When incorporated onto the metallic electrode of bulk-heterojunction photovoltaic test devices the nanoantennas will be shown to render the electrode optically active resulting in improved red response in the photocurrent spectra.

8115-39, Session 7

Carrier-blocking nature of polarized organic-organic interfaces studied by DCM, UPS, and TOF methods

H. Ishii, Y. Miyazaki, N. Ogawa, T. Nishi, Y. Nakayama, Y. Noguchi, Chiba Univ. (Japan)

We have investigated the interface charge of Alq3-based OLED. The charge is due to orientation polarization of Alq3 layer, and is a key to understand carrier-blocking mechanism at organic-organic interfaces. Recently we have found not only Alq3 but also other OLED materials such as BCP show similar effect. In this presentation, we will report on an effort to clarify the carrier-blocking nature of these materials by several methods.

Displacement current measurement (DCM) and Time-of-flight (TOF) measurement allow us to directly monitor how the carrier is accumulated and blocked. So far TOF measurement has been applied to single layer device to determine mobility. We applied it to a double-layered device, and successfully observed the carrier behavior in the operating state with light emission.

Kelvin probe (KP) measurement and ultraviolet photoemission spectroscopy (UPS) give us the information of the polarization and energy barrier at the interfaces. KP results confirmed that orientation polarization is formed in the exact device structure. This is necessary to estimate the blocking nature due to the interface charge. UPS determined the barrier heights at organic-organic interfaces. This information is necessary to discuss the blocking nature due to barrier height. From the obtained results, we will discuss on the blocking nature of OLED interfaces.

8115-40, Session 7

Electroabsorption spectroscopy of vacuum-sublimed organic light emitting diodes and solar cells

P. A. Lane, U.S. Naval Research Lab. (United States)

We studied the influence of interfaces on the electric field distribution in organic devices by electroabsorption spectroscopy. Incorporation of a polymer hole injection layer in bilayer organic LEDs profoundly alters the field distribution. In reverse bias, the electric field is suppressed within the hole transport layer and concentrated in the electron transport layer. Excited state absorption by field-modulated cations dominates the forward bias spectrum. We also studied multilayer films of C60 and zinc phthalocyanine, a model system for organic photovoltaics. Dipoles at the organic heterojunction oppose the external field, emphasizing the importance of drift diffusion for charge transport.

8115-41, Session 7

Probing light emitting films with neutrons

P. L. Burn, A. R. G. Smith, I. R. Gentle, The Univ. of Queensland (Australia)

Advances in light-emitting materials design and manufacturing have brought the first organic light-emitting diodes (OLEDs) to market. For all the materials used as light-emitting layers the morphology of the film plays an important role in controlling their opto-electronic and device properties. Neutron techniques such as neutron reflectometry (NR) and small angle neutron scattering are important methods for studying physical structures of (macro)molecules and their interactions in solution and/or the solid state. We have been using an in situ photoluminescence-NR measurement for elucidating the relationship between physical structure and emissive properties. In this presentation we discuss the structure of films comprised of phosphorescent iridium(III) complexes. OLEDs containing iridium(III) complexes are highly efficient but achieving this efficiency usually involves diluting the emissive complex in a host material such as 4,4'-bis(N-carbazolyl)biphenyl. We will report our study on blended films containing fac-tris(2-phenylpyridyl)iridium(III). We will show that not only is the concentration of complex in a blend important for the emissive properties of the film but also the morphological thermal stability. In addition, we will discuss the effect of thermal annealing on multilayer OLED structures.

8115-42, Session 7

Molecular orientation in OLEDs

D. Yokoyama, Yamagata Univ. (Japan); C. Adachi, Kyushu Univ. (Japan); J. Kido, Yamagata Univ. (Japan)

The molecular orientation in organic amorphous films has been disregarded for ~20 years in the research in OLEDs, and its effects on device characteristics have not sufficiently been discussed at the microscopic molecular level. Only recently, the intermolecular interaction and the subsequent horizontal molecular orientation in OLEDs have been investigated and reported. In this presentation, the overview of the recent studies on the molecular orientation in OLEDs will be presented.

First, the general properties of the molecular orientation in OLEDs will be discussed. By variable angle spectroscopic ellipsometry (VASE), it was demonstrated that molecules in amorphous organic semiconductor films are generally oriented on any underlying layer and even in doped films depending on the anisotropy of the molecular shape [1-3].

Then, the effects of the orientation on the optical and electrical performances of OLEDs will be discussed. The horizontal molecular orientation of emitting materials improves the outcoupling efficiency of OLEDs, and the horizontal orientation of charge transport materials improves the carrier mobilities in the films [4,5]. Furthermore, it was reported that the singular molecular orientation induced by intermolecular hydrogen bonds can contribute to the enhancement of mobility [6].

These results show the vital importance of the molecular orientation in OLEDs for the improvement of the device characteristics and the development of new materials.

8115-43, Session 7

Thermal study of the photonic band-gap effect on a resonant energy transfer process

L. González-Urbina, K. Clays, Katholieke Univ. Leuven (Belgium)

Optical confinement can induce enhancement of the resonant energy transfer between fluorescent molecules by modifying the available energy levels. In this work we study the energy transfer between a pair of molecules, fac tris (2-phenylpyridine) iridium (Ir(ppy)3) and bis(2-methyl-8-quinolinato)-4-phenylphenolate aluminum (BAlq) which are extensively used in OLED technology. These chelates have previously shown both Dexter and Förster energy transfer giving rise to phosphorescence emission at low temperatures. Here, we present the result of the dipolar coupling of these two molecules embedded in a polymer film and inserted in a colloidal photonic crystal and how the photonic crystal may improve the efficiency of the energy transfer. A thermal study of the emission under the effect of the photonic band gap is performed.

8115-44, Session 7

Nearly zero-gap formation between singlet- and triplet-excited states and application for organic light emitting diodes

K. Sato, K. Goushi, C. Adachi, Kyushu Univ. (Japan)

Recently, in order to improve the exciton production efficiency at a singlet excited level (S1) in OLEDs, we employed the mechanism of thermally activated delayed fluorescence (TADF). To realize high TADF efficiency, we need materials that have a small energy gap between S1 and a triplet excited (T1) levels (EST). EST becomes smaller when the exchange energy that is overlapping between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) is small. Therefore, the separation of the HOMO from the LUMO is crucial to enhance the up-conversion from T1 to S1 (RISC). More recently, based on this conception, we developed a triazin derivative (PIC-TRZ) that realizes a small EST of 0.1 eV and the OLED using PIC-TRZ for an emitting layer achieved a high external quantum efficiency of ext=5.3% that exceeds the theoretical limitation of ext in conventional fluorescence OLEDs. In this study, to achieve higher EL efficiency using TADF, we developed a novel triazin derivative (PIC-TRZ2) having a nearly zero energy gap between S1 and T1, which was confirmed by the fact that fluorescence and phosphorescence spectra of PIC-TRZ2 shows exactly same 0-0 transition peak (T=5 K). Furthermore, intense delayed fluorescence is confirmed in both the neat and a 6 wt%-PIC-TRZ2:1,3-bis(9-carbazolyl)benzene (m-CP) co-deposited film under photo-excitation at room temperature. In addition, the OLED using PIC-TRZ2 shows a high external quantum efficiency of ext=7.9% at 0.01 mA/cm2 with delayed fluorescence.

8115-45, Session 7

Delayed electroluminescence measurements: a technique for investigating the emission mechanism in phosphorescent organic light emitting devices

H. Zamani Siboni, H. Aziz, Univ. of Waterloo (Canada)

Delayed electroluminescence (Delayed EL) measurements are used to investigate the emission mechanism in typical Phosphorescent Organic Light Emitting Devices (PHOLED). In this study, the emission layer is doped with various concentrations of the emitter guest. Delayed EL is used to understand whether the EL emission arises from charge recombination directly on guest sites or from recombination on host material followed by host to guest energy transfer. The results show that the emission mechanism changes with guest concentration. At low guest concentration, device shows strong host triplet-triplet annihilation (TTA), suggesting the presence of significant energy transfer from host to the guest. At high guest concentration, on the other hand, host triplet-triplet annihilation is insignificant suggesting that direct charge trapping on the guest is the main emission mechanism. Results also show no significant guest TTA in the latter, indicating guest TTA does not significantly influence emission. Observations related to the role of guest concentration on the operational stability of PHOLEDs are also reported.

8115-46, Session 7

Precise determination of OLED emitter properties

M. Flämmich, D. Michaelis, C. A. Wächter, N. Danz, Fraunhofer-Institut für Angewandte Optik und Feinmechanik (Germany)

The detailed properties of the internal dipolar emission (which are e.g. the internal electroluminescence spectrum, the profile of the emission zone, and the orientation of the transition dipole moments) strongly affect the device efficiency and the radiation pattern of OLEDs. In recent years, the characterization of OLED emitter properties by optical analysis of the far-field radiation patterns of OLEDs in electrical operation was established as a method to determine these data experimentally. Unfortunately, bottom emitting standard devices optimized for maximum emission in air are not suitable to measure all active emitter properties exactly.

In our contribution a simplified layered stack is discussed as an example of typical bottom emitting OLED structures. As known from rigorous optical modeling, the distance of the emissive sites to the metal cathode is the most crucial parameter to enhance or suppress certain emitter contributions to the far-field emission. Varying this emitter-cathode distance allows changing the different emitter contributions advantageously. In result, the emitter properties can be determined with highest precision from radiation pattern analyses when utilizing adapted

OLED stacks. General rules for setting up adapted OLED systems for emitter characterization in electrically driven OLED devices are concluded. Furthermore, selected experimental results will accompany the theoretical discussion in order to illustrate and to demonstrate the applicability of this approach.

8115-47, Session 7

Carrier mobility and diffusion length measurements via impedance-voltage characteristics in organic light emitting diodes

I. Wu, J. Chang, C. Wu, National Taiwan Univ. (Taiwan)

The correlation between the impedance versus voltage (Z-V) characteristics and the carrier mobility and diffusion length of OLEDs was investigated. With the existence of the accumulation charges at the organic layers interfaces, the Z-V characteristics present a particular transition before the device turns on and the voltage at where the transition occurs is related to the film thickness and the density of the accumulation charges. Devices with systematically varied film structures, including various cathode structures and different thicknesses of the organic layers were investigated. For the devices with common structures, NPB as the hole transport layer (HTL) and Alq3 as the electron transport layer (ETL), the density of the accumulation charges is constant. However, the impedance transition happens at different voltage bias in the devices with an electron injection layer, which may result from the decrease of the effective thickness.

The devices with other combinations of HTLs and ETLs were also studied and the results showed that there is an extra impedance transition only in the devices with the hole mobility in the HTL much larger than the electron mobility in the ETL. It implies that the extremely different carrier mobilities somehow have a great influence on the existence of the accumulation charges. Thus the difference between the carrier mobilities in the HTL and the ETL can be surveyed through the Z-V characteristics of OLEDs, and this property makes the Z-V characteristics a potential tool to quickly estimate the carrier mobility in organic materials.

Study of charge injection in inverted organic unipolar devices using n-type hole injection layers

C. E. Small, J. Subbiah, K. R. Choudhury, F. So, Univ. of Florida (United States)

Improved hole injection efficiency was demonstrated by inverting the device architecture of small molecule unipolar devices with n-type hole injection layers. Current-voltage and dark-injection space-charge-limited current (DI-SCLC) techniques were used to characterize normal and inverted N,N'-diphenyl-N,N'-bis(1-naphthyl)(1,1'biphenyl)-4,4'diamine (NPB) unipolar devices consisting of molybdenum trioxide (MoO3) or 1,4,5,8,9,11-hexaazatriphenylene hexacarbonitrile (HAT-CN) hole injection layers. Both normal and inverted devices with HAT-CN showed larger injection efficiencies compared to similar devices with MoO3. The injection efficiency enhancement observed by inverting the device architecture was attributed to improved charge transfer at the n-type layer/NPB interface due to improved interfacial doping. We validate this claim by fabricating NPB unipolar devices with MoO3-doped NPB injection layers, in which further enhancement in injection efficiency is observed.

Organic light up-conversion devices with hole-blocking layers

D. W. Song, D. Y. Kim, F. So, Univ. of Florida (United States)

The integration of organic photodetector and organic light-emitting diode (OLED) enables the fabrication of infrared-to-visible up-conversion devices. However, due to the proximity between the work function of indium-tin oxide (ITO) and the HOMO level of IR absorbing tin (II) phthalocyanine (SnPc), hole injection from ITO starts even at low voltages, and hence decreasing the sensitivity of the up-conversion performance. In this presentation, we report the enhancement in the up-conversion performance by controlling hole blocking properties.

We have fabricated control OLED devices, devices with an IR sensitizing mixed layer of SnPc:C60, and devices with hole blocking layer. The control devices had the following structure: ITO/SnPc:C60 (1:1 ratio, 20 nm)/1,1-bis[(di-4-tolylamino)phenyl]cyclohexane (TAPC) (45 nm)/7% fac-tris(2-phenylpyridinato)iridium(III) (Ir(ppy)3):4,4-N,Ndicarbazole-biphenyl (CBP) (30 nm)/tris[3-(3-pyridyl)-mesityl]borane (3TPYMB) (45 nm)/LiF(1 nm)/Al (100 nm). We used p-bis(triphenylsilyly)benzene (UGH2) and bathocuproine (BCP) as hole blocker between ITO and the IR absorbing layer. The luminance-current-voltage (LIV) characteristics were measured with and without the 830 nm infrared light irradiation.

The comparison between the devices with different thickness of the IR sensitizing mixed layer and the devices with various hole blocking layers will be presented. Without infrared light irradiation, emission was not observed until 14.5 V in the up-conversion device with 10 nm thick BCP, compared with the control device was turned on at 6 V. It shows that hole injection from ITO was effectively limited by the hole blocking layer. On the contrary, when the device was irradiated with infrared light, photo-generated holes were injected to the light-emitting layer and the device turned on at around 3 V, without a significant change of current efficiency (80 cd/A). The maximum photo-conversion efficiency was measured as 2.5 %.

8115-66, Poster Session

Organic light emitting diodes with polyaniline/silver nanocomposites or aniline oligomers as a hole injection layer

J. Wu, J. Chiu, A. Wang, C. Chang, S. Tang, K. Chiu, Chung Yuan Christian Univ. (Taiwan)

Effects of hole injection layer (HIL) on the performance of organic light emitting diode (OLED) with a basic heterostructure of ITO/HIL/NPB/Alq3/LiF/Al were studied; and polyaniline/silver nanocomposites or aniline oligomers were adopted as a HIL. At first, the surface morphology of HIL after spin-coating on top of ITO substrate was observed by SEM and AFM. Then, the characteristics of current density (J) and electro-luminance (L) versus bias voltage (V) of these as-fabricated OLEDs were measured. The experimental J-L-V curves were numerically analyzed by a model/equivalent circuit. From experimental J-L-V data, an enhancement of L by factor of around 11 at the same V was obtained for an OLED with polyaniline/silver nanocomposite of a specific ratio being used as a HIL, as compared with the one without a HIL. From numerical fitting results, the causes of this improvement were explored. Finally, the physical significance of polyaniline/silver nanocomposites or aniline oligomers used as a HIL on OLED was discussed.

8115-68, Poster Session

CMOS-compatible high-brightness and low-operating voltage green OLEDs

V. Gohri, J. Boizot, MicroOLED (France); H. Doyeux, Commissariat à l'Énergie Atomique (France); G. Haas, MicroOLED (France)

We report high brightness and low operating voltage efficient green organic light-emitting diodes (OLEDs) based on silicon CMOS backplane which can be used in applications such as microdisplays. The small molecule top-emitting OLEDs are based on a fluorescent green emitter accompanied by blocking, doped charge transport layers and an anode fabricated with standard CMOS processes of a 200 mm IC fab. The devices are designed to maximize the efficiency under low operative bias so as to fit the limited voltage budget of the IC. This was done by making optical simulations of the device structure to maximize light outcoupling within a 20° extraction cone, optimizing the organic layer thicknesses and charge injection in the n and p transport layers and utilizing a double emission layer stack. The resulting OLED has a current efficiency of 21 cd/A at a luminance of 20,000 cd/m². Furthermore, the device exhibits a voltage swing of just 2.2 V for a contrast ratio of 1000. The device has a lifetime of 6,000 hours at 5000 cd/m². Similar device performances were reproduced on an active matrix 5 megapixel microdisplay.

8115-69, Poster Session

Nanotransfer for light extraction in top-emitting organic light emitting devices

Z. Wang, J. Hauss, C. Vannahme, U. Bog, S. Klinkhammer, T. Mappes, U. Lemmer, Karlsruher Institut für Technologie (Germany)

Organic light-emitting devices (OLEDs) have attractive and promising applications in next-generation lighting and displays. Even though the internal quantum efficiency of OLEDs with phosphorescent emitters could increase to nearly 100%, the external quantum efficiency of conventional OLEDs is as low as ~20%. And up to 50% of the generated light is trapped in waveguide modes and surface plasmon polariton modes. Therefore, aiming to extract those trapped modes for enhanced emission, we explored a rigiflex mold-assisted nanotransfer method for damage free integration of nanostructures into OLEDs. Compared to the conventional nanofabrication method, for example, interference lithography, this technique offers the possibility to optimize nanofabrication and OLED fabrication independently, and could avoid detriments on electrical properties of OLEDs from the nanofabrication process.

In this work, nanogratings were transferred under low pressure and low temperature on top of top-emitting OLEDs without damage by rigiflex cyclic olefin copolymer molds. Waveguide mode extraction was investigated by Photoluminescence and electroluminescence (EL) measurements. A transfer matrix method and rigorously coupled wave theory based numerical simulations were carried out to identify those extracted waveguided modes. Furthermore, the scanning electron microscopy image shows no damage on the top-emitting OLED structure by this nanotransfer process. EL properties of the EL devices with nanogratings exhibit that this nanostransfer process does not adversely affect the OLED performance. All the results indicate that top-emitting OLEDs and other organic optoelectronic devices could benefit from this one-step, solvent-free and etchless nanotransfer approach, which is compatible with roll-to-roll printing techniques suitable for industrial production schemes.

8115-70, Poster Session

Highly efficient fluorescent flexible green and white organic light emitting diodes with multilayered graphene anode

T. Han, Pohang Univ. of Science and Technology (Korea, Republic of); Y. Lee, Sungkyunkwan Univ. (Korea, Republic of); S. Woo, Pohang Univ. of Science and Technology (Korea, Republic of); B. H. Hong, J. Ahn, Sungkyunkwan Univ. (Korea, Republic of); T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

We realized the highly efficient fluorescent green and white organic light-emitting diodes (OLEDs) with multilayered graphene anode which was modified with self-organized polymeric hole injection layers (HILs). Traditionally, conventional transparent anode, indium-tin-oxide (ITO), has been used as anode for OLEDs. However, the ITO anode has many weeknesses for application to organic electronic devices such as increasing cost of raw material, non-flexible substrate, and problems of diffusion of indium and tin atoms into overlying organic layers during the device operation. To overcome these problems of conventional ITO anodes, alternative anode which has appropriate optical and electrical properties is are strongly required like graphene anode. Graphene has unique electrical and transparent properties as a promising transparent and flexible conductor, there is major drawback for application to electrodes for OLEDs. The relatively low workfunction of graphene (~ 4.4 eV) compared with that ITO anode (~4.8 eV) makes OLEDs difficult to inject holes overlying layers (e.g. EML). Our self-organized polymeric hole injection layer (HIL) has gradient work function toward overlying organic layers and thus makes holes be injected efficiently to the organic layer despite high injection barrier for holes at interface between graphene anode and organic layer. The good ohmic injection of holes between graphene anode and overlying organic layers with our workfunction tunable polymeric HIL is demonstrated by Dark Injection space charge limited current (DI SCLC) measurement. Furthermore, we found very high and much higher luminous efficiency of fluorescent green and white OLEDs with graphene anode than those with ITO anode by using our workfunction tunable polymeric HILs. This kind of strategy to molecularly modify the workfunction of graphene anode with self-organized polymeric hole injection layers make chances to very efficient replacement of ITO anode to flexible graphene anode without sacrificing luminous efficiency.

Highly efficient simple-structure small-molecule organic light emitting diodes by using a molecularly controlled polymeric hole injection layer

T. Han, M. Choi, Pohang Univ. of Science and Technology (Korea, Republic of); C. Lee, Gwangju Institute of Science and Technology (Korea, Republic of); T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Since the standard fabrication method to make multilayered small-molecule organic light-emitting diodes (OLEDs) is thermal vacuum deposition with a series of shadow masks, which needs considerably high material and processing cost. Therefore, we have focused on the reduction of small molecule OLED layers to avoid the high cost issue caused by using many vacuum deposition steps. This paper presents very simplified small molecule OLEDs with a very high luminous efficiency which include only a single layer of small molecules on top of a spin-coated polymeric hole injection layer. We found that the simplification of the device structure using well-known small molecular and polymeric HIL such as 2-TNATA and PEDOT:PSS resulted in significant drop of the luminous efficiency comparing with multilayered structure each. However, when we applied our hole injecting conducting polymer compositions composed of PEDOT:PSS and a perfluorinated ionomer (PFI)

(PEDOT:PSS/PFI) as a hole injecting conducting polymer buffer layer, the luminous efficiency of the simplified device (~ 20 cd/A) was dramatically enhanced compared with standard multilayered small molecule OLED devices (~ 12 cd/A). Furthermore, with comparing the device comprising multilayered structure with PEDOT:PSS:PFI (~18 cd/A), the very simplified device with same polymeric HIL compositions (PEDOT:PSS:PFI) showed a little higher luminous efficiency. Since PFI has a lower surface energy and a higher ionization potential than PEDOT:PSS respectively, this polymeric HIL has gradient work function by self-organization of the PFI. This gradient workfunction of HIL makes holes be injected very efficiently to THE overlying emitting layer (EML) and insulating properties of self-organized PFI layer shows great capability of preventing quenching of excitons at interface between HIL and EML, which was supported by relative photoluminescence intensity measurements and time-correlated single photon counting experiments. In this manner, the very simplified OLEDs can have highly efficient radiative recombinations of holes and electrons without quenching of excitons in recombination zone of these devices nearby the interface between the HIL and the EML.

8115-72, Poster Session

Device failure mode analysis of highly efficient and reliable small-molecule organic light emitting devices with a self-organized polymeric hole injection layer

T. Han, M. Choi, T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

We realized the effect of a self-organized polymeric hole injection layers (HILs) with various composition of polymeric HILs ,PEDOT:PSS:PFI, on the luminous efficiency and device lifetime in small-molecule organic light-emitting diodes (OLEDs). Our high performance polymeric HIL comprising PEDOT/PSS and a perfluorinated ionomer (PFI) has gradient work function toward overlying organic layers. Since the PFI has a lower surface energy and a higher ionization potential than the PEDOT:PSS, this polymeric HIL has gradient work function by self-organization of PFI. Therefore, this polymeric HIL makes holes be injected very efficiently to the emitting layer and blocking electrons at the interface between HIL and emitting layer. This good hole-injection capability makes good charge balance and reliable operation in small-molecule OLEDs. This good hole injection contact is demonstrated by Dark Injection Space Charge Limited Current (DI SCLC) measurement with various PFI compositions in PEDOT:PSS:PFI. OLEDs fabricated by using a hybrid process of solution process of HIL and vacuum deposition process showed a very high luminous efficiency (~18 cd/A), a much higher luminous efficiency compared with conventional small-molecule OLEDs comprising only vacuum deposited small molecules (~12 cd/A). To analyze the influences of our high performance HIL, PEDOT:PSS:PFI on the device, we performed various device characterizations with the varying PFI concentrations in the conducting polymer compositions with a function of luminance degradation percentage by measuring current-voltage characteristics, capacitance-voltage characteristics, photoluminescence and electroluminescence spectra, transient electroluminescence, and mechanical properties of degraded films by nanoindentation.

Highly efficient solution-processed small-molecule organic light emitting devices with novel tetraphenylsilane blue phosphorescent host materials

T. Han, Pohang Univ. of Science and Technology (Korea, Republic of); D. Oh, S. Kwon, Y. Kim, Gyeongsang National Univ. (Korea, Republic of); T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

We report highly efficient solution-processed blue electrophosphorescent small-molecule organic light emitting devices using novel small molecular blue phorsphorescent host materials. We have commonly used commercially available phosphorescent blue guest, Iridium( ) bis(4,6-difluorophenylpyridinato)picolate (FIrpic) and poly N-vinylcarbazole (PVK) as an interlayer between a hole injection layer (HIL) and the emitting layer (EML) respectively. The EML consists of an electron and hole transporting co-host and a blue dopant (FIrpic). 4,4',4"-tris(N-carbazolyl)-triphenylamine (TCTA) and (1,3-bis(N-carbazolyl)benzene (mCP) were commonly used for the hole transporting host materials. We presents three kinds of new tetrasilane electron transporting hosts materials, diphenylbis(3-(pyridine-x-yl)phenyl)silane (x=2,3,4) (2, 3, and 4PTPS), for blue phorsphorescent solution-processed small-molecule OLEDs which have the maximum luminous efficiency reached about 15 cd/A with a conventional PEDOT:PSS HIL. Comparing with 1,3,5-tris N-phenylbenzimidazol-2,yl benzene (TPBI) as a electron transporting host with PEDOT:PSS HIL (~9 cd/A), devices with our new blue phorsphorescent co-host showed much higher efficiency than that with conventional host materials because of more efficient charge balance in the EML and efficient energy transfer to the guest molecules. Furthermore, the use of our self-organized polymeric hole injection layer, PEDOT : PSS : Perfluorinated ionomer (PFI) compositions resulted a in even higher luminous efficiency with 3PTPS (~20 cd/A) and TPBI (~12cd/A) in solution-processed small molecular OLEDs than those with the conventional PEDOT:PSS.

Enhancement of current injection in organic light emitting diodes with sputter-treated molybdenum oxides as hole injection layers

P. Wang, I. Wu, W. Tseng, C. Wu, National Taiwan Univ. (Taiwan)

Molybdenum oxide (MoO3) has been widely used in organic light emitting diodes (OLEDs) to provide superior hole injection efficiency. The origins of assistance in hole injection from MoO3 hole injecting layers are the lowering of injection barrier and formation of gap states between valence band edge of MoO3 and the Fermi level of electrodes when N,N'-di(naphthalene-1-yl)-N,N'-diphenyl-benzidene (NPB) molecules are deposited on MoO3 layers. The chemical reaction between NPB and MoO3 reduces the oxidation states of molybdenum atoms in MoO3 and results in gap state formation. These gap states enhance the conductivity of MoO3 and provide transition paths of carrier to assist the injection of hole from indium tin oxide (ITO) anodes to NPB layers. To enhance the metallic characteristics of MoO3 and facilitate better hole injection directly, in-situ Argon ion sputter is incorporated with the fabrication process of OLEDs in this work. When treating the surface of MoO3 with slight Argon sputtering, ion bombardment removes the bonding oxygen atoms in MoO3 layers. As a result, the oxidation states of molybdenum atoms in MoO3 are reduced. The enhancement of current density in OLEDs is effectively achieved by treating MoO3 layers with slight argon sputtering. After sputter treatment for 10 seconds, the modified MoO3 layers provide improved current injection efficiency, resulting in better current density which is about ten times higher than that of the reference devices. Ultraviolet and X-ray photoemission spectra provide evidences that molybdenum atoms are reduced to lower oxidation states after sputter treatment due to the removal of oxygen atoms.

Highly efficient, ITO-free white organic light emitting diodes (WOLEDs) fabricated by solution processes

M. Choi, S. Woo, T. Han, T. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

White organic light-emitting diodes (WOLEDs) have aroused a great attention due to their potential as solid-state lighting sources and

application in full-color displays. Recently, solution processable WOLEDs have been received much interest to realize low-cost, large-area and printable displays. In this work, we demonstrate high-performance, solution-processed small molecule WOLEDs. A single white-emitting layer was composed of two complementary phosphorescent dopants of sky blue and orange red (FIrpic and Bt2Ir(acac)) doped into a co-host of hole-transporting and electron-transporting small molecules. We achieved a very high luminous efficiency (~ 25 cd/A) and external quantum efficiency (EQE.) (~ 10 %). We also fabricated highly efficient simplified ITO-free solution-processed small-molecule WOLEDs by incorporating polymeric anodes with high hole injection efficiency (we call this anode as AnoHILs). The AnoHIL is a single spin-coated polymeric conductive layer functioning as both the anode and the HIL in the OLED device. Luminous efficiency (~ 32 cd/A) and EQE (~ 13 %) of ITO-free WOLEDs were much higher than those of ITO-based WOLEDs due to high work function and injection efficiency of AnoHILs. These results suggested the possibility of high-efficient flexible WOLEDs via a simple solution process for next generation lighting sources.

Highly efficient top-emitting organic light emitting diodes with LiF/Yb bilayer as an electron injection layer

H. Ahn, W. Song, H. Lee, K. Char, S. Lee, C. Lee, Seoul National Univ. (Korea, Republic of)

We demonstrated the highly efficient top emitting organic light emitting diodes (TOLEDs) with lithium fluoride (LiF) and ytterbium (Yb) bilayer as an effective electron injection layer (EIL) from the silver (Ag) semitransparent cathode. Furthermore we employed 2,2',2"-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) [TPBi] for a capping layer to enhance the efficiency as well as an electron transporting layer. Depending on the results of the simulation, the transmittance of the top side has the highest value of 80.4% (λ=530 nm) at the thickness of TPBi cap layer of 45 nm. Using this, we fabricated the TOLEDs with structure of Al (80 nm)/MoO3 (10 nm)/di-[4-(N,N-ditolyl-mino) -phenyl]cyclohexane [TAPC] (50 nm)/4,4'-Bis(carbazol-9-yl) biphenyl [CBP]:tris(2phenylpyridine) iridium(III) [Ir(ppy)3] (8%, 30 nm)/ TPBi (40 nm)/Yb (4 nm) or LiF (0.5 nm)/Yb (4 nm) and Ag (12 nm)/TPBi (45 nm). The device with an EIL of LIF/Yb bilayer shows drastically reduced driving voltage of 11.3 V at 100 mA/cm2 and operating voltage of 7.2 V at 1000 cd/m2 compared to 12.2 V and 7.9 V of the device with Yb as an EIL because of lower electron injection barrier and better balance of carriers. And the device with LiF/Yb bilayer exhibits peak efficiencies of 16.9%, 24.3 lm/W and 53.2 cd/A. These values are higher than that of 15.3%, 21.4 lm/W and 48.8 cd/A with Yb as an EIL. The highly efficient characteristics of the TOLEDs are attributed to efficient electron injection from Ag cathode by using LiF/Yb bilayer as well as capping layer effect.

A study on the improved performances of OLED using horizontal oriented amorphous material

J. Kim, C. Adachi, Kyushu Univ. (Japan)

Recently, horizontally oriented amorphous thin films have been used in organic light-emitting diodes (OLEDs), making use of their high-performance electrical characteristics based on the enhancement of π-π interaction between adjacent molecules. Also, horizontally oriented amorphous materials have been developed for hole and electron injection in the organic layer/electrode interface. To determine the effects of the orientation of these films, we investigated optical anisotropy of the films by using variable angle spectroscopic ellipsometry (VASE). When the molecules have anisotropic orientation in the films, the ordinary refractive indices and extinction coefficient were different from the extraordinary ones. We found that BT-DDP and Bpy-OXD having disk-like and rod-type shape clearly showed a horizontal orientation based on the VASE measurement. We fabricated multilayer OLEDs using horizontally oriented amorphous thin films of all components. The devices based on N1, N1, N4, N4-tetrakis(4-(benzo[b]thiophen-2-yl)phenyl)benzene-1,4-diamine (BT-DDP) as a hole-transport layer (HTL) and 1,3-bis[2-(2,2'-bipyridin-6-yl)-1,3,4-oxadiazo-5-yl] (Bpy-OXD) as an electron-transport layer (ETL) achieved low driving voltage of 3.7 V at 20 mA/cm2. Also, Carrier balance condition is achieved due to the corporation of horizontally oriented BTDDP and Bpy-OXD. We expect that, by combination of HTL, EML and ETL having horizontally oriented amorphous materials, very low driving voltage with highly efficiency can be surely achieved in OLEDs.

Charge carrier generation efficiency in reverse biased organic p-n junctions

S. Lee, J. Lee, Seoul National Univ. (Korea, Republic of); C. Park, Samsung Mobile Display Co., Ltd. (Korea, Republic of); J. Kim, Seoul National Univ. (Korea, Republic of)

Charge carrier generation efficiency in organic semiconductor p-n junctions under reverse bias will be presented, which is important as a charge generation layer (CGL) in tandem organic light-emitting diodes (OLED). 1,4,5,8,9,11-hexaazatriphenylene hexacarbonitrile (HAT-CN) possessing deep lying lowest unoccupied molecular orbital (LUMO) energy level was used as the p-layer and various electron transporting materials doped with rubidium carbonate (Rb2CO3) as the n-layers in the CGL unit. Current density-voltage and capacitance-voltage characteristics of the CGL units showed that the voltage drop for charge carrier generation in CGL unit depends on the vacuum level shift, electron mobility, and free carrier density of ETL, rather than the LUMO energy level of ETL. Moreover, the voltage drop for charge generation in CGL unit can be further reduced by increasing the doping concentration of n-ETL. Consequently, the CGL unit with 30 mol% Rb2CO3 doped BPhen with HAT-CN have been demonstrated that the voltage drop at junction for the current density of 10 mA/cm2 was around 0.17 V, which is infinitesimally small comparing with other literatures. The mechanism of charge generation and recombination is suggested by tunneling of electron through the thin depletion layer.

On the way to efficient: bright and wafer-level Quantum dot light emitting diodes

H. Bourvon, S. Le Calvez, H. Kanaan, S. Meunier-Della-Gatta, Lab. d'Electronique de Technologie de l'Information (France); C. Philippot, P. Reiss, Commissariat à l'Énergie Atomique (France)

Solution-processed Quantum Dot Light Emitting Diodes (QDLEDs) have recently paid the way for low-cost and colour saturated displays. Indeed, Quantum dots (QDs) have the appealing property to emit at a tunable wavelength determined by their nature and diameter. According to materials, emission can be tuned from visible to near infrared range. Therefore, QDLED electroluminescent spectra exhibit a narrow bandwidth (FWHM ~30nm) and QDs-based displays offer high colour purity and saturation. Moreover, QDs deposit is compatible with methods such as spin coating, inkjet printing or stamping already implemented for Polymer Light Emitting Diodes at wafer-level. We present in this conference our optimization steps and our recently developed QDLEDs. We established a layer by layer strategy, from a whole evaporated small molecule based OLED to our first QDLED developed by wet deposition techniques for the first layers and by evaporation for the last ones. In an intermediary step, we managed to develop hybrid OLEDs where efficacies of 12cd/A at 4V were obtained, with 2.17 % of EQE, and a luminance of 4000 cd/m² at 4V. In QDLEDs cases, QDs were spin coated, inkjet printed or stamped with a PDMS stamp. The problematic was to find an economical method to form a continuous monolayer of QDs on our 200mm wafers. Trials were done as well by mixing QDs in a polymer matrix for carrier injection

requirements. We present advantages and drawbacks relative to each method of QDs deposition. Finally, we report our first Near Infrared QDLEDs, emitting at around1,5 micron based on PbS QDs.

Inorganic/organic composite structures in OLEDs: new approaches for efficiency enhancement

B. Riedel, J. Hauss, Y. Shen, U. Lemmer, Karlsruher Institut für Technologie (Germany); M. Gerken, Christian-Albrechts-Univ. zu Kiel (Germany)

Organic light-emitting diodes (OLEDs) already being used in commercial display applications or general lighting lack a high efficiency. The high internal quantum efficiency, which is achieved by phosphorescent emitters, is lowered by a poor outcoupling efficiency. A large fraction of the generated light is trapped as waveguide modes inside the glass substrate, the anode and the organic layers as well as in surface plasmon polaritons at the metal/organic interface. The total internal reflection of substrate modes may be overcome by simple techniques such as applying microlenses or other microstructures on the substrate/air interface. The waveguide modes within the OLED stack demand for more sophisticated approaches. Bragg gratings or low-index-grids are two common structures being used to extract these trapped modes. In this work, we report on an approach for extracting waveguided modes in OLEDs by scattering in inorganic/organic composite layers. We fabricated OLEDs with thick (up to 1000 nm), transparent, nanocomposite hole transport layers consisting of the hole transporting polymer PEDOT:PSS and varying volume fractions of SiO2-nanoparticles and TiO2-nanoparticles. These layers reveal a dense packing of nanoparticles. Even for a volume fraction of more than 80% of SiO2-nanoparticles and thus less than 20% PEDOT:PSS functioning OLEDs with enhanced efficiency are demonstrated. This is attributed to scattering effects, which occur in the nanocomposite layer. The TiO2-particles are used to increase the index of refraction. By changing the nanoparticle concentration and the thickness, the optical properties of OLEDs may be optimized further.

A carbazole-based compound capable of bipolar transport for application in green phosphorescent and fluorescent OLEDs

C. Chang, Yuan Ze Univ. (Taiwan); M. Kuo, National Taiwan Univ. (Taiwan); W. Lin, Yuan Ze Univ. (Taiwan); K. Wong, National Taiwan Univ. (Taiwan)

In general, charge transporting and balancing are two crucial factors for high-efficiency OLEDs. One promising strategy for carrier balancing is to incorporate an electron-donating moiety and an electron-withdrawing moiety into a single host material. However, host materials possessing the bipolar characteristics as well as a large triplet gap are scarce. In addition, the developments of true-blue phosphors so far were still immature and thus blue phosphors were not widely adopted in the industries. The commonly techniques were employing blue fluorophor combined with green and red phosphors to display full-color images. Here, a study of newly developed bipolar host material, 9-(4,6-diphenyl-1,3,5-triazin-2-yl)-9'-phenyl-3,3'-bicarbazole (CzX), is presented, including synthesis, characterization, and electroluminescent device applications. The molecular design was combining N-phenylcarbazole moiety as electron donor (D) and 1,3,5-triazine moiety as electron acceptor (A) for the bipolar transport purpose. The hole-transport and electron-transport abilities of CzX were superier to that of 4,4'-Bis(carbazol-9-yl)biphenyl (CBP). By using the CzX as emitting host, the maximum efficiencies of 20%, 75.7 cd/A and 71.3 lm/W were achieved in green Ir(tmp)2-doped OLEDs with a simplified architecture. Particularly, the CzX can not only be used as host material for phosphorescent emitters, but also used as a green fluorescent emitter for non-doped fluorescent OLEDs. The maximum efficiencies of green fluorescent OLEDs were up to 7.0 %, 21.6 cd/A, and 22.5 lm/W. These results provided useful insights for the design of bipolar host materials and efficient electrofluorescent and electrophosphorescent devices.

Modelization of the chaotic-like behavior of external quantum yield as a function of humidity during fabrication

S. Gauvin, Univ. de Moncton (Canada)

It is well known that organic light-emitting devices (OLEDs) and other organic electronic devices are generally sensitive to atmospheric water, especially when combined with oxygen. It is generally admitted that such gas are responsible to a great extent for a systematic and irreversible degradation of the organic devices performance. In this study, have chosen absolute humidity as the (statistical) independent variable instead of relative humidity because the number of water molecules per unit of volume in the atmosphere surrounding an OLED is a more significant parameter than relative humidity. Our experimental data stand for a quantitative confirmation that the reproducibility of OLEDs performance is better when they are fabricated under dry atmospheric condition. Accordingly, at high humidity level (7 g/m^3 to 13 g/m^3) we observe an increase in the dispersion of external quantum yield. This strongly suggest that the occurrence of antagonist mechanisms and a devices sensitivity to initial structural conditions therefore lead to an unpredictable, chaotic-like, behavior of organic light-emitting external quantum yield after they are exposed to atmospheric water vapor. Even though the dispersion in performance data increases at high humidity level, surprisingly a significant amount of samples (~50 %) show better performance than those prepared at low humidity level. Thus high humidity level is not only detrimental to OLEDs. In some circumstances, oxidation processes accelerated by water vapor can be beneficial to performance. Through suitable theoretical modelization, based on interfacial insulating layers and electrode porosity we get a better understanding of the required conditions that lead to an increase of performance. Finally, we suggest a process (before encapsulation) to enhance the external quantum yield and obtain better reproducibility in performance of OLEDs.

Organic interlayer for OLED passivation using vacuum thermal evaporable acrylic monomer

W. M. Yun, S. H. Kim, J. Jang, S. Nam, C. Park, Pohang Univ. of Science and Technology (Korea, Republic of)

In this paper, vacuum thermal evaporable acrylic monomer is investigated for simple fabrication of organic interlayer for OLED multi-layer passivation so that the steps for passivation can be compatible with other steps of conventional vacuum processed OLED fabrication process. Thermal evaporation of metallic acrylate monomer and consecutive UV crosslinking is performed for organic interlayer formation. FTIR and breakdown voltage measurement show formation of polymeric film. In addition, resulting film shows good surface morphology (roughness < 0.7nm), good photo-patternability and somewhat weak barrier characteristics (WVTR: 2.929 g/m2day). For OLED passivation application, plasma enhanced atomic layer deposited Al2O3 layer is used as an inorganic passivation layer. As a result, single interlayer insertion of 50nm acrylate film between two 50nm Al2O3 layers shows over 1,500 hr shelf lifetime without shrinkage of emission area under 60°C, 90% RH condition even though 100nm Al2O3 only passivated OLED device show 1,000 hr shelf lifetime.

A high-performance inverted bottom-emission organic light emitting diode using an electron-transporting material with no-energy barrier for electron injection between the doped and undoped homojunctions

J. Lee, Seoul National Univ. (Korea, Republic of); P. Wang, National Taiwan Univ. (Taiwan); H. Park, Seoul National Univ. (Korea, Republic of); C. Wu, National Taiwan Univ. (Taiwan); J. Kim, Seoul National Univ. (Korea, Republic of)

We investigated the effect of the n-doped electron transporting layer (n-ETL)/electron transporting layer (ETL) interface in homojunctions on the performance of inverted bottom emission organic light emitting diode (OLED). Among three kinds of devices having different electron transporting materials (ETMs) like bis-4,6-(3,5-di-3-pyridylphenyl)-2-methylpyrimi-dine (B3PYMPM), 4,7-diphenyl-1,10-phenanthroline (Bphen), and 2,2',2"-(1,3,5-benzenetriyl)tris-[1-phenyl-1H-benzimidazole] (TPBi), the device with the B3PYMPM resulted in the lowest injection and turn-on voltages of 1.9 V, and 2.4 V, respectively, and the highest maximum external quantum efficiency (EQE) of 20% which is the highest efficiency reported up to now in the inverted bottom emission OLEDs to the best of our knowledge. Furthermore, the maximum power efficiency of the device with the B3PYMPM ETL is very high with the value of 80 lm/W, followed by 43 lm/W for TPBi ETL and 37 lm/W for Bphen ETL. The characteristics were interpreted based on the charge injection from ITO to the n-ETL and from n-ETL to ETL, and electron transport in the ETM by fabricating electron only devices. The electron only device with the B3PYMPM exhibited a large increase in current at a much lower voltage than the other two materials. Ultra-violet photoelectron (UPS) spectroscopy also showed that there is no energy barrier for electron injection between n-B3PYMPM and B3PYMPM, while Bphen and TPBi have energy barriers of 0.2 eV and 0.25 eV, respectively. As a result, we demonstrated that the interface between n-ETL and ETL even in homojunctions is one of the most important factors for high performance inverted OLEDs.

Charge generation efficiencies of p-dopants in organic semiconductors

J. Lee, H. Kim, K. Kim, Seoul National Univ. (Korea, Republic of); R. Kabe, P. Anzenbacher, Jr., Bowling Green State Univ. (United States); J. Kim, Seoul National Univ. (Korea, Republic of)

We report that an organic p-dopant tri[1,2-bis(trifluoromethyl)ethane-1,2-dithiolene] [Mo(tfd)3] resulted in higher density of holes than inorganic metal oxide dopants of rhenium oxide (ReO3) or molybdenum oxide (MoO3) in 1,4-bis[N-(1-naphthyl)-N'-phenylamino]-4,4'-diamine (NPB) even though the metal oxide dopants possess deeper work functions compared to Mo(tfd)3. Higher charge generation efficiency which is defined as the ratio of generated carriers to dopant molecules, results largely from the homogeneous dispersion of Mo(tfd)3 in the host. In contradistinction, the transmission electron microscopy (TEM) analysis shows that an origin of the low charge generation efficiency of metal oxide dopants is revealed to be the formation of dopant nanoclusters. The number ratio of the nanoclusters to dopant molecules (dispersion efficiency) was measured to be 0.62-1.3% for the ReO3-doped NPB. The low dispersion efficiency is close to the charge generation efficiency of 0.7-1.1%, indicating that charge generation efficiency in the dopants is predominantly controlled by the dispersion of dopants in organic semiconductors. This highlights the importance of homogeneous dispersion for an efficient doping. It is expected that our findings will be valuable for indentifying efficient dopants for various organic semiconductors.

Polarizer-free high-contrast top-emitting organic light emitting diodes with high-intensity ratio

S. Kim, J. Lee, H. Park, J. Lee, J. Kim, Seoul National Univ. (Korea, Republic of)

Top emitting organic light emitting diodes (TOLEDs) are widely used in mobile display technology such as portable media player (PMPs), and smart phone etc. Unfortunately, in outdoor environment, ambient light significantly degrades the contrast ratio (CR) of TOELDs due to strong reflection of ambient light by reflective metal electrode of TOLEDs. Therefore, suppressing reflection from surface of OLEDs is key parameter to fabricate TOLEDs with high contrast ratio. In commericial fields, circular polarizers (CPs) are most favorable technique to fabricate high CR TOLEDs. However, CP is generally thick, expensive and not flexcible. First of all, CPs show a reduction of output power to half of conventional device, which is critical disadvantage to fabricate high performance OLEDs. In addition, CPs are difficult to integrate conventinal OLEDs fabrication process because CP does not apply to fabrication of OLED by evaporation or solution process. In this presentation, we demonstrate a high CR and high performance TOLEDs using multilayer cathode structures, which is composed to metal and dielectric layer. From their asymmetric reflectance properties, our cathode structures have advantages, which is fully adoptable with any kind of TOLEDs regardless of using highly reflective metal (Al or Ag etc.) as top and bottom electrodes. Therefore, contrary to the restuls of other groups, enhancement of light emission is expectable due to maintaining strong microcavity effect. Through theoretical and experimental procedures, our polarizer free TOLEDs demonstrate low luminous reflectance and high intensity ratio comparing with TOELDs with CR.

Bipolar spirobifluorene: highly efficient electroluminescence based on thermally activated delayed fluorescence

T. Nakagawa, Kyushu Univ. (Japan); S. Ku, K. Wong, National Taiwan Univ. (Taiwan); C. Adachi, Kyushu Univ. (Japan)

A highly luminescent organic light emitting diode based on thermally activated delayed fluorescence(TADF) is achieved by using spirofluorene derivatives (Spiro-CN) as an emitting layer. The spirofluorene derivatives are composed of two di-p-tylamine and cyano units as electron donating and electron accepting units, respectively, which are connected in the central spirofluorene core. This specific structure provides the high efficient TADF. Spiro-CN emits yellow fluorescence with photoluminescence efficiency of 27 % in the thin films. Highly efficient yellow-light-emitting diodes were fabricated using the Spiro-CN as an emitting layer. The device structure used in this study is ITO/α-NPD/6wt% Spiro-CN:mCP/Bphen/MgAg/Ag, where α-NPD and Bphen are used as a hole-transporting and a hole-blocking/electron-transporting layer. The Spiro-CN based devices displayed a low turn-on voltage of 3 V and a maximum luminance of 12000 cd/m2 at voltage of 15 V. The maximum external quantum efficiency, maximum luminous efficiency and maximum power efficiency of the Spiro-CN based devices reached 4.4 %, 13.5 cd/A and 13.0 lm/W, respectively. The transient PL and EL clearly demonstrated the presence of TADF, contributing high EL efficiency. In this study, we also succeeded to obtain a relationship between the molecular design and small ΔES-T, the energy difference between the S1 and T1 energy levels.

Photonic crystal electrode for enhanced light extraction in OLED

L. L. Petti, M. Rippa, Consiglio Nazionale delle Ricerche (Italy); G. Nenna, A. De Girolamo Del Mauro, V. La Ferrara, C. Minarini, ENEA (Italy)

In this work we show how it is possible to realize a high index grid embedded in a relatively large-area photonic crystal (PC) structure to drastically reduce the light trapped in the OLED device. Thus, a 2D-PC pattern with a period of 392 nm and a depth of 350 nm has been uniformly modelled by Electron Beam Lithography (EBL) technique on a surface of 2x2 mm2 removing partially a resist co-polymer (ZEP-520) deposited on a thin Indium Tin Oxide (ITO) grown itself on a glass substrate. The PC was realized taking into account the relationship between the guided light spectrum and Bragg's diffraction condition. Luminance measurements showed a peak emission at 592 nm with a full width half-maximum of 20 nm.

A Focused Ion beam (FIB) was then used for milling the large area PC structure realizing holes into the ITO layer using the structured ZEP-520 as a lithographic mask. FIB working conditions were optimized to control the ITO milling process until the glass-substrate. After removing the resist, highly conductive PEDOT:PSS was deposited filling the holes, realizing a continuous path for the current and obtaining a high refractive index jump for the PC structure. Finally, the OLED was grown on the PC to monitor the efficacy of the realized structure.

In conclusion, we demonstrated the possibility to realize a discontinuous refractive index path directly on the substrate surface combining EBL and FIB processes enhancing the performance of the PC structure and removing a further refractive index jump between the PC and the substrate.

Top emission organic light emitting diodes with high reflective Ag alloy

M. Kim, J. Lee, K. Kim, K. Kim, K. Lee, J. Yoon, S. Yoon, C. Kim, S. Lee, LG Display (Korea, Republic of)

Top emitting OLEDs (TOLEDs) need the efficient reflecting layer underneath anode to minimize absorption loss and to maximize the efficiency. Previously aluminum-Neodymium (AlNd) reflecting layer was commonly used in fabricating OLED display panel. Here, Ag alloy is used as reflecting layer to enhance the efficiency of TOLED rather than pure Ag layer due to its easy process and stable adhesion property. The efficiency enhancement of 30, 33, and 45% for each RGB TOLED devices with Ag alloy reflecting layer, although the difference of reflectance (R) between AlNd (RAlNd = 88% @ 530 nm) and Ag alloy (RAg alloy = 99% @ 530 nm) is only 11%. Optical simulation analysis of AlNd and Ag alloy TOLED shows that reflective difference of 11% in reflective layer amplifies the efficiency gap due to strong resonant micro-cavity effect.

We fabricate TOLED with reflective anode/hole injectionlayer/hole transporting layer/emitting layer/electron transporting layer/ Mg:Ag cathode/capping layer on the top of glass substrate. Mg:Ag with the transmittance of 30%~70% in the visible regions is used as thin metal cathode. For reflective anode, Ag alloy/ITO and AlNd/ITO are sputtered on the glass substrate before thermal evaporation of organic and cathode layers. The comparison of TOLED performances with the Ag alloy/ITO and AlNd/ITO reflective anode will be shown here.

High work function transparent electrodes by UV halogenation

M. G. Helander, Z. Wang, Z. Lu, Univ. of Toronto (Canada)

Transparent electrodes, such as indium tin oxide (ITO), are required in state-of-the-art organic photovoltaics (OPVs), organic light emitting diodes (OLEDs) and flat-panel displays. Controlling the interface properties between transparent electrodes and organic materials is of great importance for device engineering since the performance, stability and lifetime of organic devices are greatly influenced by the electrode/organic contacts. Unfortunately the work function of many transparent electrodes is too low to form a goo electrical contact with many of the commonly used organic semiconductors and polymers. We report a simple method for tuning the work function of transparent electrodes using a novel UV assisted halogenation technique. We demonstrate that decomposition of halogenated solvents using UV treatment can be used to functionalize the surface of a variety of different transparent electrodes with halogen atoms. Using this facile technique we achieve unprecedented high work functions of ~6 eV for various transparent conducting oxides, transition metal oxides and metal thin films. Organic devices fabricated using these halogenated transparent electrodes show markedly improved performance in highly simplified device structures.

Phosphorescent organic light emitting diode with >60% external quantum efficiency at >10,000 cd/m2

Z. Wang, M. G. Helander, Z. Lu, Univ. of Toronto (Canada)

Phosphorescent organic light emitting diodes (PHOLEDs) attracted considerable research interest due to their potential to reach 100% internal quantum efficiency. However, two major factors limit the external quantum efficiency (EQE) for PHOLEDs, i.e. the light out-coupling factor and the efficiency roll-off. In this work, a novel out-coupling enhancement method is presented. Using this new enhancement, a green PHOLED with up to 63 % EQE is realized. Moreover, the efficiency remains as high as 60% at 10,000 cd/m2. The peak value of power efficiency reaches 290 lm/W without using electrical doping.

8115-94, Poster Session

Enhanced efficiency OLEDs with semitransparent anode

H. Zhang, W. C. H. Choy, The Univ. of Hong Kong (Hong Kong, China)

Through introducing dielectric distributed Bragg reflectors (DBRs) into the OLED structure, the light emitting properties can be enhanced by microcavity effects [1-4]. However, typical DBR structures are made from dielectric materials and not electrically conductive. In addition, semitransparent thin metals such as Ag and Au with relatively high work function [5,6] and good reflectance which can be used as the anode material and offering the Purcell effect [7,8]. Furthermore, no ITO is required in our OLEDs with semitransparent DBRs while the shortage of indium has become an alarming issue for the use of ITO. In addition, there are no clear study to combine DBRs and the metals together to offer both microcavity effect and electrical conduction.

In this article, we report enhanced light outcoupling and efficiency from the bottom-emitting microcavity OLEDs by using semitransparent thin Au layers integrated with DBR as an anode. Our results indicate that using metal Au combining with DBR instead of ITO, the electroluminescent (EL) efficiency of the microcavity OLEDs is significantly enhanced due to the strong microcavity caused by Au. For the OLEDs with DBR/Au anode, the maximum luminance efficiency (4.8 cd/A) is about 1.7 times higher as compared with that of the OLED (2.8 cd/A) with ITO/V2O5 anode. The OLEDs with DBR/Au anode have also about 1.2 times higher efficiency than that of the OLEDs (4.1cd/A) with Au/V2O5 anode and with DBR/ITO anode. In addition, the EL saturated color has better purity, due to the effective modification of the spontaneous emission through microcavity effect.

From dark to bright: novel daylighting applications in solid state lighting

H. G. Adler, OSRAM SYLVANIA Inc. (United States)

The term “daylighting” is used in various ways, on one hand in a more architectural sense, i.e. using existing daylight to illuminate spaces, and on the other, more recently, for using light sources to replicate daylight. The emergence of solid state lighting (SSL) opens up a large number of new avenues for daylighting. SSL allows innovative controllability of intensity and color for artificial light sources that can be advantageously applied to daylighting. With the assistance of these new technologies the combination of natural and artificial lighting could lead to improvements in energy savings and comfort of living beings. Thus it is imperative to revisit or even improve daylighting research so that lighting and building networks of the future with their sensor, energy (e.g. HVAC) and lighting requirements can benefit from the new emerging capabilities. The current talk will review existing daylighting concepts and technology and discuss new ideas. An example of a tunable multi-color SSL system will be shown.

Intensity shaping and the application efficiency of indoor OLED lighting

P. Y. Ngai, J. Fisher, M. M. Lu, Acuity Brands Lighting, Inc. (United States)

Most indoor lighting is uniform, targeted for the most demanding visual tasks, a practice driven by limitations of conventional lighting systems, resulting in waste. It has been shown that discrete low-luminance tiles of OLED lighting can achieve a practical overhead lighting system that precisely tunes illumination for user requirements, resulting in energy savings, increased comfort, and enhanced flexibility. In this paper, the application efficiency of OLED lighting is further explored by evaluating how intensity shaping can vary photometric performance, create more targeted lighting effects, and increase the types of lighting applications for which OLED can be considered. Several non-Lambertian distributions are considered, along with multiple configurations of OLED panels.

8115-49, Session 8

Toward mass production of OLED lighting

C. Lee, C. Chen, C. Yang, C. Fang, T. Chang, AU Optronics Corp. (Taiwan)

Toward mass production of OLED lighting, differential application field, satisfying performance and competitive cost structure are all very important. In this article, from manufacture point of view, challenges and potential approaches to achieve such performance and cost structure will be discussed. Besides, comparison of OLED lighting with other light sources in some specific application field will be also described.

8115-50, Session 9

Transparent and reflective electrodes of organic light emitting diodes for solid state lighting

J. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Specific developments in electrode materials of organic light emitting diodes (OLEDs) including transparent and reflective electrodes will be discussed. Because of its high transmittance (> 85%) and excellent electrical properties (RS < 20 ohm/sq), thin film of indium-tin-oxide (ITO) has been the most widely used transparent electrode in OLEDs for general lighting. To reduce the cost of processing ITO films, thermally deposited dielectric/metal/dielectric multilayer was proposed as an ITO alternative. Due to the multiple reflections and interferences, WO3/Ag/WO3 (WAW) multilayer showed high transmittance of ~90% and low sheet resistance (7.22 ohm/sq). The luminance and power efficiency of OLEDs in glass substrate could be increased about 22% and 36%, respectively, by employing the combination of nano-facet structured MgO and WAW electrode instead of ITO. Recent progress of dielectric constant (ε) matching technique will be described on the basis of our recent results. When Ag film deposited on metal oxide (MO) layer with large ε, surface plasmons at the MO/Ag interface could be suppressed and optical transmittance can be significantly enhanced from 41.1 to 78.1%.

From the requirement to possibility of highly rugged, enhancing design freedom, and low-cost roll-to-roll manufacturing for lighting source, flexible OLEDs with steel substrate have been proposed. Because the steel is an opaque substrate, highly reflective metal (Al, Ag) films have been employed as a bottom electrode. Metal/ITO bilayer showed not only high reflectivity but excellent charge injection efficiency and distributed Bragg reflector/ITO gave the most improved luminance and efficiency of OLEDs on steel substrate.

8115-51, Session 9

High efficiency white organic light emitting device using a single emitter

J. Li, Arizona State Univ. (United States)

The white organic light emitting diodes (WOLEDs) with high power efficiency (>100 lm/W) are considered as strong candidates for next generation illumination devices. Especially, WOLEDs use environmentally benign organic materials and their fabrication cost can be significantly reduced with potential roll-to-roll processing technology. To date, however, the white electroluminescent (EL) spectrum is generated using multiple emitters embedded in a comparably complex device structure. In this presentation, we will discuss some of our efforts towards the development of efficient WOLEDs using a single emitter, which include our progress on 1) excimer-based WOLEDs, 2) the development of halogen-free Pt-based blue phosphorescent emitters and 3) the design and the synthsis of broadband phosphorescent emitters.

8115-52, Session 9

Phosphorescent OLEDs for high-efficacy long-lifetime solid state lighting

P. A. Levermore, H. Pang, R. Ma, J. J. Brown, Universal Display Corp. (United States)

In this paper we report on the rapid development of high efficacy, large area phosphorescent OLED (PHOLED) lighting panels with excellent operational stability. In particular, we focus on device performance at high luminance levels typically required for mainstream commercial lighting applications. We report a 15 cm x 15 cm all-phosphorescent OLED lighting panel with lifetime to LT70 > 4,000 hrs and 49 lm/W power efficacy when operating at 3,000 cd/m2 with CRI = 82, CCT = 3100 K and CIE 1931 (x, y) = (0.439, 0.422).

The OLED lighting panel uses a simple non-stacked 6 layer all-phosphorescent layer design that ensures excellent power efficacy. The all-phosphorescent device stack also enables extremely low operating temperature of < 30C at 3,000 cd/m2, without any thermal management, because the phosphorescent emitters have close to 100% internal quantum efficiency (IQE), so minimal heat is generated from non-emissive excited states. The OLED lighting panel has also been carefully designed to minimize any Joule heating arising from the distribution of electronic charge from the electrode contacts to the emissive area. This marriage of high IQE and careful panel design enables extremely low panel temperature, even at high luminance, which in turn, allows for exceptional operational lifetime.

In this paper, we describe some simple techniques that may be used to design OLED lighting panels for low operating temperature and long lifetime, and describe a basic thermal characterization of a 15 cm x 15 cm panel.

8115-53, Session 9

White top-emitting OLEDs: from optical simulations to highly efficient devices

B. Lüssem, P. Freitag, M. Furno, S. Hofmann, M. Thomschke, K. Leo, Technische Univ. Dresden (Germany)

Organic light emitting diodes (OLEDs) are highly promising for lighting applications due to their advantageous properties such as high power efficiency, good color quality and new design possibilities. To reduce OLED production cost significantly, a roll-to-roll fabrication of top-emitting OLEDs onto low-cost, flexible but opaque metal foils is envisaged. However, the optimization of top-emitting OLEDs is still challenging as the strong optical micro-cavity formed between the metallic top and bottom electrodes leads to a narrowing of the emission spectrum and a strong dependence of the spectrum on the viewing angle.

In this presentation it is shown how the transmission of the top electrode can be optimized and the micro-cavity effect can be weakened. By detailed optical simulations, the different loss channels in top-emitting OLEDs (waveguided and plasmonic modes, absorption, electronic and non-radiative losses) are quantified and the effect of an additional outcoupling layer is clarified. By thoroughly optimizing the optical properties of the OLED, monochrome red OLEDs with external quantum efficiencies of 29% are obtained, which clearly demonstrates the potential of top-emitting devices.

Furthermore, it is shown how the knowledge obtained from optical simulations can be used to realize white top-emitting OLEDs. Using a hybrid fluorescent blue/phosphorescent red and green device setup, white top-emitting OLEDs with high power efficiency, good color quality and a spectrum almost insensitive the viewing angle are obtained. These white OLEDs are highly promising for low-cost but high efficiency lighting applications.

8115-54, Session 9

White organic light emitting diodes with improved angular emission characteristics employing silver nanowire electrodes

S. Hofmann, Technische Univ. Dresden (Germany); W. Gaynor, G. Christoforo, Stanford Univ. (United States); C. Sachse, M. Thomschke, L. Müller-Meskamp, B. Lüssem, K. Leo, Technische Univ. Dresden (Germany)

We report on white bottom-emitting organic light-emitting diodes (OLEDs), where the commonly used indium tin oxide (ITO) electrode is replaced by a spray-deposited silver nanowire (NW) contact on the polymer Poly(methyl methacrylate) (PMMA).

By mechanical pressing, the surface of the NW electrode is smoothed and the roughness is considerably reduced. Hence, shorts in the OLEDs can be avoided, the leakage current is lowered, and the device performance is enhanced.

For the OLED, we use p- and n-doped charge transport layers, and a hybrid arrangement of red and green phosphorescent and blue fluorescent emitters, where the distribution of excitons is controlled by a thin interlayer. The placement of the red emitter into the second field maximum of the electromagnetic field, and at the same time the blue emitter into the third one, allows the employment of a thick (180nm) p-doped transport layer on top of the NW. This fills the cavities between the single NW and results in lower leakage currents for the devices. Furthermore, coupling to surface plasmons is reduced.

We achieve slightly increased efficiencies with the NW-OLEDs compared to control samples. At 1000cd/m², we reach 7% external quantum efficiency and 12 lm/W luminous efficacy for the ITO-OLED, respectively, for the NW-OLED we obtain 7.5% and 13 lm/W.

Additionally, the NW scattering causes Lambertian emission at viewing angles up to 70° with improved color stability. The CIE color coordinates shift from (0.453/0.376) at 0° to (0.458/0.386) at 70°, whereas for the ITO-OLED the CIE coordinates are (0.453/0.398) at 0° and (0.426/0.358) at 70°.

8115-55, Session 9

Highly efficient long-lived phosphorescent white-stacked OLEDs for solid state lighting

V. Adamovich, P. A. Levermore, A. Dyatkin, Z. Elshenawy, M. S. Weaver, J. J. Brown, Universal Display Corp. (United States)

Organic light emitting devices (OLEDs) are an attractive and energy saving form of solid-state lighting. Key requirements to their commercialization are high color rendering index (CRI), high power efficacy and long operational lifetime. Single unit structure (no internal junction) warm white phosphorescent OLEDs (WOLEDs) have been demonstrated with power efficacies over 100 lm/W , . However, achieving commercial lifetime for single unit WOLEDs is challenging. For example for a WOLED with a correlated color temperature of 2,600K, a CRI of 85 and a power efficacy of 75lm/W at 1,000cd/m2 the best lifetime to date is 30,000h LT70% . This is approximately an order of magnitude less than inorganic LED lighting sources.

Stacked OLEDs (SOLEDs) offer higher device efficiency (due to multiple stacks) and increased operational stability , . We demonstrated a 5x5cm2 white SOLED panel with an active area of 19.1cm2 and achieved 55.7 lm/W at 1,000cd/m2 with 2,900K CCT, CRI of 90, 11,000h LT70% at 3,000cd/m2 with ~1.5x light outcoupling enhancement.

The combination of extremely high efficiency phosphorescent OLEDs and SOLEDs resulted in outstanding WOLED performance.

8115-56, Session 10

Light management in OLED devices: from generation to extraction

D. S. Setz, B. C. Krummacher, T. Reusch, T. D. Dobbertin, OSRAM Opto Semiconductors GmbH (Germany); A. Winnacker, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Topic of the present talk is the Light Management of organic light-emitting diodes (OLEDs). We discuss the entire path of the light through the device. From the generation of light in the thin film stack to the formation of desired emission profiles. First the properties of the light emitting zone are discussed: The internal luminescence quantum efficiency, emitter orientation and shape of the emission zone have strong influence on the light extraction efficiency of OLED device. Furthermore the light losses by the different waveguides in the device are analyzed by optical simulation. It is shown, that the extraction of so-called ITO/Organic modes leads to significant efficiency enhancement. Finally, we demonstrate, how the formation of application tailored emission profiles increases the application efficiency of the device.

8115-57, Session 10

Light extraction from organic light emitting diodes by silica microsphere array pattern

W. Koo, W. Yun, Univ. of Florida (United States); X. Li, R. Song, N. Tansu, Lehigh Univ. (United States); F. So, Univ. of Florida (United States)

Organic light emitting diodes (OLEDs) consisting of organic layers, indium tin oxide (ITO), and a glass substrate with different refractive indices inevitably accompany the waveguide modes trapped in the ITO/organic layer and the glass substrate, which significantly limits the device efficiency. Although many grating structures with the short periodicity of 300 ~ 500 nm have been studied to extract the ITO/organic waveguide mode directly into the air mode by Bragg diffraction, there is no report about grating with a long periodicity around 1 μm in OLED because of its insufficient grating vector for countering the ITO organic mode. In this study, we report, for the first time, that a grating with the long periodicity of 1 μm also can effectively outcouple the ITO/organic mode as well as the substrate mode through appropriate device dimensions. Hexagonal closed-packed array of 1 μm-diameter-silica sphere embedded in a polystyrene layer was by rapid convection deposition and used as a template for grating. The hexagonal closed-packed pattern of the template was transferred to an epoxy layer by imprinting technique for device fabrication. With the 1 μm period grating, the power of the ITO/organic waveguide modes can be transferred to the substrate modes and the amplified substrate modes can be extracted through multiple reflection of the guiding light with the corrugated aluminum electrode in a 0.1-mm-thick glass substrate. The device with grating showed 50% enhancement in the current efficiency and the additional enhancement was obtained with a 3mm-diameter-hemisphere lens on the back of the substrate. Finally, we investigated the light extraction mechanism by the long period grating.

8115-58, Session 10

Periodic nanostructures for efficient waveguide mode extraction in OLEDs

J. Hauss, B. Riedel, T. Bocksrocker, C. Vannahme, S. Klinkhammer, M. Guttmann, U. Lemmer, Karlsruher Institut für Technologie (Germany); M. Gerken, Christian-Albrechts-Univ. zu Kiel (Germany)

Organic light emitting diodes (OLEDs) are found in a variety of commercial display and even lighting applications. OLEDs with phosphorescent emitters, harvesting also triplet excitons, reach nearly 100% internal quantum efficiency. However, poor light extraction still limits the external quantum efficiency of common OLEDs. A typical thin film OLED has a planar waveguide structure, giving rise to guided modes in anode and organic layers, surface plasmons at the cathode/organic interface, and substrate modes in the glass substrate. The substrate mode extraction is widely studied and established. Waveguide mode extraction is more difficult to realize, because the extraction structures need to be located inside or close to the OLED thin film stack. Furthermore, highly efficient extraction structures are necessary to achieve extraction within the absorption length of the waveguide modes. OLEDs with periodic dielectric nanostructures (Bragg gratings, planar photonic crystals) as well as periodic metallic nanostructures for waveguide mode extraction were designed and fabricated. Photoluminescence and electroluminescence results are presented and analyzed. We investigate the influence of the nanostructure geometry and quality as well as the influence of waveguide mode absorption and OLED stack design on the extraction efficiency. The experimental results are compared to optical device simulations with a transfer matrix code and the software Setfos from Fluxim AG. Based on the experimental and theoretical results, design rules for efficient waveguide mode extraction structures in OLEDs are deduced.

8115-59, Session 11

How to make ITO a better anode

I. Irfan, S. Graber, Y. Gao, Univ. of Rochester (United States)

Indium tin oxide (ITO) is predominantly employed as a transparent conducting electrode in devices including organic photovoltaic (OPV) cells, and organic light-emitting diodes (OLED). As ITO is used as an anode, the higher the workfunction (WF) the better anode it will be. As received ITO surface WF is usually around 4.5 eV. We investigated changes introduced by oxygen plasma treatment of ITO with ultraviolet photoemission spectroscopy (UPS), inverse photoemission spectroscopy (IPES), and x-ray photoemission spectroscopy (XPS), and found that the workfunction can be increased up to 6.15 eV. We also investigated the evolution of the ITO surface WF as a function of oxygen and air exposure, and found that the WF was reduced to 4.8 eV by 1014 L of air exposure. We have also investigated the interface formation of the high WF ITO with organic materials, and found that it introduced barrier reduction and interface band bending, indicating that the high WF ITO should be a better anode.

8115-60, Session 11

Laser patterned flexible organic light emitting diode

R. Mandamparambil, TNO Science and Industry (Netherlands); G. Van Steenberge, S. Van Put, Univ. Gent (Belgium); H. Fledderus, TNO Science and Industry (Netherlands); A. Gielen, J. Debaets, Univ. Gent (Belgium); A. Dietzel, TNO Science and Industry (Netherlands)

Techniques such as slot-die are highly suited for fast large area coating and can yield extremely uniform layers. Yet, no solution exists currently for patterning the resulting layers, casting them impossible to use for the roll to roll (R2R) processing for flexible OLEDs (Organic Light Emitting Diode) and flexible OPVs (Organic Photo Voltaics). Selective laser patterning enables post-patterning of large area coated OLED or OPV layers in a R2R manufacturing process such as opening the contacts and tiling to enable encapsulation. Most of the laser patterning work reported so far concentrates on patterning of inorganic TCO (transparent conductive oxides) layers on glass. In this paper we report the first TCO less FOLED (Flexible OLED) made by laser patterning utilizing

a high conductive PEDOT: PSS (Poly (3,4-ethylenedioxythiophene) poly(styrenesulfonate)) and a white LEP (Light Emitting Polymer). The layers are uniformly coated on a multilayer barrier stack on PEN (Poly (ethylene naphthalate)) substrate. A 248nm excimer laser with a 10 ns pulse width operating at a pulse repetition frequency of 100 Hz is utilized for the experiments. The laser patterning is carried out to isolate the contacts and for device encapsulation. Laser processing steps include selectively removing PEDOT and LEP layers on top of the multilayer barrier stack (SiN-Organic-SiN) and from metal bus bars. Al cathode is deposited by shadow masking technique afterwards and is followed by thin film device encapsulation. The devices are then successfully tested under accelerated conditions for its robustness. Major findings will be discussed in the manuscript.

8115-61, Session 11

Digitally-controllable Jet-On-Demand Organic Vapor-Jet Printing (D-OVJP) for OLED displays

C. Yun, J. Choi, T. Koh, H. Cho, S. Yoo, KAIST (Korea, Republic of)

We present our study on a digitally-controllable organic vapor-jet printing (D-OVJP) system in which deposition of organic materials is controlled point by point in a digital manner by producing a jet of organic vapor in a pulsed mode only on demand. D-OVJP inherits all the benefits of a conventional OVJP such as solvent-free deposition, mask-less pattern formation, a good scalability, and, moreover, use of well-established, sublime-grade small molecules that can promises both performance and long-term reliability. In addition to such benefits, however, D-OVJP further provides the real analogue of modern inkjet printing such that (i) deposition can occur only on the desired pixels; and (ii) thickness can be modulated in a straightforward way by a input digital signal; To realize the enhanced OVJP system with such capabilities, the fast solenoid valves are incorporated at the inlets of the carrier gas in OVJP nozzle modules, thus enabling “jet-on-demand”-type deposition of organic materials in which the thickness of organic materials can be controlled by the number of the pulses and/or the duty ratio of the digital signal applied to the valve. With the careful configuration of the valve/ exhaust structure, the thickness control of organic thin films in a resolution of ~ nm/pulse is successfully demonstrated. After presenting the overall concept of the proposed D-OVJP system and its operation, we provide the results of case studies utilizing the enhanced capabilities of D-OVJP methods. Their potential applications are then discussed from the perspectives of OLED displays.

8115-62, Session 11

Multilayer blade coating and cathode printing for large-area efficient organic light emitting diodes

H. Meng, H. Zan, National Chiao Tung Univ. (Taiwan); S. Horng, National Tsing Hua Univ. (Taiwan)

Small-molecule and polymer semiconductors are deposited in large area by rapid blade coating followed by immediate solvent evaporation by heating. Multilayer structure can be made as dissolution is avoided. Uniform film over 10 cm is achieved without spinning. Small molecules even with low solubility can be coated. Blade coated phosphorescent and fluorescent OLED has efficiency about 60 percent of the best vacuum deposited devices for all colors. A three-layer structure including hole transport, emissive, and electron transport layers are used. Cathode is LiF/Al. For phosphorescence polymer is used for hole transport layer and host for the triplet emitter. For fluorescence small molecules are used for the entire device for all three colors. PEDOT:PSS can also be deposited by blade coating for the same device performance as spin coating. In addition to ITO glass this process is made on stainless steel substrate for top emission. The cathode deposition is further simplified by vacuum-free transferring from a soft silicon rubber mold. Surface modification of Al is used to reduce the work function to 3-3.5 eV. A low-melting point sacrificial polymer layer is inserted between the cathode and the soft mold for easy transfer and subsequent mold removal. Current efficiency close to the device with evaporated cathode is achieved, with slightly higher voltage. Combination of multi-layer blade coating for organic films and printing for cathode makes high throughput production of efficient OLED possible. Such method is extended to polymer solar cell with efficiency close to that of spin coating.

8115-63, Session 11

OLED fabrication by means of OVPD®

D. Keiper, M. Gersdorff, M. Long, B. Beccard, C. Cremer, M. Kunat, J. Kreis, M. Schwambera, M. Heuken, AIXTRON SE (Germany)

Organic Light Emitting Diodes (OLEDs) are emerging as a promising technology for new, high efficient area light sources.

Today, OLED fabrication is dominated by evaporation techniques under vacuum conditions using small organic molecules. Here the Organic Vapor Phase Deposition (OVPD®) works in the fine vacuum utilizing the advantages of carrier-gas enhanced vapor phase deposition, where the materials are transported to the substrate by an inert carrier gas. AIXTRON combined its proprietary Close Coupled Showerhead® (CCS) with the OVPD® technology, enabling organic film deposition with high thickness uniformity and high material utilisation efficiency. We will present this deposition technique focusing on the options for sophisticated OLED stacks design concepts, namely mixing of more than 2 materials through gradual concentration changes. This enables new freedom for OLED stack optimization with respect to device performance, such as 100% efficacy increase. These new concepts of OLED fabrication will be discussed together with illustrating examples and latest results.

OVPD® technology has been exclusively licensed to AIXTRON from Universal Display Corporation (UDC), Ewing, N.J. USA for equipment manufacture. OVPD® technology is based on an invention by Professor Stephen R. Forrest et al. at Princeton University, USA, which was exclusively licensed to UDC. AIXTRON and UDC have jointly developed and qualified OVPD® pre-production equipment.

Part of this work was financially supported by the Federal Ministry of Education and Research in Germany (BMBF) within the Projects Solight, TOPAS, and OPAL.

Achieving high-performance polymer solar cells via incorporating alcohol/water-soluble conjugated polyelectrolytes as cathode interlayer

H. Wu, Z. He, C. Zhong, C. He, Y. Cao, South China Univ. of Technology (China)

Polymer solar cells (PSCs) based on a blend of semiconducting polymer and fullerene derivatives have attracted a lot of attention in recent years because they can produce inexpensive electricity directly from the sun due to their ease of fabrication and inherent low cost of solution processing.[1,2,3] The power conversion efficiency of PSCs is mainly determined by the quantum yield of the photoexication and the exciton dissociation and the charge collection. It has been previously shown that incorporating alcohol/water-soluble conjugated polyelectrolytes (CPE) as cathode interlayers can substantially enhance the open circuit voltage (Voc) of bulk heterojunction polymer solar cells. [4, 5] We present a detailed study on the influence of the alcohol/water-soluble conjugated polyelectrolytes interlayer on the exciton generation, dissociation and charge collection process by performing electroabsorption measurement, space-charge limited current characteristics analysis and surface potential measurement.

Optimization of transparent electrode processing conditions for bulk heterojunction solar cells

Y. Sun, A. Ng, M. K. Fung, The Univ. of Hong Kong (Hong Kong, China); A. M. C. Ng, The Univ.of Hong Kong (Hong Kong, China); A. B. Djurisic, W. K. Chan, The Univ. of Hong Kong (Hong Kong, China)

Among different device architectures of bulk heterojunction solar cells, semi-transparent bulk heterojunction solar cells are of interest due to their potential use in window applications and tandem cells. For such applications, it is necessary to achieve a compromise between transmission and the conductivity of the transparent electrode. While indium tin oxide is commonly used as a transparent bottom electrode, its deposition on top of the polymer layer is difficult due to the need for high substrate temperature and sputtering damage of the polymer. Therefore, other materials such as conductive polymers are of interest. The use of poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) as a top electrode is promising due to its compatibility with large scale roll-to-roll fabrication process and its mechanical flexibility. The challenge in using PEDOT:PSS for top electrodes mainly concerns spin-coating of the hydrophilic PEDOT:PSS on top of the hydrophobic photoactive layer and the low conductivity of PEDOT:PSS.

In this work, semi-transparent inverted polymer solar cells with PEDOT:PSS top electrode were fabricated by spin-coating process. Poly(3-hexylthiophene) (P3HT):[6,6]-phenyl C61-butyric acid methyl ester (PCBM) was used as a model material combination for a bulk heterojunction solar cell. For enhancing the wetting of P3HT:PCBM blend film, different plasma etching conditions were tried. In addition, different organic additives were tried to enhance the conductivity of PEDOT:PSS. The performance of solar cells with different fabrication conditions for the top electrode was compared. The best performance was obtained for Ar plasma etching to improve wetting of PEDOT:PSS and the addition of ethylene glycol to improve conductivity.

Synthesis, characterization, and photovoltaic properties of donor-acceptor copolymer based on 2,1,3-benzooxadiazole with high open-circuit voltage

J. Jiang, K. Wei, National Chiao Tung Univ. (Taiwan)

We have used Suzuki polycondensation to prepare a serious of low-bandgap copolymers, PFLUBO and PBDTBO by conjugating the electron-accepting benzo[c][1,2,5]oxadiazole (BO) moieties with the electron-rich fluorene (FLU) or benzo[1,2-b:3,4-b]dithiophene (BDT) units. All of these polymers exhibited excellent thermal stability and sufficient energy offsets for efficient charge transfer and dissociation, as determined through thermogravimetric analyses and cyclic voltammetry, respectively. The bandgaps of the polymers could be tuned in the range 1.8-2.0 eV by using the two different donors, which have different electrondonating abilities. Through these two structurally related polymers, we demonstrate that incorporating electron-withdrawing BO unit would lead to a lower HOMO energy level. This lower HOMO energy level translates into a higher open circuit voltage (Voc) of 1.04V in PFLUBO based BHJ devices. In contrast, the slightly higher HOMO energy level (- 5.4 eV) of PBDTBO limits the Voc to 0.9V. Since the LUMO levels of both polymers are similar, the higher HOMO energy level of PBDTBO leads to a smaller band gap of 1.8 eV. The BHJ devices based on PFLUBO as the donor polymer (with PC61BM as the acceptor and 1:1 weight ratio) exhibit overall efficiencies of 2.57% under the illumination of AM1.5, 100 mW/cm2.Future research needs to focus on the employment of even lower electron donating ability donor and stronger electron withdrawing ability acceptors via innovative structural modification in order to achieve a deeper HOMO and a lower band gap to expect the high Voc, Jsc and the better efficiency.

8116-57, Poster Session

Effects of exciton-blocking layers on the performance of organic photovoltaic cells

C. Chang, R. Lin, J. Chiu, K. Lin, S. Tang, K. Chiu, Chung Yuan Christian Univ. (Taiwan)

Effects of exciton blocking layer (EBL) on the performance of organic photovoltaic cell (OPVC) with a basic heterostructure of ITO/CuPc/C60/EBL/Al were studied; and Alq3, CuPc, and/or LiF thin layers of various thicknesses were adopted as an EBL. The characteristics of current density (J) versus bias voltage (V) of the as-fabricated OPVCs were measured in a dark room and under illumination, respectively. Then, these J-V curves were numerically analyzed by a model/equivalent circuit. From experimental J-V data, an enhancement of the overall efficiency by 20% was achieved for an OPVC with Alq3 layer of 10 nm thick being adopted as an EBL, as compared with the one without an EBL. From numerical fitting results, this improvement can be identified dominantly by an increase of photo-current density (Jph) and a decrease of series resistance (Rs). In addition, from a durability test, the OPVC with Alq3 EBL can also have the best performance than that one without EBL. Finally, the physical significance of EBL on the improvements of OPVC was discussed.

8116-58, Poster Session

Solvent induced self-organization of crystalline conjugated polymer and fullerenes for heterojunction solar cells

M. Su, K. Wei, M. Chiu, M. Yuan, C. Kuo, National Chiao Tung Univ. (Taiwan); U. Jeng, National Synchrotron Radiation Research Ctr. (Taiwan)

The nature of the processing solvent critically affects the phase-separated morphologies and orientations of PBTTPD crystallites in thin films of PBTTPD/PCBM blends and, therefore, the performance of BHJ solar cells incorporating such PBTTPD/PCBM blends as active layers. Specifically, highly crystalline fibrillar PBTTPD structures and much smaller PCBM aggregates were present in PBTTPD/PCBM thin films that had been processed with CF. Through optimization of the active layer's composition, a device incorporating a PBTTPD/PCBM blend (1:1.5, w/w) that had been processed using CF displayed balanced carrier mobility transport in the BHJ thin film and, therefore, a solar power conversion efficiency of 6.15%.

Here, we report the effects of the processing solvent and the composition on the morphology and photovoltaic device performance of thin films comprising the highly crystalline polymer and PCBM. Using atomic force microscopy (AFM) and transmission electron microscopy (TEM), the relationship between the nano-morphology and the device performance is allowed to be elucidated. In addition, grazing incidence small-angle X-ray scattering (GISAXS) provided information relating to the dimensions and orientations of the PBTTPD crystallites and the sizes of the PCBM aggregates in the PBTTPD/PCBM films.

Synthesis and characterization of indolocarbazole- and indenofluorene-based low-band-gap polymers for photovoltaic cells

W. Lee, L. T. Nguyen, E. Jeong, Pusan National Univ. (Korea, Republic of); G. Kim, J. Y. Kim, Ulsan National Institute of Science and Technology (Korea, Republic of); H. Y. Woo, Pusan National Univ. (Korea, Republic of)

Polymeric solar cells (PSCs) have emerged as a promising candidate for renewable energy sources due to its low cost, light weight, mechanical flexibility and portability, etc. A bulk-heterojunction structure realized an ideal morphology for efficient PSCs because it increases the interfacial area between a donor polymer and acceptor PCBM resulting in high yields of exciton dissociation. In order to realize the high efficiency of devices, the active layer must have broad absorption of sunlight and high carrier mobility. Here, Donor-acceptor type copolymers, poly[{5,11-di(9'-Heptadecanyl)indolo[3,2-b]carbazole}-alt-{2,5-di(thiophen-2-yl) thiazolo[5,4-d]thiazole-5,5'-diyl}] (PIC-TZ) and poly[{6,6',12,12'-tetraoctylindeno[1,2-b]fluorene}-alt-{2,5-di(thiophen-2-yl)thiazolo[5,4-d] thiazole-5,5'-diyl}] (PIF-TZ), were synthesized by Suzuki polymerization and examined for applications in polymeric photovoltaic solar cells (PSCs). The number-average molecular weights (Mn) of the synthesized polymers were determined to be 11,000 g/mol (PDI = 2.27) for PIC-TZ, and 17,000 g/mol (PDI = 1.77) for PIF-TZ by gel permeation chromatography (GPC) using a polystyrene standard. PIC-TZ and PIF-TZ showed good solubility in common organic solvents. These polymers exhibited good thermal stability, showing < 5% weight loss up to 410 ~ 430 °C. The optical band gap of PIC-TZ and PIF-TZ thin film was measured to be 2.14 V~2.21 eV. SCLC mobility measurements showed hole mobility of ~10-3 cm2·V-1·s-1 for the copolymers. When the polymers were blended with PCBM, PIC-TZ exhibited the best performance with an open circuit voltage of 0.86 V, short-circuit current of 4.16 mA/cm2, and power conversion efficiency of 1.64% under air mass (AM) 1.5 global (1.5 G) illumination conditions (100 mW/cm-2).

Significant enhancement in conversion efficiency of inverted organic solar cells based on ZnO thin films via aluminum incorporation

S. Tsai, W. Lien, J. He, National Taiwan Univ. (Taiwan)

The power conversion efficiency (η) of hybrid solar cells (HSCs) based on ZnO/P3HT:PCBM was improved by incorporating Al into ZnO acting as an electron transport layer. The Al-doped ZnO (AZO) thin film was deposited via an aqueous solution method. The η can be enhanced by up to 2.2 times due to Al incorporation into ZnO layers. It was found that the short-circuit current density and open-circuit voltage were affected by transmission, surface roughness, electrical conductivity, and band-gap of AZO thin films. This study provides new insights into the design optimization of the electron transport layer for HSCs.

Combination of titanium oxide-conjugated polyelectrolyte for high-performance inverted-type organic optoelectronic devices

H. Choi, Ulsan National Institute of Science and Technology (Korea, Republic of); J. S. Park, KAIST (Korea, Republic of); E. Jeong, Pusan National Univ. (Korea, Republic of); G. Kim, B. Lee, Ulsan National Institute of Science and Technology (Korea, Republic of); S. O. Kim, KAIST (Korea, Republic of); M. H. Song, Ulsan National Institute of Science and Technology (Korea, Republic of); H. Y. Woo, Pusan National Univ. (Korea, Republic of); J. Y. Kim, Ulsan National Institute of Science and Technology (Korea, Republic of)

We demonstrate the remarkable improvement in device performances of inverted polymer solar cells (iPSCs) and polymer light-emitting diodes (iPLEDs) by employing a combination of titanium oxide (TiOx) and conjugated polyelectrolyte (CPE) as an electron injection/transporting layer. For iPSCs, the CPE layer increased the power conversion efficiency from 2.65 % to 3.55 % by enhancements of the short circuit current and fill factor. For iPLEDs, the device with CPE layer exhibits increased luminance efficiency from 4.3 cd/A to 18.0 cd/A and maximum luminance from 1850 cd/m2 to 25800 cd/m2, and reduced turn-on voltage from 4.4 V to 3.8 V. These high efficiencies of inverted-type organic optoelectronic devices are attributed to spontaneously oriented interfacial dipoles within the CPE layer, which lower the energy barrier for electron injection/transport and reduce the interfacial contact resistance and inherent incompatibility between the hydrophilic TiOx and hydrophobic active layers.

Open-circuit voltage in zinc phthalocyanine-C60 organic photovoltaic cells

J. P. Mudrick, J. D. Myers, Univ. of Florida (United States); T. B. Fleetham, N. Bakkan, J. Li, Arizona State Univ. (United States); J. Xue, Univ. of Florida (United States)

Organic photovoltaic (OPV) device performance has steadily approached that of inorganic photovoltaics while offering advantages including low temperature processing, mechanical flexibility, and high throughput manufacturing capability. Despite this progress there are aspects of OPV device physics that are not well understood, the most important of which being the origin of the open circuit voltage (Voc). We have studied Voc in

vacuum-deposited zinc phthalocyanine (ZnPc)/C60 OPV devices using different sources of ZnPc: one source was obtained from a commercial vendor and the other was synthesized in house from a heated reaction between zinc chloride and excess phthalonitrile. While elemental analysis revealed no detectable differences in the bulk chemical composition of the two ZnPc materials, capacitance-voltage measurements showed a ~50% reduction in the concentration of electrically active defects in home-synthesized ZnPc. Planar bilayer OPV devices using home-synthesized ZnPc had 0.1-0.2V (20-50%) greater Voc compared to those with commercial ZnPc while also exhibiting significantly lower dark current. The type of ZnPc at the donor/acceptor heterojunction was varied to show that the ZnPc species present at the interface is responsible for the difference in Voc. Synchronous photocurrent measurement showed a slower reduction in photocurrent with the increase of forward bias for devices with home-synthesized ZnPc. We attribute the higher VOC in devices with home-synthesized ZnPc to the reduced recombination of charges at the ZnPc/C60 interface, which leads to lower dark current.

Photoelectrochemical energy conversion based on conducting polymers

T. Yohannes, Addis Ababa Univ. (Ethiopia)

The utilization of organic materials for photovoltaic devices has been investigated intensely during the last decades. Earlier studies concentrated on molecules that had high optical absorption in the visible region of the electromagnetic spectrum. Discovery of conjugated polymers having semiconductor-like behavior has started to stir excitement because such materials are not only able to function in a similar manner to the inorganic semiconductors but also have important advantages such as: low cost, light weight, ease of fabrication and the possibility of large area coatings.

In this presentation an overview of the studies carried in our research laboratory on photoelectrochemical solar energy conversion devices will be given. The photoelectrochemical cells contain a thin film of semiconducting conducting polymers as a light-harvesting unit, a redox couple and a counter electrode.

Charge-pair and free-charge carrier photogeneration and recombination in polymer/fullerene bulk heterojunction films

G. Sliauzys, Vilnius Univ. (Lithuania); V. Gulbinas, Institute of Physics (Lithuania); K. Arlauskas, Vilnius Univ. (Lithuania)

Photogeneration and recombination of charge pairs and free charge carriers in poly-3 (hexylthiophene) (P3HT) and [6,6]-Phenyl C61 butyric acid methyl ester (PCBM) bulk heterojunction has been studied at different PCBM concentrations by means of fluorescence spectroscopy, time-of-flight (ToF) and extraction of photogenerated charge carriers by a linearly increasing voltage (photo CELIV) techniques. Quenching of P3HT fluorescence by PCBM, has been used for the evaluation of the exciton dissociation efficiency. The quantum efficiency of free carrier generation has been evaluated from ToF current transients at different electric fields. The free charge carrier recombination properties have been estimated from photo-CELIV current transients at different delay times between laser ant voltage pulses. Obtained results shows better carrier photogeneration quantum efficiency, and lower geminate recombination rate in samples with higher PCBM concentration.

Transparent, conductive oxide-less cylinder type dye-sensitized solar cells (TCO-less cylinder DSC): solar cells with optical pathway

J. Usagawa, T. Kogo, K. Sadamasu, S. S. Pandey, Y. S. Ogomi, S. Hayase, Kyushu Institute of Technology (Japan)

A flexible transparent conductive oxide-less dye-sensitized solar cells (flexible TCO-less DSC) was fabricated by assembling plastic sheet without TCO layer, self-standing porous titania film (TiO sheet), gel electrolyte sheet, and Ti sheet with Pt. The efficiency increased to 6.1 %, one of the highest efficiencies for TCO-less flexible DSCs, by using a specially designed unsymmetrical TiO sheet. A TCO-less cylinder type DSC was fabricated by inserting a ring shaped-TiO sheet into glass tube, followed by ring shaped gel electrolyte sheet and Ti rod with Pt catalyst layer. The efficiency was 3.9 % (Jsc 8.85 mA/cm2, Voc 0.67 V, FF 0.65). Since this process does not need a TCO layer inside the glass tube, the fabrication process is simplified. Charge collection grids are not required, because the protected mesh does work for the charge collection grids. In addition, encapsulation is expected to be done easily because the encapsulation area is small, namely, only a portion of the end of the glass tube. The current distribution of the cylinder toward a diameter direction was measured by a LBIC method. The current distribution was flat from one edge to another edge, suggesting that reflection on a round shaped rod does not affect the efficiency seriously. This was explained by the optical simulation results that light introduced in a portion close to the edge was refracted into an inside of the cykinder. In addition, it was found by using an optical simulation that the glass cylinder wall acts as a light wave guide.

Mechanism of the improvements in efficiency using calcium cathodes in P3HT:PCBM-based organic solar cells

W. Tseng, National Taiwan Univ. (Taiwan); M. Chen, National Dong Hwa Univ. (Taiwan); J. Wang, C. Tseng, C. Wu, National Taiwan Univ. (Taiwan)

Bulk heterojunction solar cells based on poly(3-hexylthiophene) (P3HT) mixed with [6,6]-phenyl C61-butyric acid methyl ester (PCBM) have attracted much attention because to the power conversion efficiency can exceed 4%-5%. It has been reported that calcium (Ca) incorporated in the cathode structures with the P3HT:PCBM active layer improve the efficiency since it forms an ohmic-contact at the active layer/cathode interface. On the other hand, in practical device fabrications, the vapor deposition of energetic alkaline earth metals like Ca on polymer surfaces might induce chemical reactions, which will also significantly affect the performance of devices. Therefore, the mechanisms of improvements due to Ca in the cathode of the P3HT:PCBM based devices may not be just due to the formation of ohmic contacts and have not been fully explored in the previous literatures.

In this work, we propose the mechanisms of the efficiency improvement in P3HT:PCBM based organic solar cells using Ca as cathodes. The electronic properties and chemical interactions between P3HT:PCBM blended active layer and Ca cathode were studied via ultraviolet and x-ray photoemission spectroscopy (UPS and XPS). UPS results show that the HOMO level of P3HT is pulled down by 0.8 eV with respect to the Fermi level after a few angstrom of Ca deposition, which implies that the electron exchange occurs at this interface. However, no such phenomenon is found between PCBM and Ca. In addition, the XPS investigations also indicate that electrons transfer from Ca to the sulfur atom in P3HT, which results in the increase of energy difference between the HOMO of P3HT and the LUMO of PCBM, and subsequently improves the Voc in solar cell devices.

Effect of light intensity on Schottky barrier widths and I-V characteristics of polymer heterojunction photovoltaic devices

A. B. Guvenc, C. S. Ozkan, M. Ozkan, Univ. of California, Riverside (United States)

The Schottky barriers that forms on the interface between aluminum and organic semiconductor of polymer heterojunction photovoltaic devices based on poly(3-hexylthiophene): [6,6]-phenyl- C61-butyric acid methylester blend, has been investigated according to Mott-Schottky curves. We focused on the effect of light intensity on the Schottky barrier widths and I-V characteristics of the devices. In order to investigate the effect of light intensity, power of light was increased from 0 mW/mm2 to 1.34 mW/mm2. As the light power increases, the slopes of the I-V curves in the reverse saturation region increase. When the tangents to the saturation region of these curves are extrapolated, all the tangent lines intersect the voltage-axis at the same voltage value. This shows that, the increase in the slopes of the curves has a certain order. This behavior looks similar to Early effect in n-p-n bipolar junction transistors, i.e. increasing barrier width causes and increase in the slopes of the I-V curves. We used this similarity to build a mathematical model for the I-V characteristics of the devices under reverse bias which involves the effect of light intensity on the Schottky barrier widths. Comparison of the mathematical model and experimental data measured under different light intensities indicate both the dependency of Schottky barrier to the light intensity and the accuracy of the mathematical model. Additionally, increasing barrier width causes the photodetection performance of the devices to increase; however, the devices turn into ohmic devices after a light intensity threshold, because, the barriers merge and the devices break-down.

Fullerene multiadducts for higher open-circuit voltages in bulk heterojunction solar cells

M. A. Faist, T. Kirchartz, J. M. Frost, Imperial College London (United Kingdom); W. Gong, Beijing Jiaotong Univ. (China); S. Foster, N. J. Ekins-Daukes, J. R. Durrant, D. D. C. Bradley, J. Nelson, Imperial College London (United Kingdom)

Organic Photovoltaics are a promising technology because of their solution processability and potential for low-cost production. In spite of these advantages, low power conversion efficiency remains a major issue. While high external quantum efficiencies have been achieved, much energy is lost when comparing the photon energy with the final extracted voltage in the cell. Reducing this energetic loss by increasing the open circuit voltage (Voc) is a major route to achieve higher power conversion efficiency.

Fullerene multiadducts with smaller electron affinity have been shown to raise the Voc [1,2], and in combination with P3HT they have been shown to increase device performance significantly. Combinations of fullerenes multiadducts with other donor polymers, however, do not show the expected performance. In this work, we use spectroscopic [3,4] and voltammetric [5] methods as well as device measurements to investigate how the use of fullerene multiadducts influences charge pair generation, charge transport and voltage generation in polymer:fullerene heterojunction devices. We study a series of fullerenes with different LUMO levels with P3HT and other donor polymers, with the aim to understand the factors that limit device performance.

Aqueous dye-sensitized hole injection into p-GaP from organic chromophores: an alternative design for highly efficient dye-sensitized solar cells

M. J. Price, S. Maldonado, Univ. of Michigan (United States)

This poster presentation will identify and quantitatively characterize aspects of light-stimulated hole injection from a photoexcited organic chromophore into a p-type phosphide semiconductor relevant to the development of efficient, aqueous solar energy conversion systems. Data will be presented for dye sensitization of single-crystalline p-type gallium phosphide (GaP) electrodes. Such dye-sensitized photocathodes are well suited to drive reduction reactions relevant to solar-to-chemical energy conversion, and their resistance to deleterious surface oxide formation and natural compatibility with common organic chromophores make their development as ‘inverse’ analogs of traditional dye-sensitized solar cells (DSSCs) attractive. Measured external quantum efficiencies were approximately doubled for polar p-GaP(111)B versus non-polar p GaP(100) photocathodes, suggesting that hole injection occurs from dye molecules that are only loosely physisorbed to the electrode surface via coulombic attraction. Hole injection was only observed for sensitizers with highest occupied molecular orbital (HOMO) energies more positive than the p-GaP valence band edge in acidic to neutral pH aqueous solutions, suggesting surface trap-state mediated injection pathways were not operative. Further analysis will be presented illustrating the advantages for dye sensitization of nanostructured phosphide photoelectrodes that feature (a) a mid-sized bandgap that eases the requirements for the panchromaticity of sensitizing dyes, (b) strong internal electric fields that simultaneously support the large emf values compatible with water photoelectrolysis and high internal quantum efficiencies for hole injection and (c) strong optical absorption dictated by selective light scattering. Collectively, this work will explore the plausibility of developing dye sensitized phosphide photoelectrodes that parallel the success of conventional n-type DSSCs.

Charge transport and recombination in small molecule non-fullerene electron acceptors for organic solar cells

K. B. Krueger, P. E. Schwenn, K. Gui, A. Pandey, The Univ. of Queensland (Australia); A. Pivrikas, Johannes Kepler Univ. Linz (Austria); P. L. Burn, P. Meredith, The Univ. of Queensland (Australia)

Fullerenes and their derivatives are the most successful electron accepting materials in organic Bulk Heterojunction (BHJ) Solar Cells today. In this presentation we report on our studies on a family of solution processable non-fullerene electron acceptors, based on the small molecule 2-[{7-(9,9-di-n-propyl-9H-fluoren-2-yl)benzo[c][1,2,5]thiadiazol-4-yl}methylene]malononitrile (K12). Devices comprising of blends of poly(3- n -hexylthiophene-2,5-diyl) P3HT as donor and K12 as acceptor have been shown to reach efficiencies of up to 0.73% under AM1.5G simulated sunlight.

To understand K12 and its application in BHJ Solar Cells, Photo Induced Charge-Extraction-in-Linearly-Increasing-Voltage (PhotoCELIV) and Transient Photo Voltage measurements (TPV) were employed to investigate the charge transport properties and recombination of free charge carriers. It was found that in neat films of K12 the molecular order

in as-cast films can be dramatically improved by annealing at moderate temperatures (60 °C) leading to a greatly enhanced electron mobility to be as high as 10^−4 cm^2V^−1s^−1, comparable with some of the best non-fullerene acceptor materials reported to date. In the blend, similar high average carrier mobilities could be found but the overall carrier extraction was limited by carrier recombination. Furthermore, we found that the free carrier lifetime in the devices is strongly dependent on the carrier concentration. In our paper we will present our results and compare the findings with those obtained on state-of-the-art solar cell systems based on low-bandgap polymers.

Impact of temperature and thickness of an active layer on charge transport of bulk-heterojunction cells

A. M. Syed, Hanyang Univ. (Korea, Republic of); C. W. Chul, Sungkyunkwan Univ. (Korea, Republic of); H. Um, S. Jee, M. Park, Y. Nam, K. Park, Hanyang Univ. (Korea, Republic of); J. Jung, Hanyang Univ. (Korea, Democratic Peoples Republic of); Z. Guo, Hanyang Univ. (Korea, Republic of); S. Kim, H. K. Cho, Sungkyunkwan Univ. (Korea, Republic of); J. Lee, Hanyang Univ. (Korea, Republic of)

Despite numerous advantages of poly[N-9′-heptadecanyl-2,7-carbazole-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole)] (PCDTBT) in bulk heterojunction (BHJ) composited with a fullerene derivative [6,6]-phenyl C70-butyric acid methyl ester (PC70BM), the charge transport mechanism required for device optimization is still not clear. To address this challenge, systematic studies on carrier transport in pristine thin films of PCDTBT, PC70BM and PCDTBT:PC70BM sandwiched between indium-tin-oxide (ITO) and silver electrode were carried out using various PCDTBT:PC70BM blend ratios (from 1:1 to 1:5) as functions of temperature and a film thickness. Compared to a pristine PCDTBT, significant enhancement in mobility was observed for all room-temperature blended devices owing to intercalation of PC70BM molecules between the side chains of PCDTBT polymer for efficient carrier transport from donor to acceptor molecules. Since the excessive amount of PC70BM degrades the crystallinity of PCDTBT with mobility, an optimal blend ratio of PCDTBT:PC70BM was estimated to be 1:3 through the tradeoff relation in mobility of BHJ cells. While interpreting the temperature and electric field dependent experimental results of PCDTBT:PC70BM (1:3) correlated with the Gaussian disorder and correlated disorder models, the influence of active layer thickness on a charge carrier mobility is also investigated and discussed in term of energetic and spatial disorder in bulk heterojunction cells. Negative field dependence mobility was observed at low electric field for small thickness BHJ cells and vanished gradually when the cell sizes is increased. Such occurrence of negative field dependent mobility is attributed by the small energetic, but large spatial disorder.

Synthesis and photovoltaic properties of quinoxaline-based alternating copolymers for high-efficiency bulk-heterojunction polymer solar cells

S. K. Lee, W. S. Shin, J. Lee, S. Moon, Korea Research Institute of Chemical Technology (Korea, Republic of)

Polymer solar cells (PSCs) have attracted considerable attention over previous decades because of their unique advantages, which include low cost, lightweight, solution processability, and flexibility. Despite considerable progress in this field, power conversion efficiencies (PCE) of PSCs must be further improved for commercialization. So far, poly(3-hexylthiophene) (P3HT) is typically used in construction of PSCs. However, a bottleneck in conversion efficiency seems to be reached by using P3HT because it harvests a small absorption portion with respect to the solar spectrum. Recently, several classes of low-bandgap polymers by using internal charge transfer (ICT) from an electron-rich unit to an electron deficient moiety within the fundamental repeat unit have been developed to better harvest the terrestrial solar spectrum. Among them, relatively high-performance polymer solar cells made from a mixture of poly(2,7-carbazole) derivatives, PCDTBT, and [6,6]-phenyl C71 butyric acid methyl ester (PC70BM) have been reported, with maximum power conversion efficiency of 6.1%. In this poster, we report a series of quinoxaline-based copolymers. We systematically investigated the synthesis, thermal stability, as well as the optical and electrochemical properties of these polymers. Bulk heterojunction solar cells made from the result polymer produced a power conversion efficiency of 4.0% under AM 1.5 conditions. Detailed synthetic scheme, optical, electrochemical, and photovoltaic properties of the copolymers will be presented.

Bulk-heterojunction solar cells utilizing solution-processable phthalocyanine derivative

T. Hori, Osaka Univ. (Japan); Y. Miyake, National Institute of Advanced Industrial Science and Technology (Japan) and Osaka Univ. (Japan); N. Fukuoka, T. Masuda, T. Hayashi, H. Yoshida, A. Fujii, Osaka Univ. (Japan); Y. Shimizu, National Institute of Advanced Industrial Science and Technology (Japan); M. Ozaki, Osaka Univ. (Japan)

Organic semiconductors are classified into two types, pi-conjugated polymers and low-weighted molecules. Organic thin-film solar cells based on a bulk heterojunction active layer utilizing pi-conjugated polymers fabricated by a wet process achieved high energy conversion efficiency. On the other hand, some low-weighted molecular semiconductors demonstrate a high crystallinity and charge mobility by strong intermolecular interactions, however, they are inappropriate for wet processes because of their poor solubility in typical organic solvents. Recently, we have demonstrated ambipolar high carrier drift mobility of 1.4 cm2/Vs of a soluble and mesogenic phthalocyanine derivative, 1,4,8,11,15,18,22, 25-octahexylphthalocyanine (C6PcH2) which was evaluated by means of time-of-flight measurement.

In this study, we demonstrate the photovoltaic properties of simple bulk heterojunction solar cells based on the blend film of phthalocyanine derivative C6PcH2 and a fullerene derivative (PCBM) as the active layer, which was fabricated by spin-coating.

As a results, two broad peaks exist in the external quantum efficiency (EQE) spectrum, which correspond to the absorbance spectrum. One of the peaks, which originates from the Q-band absorption of C6PcH2, exhibited an EQE higher than 70%. The energy conversion efficiency of the solar cell with the C6PcH2:PCBM composite layer at a weight ratio of 2:1 reached 3.1% with Voc of 0.84 V, Isc of 8.4 mA/cm2, and FF of 0.44 under AM1.5G (100 mW/cm2) solar-illuminated condition. It is considered that C6PcH2 is a promising donor material for organic thin-film solar cells fabricated by a solution process.

Functionalized cyclopentadithiophene-based low-bandgap copolymers for photovoltaic applications

S. Van Mierloo, Univ. Hasselt (Belgium); W. Maes, Univ. Hasselt (Belgium) and Katholieke Univ. Leuven (Belgium); L. J. Lutsen, D. J. Vanderzande, Univ. Hasselt (Belgium)

Third generation low bandgap copolymers such as poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b']dithiophene)-alt-4,7-

(2,1,3-benzothiadiazole)] (PCPDTBT), which exceed 5% efficiency when blended with PC70BM in organic bulk heterojunction solar cells, have gained substantial interest in recent years. In this contribution we present the synthesis of novel low bandgap copolymers based on functionalized 4H-cyclopenta(2,1-b:3,4-b')dithiophenes (CPDT) alternating with 2,5-bis(3-alkylthiophene-2-yl)thiazolo[5,4-d]thiazoles (TzTz), and solar cell performances of films of these polymers blended with fullerene acceptors. Elaborated synthetic studies have resulted in the development of a convenient and efficient three-step route toward both symmetrically and asymmetrically functionalized CPDTs. Using this method a broad collection of functionalized bridged bithiophenes can smoothly be accessed. Starting from 3-bromo-2,2'-bithiophene, lithiation and subsequent reaction with dialkyl ketones afforded (a) symmetrically dialkylated tertiary alcohol derivatives. By means of a Friedel-Crafts dehydration cyclization in sulfuric acid medium, these derivatives were converted to 4,4-dialkyl-4H-cyclopenta(2,1-b:3,4-b') dithiophenes. The developed three-step procedure also allows introduction of functional groups on the alkyl substituents starting from a versatile ester-functionalized CPDT scaffold. The ester function could further be converted into carboxylic acid and amide moieties. The variety of CPDT building blocks could be coupled to alkylated TzTz monomers via Suzuki polymerization generating a new series of low bandgap polymers. Incorporation of specific functional groups on the monomers offers the opportunity to control the morphology of the conjugated polymer:fullerene blend (toward optimization of the efficiency of the devices) and to explore its (thermal) stability in organic solar cells. Hence, this study represents a rational approach toward morphology control via modification of the chemical structure rather than via processing.

Controlling of initial molecular arrangement of copper(II) phthalocyanine for interpenetrating networks in a mixed donor/acceptor layer

H. J. Kim, J. W. Kim, T. Kim, J. Jang, Seoul National Univ. (Korea, Republic of); H. H. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

We observed that thermally evaporated Copper(II) Phthalocyanine (CuPc) ultra thin layer (5 nm) was consisted in disc type CuPc nano grains on a hydrophilic Si surface, which was analytically confirmed by structure factors in GISAXS measurement. The disc type grains were consisted in crystalline part and non-crystalline part. On the other hand, the disc type grains disappeared in case of the evaporation on a octadecyltrichlorosilane (ODTS) treated hydrophobic Si surface, which showed lower cyrstallinity with random distribution. Interestingly, the mobility was lower in a FET device fabricated on a hydrophilic surface than on a ODTS Si surface due to the low average density of molecules relating porous molecular packing between nano grains on a hydrophilic surface. Despite of the low FET mobility, the disc type CuPc has a potential to be applied to fabricate bulk heterojunction (BHJ) donor/ acceptor (D/A) mixed layer with C60 for organic photovoltaic devices, and the device showed improved current voltage characteristics. The initial molecular arrangement of CuPc was also affected by the adoption of thin CuI layer before evaporating CuPc. The nano structure of a mixed D/A layer on CuI was characterized in detail with AFM, GIWAXD, and GISAXS measurements. The device performance supported improved nano structure of a mixed D/A layer on CuI.

Charge photogeneration in organic donor/ acceptor blends

S. Shoaee, Imperial College London (United Kingdom)

Organic solar cells formed from conjugated polymers based on dialkylpyrrolopyrrolrd, thiazolothiazole and dithienosilole moieties blended with small molecules are gaining interest for low cost, high efficient (> 5%) solar energy conversion. The function of such devices is based on photoinduced charge separation (CS) at the donor /acceptor (D/A) interface. There is increasing evidence that the efficiency of this CS process can be determined by the presence of coulombically bound charge transfer (CT) states at the D/A interface.1-3 In this work we focus upon the role of interfacial energetics in influencing the separation of these CT states into dissociated charge carriers. In particular, we undertake transient optical studies of D/A blend films. Transient absorption spectroscopy has proven useful in this regard and can monitor the formation and decay dynamics of the charged species present in the blends. In this work, this technique has been applied to a range of D-A and polythiophene-based materials in blends with series of perylene diimide derivatives and PCBM.3 The efficiency of charge photogeneration in organic D/A blend films has been reported to depend on a range of factors, including film nanomorphology, and the energy difference driving charge separation (GCS).2,3,4 The photoluminescence quenching has been used in conjunction with the transient dynamics data to create a model of charge generation and dissociation. For these film series, we observe a close correlation in the yields of charge separation with the GCS.

In this work we aim to address:

1) Charge generation

2) Carrier mobility

3) Free energy for charge separation

CuInS2-polymer nanocomposite solar cells

A. Pein, E. Strunz, W. Haas, F. Hofer, T. Rath, G. Trimmel, Technische Univ. Graz (Austria)

Inorganic-organic nanocomposite solar cells (NCSCs) have attracted considerable interest in recent years due to several advantages compared to organic solar cells. One of the main advantages is that the optical and electronic properties of the acceptor phase can be tuned by the size and shape of the nanoparticles. Moreover, also the acceptor phase contributes to the absorption of light and therefore higher current densities are expected. This contribution deals with the synthesis of CuInS2 and its use in solar cells. The high absorption coefficient and the ideal bandgap of 1.5 eV provide promising properties in combination with polymers of suitable energy levels. Using the oleylamine route particles of different size and shapes were prepared by variation of the temperature profile, the heating mechanism and the used reagents. The size and crystal structure of the obtained nanoparticles was characterized by x-ray diffraction, dynamic light scattering and transmission electron microscopy. The optical properties were investigated by absorption and emission spectra. One crucial point in nanoparticle synthesis is the surface of the particles that have to be stabilized with long-chained organic molecules that prevent the agglomeration. However, while necessary during the synthesis and for the solubility that ensures mixing with polymers in common organic solvents, the performance of prepared solar cells is negatively influenced by this isolating, organic capping sphere. Therefore different strategies to minimize this effect will be discussed including acid treatment and capper exchange. The influence of the performance of solar cells will be argued in terms of current density-voltage plots and incident photon to current efficiency spectra.

Low-bandgap thiophene-based heterophenoquinones for organic photosensitive films

E. V. Canesi, L. Colella, Istituto Italiano di Tecnologia (Italy); C. Bertarelli, Politecnico di Milano (Italy) and Istituto Italiano di Tecnologia (Italy); G. Lerario, P. E. Keivanidis, Istituto Italiano di Tecnologia (Italy)

Thiophene-based quinoidal molecules (QBTs) have found a renewed interest in the recent literature; their amphoteric redox character makes them suitable materials for ambipolar [1] and n-channel [2] organic transistor applications, while their intense absorption band in the red and near-infrared spectral region suggests the use in photodetecting and photovoltaic (PV) devices. Particularly for the case of a blend film of a QBT species, 5,5'-bis(3,5-di-tert-butyl-4-oxo-2,5-cyclohexadiene-1-ylidene)-5,5'-dihydro-2,2'-bithiophene, with poly[2-methoxy-5-(2'-ethyl-hexyloxy)-1,4-phenylene vinylene] (MEH-PPV), it was recently shown that photocurrent generation can be driven by a photo-induced hole transfer from QBT to MEH-PPV, which is enabled by the absorption of 700 nm photons.[3]

In this work we present a series of newly synthesized symmetric and asymmetric QBT derivatives, bearing side-chains of different length and diverse electron-active groups.

We focus our attention on the effect of structural variation on the tendency of the QBT species to aggregate when deposited as thin films. Our study employs time-integrated UV-Vis absorption and photoluminescence spectroscopy experiments combined with optical and atomic force microscopy imaging techniques. We investigate pure QBT thin films and blend films of QBT composites prepared by mixing QBTs either with poly(3-hexylthiohene) (P3HT) or with poly(styrene) host matrices.

Finally, the electrical characterization of photodiodes based on P3HT:QBT active layers will be presented.

Al2O3:ZnO nanolaminates as electron-collecting electrode in inverted polymer solar cells

H. Cheun, H. Li, Y. Zhou, Y. Fang, Y. Cai, J. W. Shim, C. Fuentes-Hernandez, K. H. Sandhage, J. Brédas, B. Kippelen, Georgia Institute of Technology (United States)

Recently, polymer solar cells with a transparent electron collecting electrode have been fabricated to improve stability in air. In such a structure, called an inverted structure, ITO is commonly used as transparent electrode. To serve as electron-collecting electrode, ITO must be modified in order to reduce its work function. An alternative is to replace ITO with another transparent conductive oxide that has a lower work function.

Here, we propose (Al2O3)x:(ZnO)y nanolaminates fabricated by atomic layer deposition (ALD) as electron-collecting electrodes in organic solar cells. In this work, we studied the structural, electrical, and optical properties of these nanolaminates as a function of the relative values of x and y. 300-nm-thick (Al2O3)1:(ZnO)20 nano-laminates on a glass substrate showed a high optical transmittance (> 80%) in the visible region with a high conductivity of 2500 S/cm and a low work function (4.2 eV). A 60 times increase of the electrical conductivity of these (Al2O3)1:(ZnO)20 nanolaminates compared with neat ZnO films fabricated by ALD is attributed to a combination of morphological changes, doping, and quantum confinement effects. We tested these electrodes in P3HT:PCBM polymer-based inverted solar cells and obtained power conversion efficiency values of 3 % under simulated AM 1.5G, 100 mW/cm2 illumination.

Technological challenges and future prospects for improvement in the performance of organic solar cells

S. Baghel, R. Jha, Netaji Subhash Institute of Technology (India)

The field of organic solar cells is rapidly accelerating due to the need of new clean and cheap energy sources. A large fraction of the cost of Si based solar cells is attributed to sophisticated and energy intensive processing technologies. The organic solar cells offer a cost effective alternate and are promising as they can be manufactured on plastic substrates by various types of printing techniques. This technology offers several advantages over silicon solar cells or other inorganic counterparts: the polymers are soluble in common organic solvents allowing the deposition of ultra-thin semiconductor films.

This paper presents, an overview of basic operational principles and recent development of polymer solar cells paying particular attention to possible routes for improving stability, absorption, open circuit voltage, power conversion efficiency and development of new device design and materials that includes development of ITO free flexible solar cells, use of metal gratings as transparent electrodes . Future prospects and possible solutions to problems related to practical application of organic solar cell technology have been addressed.

This study on material requirements and current technical challenges in making more efficient solar cells will serve as a guide to new researchers in this field who plan to develop better materials and optimize devices for better conversion efficiency. This study on material requirements and current technical challenges in making more efficient solar cells will serve as a guide to new researchers in this field who plan to develop better materials and optimize devices for better conversion efficiency.

Inverted organic solar cells using a water-soluble polymer-modified indium tin oxide as an electron-collecting electrode

Y. Zhou, J. W. Shim, H. Cheun, A. Dindar, C. Fuentes-Hernandez, Georgia Institute of Technology (United States); J. Meyer, A. Kahn, Princeton Univ. (United States); B. Kippelen, Georgia Institute of Technology (United States)

Organic solar cells are emerging as a potentially low-cost, flexible, and portable renewable energy source. Organic solar cells with an inverted structure typically have better air stability than non-inverted geometries because they do not use low-work function metals that are sensitive to air. Inverted solar cells can be fabricated by reducing the work function of indium tin oxide (ITO) in order to turn it into an electron-collecting electrode. Metal oxides such as ZnO, TiOX, Al2O3, or Cs2CO3, are commonly used as interlayers to modify the work function of ITO. However, they typically require either vacuum deposition techniques or high processing temperatures when processed from solution. Water-soluble polymeric modifiers are highly desirable because they could be mass-produced at a low-cost onto large areas.

Here, we report on the properties of inverted organic solar cells with an ITO electrode modified with polyvinylpyrrolidone (PVP) prepared by spin-coating from a water solution. This modification reduced the work function of ITO from 4.6 eV to 4.2 eV, and allowed ITO to act as an electron collecting electrode. Changes in work function were measured independently by a Kelvin probe and by UV photoemission spectroscopy. Inverted solar cells based on Poly(3-hexylthiophene) (P3HT):[6,6]-phenyl C61 butyric acid methyl ester (PC60BM) yielded a power conversion efficiency of 3.2% under 100 mW/cm2 air mass 1.5G illumination, after

exposing them for 20 minutes to an ultraviolet (UV) lamp. The current density-voltage characteristics of the newly-fabricated devices showed an S-shape kink which was efficiently removed after UV treatment. The origin of this kink and its reversible control will be discussed.

Performance prediction of dye-sensitized solar cells using innovative nanomaterials

R. Jha, S. Baghel, Netaji Subhash Institute of Technology (India)

Dye sensitized solar cells have attracted the attention of researchers as a cost effective alternative to the conventional solar cells. Till now solid state junction based photovoltaic devices dominated this field. The basic difference between dye sensitized solar cells and their conventional counterparts lie in the fact that, the process of both light absorption and charge transportation are carried out separately. Sensitizer molecules which are adsorbed on the semiconductor material absorb light and initiates the charge separation process. To enhance the photovoltaic performance of dye solar cells many new techniques and materials have been used, which includes electrode modifications using single walled carbon nanotubes that leads to low cost and minimal material use, fabrication of dye sensitized solar cells using graphene based carbon nanocomposite as counter electrode. Dye sensitized solar cells with liquid electrolyte have attained efficiency over 10%,but the possibility of evaporation of electrolyte and its leakage from the cell, pose as a threat to the stability of these cells. This led to the use of nanoparticle based gel electrolyte, replacement of electrolyte with solid p type semiconductor and development of solid state heterojunction dye solar cells.

To increase the photovoltaic efficiency, many alternatives have been explored including the use of metal oxide nanoparticles based light scattering structures, application of photonic crystals to enhance light path length, also development of sensitizing dyes using quantum dots to extend absorption range. The recent developments and current efforts that are being made in this field including the development of new hybrid tandem designs, application of nano-wires and analysis of the future prospects of the technology have been presented in this paper.

A new approach for dye studies of dye-sensitised solar cells

L. L. Tobin, D. Zerulla, J. T. Sheridan, Univ. College Dublin (Ireland) and SFI-Strategic Research Cluster in Solar Energy Conversion (Ireland)

Dye-sensitised solar cells (DSSCs) are 3rd generation solar cells. DSSCs are biomimetic solar cells, they mimic the process of photosynthesis i.e. incoming light is absorbed by an organic dye and electrons are produced thereby producing both positive and negative charge carriers. The appeal of these cells is due to their low cost, flexibility and the ability to work in diffuse light. At present their efficiencies are far lower than that of the more common 1st generation single junction silicon solar cells. In order to improve DSSCs efficiencies, suitable dyes must be used. We present a new approach to dye studies for DSSCs involving dyes in-situ in polymer (organic) layers.

Organic n-type interfacial layer for organic photovoltaic devices having inverted architecture

A. W. Hains, H. Chen, T. H. Reilly III, B. A. Gregg, National Renewable Energy Lab. (United States)

A crosslinking perylene derivative is synthesized, characterized, and employed as an n-type interfacial layer (IFL) situated between the tin-doped indium oxide (ITO) and the active layer in organic photovoltaic (OPV) devices having inverted geometry. The initial 1,6,7,12-tetrachloroperylene-3,4,9,10-tetracarboxylic acid (Cl4PTCDA) is synthetically fitted with two trimethoxysilylpropyl linkages to form Cl4PSi2. These silanated “tethers” function both to chemisorb the molecule to the hydroxylated ITO surface and to crosslink the film, rendering it insoluble and thereby enabling successive spin-coating steps in the device fabrication process without worry of problematic IFL dissolution. Smooth, thin films of Cl4PSi2 are deposited by substrate immersion into a dilute solution, followed by annealing in air to complete the crosslinking process. The thickness and surface morphology of these films are characterized by profilometry and atomic force microscopy, and the optoelectronic properties of the film are examined with cyclic voltammetry (CV) and UV-visible spectroscopy to determine the LUMO energy and the optical band gap. The LUMO energy of 4.0 eV properly aligns the IFL with LUMO energies of many common electron-accepting species in the OPV active layer such that electron transfer to the IFL should be energetically unhindered. Finally, OPV devices are fabricated having an n-type IFL consisting of either Cl4PSi2 or Cl4PSi2 blended with an n-type polymer, poly(9,9-dioctylfluorene-co-benzothiadiazole) (F8BT), to enhance film-forming properties, and device power conversion efficiencies of around 2% are observed. The effect on film and device properties of the addition of charges to Cl4PSi2 is also explored by adding N-trimethoxysilylpropyl-N,N,N-trimethylammonium chloride (APMS+) in various amounts.

Electronic properties of polymer electrode materials for polymer photovoltaics

A. J. Moule, Univ. of California, Davis (United States); D. Huang, Univ. of Adelaide (Australia); S. Mauger, Univ. of California, Davis (United States); S. Friedrich, Lawrence Livermore National Lab. (United States); C. Rochester, Univ. of California, Davis (United States)

Polyethylenedioxythiophene Polystyrenesulphonate (PEDOT:PSS) is a highly conducting transparent polymer mixture that is used as a hole carrying electrode for nearly all organic optoelectronic devices, including OLED’s and solar cells. Its ability to conduct exclusively holes is essential for high filling factors for OPV devices. We show that the hole selectivity of PEDOT:PSS comes partially from heat induced mixing with donor polymers and oxidization of the donor polymers at the PEDOT:PSS / BHJ layer interface. This mechanism is proven using x-ray absorption spectroscopy, neutron scattering, UV/vis absorption, and detection of H2, a side product of the reaction, using GCMS. The electronic significance of a mixed polymer/PEDOT:PSS layer is shown by observing the change in the IV characteristics that comes about through the growth of a mixed layer with the polymers P3HT, OC1C10-PPV, APFO-3, and F8BT followed by deposition of a BHJ layer. We show that the dopant HPSS is only strong enough to oxidize donor polymers with work function values below -5.1 eV so that the nature of the mixed layer depends strongly on the mixed polymers.

The research is broadened by examination of the transparent electrode materials PTMESS and doping using both small molecule and polymeric dopants. We show that the interface layer formed is not unique to PEDOT:PSS and that the apparent work function of the electrode layer is not a strong indicator of the ability of the layer to preferentially conduct holes. Instead formation of doped surface layers and morphology of the transparent organic conductor is for more important.

Novel concepts for light management in organic photovoltaics

E. J. Klem, RTI International (United States); M. Dickey, North

Carolina State Univ. (United States); J. Lewis, RTI International (United States); J. Maria, North Carolina State Univ. (United States)

We have explored novel concepts for light management suited for thin film photovoltaics by engineering surface topography in an effort to enhance the overall efficiency light absorption. The concepts utilized surface instabilities that produced hierarchically corrugated surfaces on the nanometer scale without lithographic patterning. These processes are applicable to many thin-film photovoltaic technologies and are particularly well-suited for mechanically flexible, low-cost systems. We developed techniques for generating corrugated surfaces on substrates suitable for photovoltaic device processing and then applied these substrates to the fabrication of thin film small molecule organic photovoltaic (OPV) devices as well as to quantum dot photovoltaics (QDPVs).These are appealing technologies for their low-cost and compatibility with flexible substrates and have a common feature; relatively short charge transport lengths requiring devices with thin active regions for efficient charge separation. Small molecule OPV devices fabricated using these high surface topography substrates have demonstrated a 30% increase in the short circuit current densities and a 20% increase in the power conversion efficiency as compared to their planar

Flexible polymer solar cells with oxide/metal/oxide trilayer as transparent anode

W. Cao, Y. Zheng, E. Wrzesniewski, W. Hammond, J. Xue, Univ. of Florida (United States)

Organic solar cells (OSCs) have attracted much attention as a renewable energy conversion system, owning to the low-cost and easy-processing nature of organic materials. Transparent electrode is an essential component in OSCs and the material of choice so far has been indium tin oxide (ITO). However, the rising cost of indium, brittleness and the high temperature process make it not compatible for low-cost and large-area applications.

Here we use a semi-transparent oxide/metal/oxide (OMO) trilayer structure to replace ITO in OSCs. This trilayer structure has a similar conductivity and transparency to ITO and can be deposited through vacuum thermal evaporation to avoid the damage to the active layers. The ITO-free devices were fabricated by successively spin-coating ZnO nanoparticles and poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) blend onto glass with Al electrodes, finished by thermally evaporating MoO3/Au/MoO3 trilayer as the anode. Such ITO-free device on glass shows a power conversion efficiency (PCE) of ~2.5% under simulated 1 sun AM1.5 solar illumination. We also fabricated ITO-free devices on flexible PET substrates, which show almost the same performance (~2.4% PCE) as that on rigid glass substrates. Due to the high flexibility of the trilayer electrode, the efficiency of the flexible device is only reduced by ~6% from its original performance after 500 cycles of bending test with a bending radius of 0.5 inch. The performance of these ITO-free devices suggests that this oxide/metal/oxide trilayer electrode is a promising candidate to replace ITO in OSCs.

Effect of processing additives on the structural and electrical properties of bulk heterojunction films for organic photovoltaics

N. Shin, X. Zhang, R. J. Kline, L. J. Richter, D. M. DeLongchamp, National Institute of Standards and Technology (United States)

Bulk heterojunction (BHJ) organic photovoltaic (OPV) cells based on polymer : fullerene blends have offered a promising solution for future energy need. Recently, it has been shown that the power conversion efficiency of BHJ OPV devices can be increased by the addition of small amounts of processing additives with high boiling points, which are believed to affect the morphology of the BHJ active layer. In this work, we apply detailed microstructure measurements to BHJ films based on a poly(3-hexylthiophene) (P3HT):[6,6]-phenyl-C61-butyric acid methyl ester (PCBM) blend and prepared with various processing additives (1,8 diiodooctane and 1,8 octanedithiol, and 1 chloronaphthanlene) and different processing methods. Aspects of thin film microstructure such as degree of ordering, molecular orientation, and nanoscale morphology were systematically characterized by techniques including grazing incidence X-ray diffraction, near edge X-ray absorption fine structure spectroscopy, variable angle spectroscopic ellipsometry, and transmission electron microscopy. The results were correlated with device performance, illuminating the mechanism by which these additives improve the power conversion efficiency of BHJ OPV devices.

The impact of squaraine functionalization on the efficiencies of NIR-active bulk-heterojunction photovoltaics

C. J. Collison, J. Cody, S. D. Spencer, A. Ioannidis, A. Monfette, H. Hu, B. Zhu, Rochester Institute of Technology (United States)

Organic photovoltaic (OPV) solar cells are inexpensive since their manufacture relies only upon spin-coating or spray coating technology. Yet organic solar cells suffer from lower efficiencies when compared to their more expensive silicon-based counterparts. Low efficiencies ultimately mean excessive investment costs, which prevent their widespread use.

We describe a series of squaraine dyes that will be targeted specifically for optimal application in more efficient NIR tandem cells, so as to broaden the range of spectral harvesting from the sun. Squaraines form a family that is among the very few successful solution processable molecular chromophores. Our current goal is to describe how 2,4-Bis-(4-diisobutylamino-2,6-dihydroxy-phenyl)-cyclobutane-1,3-dione can be substituted in order to achieve high power conversion efficiencies for our devices. We will systematically vary the functional groups on synthesized squaraines and we will measure the impact on isolated variables, in particular the aggregation/morphology, the exciton diffusion length and the mobilities of photogenerated charges in bulk heterojunction devices with PC[60]BM as the electron acceptor. We will present corresponding increases in power conversion efficiencies given a baseline efficiency of 0.5% for a single active-layer device as measured in our laboratory. The results of this work will allow us to prescribe improved device efficiency through chemical tuning and design.

Enhanced efficiency of polymer and organic small-molecule-based solar cells by improved charge extraction

T. Xiao, W. Cui, J. Shinar, R. Shinar, Iowa State Univ. (United States)

Power conversion efficiency (PCE) of organic solar cells based on commercial materials remains low. We present approaches that improve the PCE by up to 27%. These include spin-coating ethylene glycol (EG) on PEDOT:PSS layer in devices of the structure ITO/PEDOT:PSS/EG/P3HT:PCBM/Ca/Al, and depositing a thin, plasma etched LiF layer in cells of the structure ITO/LiF/CuPc/C70/BPhen/Al. Via comprehensive measurements, including surface morphology and chemistry, in P3HT:PCBM cells we observed improved absorption with higher short-circuit current and fill factor, including a more favorable vertical phase segregation in the active layer, leading to improved charge extraction. Improved PCE in the small-molecule-based cells is possibly associated with a LiF-induced modified interface and consequently improved energy level alignment.

Cathode modifications in organic photovoltaic cells

J. Chen, South China Univ. of Technology (China)

Recently, the special solubility of conjugated polymers in alcohol or water has drawn tremendous attention for the realization of optoelectronic devices consisting multilayer polymers as well as for the enhanced device performances in polymeric LEDs and FETs. Here, alcohol-soluble conjugated polymers (ASCPs) as cathode buffer layer in organic photovoltaic cells (PVCs) were evaluated. The ASCP/Al bilayer cathode showed obvious contributions to elevate the photovoltaic performances in comparison to the sole Al cathode. Not only the loss of open-circuit voltages could be recovered, but also short-curcuit current and fill factor could be improved. The N-N interactions between a polymer donor and a ASCP may modify interfacial contact, resulting in enhancement of electron extraction and decreasing hole-electron recombination in the active layer. Consequently, significant increasing of power conversion efficiency (PCE) from a level of ~3% to ~6% could be realized for certain polymer donors, suggesting that the bilayer cathode would have great potential to elevate PCE of PVCs.

Multilayer transparent cathode of organic-inorganic hybrid materials for solar cells

G. H. Jung, K. Hong, W. J. Dong, J. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Thin-film solar cells based on organic and inorganic have various advantages of high efficiency, low-cost, and flexible solar cells. However, such cells using a glass substrate have the inherent disadvantages of high cost, low flexibility, and careful handle. Replacing the glass substrate with flexible opaque materials such as steel sheets or plastic films makes possible the fabrication of flexible, thin, and low-cost solar cell through roll-to-roll mass production. For the thin-film solar cells with these substrates, the direction of incoming light has to be from top to the bottom. Thus, formation of a high transparency top cathode which has high efficiency of electron collection is one of the most significant factors for high efficiency thin-film solar cells.

We investigated the optical properties of dielectric/metal/dielectric (DMD) structured bathocuproine (BCP)/silver (Ag)/MoO3 transparent cathode. Different optical effects between BCP, Ag layer, and outer MoO3 layer were identified in experimental measurement and theoretical calculation. From these studies, we optimized the suitable multilayer structure for transparent top cathode in OPVs. Thermally evaporated BCP (10 nm)/ Ag (10 nm)/MoO3 (25 nm) cathode showed high transmittance (81.2 %) and low sheet resistance (8.6 ohm/sq). Organic photovoltaics (OPVs) of poly(3-hexylthiophene):[6,6]-phenyl-C61 butyric acid methyl ester (P3HT:PCBM) with BCP/Ag/MoO3 multilayer as a transparent top cathode exhibited the Jsc = 5.8 mA/cm2, Voc = 0.573 V, and PCE = 1.8 %. Thus, we can expect this thermally evaporable BCP/Ag/MoO3 with high transmittance and low sheet resistance multilayer can be applicable to general transparent cathode organic opto-electronic devices.

Oxide/polymer interfaces for hybrid and organic solar cells: Anatase versus Rutile TiO2

M. Lira-Cantu, CIN2 (Spain)

We report the effect of the crystalline structure of TiO2 and the polymer applied in polymer/oxide solar cells interfaces. The presence of TiO2 in its the Rutile phase increase solar cell stability under inert atmospheres than devices fabricated with the Anatase phase and devices based on MEH-PPV show higher Voc (as high as 1 V), while the application of P3HT results in lower Voc, but higher Jsc and longer device stability. Our findings suggest that P3HT can be linked to the TiO2 though the S-end atom, which results in devices with lower Voc. All these observations are also valid for devices, where the bare TiO2 is replaced by an Nb-TiO2 but the solar cells applying the doped oxide resulted in devices with photoresponse under inert atmosphere even after several hours under inert (or encapsulated) conditions. We conclude that the application of TiO2 in its Rutile phase is beneficial for long-term stability devices. Moreover there is an interplay between low Voc and Jsc in devices applying P3HT, since power conversion efficiency can be partially canceled by their lower Voc in comparison with MEH-PPV. These findings are important for polymer/oxide solar cells, but also for organic solar cells, where a layer of semiconductor oxides are in direct contact with a polymer, like in inverted or tandem organic solar cells.

Self-assembled indium-tin-oxide (ITO) nano-branches for high-efficient polymer solar cells

W. J. Dong, H. K. Yu, G. H. Jung, J. Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

Developments in three-dimensional highly conductive and transparent electrode of organic photovoltaics (OPV) will be discussed. Thin-film solar cells based on organic materials have various advantages of easy fabrication, low-cost, and flexibility. However, OPVs have lower hole mobility in donor materials (2 10-4cm2V-1s-1) compare to electron mobility in acceptor (3 10-3cm2V-1s-1). Relatively low hole mobility induces unbalanced charge transport, leading to limited photocurrent generation of solar cell device. Since two-dimensional morphology of ITO film cannot efficiently extract holes in bulk region of active layer, three-dimensional nanostructure is proposed as efficient hole collecting electrode to balance the charge transport.

Self assembled and single crystalline ITO nano-branches were fabricated by vapor-liquid-solid process using electron beam evaporation process, which is free of any catalyst and carrier gas. The {100} family planes of bixbyite In2O3 have the termination of metallic indium; self In-Sn catalyst could be easily formed at those planes, resulting in ITO nano-branch structure with 90o rotation angle. The large surface to volume ratio in anode by ITO nano-branches increases not only the hole mobility by 3-dimensional pathway but also the light absorbance by light scattering at a time. Highly conductive (RS < 8 ohm/sq) and transparent (84.8%) single crystalline ITO nano-branches result in increase of 12% photocurrent (8.4 mA/cm2 to 9.4 mA/cm2) and 20% photo conversion efficiency (3.03% to 3.67%) of polymer solar cells based on bulk hetero-junction of regioregular poly(3-hexylthiophene) and phenyl-C61-butyric acid methyl ester. In this study, we successfully fabricated nanostructured hole conducting electrode for high efficient bulk hetero-junction OPVs.

An investigation on solution processed films for organic solar cells via multiple techniques

A. K. Chilvery, Alabama A&M Univ. (United States)

The demand for low cost and durable solar cells has paved the way for unprecedented advancement in usage of organic semiconductors. Organic solar cells (OSC) hold the potential of low-cost production and a high throughput as compared to inorganic solar cells besides the increase in efficiency. To realize these possibilities, objective should be to fabricate most of functional films in OSC structure via solution-process technologies: spin; spray; brush and other coating methods. We merged all the solution-processed techniques in order to fetch a better quality films. We discovered this is a high-rate, large-area deposition technique that ensures an ideal coating on a variety of surfaces with different morphologies and topographies. Systematic efforts are being made to

fabricate various films of important efficient OSC materials such as ZnO, TiO2, P3HT, PCBM, and others by solution-processed techniques. The results obtained in regard to their microstructures, dark- and photo-electric transport and junction characteristics are promising and shall be presented. Also the complete process and electrical characterization results will be presented and discussed.

The 'process-property' relations shall be described in order to obtain best set of performance characteristics. The details of modified fabrication techniques along and facilities established for testing the films and organic solar cells will also be presented. * work supported by NSF-RISE grant: id 0927644.

Schottky devices based on polyaniline doped with different metals chloride

H. A. Motaweh, A. H. Elsayed, M. M. Saad, A. H. A. Sakr, Alexandria Univ. (Egypt)

Polyaniline (PANI) doped with metal chloride with nanometer size were used to fabricate the Schottky device Al/PANI -Fe3O4 /Au. Current density -voltage (J-V) and capacitance-voltage(C-V) characteristics for this device resemble the typical characteristic for conventional Schottky diode. The characteristic parameters of the structure such as ideality factor, series resistance, barrier height, built-in potential at zero bias and depletion width (W) have been determined from J-V and C-V measurements.

Synthesis of low bandgap polymers and their applications in photovoltaics and organic thin film transistors

D. Chandran, P. Kandoth Madathil, Y. Koh, T. Kim, K. Lee, Hannam Univ. (Korea, Republic of)

Organic low bandgap polymers were designed and synthesized for high performance bulk heterojunction (BHJ) photovoltaic (PV) cells and polymer based organic thin film transistors (OTFT). Simple organic units yielding high power conversion efficiencies (PCE) from both small molecules and polymers were adapted as design motifs for the synthesis of donor-acceptor-type materials well suited for use in OPVs. Monomer units were designed to extend the polymer coplanarity and promote a more delocalized HOMO distribution along the backbone. A series of polymers based on diketopyrrolopyrrole (DPP) derivatives and thienothiophene derivatives has been synthesized for this study. The substituents were optimized to get better solubility. Structural characterization of new monomer molecules and the polymers were done based on their 1H NMR, 13C NMR and gel permeation chromatography (GPC). Their optical characteristics were studied with ultraviolet (UV) and photoluminescence (PL) spectroscopy. Cyclic voltametric analysis, small angle XRD and atomic force microscopy (AFM) were done to collect further information of the materials. Thermal properties of the polymers have been determined by thermo gravimetric analysis (TGA) and differential scanning calorimetry (DSC). Devices were optimized for the new materials to get high power conversion efficiency for PV cells and better mobility for the OTFT.

8116-109, Poster Session

Manipulating the morphology and ordering of polymer blends for improving performances of bulk-heterojunction polymer solar cells

F. Xie, W. C. H. Choy, The Univ. of Hong Kong (Hong Kong, China); X. Li, Z. Li, Shanghai Institute of Applied Physics (China)

Bulk-heterojunction polymer solar cells (PSCs) have attracted considerable attention for its remarkable advantages1, 2. The solution based film-growth dynamics of polymer blends become one of the crucial processes to improve the efficiency from bulk-heterojunction structures3, 4. However, the nanoscale network structure in this blend system may change for different solution parameters and spin-coating conditions3, 4.

In the work, we will study driving force effects on the order and phase of crystallization of the blended polymer in solution based self-assembly, which is a key factor of self-assembly of soft materials5 but has been neglected in studying PSC morphology. We investigate driving force effects by flipping the substrate up-side-down after spin-coating the wet polymer blend. We introduce Brown's capillarity theory to explain the polymer film formation and study the effects of downward driving force. Our results of absorption spectrum, atomic force microscopy (AFM) and 2D grazing incidence X-ray diffraction (GIXRD) measured using synchrotron radiation show that better chain packing and local order of polymer is formed by the up-side-down method as compared to that by the conventional method. Therefore, the hole transport, carrier balance, short-circuit circuit (Jsc), and fill factor (FF) and power conversion efficiency (PCE) improve. For un-annealed devices, PCE improves from 1.68% (conventional device) to 2.64% (up-side-down). For annealed PSCs, PCE of up-side-down devices is also better than that of the conventional ones. When the thickness of active layer increases to 300nm, the PCE of the up-side-down device increases to 3.58% when that of conventional device drops to 2.55%.

8116-110, Poster Session

Dye sensitized solar cells using non-aggregated silicon phthalocyanines

L. Martín-Gomis, Univ. Miguel Hernández de Elche (Spain); E. M. Barea, Univ. Jaume I (Spain); F. Fernández-Lázaro, Univ. Miguel Hernández de Elche (Spain); J. Bisquert, Univ. Jaume I (Spain); Á. Sastre-Santos, Univ. Miguel Hernández de Elche (Spain)

Two new silicon phthalocyanines (SiPcs 1 and 2) axially substituted with carboxylic acid appends have been synthesized and chemically characterized. DSC devices using SiPcs as sensitizers have been prepared for the first time. Although similar HOMO-LUMO values are obtained for both SiPcs, the device prepared with the SiPc 2 gives both higher open circuit voltage (Voc) and also higher inyection (jsc), so the overall conversion efficiency is longer than for the one where SiPc 1 is used as a dye. The results we obtained are fairly promising and should encourage further studies on DSCs using axially anchored SiPc derivatives substituted with withdrawing groups.

8116-01, Session 1

Advances in polymer and dye-sensitized solar cells

M. D. McGehee, Stanford Univ. (United States)

Using synchrotron x-ray diffraction and molecular mechanics simulations we have determined the unit cell of polymer-fullerene co-crystals that are found in bulk heterojunction solar cells. We will show how this detailed picture of molecular packing makes it possible to model and understand the electronic processes that occur in the solar cells.

Light harvesting in dye sensitized solar cells can be improved by introducing energy relay dyes that absorb light and transfer it to the sensitizing dyes that are attached to the titania. We will show recent progress towards increasing the amount of dye that can be incorporated into the cells. We will also show that light absorption can be improved by 5 to 20% by incorporating a plasmonic back reflector.

We have measured a seven-year lifetime in polymer solar cells and will discuss our efforts to determine the degradation mechanisms and extend this lifetime.

8116-02, Session 1

Small-molecule organic solar cells employing novel materials

M. K. Riede, Technische Univ. Dresden (Germany)

In contrast to polymer solar cells, which are investigated by a large number of researchers and where many materials have been tested, the activities in the field of small-molecule solar cells and the number of available materials classes are much more limited. However, small molecules can be synthesised and purified to high purity and deposited by vacuum sublimation, allowing e.g. for electrically doped organic layers, a high control of layer thicknesses, and simple access to multilayer structures. These advantages yield on the one hand the opportunity to systematically study the device physics using homologous series of materials, e.g. using different side chain lengths in oligothiophenes to study the exciton separation process with spectroscopy. On the other hand, tandem structures are easily accessible for harvesting a large part of the sun spectrum with complementary absorbers. Here, doping of transport layers can create an efficiency recombination contact as well as facilitates the optical optimisation of the stack with optical spacers based on numerical simulations. Both topics are currently under intense investigation and the current state of the art for vacuum deposited small-molecule solar cells will be presented.

8116-03, Session 1

Efficiency enhancement in narrow-bandgap-based polymer solar cells via introducing processing additives and titanium oxide optical spacer

K. Lee, Gwangju Institute of Science and Technology (Korea, Republic of)

We report the fabrication and measurement of bulk-heterojunction (BHJ) solar cells using a narrow-bandgap conjugated polymer, poly[(4,4-didodecyldithieno[3,2-b:2',3'-d]silole)-2,6-diyl-alt-(2,1,3-benzothiadiazole)-4,7-diyl] (P1) in composites with the fullerene derivative [6,6]-phenyl C70-butyric acid methyl ester (PC70BM). In particular, we focus on the enhancement in the device performance by introducing a processing additive and titanium sub-oxide (TiOx) optical spacer simultaneously. When we introduced 4 % 1-chloronaphthalene (1-CN) as a processing additive to the P1/PC70BM BHJ composite, the morphology of the BHJ layers was improved dramatically, thereby resulting in ~70% increase in the short-circuit current (Jsc) with 4.5% power conversion efficiency (PCE). Moreover, the excellent surface smoothness of the BHJ layer with 1-CN enables to incorporate the TiOx optical spacer to the devices, which has not been achieved previously in any BHJ cells using narrow bandgap polymers. The TiOx optical spacer further increased Jsc with PCE~5%. The significance of our results is the fact that the TiOx layer also acts as a lifetime enhancing layer as confirmed in our previous studies. The devices processed with the 1-CN additive and also with the TiOx optical spacer layer exhibited not only enhanced efficiency, but also prolonged device lifetime without sacrificing any device performance.

8116-04, Session 1

Novel p-type oxides as hole transport layers in organic photovoltaic cells

D. S. Ginley, J. J. Berry, M. T. Lloyd, A. Garcia, N. Kopidakis, X. Steires, A. Sigdel, N. Widjonarko, J. Perkins, A. Zukutayev, P. Ndione, D. C. Olson, National Renewable Energy Lab. (United States)

Organic Photovoltaics offer one key route for impacting the world's energy problems. However, in order to achieve both efficiency and lifetime requires robust contacts to complex organic materials achieving carrier transport, interfacial adhesion and band edge alignment simultaneously.

We have recently shown that the conventional PEDOT:PSS (Poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) can be replaced effectively by a thin layer of p-type NiO. While this effect is not fully understood at present a clear question that arises is if this is a general effect or if NiO is unique. Also as the active polymer goes to increasingly deep HOMO materials such as the change from P3HT (poly 3 hexyl thiophene) to PCDTBT (Poly[[9-(1-octylnonyl)-9H-carbazole-2,7-diyl]-2,5-thiophenediyl-2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophenediyl]) the work function and transport properties of the contact layer will need to be adjusted.

We have been trying to develop new p-type TCO materials for a wide variety of applications from the general class of spinels and inverse spinels based on Co, Ni and Zn oxides. In particular we have investigated NiCo2O4 and a-ZnCoO as HTL layers using P3HT and PCDTBT respectively. We report on the efficiencies of devices based on these two HTL materials in comparison to PEDOT;PSS control devices. We will also report on recent results on the lifetime of devices with oxide HTLs.

We will discuss our efforts to use combinatorial approaches to develop new materials in the general class of p-type spinel based materials and their subsequent application as HTL layers. These results demonstrate that the NiO effect is not unique and can be generalized to a broader class of p-type oxides both crystalline and amorphous. These materials point the way to improving both efficiency and lifetime in high performance OPV devices. Many of these results may be applicable to contacts for OLEDs as well.

We gratefully acknowledge the support of the DOE PV program and the Center for Inverse Design EFRC at NREL and the Center for Interface Science for Hybrid Solar Electric Materials centered at the University of Arizona

8116-05, Session 2

High-efficiency solution-processed hybrid polymer: colloidal nanocrystal photovoltaic cells

R. Zhou, Y. Zheng, D. Xie, W. Cao, Y. Yang, R. Stalder, M. Plaisant, K. S. Schanze, P. H. Holloway, J. R. Reynolds, J. Xue, Univ. of Florida (United States)

Hybrid polymer:colloidal nanocrystal photovoltaic (PV) cells have attracted significant attention as an alternative for all-organic solar cells. However, so far the highest efficiencies for hybrid PV cells have been limited to 2-3%, significantly lower than that of all-organic PV cells. One main reason for the lower performance is attributed to the complex interfaces and surfaces involving the inorganic nanocrystals.

Here we demonstrate that power conversion efficiencies (ηP) of hybrid PV cells can be significantly enhanced by chemically treating the hybrid active layer, containing CdSe nanorods and either P3HT or the lower-gap

PCPDTBT, in an acetonitrile solution with 1% ethanedithiol (EDT) prior to the deposition of the metal cathode. The P3HT:CdSe devices showed a ~30% increase in ηP from 2.2% to 2.9% after the EDT treatment. The efficiency of the hybrid PV cells can be improved by using PCPDTBT to better harvest near-infrared photons, leading to ηP = 3.4% without the EDT treatment, and an efficiency of approximately 5.0% after the EDT treatment was obtained, which is the highest reported efficiency for hybrid PV cells. The efficiency enhancement upon EDT treatment is primarily due to an increase in the photocurrent, with a secondary contribution from the increased fill factor. Detailed characterizations of the hybrid active layers before and after the EDT treatment revealed no appreciable differences in their morphology and absorption spectra; however the phosphonic acid organic ligands on CdSe nanocrystals are more completely removed, and an improved electron mobility was obtained upon EDT treatment.

8116-06, Session 2

Developing oxide: organic hybrid photovoltaics

J. B. Franklin, J. Downing, R. Hewlett, S. Thomas, M. P. Ryan, N. Stingelin-Stutzmann, T. D. Anthopoulos, M. A. McLachlan, Imperial College London (United Kingdom)

The development of hybrid (oxide:organic) photovoltaic devices (h-PV) is an attractive prospect because of the suitability of such devices for low-cost solution processing. Despite this promise the development of such devices has been slow and the best reported efficiencies (< 0.5%) are significantly lower than even modest organic photovoltaics (OPVs). Our efforts to overcome current performance limitations have been focused on two complementary approaches, i) preparation of highly crystalline planar heterojunctions and ii) preparation of controlled interdigitated architectures.

i) Using pulsed laser deposition (PLD) we have been able to deposit highly crystalline ZnO on rigid and flexible substrates at temperatures as low as 50°C. The low temperature processing has allowed the preparation of normal and inverse device architectures based on ZnO and a range of polymers (P3HT, P3HS) and small molecules (pentacene). Additionally the planar devices have allowed charge transfer at the organic:oxide interface to be studied effectively for the different compositions, allowing correlation between device performance, composition and configuration to be made unambiguously.

ii) Using a modified hydrothermal growth method we have successfully formed a range of ZnO nanorods in which the aspect ratio has been controllably varied. We report the preparation of highly interpenetrating networks using these rods and P3HT infiltrated using both conventional solution and novel solid state processing techniques. The role of rod length/spacing in addition to infiltration method on measured device performance will be discussed in addition to limitations of the processing encountered during our studies.

For both families of structures we describe the changes in measured device performance observed as structure and composition are varied. We pay particular attention to the bulk and interfacial properties of the oxide:organic components. The measurements are supported by detailed structural (SEM, AFM, XRD) and electronic (mobility, resistivity) characterization of the individual layers and (where appropriate) the complete device structures

8116-07, Session 2

Improved energy conversion in confined, inverted bulk-heterojunction solar cells with radial electron contacts

J. E. Allen, C. T. Black, Brookhaven National Lab. (United States)

We demonstrate a new organic semiconductor solar cell device structure that improves energy conversion in the active material by over 50%. Inverted devices are fabricated using nanoporous aluminum oxide templates to confine blended poly(3-hexylthiophene): [6,6]-phenyl-C61-butyric acid methyl ester to nanoscale volumes. Prior to organic blend infiltration, the porous template is coated with TiO2 via atomic layer deposition to serve as a radial electron contact layer. The final structure is shown to dramatically improve the internal quantum efficiency compared to planar devices and those confined within uncoated templates. Both planar and coated confined devices achieve power conversion efficiencies of over 2% while the confined structure utilizes 60% less active material. Ultra-violet visible light spectroscopy confirms that the confined structure absorbs just 45% of the light of a planar device indicating an improvement in charge collection by over 50%. Improved performance is attributed to enhanced hole mobility in the poly(3-hexylthiophene) due to nano-confinement in addition to accelerated electron extraction by the radial electron contact. Organic semiconductor solar cells may enable large-scale integration of solar energy solutions through easily scalable and low-cost manufacturing. Much of the recent exciting scientific and technological progress in this vibrant field has largely come through the introduction of new polymer semiconductor materials. In this work, we demonstrate that nanostructuring the organic semiconductor solar cell active material can dramatically increase the performance in existing, well-established materials - an approach that may provide benefits for new organic semiconductors as well.

8116-08, Session 2

Effect of low-concentration donor doping in bulk-heterojunction fullerene photovoltaic cells

M. Zhang, H. Wang, C. W. Tang, Univ. of Rochester (United States)

The effect of doping MoOx/C60 bulk-heterojunction (BHJ) photovoltaic cells with a non-absorbing, hole-transport donor, 1,1-bis-(4-bis(4-methyl-phenyl)-amino-phenyl)-cyclohexane (TAPC), has been investigated. With very low TAPC concentration in C60 (~1%), the TAPC:C60 BHJ cells exhibit a high Voc (~ 1.0 V) along with low short-circuit current (Jsc) and fill factor (FF), a characteric which is of typical MoOx/C60 Schottky-barrier cells. With high TAPC concentration (~50%), the photovoltaic characteristics are largely determined by the TAPC:C60 BHJ, showing improved Jsc and FF but reduced Voc (~0.7 V) due to HOMO-LUMO gap limitation. The BHJ cell performance is optimized at about 5% TAPC with Voc =0.91 V, Jsc = 5.94 mA/cm2, and FF = 0.52. At this low concentration range, the TAPC:C60 BHJ cells exhibit a high Voc derived from the MoOx contact. Also both Isc and FF are relatively high, as they are enhanced by the improved charge generation and hole-transport in the BHJ. At higher TAPC concentration, the roll-off in efficiency can be attributed not only to a reduction in the built-in potential, but also to a reduction in absorption, dielectric constant, and electron mobility in the BHJ due to the dilution of C60. A power conversion efficiency of 3.2 % has been achieved for 5% TAPC:C60 BHJ cells based on a thicker BHJ (150 nm) deposited at an elevated temperature (75 oC).

8116-09, Session 3

Broadband absorption enhancement in organic photovoltaics based on nanopatterned ultra-thin metal films

Q. Gan, Univ. at Buffalo (United States); W. Bai, Institute of Semiconductors (China); Z. H. Kafafi, National Science Foundation (United States) and Lehigh Univ. (United States); F. J. Bartoli, Lehigh Univ. (United States)

Three-dimensional finite-difference time domain calculations have shown that plasmonic structures can significantly enhance the optical absorption of active layers in polymer- or molecular-based organic photovoltaics (OPVs).* A polarization-independent nanopatterned

ultra-thin metallic structure supporting short-range surface plasmon polariton (SRSPP) modes is used to improve the performance of OPVs via broadband absorption resonances. The physical mechanism of the excited SRSPP modes is delineated and their distributions are analyzed. In this talk, we will demonstrate that the SRSPP-assisted broadband absorption enhancement could be spectroscopically tuned by carefully designing the OPV devices and tailoring the parameters of the nanopatterned metallic structure(s). These results are very promising for the development of OPVs with enhanced performance.

8116-10, Session 3

Towards fully printed organic solar cells: material aspects and process challenges

C. J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); M. Heyder, Bavarian Ctr. for Applied Energy Research E.V. (Germany); F. Jakubka, F. Machui, T. Stubhan, I. Litzow, J. Krantz, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Organic PV is rapidly gaining high attraction because of its simple production process and its potential for a true low cost solar technology. The compatibility with printing and coating requires a careful stack design - in the simplest scenario, functional solar modules consist of only three layers, while more advanced and efficient device concepts require the deposition of 5 layers. This is an outstanding simple production process compared to inorganic thin film PV technologies. However, the challenge is in the detail of the printing process and in the formulation of suitable inks.

In this contribution we introduce and discuss material aspects and process challenges towards fully printed solar cells, including the replacement of the ITO electrode. Various concepts were already discussed to develop a fully printed OPV stack, including lamination techniques, printing of CNT networks as well as deposition of highly conductive PEDOT. However, none of these material combinations and concepts currently does fulfill the specifications for highly performing solar modules.

In detail, we discuss the combination of printed metallic nanowire electrodes in combination with metal oxide interface layers as a viable process towards fully printed organic solar modules. Experimental data for fully printed cells will be combined with results from process simulation. The overall process will be evaluated by a cost estimations to give a realistic picture on the potential cost scenario for organic photovoltaics.

8116-11, Session 3

Transparent, non-TCO electrodes for organic photovoltaics

L. Müller-Meskamp, C. Sachse, Y. H. Kim, C. Häfner, A. Zakhidov, Technische Univ. Dresden (Germany); O. R. Hild, Fraunhofer-Institut für Photonische Mikrosysteme (Germany); K. Leo, Technische Univ. Dresden (Germany)

Transparent conducting oxides (TCO) are still the first choice for transparent electrode applications. However, for organic photovoltaics, strong demand for flexible and low-cost substrates led to several alternative technologies and ideas. Using our highly efficient OPV technology, based on the evaporation of small molecules, doped transport layers and bulk-heterojunction geometries, we have studied polymer electrodes (PEDOT:PSS), Ag-nanowire electrodes, and carbon nanotube based electrodes. For PEDOT:PSS, we could enhance the conductivity by optimized solvent treatment, resulting in a selective removal of PSS from the electrode film, as could be shown by XPS and optical spectroscopy. Using these materials, we could achieve the same cell performance than for ITO on small area. Nanowire based electrodes, using random networks of highly conductive material, such as silver or CNTs, are very promising candidates, with Ag-NWs achieving similar transmission and conductivity properties as ITO (ca. 85% Transmission, <10Ohm/sq.). We used different Ag-NWs (diameter, length) coated by dipping or spraying from solution, show the influence of different post-treatment methods, and examined the optical and electrical properties of the network layer. For integration into solar cells, these electrodes were combined with an additional polymer coating, to improve the surface roughness. Carbon nanotubes were used in form of free-standing membranes, as top electrodes in semitransparent solar cells. All systems are shown to yield decent solar cells, with every technology having certain benefits and specific issues, but certainly with huge potential to rival ITO in the future.

8116-12, Session 3

Efficient heterojunction photovoltaic cell utilizing nanocomposites of lead sulfide nanocrystals and a low-bandgap polymer

J. Seo, M. J. Cho, D. Lee, A. N. Cartwright, P. N. Prasad, Univ. at Buffalo (United States)

Hybrid polymer-inorganic nanocrystal (NC) solar cells consisting of a hole-conducting conjugated polymer and inorganic semiconducting quantum dots, like cadmium selenide (CdSe), lead sulfide (PbS) and lead selenide (PbSe), have attracted considerable research attention since the advantages of two classes of materials can be effectively combined. In this work, we demonstrate a facile approach to make an efficient hybrid bulk heterojunction photovoltaic device with PbS NCs and a polymer. Herein, we introduced a low band gap polymer as the electron donor host and fabricated a blended film of oleic acid (OA)-capped PbS NCs with a polymer. Direct post-deposition chemical treatment using a short length cross-linker molecule, 1,2-ethanedithiol, applied to the blend film on the PEDOT:PSS layer kept the bulk heterojunction intact by selectively solubilizing the OA ligand of the PbS NCs without affecting the polymer matrix during the process of ligand exchange. Subsequently, inspired by the use of a multifunctional buffer layer in organic polymer photovoltaic devices, we deposited a titanium dioxide (TiO2) thin layer (through non-hydrolytic sol-gel method) on the blend film to facilitate efficient electron transfer and extraction from the blend toward the metal and to prevent holes from reaching the metal. In addition, the effect of the PbS NC size, and thus excitonic energy, on the power conversion efficiency was studied. Power conversion efficiencies of 2~3% were observed in the resulting devices.

8116-13, Session 3

Polymer nanocomposite solar cells based on in-situ formed CuInS2

C. Fradler, T. Rath, M. Edler, A. Fischereder, S. Moscher, A. Pein, Technische Univ. Graz (Austria); R. Trattnig, E. J. W. List, JOANNEUM RESEARCH Forschungsgesellschaft mbH (Austria); W. Haas, F. Hofer, G. Trimmel, Technische Univ. Graz (Austria)

Inorganic-organic nanocomposite solar cells have become a research topic of great interest within the last decade as, by choosing a suitable inorganic compound as acceptor phase, e.g. CdSe, CuInS2, the amount of absorbed light can be enlarged. Such inorganic semiconductors have a bandgap matching the maximum of the solar spectrum quite well, and therefore significantly contribute to the light absorption in a solar cell.

We developed a CuInS2 in-situ formation process by using new metal xanthate precursor materials. We were able to prepare stable bulk solutions containing the mentioned metal xanthate precursor materials and photoactive polymers like PCDTBT (poly[[9-(1-octylnonyl)-9H-carbazole-2,7-diyl]-2,5-thiophenediyl-2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophenediyl]) or PSiF-DBT (poly[2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophenediyl(9,9-dioctyl-9H-9-silafluorene-2,7-diyl)-2,5-

thiophenediyl]) from solvents like toluene or chlorobenzene. In order to prepare nanocomposite solar cells this precursor solution can be coated by spin coating or doctor blading on glass/ITO substrates that have been coated with a thin PEDOT:PSS layer first. The conversion of the precursor material to CuInS2-nanostructures is performed by an annealing step and takes place at a temperature below 200°C. The annealing leads to a homogenous network of the organic and the inorganic phase. In a final step a photocathode was put about the photoactive layer. This solar cell assembly led to efficiencies above 2% up to now.

The solar cells were analyzed by their I-V curves as well as by transmission electron microscopy, optical spectroscopy and IPCE measurements

This work was funded by the Austrian Ministry of Economy, Family and Youth and Isovoltaic AG.

8116-31, Session 3

GaAs nanowire/PEDOT:PSS hybrid solar cells: the relationship between nanowire morphology and device performance

J. Chao, S. Shiu, C. Lin, National Taiwan Univ. (Taiwan)

In this study, we demonstrate a new type of hybrid solar cell based on a heterojunction between poly(3,4-ethylenedioxythiophene):poly(styren esulfonate) (PEDOT:PSS) and vertically-aligned n-type GaAs nanowire. The GaAs nanowire arrays are fabricated by directly performing the nano-etching of GaAs wafer with spun-on SiO2 nanoparticles as the etch mask through inductively coupled plasma reactive ion etching. The use of vertically-aligned GaAs nanowire makes the interpenetrating heterojunction interface possible. Thus a large heterojunction interface and short collection paths of photo-generated carriers can be achieved. Moreover, vertically-aligned GaAs nanowire arrays with high aspect ratio can provide much smaller optical reflectance. The hybrid cells are prepared by attaching the GaAs nanowire arrays onto ITO glass substrates coated with PEDOT:PSS films. The PEDOT:PSS adheres to the surface of GaAs nanowrie arrays to form a p-n junction. Our study shows that the GaAs nanowire/PEDOT:PSS heterojunction clearly exhibits a solar cell behavior. The morphology of GaAs nanowire arrays strongly influences the characteristics of hybrid solar cells. The suppression of reflectance and the interpenetrating heterojunction interface of GaAs nanowrie arrays will offer great improvements in device performance. The reduction of reflectance is in agreement with the increase in Jsc of hybrid cells. On the other hand, a larger heterojunction interface between PEDOT:PSS and GaAs nanowire arrays results in a high Jsc. A good PEDOT:PSS coverage also provides improved Voc due to the reduction in shunts. The power conversion efficiency of GaAs nanowire/PEDOT:PSS cells under AM 1.5 global one sun illumination can achieve 5.8 %.

8116-32, Session 3

Silicon/silicon nanowire/poly(3,4-ethylen edioxythiophene):poly(styrenesulfonate) heterojunction solar cells

H. Syu, S. Shiu, C. Lin, National Taiwan Univ. (Taiwan)

Conventional manufacturing processes of solar cells, including epitaxy, diffusion, deposition and dry etching, are high cost and high power consumption. To save energy and reduce expenses, we use organic material, silicon nanostructure and solution process. The devices structure is n-type bulk Si (n-Si)/n-type silicon nanowires (n-SiNWs)/ poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) heterostructure. The active region includes n-Si and n-SiNW arrays, promising the property of ultra low reflection for high light absorption. In this work, SiNWs of only a-few hundred nanometers could lower the reflectance to below 5%. In addition, an organic material - PEDOT:PSS, instead of p-type doping, is introduced to form a p-n junction with n-Si/n-SiNWs for separating the electron-hole pairs. The use of PEDOT:PSS can also passivate the surface defects of n-SiNWs.

N-type SiNW arrays are made by aqueous etching process. The etchant contains Ag ions and HF etching vertically to the 1-10 Ω-cm Si (100) wafers. After etching and removing residual Ag and SiO2 by nitric acid and diluted HF successively, n-SiNW arrays existed on either surfaces of n-Si with very dark color; then Ti and Ag were evaporated on n-Si to be a cathode. Finally, nanowires of n-Si/n-SiNWs were stuck on the PEDOT:PSS that were spin-coated on the ITO coated glass to form a core-sheath heterojunction.

The performance and quantum efficiencies (QE) were measured. The short circuit current density and power conversion efficiency are 27.46 mA/cm2 and 8.05%, respectively, which are higher than other solar cells containing SiNWs. The external and internal QE are beyond 50% and 60% in visible range, respectively.

8116-14, Session 4

Toward bulk-heterojunction solar cells with stable morphology

S. Bertho, B. Conings, F. Piersimoni, D. F. Spoltore, J. D'Haen, L. J. Lutsen, H. Boyen, Univ. Hasselt (Belgium); B. Van Mele, G. Van Assche, Vrije Univ. Brussel (Belgium); D. J. Vanderzande, J. V. Manca, Univ. Hasselt (Belgium)

The nanomorphology of interpenetrating donor:acceptor networks is of crucial importance for state-of-the-art bulk heterojunction (BHJ) solar cells. For each combination of donor:acceptor materials, specific preparation procedures are developed and optimised in order to obtain the required 'ideal' morphology, which results in the highest photovoltaic energy conversion efficiency for the given material system. However, when these optimised solar cells with 'ideal' morphology are submitted to a prolonged storage or to a prolonged operation at elevated temperatures (e.g. solar cells in outdoor applications), a temperature induced disruption of this ideal morphology can occur and therefore also the corresponding photovoltaic performance will deteriorate. In this contribution the effect of temperature on morphology and photovoltaic properties is investigated for different sets of donor:acceptor materials by using a variety of analytical techniques (e.g. Transmission Electron Microscopy - TEM, Thermal Analysis Techniques,..) and electro-optical techniques (e.g Fourier Transform Photocurrent Spectroscopy - FTPS). This approach provides a better insight in the underlying mechanisms causing the temperature induced morphology changes. Complementary to this analytical and electro-optical characterisation, an accelerated ageing system is used to study in-situ the degradation kinetics of the BHJ solar cells at various temperatures in order to obtain an accelerated ageing model to predict lifetime. Solutions and concepts are proposed and investigated towards thermally stable morphologies and therefore towards next generation BHJ solar cells with an increased intrinsic thermal stability.

8116-15, Session 4

Understanding degradation in unencapsulated organic photovoltaics

M. T. Lloyd, A. Garcia, J. J. Berry, N. Kopidakis, M. O. Reese, D. S. Ginley, D. C. Olson, National Renewable Energy Lab. (United States)

We employed an automated combinatorial testing system to monitor the degradation rates for inverted geometry poly(3-hexylthiophene):fullerene bulk heterojunctions solar cells in air. These devices utilize ZnO and Ag for electron and hole contacts, respectively, the relative stability of which enables meaningful studies of unencapsulated device lifetimes. For inverted devices under constant illumination, we find oxygen and moisture ingress to be the primary cause for decay in power conversion efficiency (PCE) via decreased short-circuit current (while the fill factor and open-circuit voltage are unchanged). Consequently, we find that the contacts serve as a de facto encapsulation layer and the detailed method for contact preparation becomes the first order, rate-limiting

factor in determining device lifetime. In an ex-situ experiment, we evaluate the water vapor transmission rate (WVTR) of commonly used electrode materials to show that the permeability of the metal electrode is determined by its thickness and composition (in multi-layer configurations). Parallel findings confirm the observed transmission rates in devices monitored under constant illumination, where electrodes of the lowest WVTR yield devices with lifetimes extending beyond 5000 hrs. End-of-life behavior consistently results in a catastrophic loss of photocurrent. We use high-resolution photocurrent mapping to reveal circular regions of zero photocurrent in the active area indicative of pinhole ingress and lateral diffusion of oxygen and water vapor. Using a modified form of the Avrami equation, which describes nucleation and island growth in two-dimensional systems, we are able to mathematically model photocurrent vs. time as the device experiences catastrophic failure.

8116-16, Session 4

Reliability of organic materials using photothermal deflection spectroscopy

A. Bezryadina, Univ. of California, Santa Cruz (United States) and NASA Ames Research Ctr, Advance Study Labs. (United States); J. Olson, APV Research (United States); C. France, S. Carter, G. Alers, Univ. of California, Santa Cruz (United States)

Degradation of organic materials used for solar energy collection was measured with photothermal deflection spectroscopy (PDS). PDS has the ability to measure absorption over a range of 5 decades and can detect the first signs of degradation in organic films. From the tail of the optical absorption trap states and defects are deduced to quantify light induced and temperature induced degradation due to photo-oxidation and polymer/dye decomposition. In this work we look at degradation of common solar energy polymer materials like P3HT and MEH-PPV and commercial dyes that are used for photon downconversion and luminescent solar concentrators.

Most polymers have inherently weak optical absorption in the visible-IR region and might exhibit scattering due to surface roughness. PDS measurements are independent of scattering and can detect slight changes in band-edge absorption after temperature or light soaking treatments. At the tail region non-radiative absorption processes for the material are present with no detectable photoluminesence emission. A commercial red luminescent material was tested and had strong degradation after 50 hours of light soaking at 35C under 100mW/cm2 illumination from a metal-halide lamp. Absorption increased by a factor of 4 in the tail and the band-edge region. Another commercial material showed no changes in absorption after ~100 hours of light soaking. Highly sensitive PDS measurements can test optical absorption of organic films after long exposure under the sun, high humidity and/or high temperatures. Small changes in absorption can be extrapolated to quantify degradation behavior from 1000 hour measurements to predict 20-year lifetime and the long term efficiency of photovoltaic devices.

8116-17, Session 4

High-efficiency polymer-based OPV with lifetimes approaching 7 years

C. H. Peters, I. T. Sachs-Quintana, J. P. Kastrop, M. D. McGehee, Stanford Univ. (United States)

As efficiencies increase, the questions of lifetime and reliability of OPV gain importance. Current polymer-based OPV devices typically show lifetimes of 2-4 years when encapsulated. In this study we performed accelerated lifetime testing on poly(-heptadecanyl-2,7-carbazole-alt-5,5-(-di-2-thienyl--benzothadiazole) (PCDTBT). From the testing, we estimate a lifetime approaching 7 years which, to the best of our knowledge, is a record for reported polymer OPV devices.

PCDTBT has been used with PC(70)BM to achieve device efficiencies over 6.1%, making it one of the most efficient polymer-based OPV materials. 16 high-efficiency devices were encapsulated using state-of-the-art encapsulation techniques. The devices were held at the maximum power point, closely mimicking the actual conditions under which they would be operated in the field. The lamp intensity and temperature of each device were monitored in real-time. 16 P3HT:PCBM devices, encapsulated in an identical manner, were testing along with the 16 PCDTBT devices for comparison.

Results show an initial burn-in where the PCDTBT devices experience an exponential decay in efficiency, which lasts 500 hours. After this period the devices are incredibly stable, showing a linear decay for the remaining 4,000 hours of the test. Taking the initial value from the start of the linear decay period at 500 hours and extrapolating to where 20% of this initial value has been lost leads to a lifetime approaching 7 years.

The P3HT:PCBM devices show a more gradual burn-in lasting close to 1,300 hours which is also followed by a linear decay period but with a more severe slope. Performing the same lifetime analysis on these devices leads to an estimated lifetime of 3.3 years.

We will also introduce results of advanced optical and electrical characterization techniques that were used to understand degradation. This will provide the scientific community with greater insight into approaches to make more stable devices.

8116-18, Session 4

Luminescence imaging as characterization tool for polymer solar cells and modules

H. Hoppe, M. Seeland, R. Rösch, B. Muhsin, M. Bärenklau, G. Gobsch, Technische Univ. Ilmenau (Germany)

We demonstrate luminescence imaging to be a powerful tool for characterizing organic solar cells and modules with respect to deficiencies in the production process, local defects and degradation processes. As an example, the complementary use of photoluminescence and electroluminescence imaging has been employed to identify the cause and nature of polymer solar cell degradation stressed under different storage conditions. In this study we directly relate imaging results with solar cell parameters.

Furthermore we have developed a quantitative analysis for electroluminescence images obtained on organic solar cells. This approach is based on a complex device modeling employing a network of interconnected micro-diodes. The equivalent circuit network model takes interface and bulk resistances as well as the sheet resistance of the transparent electrode into account. The application of this model allows direct calculation of the lateral current and voltage distribution as well as determination of internal resistances and the sheet resistance of the higher resistive electrode. Furthermore, we have extended the micro-diode-model to also describe and predict current-voltage characteristics for devices under illumination. The local nature of this description enables important conclusions concerning the geometry dependent performance of thin film solar cells.

Finally the beneficial use of luminescence imaging as tool for quality control is shown for single devices and monolithically connected polymer solar cell modules.

8116-19, Session 4

Degradation of PCBM-P3HT organic photovoltaic cells and structure changes as determined by defect investigations

F. Reisdorffer, Univ. de Nantes (France); L. Wang, National Taiwan Univ. (Taiwan); T. Nguyen, Univ. de Nantes (France)

We present an investigation of the intrinsic degradation of organic photovoltaic cells using poly(3-hexylthiophene) (P3HT) and phenyl-C61-butyric acid methyl ester (PCBM) composite as an active layer. The encapsulated devices of structure ITO/PEDOT:PSS/P3HT-PCBM/Ca/Al were investigated using the Charge based Deep Level Transient

Spectroscopy (Q-DLTS). An efficiency of ~ 4,0% and a fill factor of the IV characteristics of ~ 64% have been obtained in fresh devices. Trap density determined in these samples is ~ 1017 cm-3 and their levels are found in the range from 0.1 to 0.5 eV from the band edges. Comparing the defect spectra obtained in freshly fabricated devices and those degraded over 1000 hours under 1.5 AM conditions, we observed a strong increase in intensity of deep traps, which indicated an alteration of the blend structure. On the other hand, a noticeable decrease of the trap peak of relaxation time of ~ 1s after degradation has occurred. The corresponding traps have been identified as defects induced by the presence of PCBM in P3HT matrix, and their reduction suggests a modification of the PCBM structure organization. We discuss the possible modifications of the blend structure induced by degradation and we propose a mechanism involving the transformations of PCBM basing on the defect measurement results.

8116-21, Session 6

Semi-random copolymers as a multichromophoric platform for bulk-heterojunction solar cells

B. C. Thompson, B. Burkhart, P. P. Khlyabich, The Univ. of Southern California (United States)

Even as the efficiency of bulk heterojunction polymer solar cells increases into the 7-8% range, it is clear that there is much room for improvement in efficiency, lifetime, and cost-effective synthetic and fabrication strategies. It has been proposed numerous times that efficiencies greater than 10% should be possible with this device platform. The main obstacle appears to be the development of ideal donor-acceptor pairs that are optimal for light harvesting, charge generation and collection, and form stable morphologies. Here, an avenue toward developing optimal donor-acceptor pairs is discussed, based on the development of optimized donor polymers that possess broad spectral absorption, high absorption coefficients, high charge carrier mobilities, and semi-crystalline structures effective for blending with fullerene acceptors. As an extension beyond the simple donor-acceptor approach to narrow band gap polymers, a route toward multichromophoric (broad spectral absorbing) polymers has been developed. A new family of semi-random hexyl-thiophene based donor-acceptor copolymers, which broadly absorb sunlight, due to their unique structure, has been synthesized. The restricted linkage pattern of monomers (due to a careful choice of functional groups) retains a high degree of structural order in polymers preserving attractive properties of regioregular poly(3-hexylthiophene) (P3HT), such as crystallinity and high hole mobility, while also taking advantage of the multichromophoric nature of random polymers, which allows broad spectral absorption of light. These donor-acceptor semi-random copolymers show broadened absorption and semicrystalline morphology, as evidenced by the high measured hole mobilities. Optimization of processing conditions has also demonstrated high solar cell efficiencies in several cases.

8116-22, Session 6

Solution-processable small molecules for highly efficient solar cells

Y. Chen, Nankai Univ. (China)

Due to the numerous advantages of small molecule compared with polymer, such as monodisperse, well defined structures and better batch-to-batch reproducibility for commercial applications, organic solar cells using solution-processable small molecules as donor materials have achieved a dramatic progress in very recent years. Here, we report a new class of solution processable small molecules with molar mass lower than 1700 g mol-1. These molecules have good solubility and film quality. By introducing different soluble alky end group, the properties can be tune very effcetively. Using the simple solution spinning process, BHJ solar cells based on these molecules have achieved a power conversion efficiency of 5.08%, with a fill factor of 55.0% and a high IPCE of 67%.

8116-23, Session 6

Molecular engineering of conjugated polymers for highly efficient bulk-heterojunction solar cells

W. You, H. Zhou, The Univ. of North Carolina at Chapel Hill (United States); S. C. Price, L. Yang, A. C. Stuart, University of North Carolina at Chapel Hill (United States)

The bulk heterojunction (BHJ) organic photovoltaic cells of regioregular poly(3-hexylthiophene) (RR-P3HT) and [6,6]-phenyl C61-butyric acid methyl ester (PCBM) represent one of the most successful systems with reproducible efficiencies approaching 5% after careful optimization. However, with a fixed band gap of 1.9 eV, P3HT can only harvest a small portion of the solar spectrum (maximum 22.4%). Therefore low band gap polymers for better light harvesting have been intensively pursued in recent years. Though impressive progresses have been made, the outstanding question remains: how to rationally design ideal polymers to approach 10% efficiency and beyond?

I will summarize the design criteria for “ideal” polymers to be used with PCBM to further improve the efficiency of BHJ photovoltaic devices. Specifically, I will focus on three main topics: (a) design of new conjugated backbone to control the band gap and energy levels; (b) the significant influence of “trivial” side chains; (c) the impact of substituents such as F. A number of new polymers will be discussed in detail to elaborate these topics. A design motif has been proposed, which successfully produced polymers that demonstrated over 7% efficiency in BHJ devices.

8116-24, Session 6

A small-molecule non-fullerene electron acceptor for organic solar cells

P. Meredith, P. E. Schwenn, K. Gui, K. B. Krueger, K. E. Lee, K. E. Mutkins, P. E. Shaw, The Univ. of Queensland (Australia); N. Kopidakis, A. Nardes, National Renewable Energy Lab. (United States); P. L. Burn, The Univ. of Queensland (Australia)

Solution processed organic BHJ solar cells predominantly use the fullerene derivatives [C60]PCBM and [C70]PCBM as the electron acceptor. These systems in combination with polymer donors have generated efficiencies in excess of 7%1. Few examples of “non-fullerene” acceptors have been reported with maximum efficiencies in combination with poly(3-n-hexylthiophene-2,5-diyl) (P3HT) of 2%. Given this situation, one is led to ask: “what is so special about the fullerenes as acceptors”? To address this question we have embarked upon a program to design a new class of acceptors based upon fluorene benzothiadiazols whose properties can be systematically varied2. In this paper, we present results on a successful candidate from this family: 2-[{7-(9,9-di-n-propyl-9H-fluoren-2-yl)benzo[c][1,2,5]thiadiazol-4-yl}methylene]malononitrile (K12). We show it can be processed by evaporation or from solution to give amorphous films and can be annealed at modest temperature to give films with greater order and enhanced charge transport. The molecule can efficiently quench the photoluminescence of P3HT and time resolved microwave conductivity measurements show that mobile charges are generated. We also find that conversion efficiencies of the resultant devices depend strongly on the acceptor packing. Optimized K12:P3HT BHJ devices have efficiencies of 0.73±0.01% which are limited by the level of crystallinity that is achievable in the blend. Building and studying such model systems will, we believe, lead to a more in-depth understanding of the requirements for high efficiency electron acceptors tailored to particular donor materials.

8116-25, Session 6

The effect of regio-regularity on the optoelectronic properties of PTVs

E. Lafalce, X. Jiang, Univ. of South Florida (United States)

Poly(thienylene vinylene) (PTV) is a -conjugated polymer with potential applications for use in photovoltaics owing to its low bandgap, good hole-mobility and low oxidation potential. It is generally considered a non-luminescent material and reports suggest its emissive properties are highly dependent upon excitation energy, conjugation length, alkyl side group and regio-regularity, complicating the interpretation of the non-radiative decay routes for photo-generated excitations. We have studied a class of PTV with controlled regioregularities, and our results are contrary to the normal understanding of the role regioregularity has played in -conjugated polymers, for instance, in the case of poly (3-hexylthiophene) (P3HT), where it has been shown that increased regioregularity enhances interchain interaction, crystallinality of polymer films, and carrier mobility, as well as drastically reduced photoluminescence quantum yield. Through a thorough investigation of photoluminescence, photoinduced absorption, Raman Scattering and electroabsorption, we have deduced the physical mechanisms competing with radiative recombination process, and evaluated phonon coupling effect on the optoelectronic properties of these polymers. By varying the excitation energy, temperature, and modulation frequency, and also by controlling the morphology through the use of different solvents, concentrations, and film preparation techniques, we offer a detailed report on recombination dynamics of various long-lived photoexcitations in this class of polymers. Complimentary characterization of films through XRD and electro-absorption yield detailed information about the semi-crystalline structure and electronic levels, respectively. Our findings could help to improve the performance of solar cells based on this low bandgap polymers, as well as a guide for better material engineering.

8116-26, Session 6

A planar alkoxy-substituted benzothiadiazole-based low-band-gap copolymer for photovoltaic solar cells

H. Y. Woo, W. Lee, Pusan National Univ. (Korea, Republic of); H. Choi, J. Y. Kim, National Institute of Science and Technology (Korea, Republic of)

Recently, bulk-heterojunction (BHJ) polymer solar cells (PSCs) have been extensively studied as one of the attractive renewable energy sources due to low cost, light weight, solution processibility and potential applications in flexible large-area devices. Their performances are affected by many factors : electronic properties of the polymers (as a donor) and fullerene derivatives (as an acceptor), morphology of the films, and interfacial properties, etc. Among them, structural planarity of the polymer is one key parameter since in mainly influences intermolecular ordering and carrier mobility. Here, we report a planar donor-acceptor type benzothiadiazole-containing copolymer, PTBT with a simple molecular structure and easy synthesis. The measured number-average molecular weight (Mn) was 30,000 g/mol (PDI=1.7) and optical band gap was determined to be ~1.72 eV with absorption spectrum covering the entire visible region in a range of 400 nm ~ 800 nm. The UV-vis absorption in film showed a fine-structure with a shoulder peak, which indicates a strong π-π intermolecular interaction. Differential scanning calorimetric (DSC) data also indicated clear melting and recrystallization points. PTBT blended with PC61BM shows high photovoltaic performance with open circuit voltage of 0.72 V, short-circuit current of 10.4 mA/cm2, fill factor of 0.68, and the resulting power conversion efficiency of ~5.0% under air mass (AM) 1.5 global (1.5 G) illumination conditions (100 mW/cm2)

8116-27, Session 7

Influence of molecular acceptor design on the blend morphology of bulk-heterojunction organic solar cells

A. Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

The dominant solution-fabricated device configuration in organic photovoltaic (OPV) devices is the bulk heterojunction, where donor and acceptor are blended during device fabrication, and self-assembly processes yield the phase separation essential to photovoltaic performance. Traditionally, this phase separation is achieved through simple size or shape incompatibility between a ribbon like donor polymer and spherical acceptor fullerene. Further aided by the high dimensionality of electron transport of fullerene materials, these acceptors have become the standard for high performance OPVs. There are compelling reasons to investigate alternatives to fullerene-based acceptors for OPVs: In order to improve OPV performance, it is critical to understand why the fullerenes are currently superior OPV acceptors. Is it strictly their shape leading to improved phase segregation? Fortuitously appropriate energy levels? High electron mobility in all dimensions? By investigating several series of other molecular acceptors that exhibit only a few of these properties, we can determine which ones are critical to OPV performance and in what way they are influencing the BHJ OPV. Here, We focus on the role of acceptor molecular design in mediating phase separation, blend morphology and domain structure of the bulk heterojunction thin film, which we relate to the photocurrent. Our results reveal important and meaningful correlations between design of acceptor molecules and the resulting bulk heterojunction formation, which should provide helpful insight for future discovery of high performance acceptor molecules.

8116-28, Session 7

Characterization of bulk-heterojunction-inverted polymer solar cells probed by depth-profiling X-ray photoelectron spectroscopy

H. Cheun, J. D. Berrigan, Y. Zhou, M. Fenoll, J. W. Shim, C. Fuentes-Hernandez, K. H. Sandhage, B. Kippelen, Georgia Institute of Technology (United States)

Polymeric bulk heterojunction solar cells show promise as a versatile portable source of renewable energy. So far, extensive efforts have been devoted to increasing their power conversion efficiencies through the development of novel polymers, but controlling the active layer morphology remains a challenge. Phase separation and vertical segregation of the donor and acceptor materials in the blend were found to strongly influence device performance. Recently, polymer solar cells with a transparent electron collecting electrode have been fabricated to improve stability in air. In such a structure, called an inverted structure, ITO is modified with a thin metal oxide layer to reduce its work function. Vertical phase segregation in such inverted structures is expected to be influenced by the different substrates on which the bulk heterojunction film is formed.

In this work, we investigated vertical phase separation in photoactive layers of poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl C61 butyric acid methyl ester (PCBM) blends on a ZnO layer using depth profiling X-ray photoelectron spectroscopy (XPS). Experiments were performed on films as a function of annealing times at an annealing temperature of 160°C. Results show that annealing leads to vertical phase segregation where P3HT-rich regions are adjacent to the bottom ZnO layer used as an electron-collecting electrode. These depth profiles were correlated with the photovoltaic performance of such films incorporated in solar cells with a structure ITO/ZnO/P3HT:PCBM/MoO3/Ag. Best performance was obtained when the polymer blend was high in P3HT near the electron collecting electrode, against the conventional wisdom. These results shed new light on the role of vertical phase segregation on the performance or bulk heterojunction solar cells.

8116-29, Session 7

Effect of vertical phase segregation in polymer solar cells using a silole-containing low-bandgap donor-acceptor polymer

J. Subbiah, F. Steffy, C. M. Amb, J. R. Reynolds, F. So, Univ. of Florida (United States)

In bulk-heterojunction (BHJ) polymer solar cells, the vertical phase morphology of the active layer plays a crucial role in determining the exciton dissociation efficiency, charge extraction efficiency and thus the overall power conversion efficiency. In order to maximize the device efficiency, the donor and acceptor molecules should segregate toward the anode and cathode, respectively. However, several polymer-PCBM systems have exhibited phase segregation that could only be optimized if the device structure was inverted such that the cathode is at the bottom and the anode is on the top. To investigate the effect of this vertical phase segregation on device performance, we fabricated inverted solar cells that exploit the natural vertical phase separation of the bulk heterojunction layer. We realized the inverted architecture by modifying the bottom ITO electrode with a solution-processed ZnO layer, followed by the BHJ layer. A thin layer of MoOx was used as a hole-extraction layer on top for efficient charge extraction.

In this work, we have studied the performance of normal and inverted BHJ solar cells with an active layer composed of a blend of poly[(4,4′-bis(2-ethylhexyl)dithieno[3,2-b:2′,3′-d]silole)-2,6-diyl-alt-(2,1,3-benzothiadiazole)-4,7-diyl] (DTS-BTD) as the donor and {6,6}-phenyl-C71 butyric acid methyl ester (PC70BM) as the acceptor. Here, the inverted devices exhibited an increase in short circuit current density (Jsc) by 32% over the conventional solar cells (16.77 mA/cm2 in the inverted devices compared to 12.71 mA/cm2 in the conventional devices). Overall, the inverted structure had a higher power conversion efficiency of 5.8% compared to 4.9% for the conventional device. The enhanced device performance for inverted device geometry attributed to the formation of favorable vertical phase segregation in the active layer where the top surface of the polymer blend is donor- rich and bottom surface is acceptor-rich resulting in a significant enhancement in the short-circuit current. With further optimization we were able to achieve a power conversion efficiency of 6.4% for the inverted device.

8116-30, Session 7

The effects of trace solvents on the morphology of P3HT:PCBM solar cells

A. J. Moule, L. Chang, Univ. of California, Davis (United States)

The efficiency of bulk-heterojunction solar cells is highly sensitive to changes in the nanostructure of the active layer. Despite exhaustive research into various processing (varying casting solvents) or post-processing (heat tempering or solvent soaking) techniques to “improve” the morphology of the active layer, the relationship between fabrication conditions and device performance is poorly understood. This work examines the role that excess solvent that remains in the active layer after coating has on the morphology and the diffusion rate of PCBM within the active layer. We examine how solvents with a range of boiling temperatures effect the stability of morphology after the device is completed and conclude that high boiling temperature solvents lead to increased PCBM agglomeration. Laser beam induced current (LBIC) mapping of the active layer suggested that PCBM agglomerations are unfavorable to device performance as low photocurrents were detected on regions were PCBM agglomerates are present.

Next we examine the role that solvent additives have on morphology, PCBM diffusion, and temperature stability of the morphology. We show that good solvents lead to poor morphological stability, an effect that can be traced to a reduction of the energy cost for melting or glass transition. Differential scanning calorimeter (DSC) results indicate that addition of a poor-solvent or non-solvent increases the onset of melting for polymer side chains and backbone. J-V (current density vs. voltage) characteristics show that a device fabricated using a nitrobenzene additive has similar performance to an annealed device but that the morphology is more stable to heat cycling.

8116-31, Session 7

Evolution of surface, sub-surface, and bulk morphology and its effects on organic photovoltaic performance

B. Lyons, N. Clarke, C. Groves, Durham Univ. (United Kingdom)

In order to maximise the performance in an organic solar cell it is necessary to balance the competing needs of efficient charge generation with the requirement of an efficient percolating network to the electrodes. This has led to considerable efforts to optimise both the bulk and surface morphologies through many techniques such as solvent or vapour annealing, use of co-solvents, self-assembled monolayers and others. In particular, a variety of recent NEXAFS and XPS data have shown that improper preparation of the substrate-blend interface can give rise to charge-blocking barriers that are detrimental to device performance.

In this work we use Cahn-Hilliard-Cook theory to examine the evolution of a 3-dimensional blend morphology during drying, including the effects of surface energy. This method provides a realistic facsimile of bulk heterojunction blend evolution through solvent evaporation and/or thermal annealing. The solar cell performance associated with these blends is then examined using a Monte Carlo model.

It is shown that the coverage and thickness of surface layers formed due to surface energy effects increase as the blend evolves, as do sub-surface features that can also impede current flow. We show how this surface and sub-surface composition variation effects organic solar cell performance, and in turn offer guidance as to when surface layers are current blocking. Additionally, we show that the optimum degree of annealing/drying differs between films where surface effects are important and are absent.

8116-32, Session 7

Time-resolved characterization of the nanoscale structure and morphology of spin-cast bulk-heterojunction photoactive thin films

K. W. Chou, R. Li, D. Marques, E. Li, King Abdullah Univ. of Science and Technology (Saudi Arabia); O. Wodo, B. Ganapathysubramanian, Iowa State Univ. (United States); R. Gassaway, A. Biocca, A. Hexemer, Lawrence Berkeley National Lab. (United States); J. E. Anthony, Univ. of Kentucky (United States); S. Thoroddsen, A. Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Despite significant improvements in organic photovoltaic (OPV) technology there still remain several issues that prevent the wide-spread use and profitable commercial production of OPVs. One major challenge is the weak control over the manufacturing processes to get tailored morphologies of the active thin films. Current state-of-the-art approaches to understand the morphological evolution and tailoring of the manufacturing processes for high efficiency organic solar cells are either limited to a combinatorial experimental investigation or single scale analysis, and provide only limited data for analysis. The main reasons for that are related to the difficulty of attaining high spatial resolution and to the requirement of good contrast between components. In situ analysis is further complicated by the incompatibility of many traditional characterization techniques with solution processes. These challenges hinder our ability to understand and subsequently control the interaction of multiple factors affecting the morphological evolution.

We report the in situ monitoring of the growth of thin films during solution processing. A compact spin coater and liquid dispensing system was

built and time-resolved grazing incidence x-ray scattering (small angle and wide angle) measurements were performed during the spin coating process with sub-second time resolution. The evolution of the liquid layer was monitored in situ using fast CCD camera imaging. The film growth was investigated for different donor and acceptor materials, as well as for blends thereof as a function of processing conditions. The results are compared to phase-field simulation model predictions of the 3D evolution of the morphology during solution-processing of the organic bulk heterojunction layer.

8116-108, Session 7

Structural measurements of polymer-fullerene blend films for organic photovoltaics

D. M. DeLongchamp, National Institute of Standards and Technology (United States)

Organic photovoltaic (OPV) technology has the potential to lower the cost of solar cell fabrication by ink-based coating techniques. In bulk heterojunction (BHJ) OPV devices, the power conversion efficiency critically depends on the distribution of the polymer absorber and the fullerene electron acceptor. I will describe measurement methods to probe the morphology of the BHJ layer.

The vertical distribution of absorber and electron acceptor in BHJ films follows segregation behavior similar to that of miscible polymer blends. The top (air) interface becomes rich in the polymer absorber, whereas the bottom interface composition depends on the substrate surface energy. I will discuss whether interfacial segregation can impact power conversion efficiency by comparing hole transport layers that have similar work functions but different surface energies. I will show that interfacial segregation strongly impacts aging-related morphology deterioration.

The nanometer-scale three-dimensional structure of the BHJ interior is critical to the efficiency of exciton harvesting. Solid-state nuclear magnetic resonance can be used to measure the size distribution of polymer and fullerene domains. The nanoscale morphology can also be directly imaged using chemical contrast tomographic transmission electron microscopy. Order and crystal orientation within domains can be probed with grazing-incidence X-ray diffraction. We consolidate this information to correlate fine structural details to performance for BHJs using poly(3-hexylthiophene) as well as small bandgap push-pull absorbers such as benzodithiophene-containing and silole-containing polymers that exhibit power conversion efficiencies in the range of 5% to 8%.

8116-33, Session 8

Charge photogeneration and recombination in organic solar cells

J. R. Durrant, Imperial College London (United Kingdom)

My lecture will focus on charge separation and recombination in polymer / fullerene solar cells and their impact upon device photovoltaic performance. The talk will be based around transient optical and optoelectronic studies of yields, lifetimes and densities of dissociated charges in blend films and solar cells. (1-3) Comparative studies will be presented of different materials systems, including over 20 different polymers, and perylene as well as fullerene acceptors. On the basis of these data, I will address the parameters which influencing charge photogeneration, including the roles of molecular structure, film nanostructure, interfacial energetics, and macroscopic electric fields

Photocarrier dynamics in nanostructured phthalocyanine: fullerene films

P. A. Lane, U.S. Naval Research Lab. (United States); E. J. Heilweil, National Institute of Standards and Technology (United States); J. S. Melinger, U.S. Naval Research Lab. (United States)

We have studied photocarrier generation and decay in zinc phthalocyanine and C60 on a wide range of time scales using transient and CW pump-probe spectroscopy. Photocarrier generation was studied by terahertz time domain spectroscopy (THz-TDS), an optical, non-contact technique which measures transient decay dynamics of photo-generated carriers on a picosecond to nanosecond time scale. We find a dependence of the THz absorption on concentration for composite films and on layer thickness for ZnPc/C60 superlattice films. Superlattices with layer thicknesses less than 10 nm show stronger THz absorption than an optimized composite and with slower decay dynamics.

The decay dynamics extend well out past the maximum pump-probe delay. In order to examine carrier yield and decay dynamics, we turned to photoinduced absorption (PA) spectroscopy. Combining THz-TDS and PA spectroscopy permits us to study carrier generation and decay on a range of time scales from picoseconds to milliseconds. We find stronger signals from the thinnest nanolayered samples, in agreement with the results of THz-TDS. This combined study reveals a simple way to improve film morphology for organic photovoltaics, free of electrical contacts or other device related characteristics.

8116-35, Session 8

Impact of trap-assisted recombination on the performance of polymer-fullerene bulk-heterojunction solar cells

C. Deibel, J. Lorrmann, A. Baumann, J. Gorenflot, A. Wagenpfahl, V. Dyakonov, Julius-Maximilians-Univ. Würzburg (Germany)

Charge carrier recombination in organic solar cells limits the power conversion efficiency, and therefore deserves a closer look. We investigated devices made from P3HT or PCDTBT and their blends with fullerene derivatives by temperature dependent transient absorption and charge extraction by linearly increasing voltage measurements. The results clearly show that recombination in the blend is trap-limited with recombination orders beyond two for low temperatures, while the recombination in the pure material is mainly rendered by a recombination order of two. We present a multiple trapping model in which the traps are intrinsic, corresponding to the tail of the density of states distribution. With this model, we can describe the experimentally determined charge carrier dynamics quantitatively. We find that a trap-induced delay of the bimolecular recombination leads to the higher apparent recombination orders. This mechanism relies on the phase separation of donor and acceptor: charge carriers trapped within one of the material phases can only recombine with a mobile charge (or be extracted from the device) once they are re-emitted from the trap. The strong dependence of the recombination rate on the energetic disorder and temperature explains the experimentally observed deviations from Langevin theory predicting second order losses. Thus, counterintuitively, a higher concentration of traps leading to a higher recombination order is connected to a longer effective charge carrier lifetime of the mobile charges. By applying a macroscopic device simulation, we discuss the impact of trap-assisted bimolecular recombination on the solar cell characteristics.

Enhanced charge separation in polymer/fullerene heterojunctions by molecular doping

E. Da Como, F. Deschler, J. Feldmann, Ludwig-Maximilians-Univ. München (Germany)

Charge separation at polymer:fullerene interfaces is the primary process for organic bulk-heterojunction solar cells. Following the ultrafast photoinduced charge transfer, electrons and holes are still bound because of Coulomb interactions, resulting in the formation of charge transfer excitons (CTEs). Those are known to play a crucial role in solar cells being responsible for the open circuit voltage and the short circuit current.

In this contribution, we propose a novel strategy to overcome some of the recombination channels due to CTEs. This new approach considers the modification of the electronic properties of the conjugated polymer by doping with 2,3,5,6-Tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ) molecules. The free holes induced by F4TCNQ on the low-bandgap polymer poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b']dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] PCPDTBT fill the tail of states in the highest occupied molecular orbital (HOMO) and in addition are expected to screen Coulomb interactions of CTEs at the interface between PCPDTBT and the fullerene derivative PCBM. By the unique combination of time resolved photoluminescence and photoinduced absorption spectroscopy, we demonstrate how doping results in a decreased population of CTEs and enhanced formation of free carriers. The spectroscopy experiments are complemented by measurements on solar cells showing an overall increase of more than 30% in the power conversion efficiency.

On the maximum power conversion efficiency of organic photovoltaics

J. C. Hummelen, Univ. of Groningen (Netherlands); S. E. Shaheen, Univ. of Denver (United States); L. J. A. Koster, Univ. of Groningen (Netherlands)

General design rules for high efficiency OPV have been given by several groups, with a strong focus on optimization of the properties of the donor material and neglecting charge carrier generation as the result of light absorption by the acceptor. We report on our analysis of a single junction donor/acceptor OPV device. We take an approach in which there is no fundamental difference between the donor and acceptor other than the fact that the donor has frontier orbitals at energies higher than the corresponding ones of the acceptor. We argue that such a symmetrical version of OPV is capable of higher efficiency. First, we investigate in a semi-empirical way the influence of bandgap(s) and band offsets on the power conversion efficiency. Second, we also include the influence of the reorganization energy of the charge generation process. Using a slightly different approach, we then consider the influence of the exciton binding energy on the maximum power conversion efficiency. Finally, we introduce the dielectric constant as a parameter in the analysis.

Our analysis suggests that there is no fundamental thermodynamic reason for OPV to have a theoretical efficiency limit lower than the Shockley-Queisser one. It simply shows that there is much work to do on improving molecular materials to overcome present limitations. The trivial conclusion is that in the limit of assuming a donor/acceptor combination of ideal organic materials the same result is obtained as when taking an ideal inorganic p-n junction.

Recombination dynamics as a key determinant of open-circuit voltage in organic bulk-heterojunction solar cells

A. Maurano, Imperial College London (United Kingdom) and Merck Chemicals Ltd. (United Kingdom); D. Credgington, B. O'Regan, I. McCulloch, Imperial College London (United Kingdom); M. Carrasco-Orozco, S. Tierney, Merck Chemicals Ltd. (United Kingdom); M. Morana, Konarka Austria Forschungs und Entwicklungs GmbH (United Kingdom); J. R. Durrant, Imperial College London (United Kingdom)

Polymer photovoltaic devices based on bulk heterojunction blends of semiconducting polymers and soluble fullerene derivatives have shown impressive advances in power conversion efficiency. However, their efficiencies are still too low to make them commercially attractive. One of the key factors limiting the efficiency is the relatively modest voltage outputs, with open circuit voltage (VOC) typically being less than half of the optical bandgap. In this work, we compare the VOC of BHJ cells fabricated from four polymer donors and we show that VOC is limited not only by material energetic[1] but also by the dynamics of non-geminate charge recombination within the blend.[2]

Transient photovoltage[3] and charge extraction[4] were used to calculate, under realistic working conditions for solar cells, the non-geminate recombination flux Jrec that affects VOC according to the formula: $VOC=(IP-EA)/e+\ln(JSC/Jrec)/\gamma(\alpha+1)$, where IP is the ionisation potential of the donor polymer, EA the electron affinity of the acceptor and α, γ are experimentally determined parameters. This formula encompasses three different influences upon VOC. IP - EA represents the ultimate limit to VOC. The charge photogeneration flux (proportional to JSC) creates electron and hole Fermi level splitting, and the charge recombination flux (proportional to Jrec) acts at open circuit conditions to limit this splitting. The values of VOC determined by this methodology are compared to measured values and show very close correspondence.

Oxide/organic interfaces: their role in controlling OPV device efficiency

N. R. Armstrong, J. Gantz, G. Macdonald, B. Zacher, The Univ. of Arizona (United States)

The composition and energetics of oxide/organic interfaces play a critical role in the efficiency of organic solar cells. These interfaces arise in cases where the donor or acceptor components are in direct contact with a transparent conductive oxide (TCO), or where an oxide "interlayer" is inserted between the TCO and the donor or acceptor layer. This talk will focus on the modeling and characterization of interfaces formed between ITO and various small molecule donors, where the polarity of the donor is quite low (e.g. pentacene) or where a strong internal dipole is present in the donor (e.g. TiOPc) leading to specific interactions between the donor layer and the oxide. Significant changes to local vacuum levels are seen during deposition of either type of donor layer, however, for the polar donors there is a clear indication that orientation of the donor matters, and affects charge harvesting, and OPV performance. For the less polar donor layers OPV performance is not strongly coupled to ITO surface composition, whereas for the polar donors even sub-monolayer changes in oxide surface composition can strongly affect OPV performance. We will also review recent conductive tip AFM studies of these interfaces, and modeling studies at small length scales which show the importance of electrode composition, and the mitigating role that interlayer films can play in improving OPV performance.

Beyond energy-level engineering: the effects of the solid-state environment on the ionisation energies and electron affinities of organic molecular semiconductors for organic photovoltaics

B. J. Powell, P. E. Schwenn, P. L. Burn, The Univ. of Queensland (Australia)

Energy level engineering has become one of the central ideas in organic optoelectronics; particularly in the field of organic photovoltaics. However, this paradigm has led to significant ambiguities and errors in the literature. To investigate and address these issues we calculate solid-state ionisation energies and electron affinities of a range of organic molecular semiconductors from density functional theory and the polarizable continuum model. We show that the differences between these results and measurements from (inverse) photoemission are on the same scale as the differences between the measured values reported by different groups. We compare our results with in vacuo calculations and estimates of the ionisation energies and electron affinities from the eigenvalues of the Kohn- Sham equations. In vacuo calculations overestimate the ionisation energies measured in the solid state, but underestimate solid state electron affinities. However, the Kohn-Sham eigenvalues predict the measured ionisation energies nearly as well as the full calculation. However, we show that the apparent accuracy of the Kohn-Sham eigenvalues is fortuitous and arises from the cancellation of the errors due to the use of Kohn-Sham molecular orbital energies as predictions of ionisation energies and electron affinities and the neglect of the polarizable solid state environment. These results stress the importance of descriptions based on molecular states rather than molecular orbitals when designing and characterising materials for organic electronic and optoelectronic devices.

Small molecules and polymers in organic photovoltaic devices: interfaces and energy levels

S. E. Watkins, F. H. Scholes, K. N. Winzenberg, J. Jasieniak, T. Ehlig, B. Singh, R. A. Evans, A. Gupta, M. Gao, G. J. Wilson, P. Kemppinen, Commonwealth Scientific and Industrial Research Organisation (Australia)

In this paper we describe several of our approaches to materials characterisation that aim to accelerate the assay of new materials for use in organic photovoltaics. We describe results for blends based on both small molecules and polymers. For the system based on dibenzochrysenes, differences between the energy transfer processes in blends with either fullerenes or conjugated polymers are described. For the former, efficient solar cells can be made in both bulk heterojunction and bilayer configurations. For the latter, incomplete fluorescence quenching shows unfavourable energy transfer pathways that differ with changes to the blend ratio. The assay of materials and material blends by Photo Electron Spectroscopy in Air is described. We also present results from our high-throughput approach to the fabrication of bilayer devices - a device structure with a simplified interface that reduces the complexities of the bulk heterojunction assembly. We demonstrate that the use of bilayer devices enables a large material and device parameter space to be effectively spanned to rapidly assay the viability of new materials in organic solar cells.

8116-42, Session 9

The impact of interfaces on the performance of organic photovoltaic cells

R. Steim, F. R. Kogler, J. Hauch, Konarka Technologies GmbH (Germany)

Organic photovoltaics (OPV) is a promising technology to solve future energy supply scenarios. The ongoing improvement of the absorber materials resulted recently in certified efficiencies of up to 8.3 % making it more and more interesting for large scale applications like Building Integrated Photovoltaics (BIPV). For BIPV applications performance under non-optimal conditions, like low light, is equally important as the efficiency at 1sun illumination. Optimal performance of OPV requires more than just an optimized absorber layer. While the interplay of the absorber layer with interface materials [1] is always a prerequisite for high performance, it is paramount for low light performance. Unadjusted interface materials can lead to the S-shape current voltage characteristics which drastically reduce the performance of OPV cells in all conditions. For low light applications however, interface materials have to provide highly selective, homogeneous and pinhole free contacts, eliminating hot spots that can be tolerated under 1sun illumination. [2, 3] In the end, the performance of the full OPV module is of importance which is determined by the interplay of all included materials.

8116-43, Session 9

Charge separation dynamics at inorganic/ organic nanostructured hybrid photovoltaic interfaces

R. Eichberger, C. Strothkaemper, I. Thomas, T. Hannappel, K. Schwarzburg, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); C. Fasting, Freie Univ. Berlin (Germany); A. Bartelt, R. Schuetz, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

In nanostructured hybrid photovoltaic devices containing thin organic interfacial absorber layers photo-induced charge separation can be divided into three basic sequences: Light harvesting, charge separation across the heterogeneous interface and charge transport through electron and hole conducting media. Depending on the chemical nature and thickness of the absorber layer, electronic alignment and density of acceptor or trap states at the interface, and finally the conductivity of the transport electrodes, the time scales of the charge separation sequences can be very diverse. For efficient light harvesting - especially in all solid state dye sensitized solar cells (DSSCs) - the hybrid interface is a major limiting part because the generated electrons and holes can recombine on a very fast time scale. We used femtosecond broadband transient absorption spectroscopy in ultrahigh vacuum and terahertz (THz) photoconductivity to study the initial injection dynamics and the early back reaction in competition with carrier escape into the bulk material. The dynamics of different absorber concepts ranging from organic model chromophores to simple antenna FRET systems adsorbed on TiO2 nanoparticle and ZnO nanorod films were measured in our complementary experimental setup. Differences in the encountered interfacial dynamics arising from properties of the two electrodes will be discussed.

8116-44, Session 10

Semi-transparent polymer photovoltaic devices with good transparency color-perception and color-rendering properties

A. Colsmann, A. Puetz, U. Lemmer, Karlsruher Institut für Technologie (Germany)

Window integrated photovoltaics for automotive and building applications are a promising market segment for organic solar modules. Besides semi-transparency, window integrated applications require a reasonable transparency perception. However, a reasonable transparency perception does not necessarily imply good color rendering. The color rendering of items under illumination of transmitted light is of utmost importance when integrating semi-transparent photovoltaic devices in windows or overhead glazings. For example, (transmitted) white light that mainly contains blue and yellow parts of the visible spectrum will render white surfaces acceptably but is incapable of rendering reddish objects.

Therefore, in this work we present efficient ($\eta \approx 3\%$) semi-transparent organic solar cells incorporating a polymer/fullerene blend poly[(4,4'-bis(2-ethylhexyl)dithieno[3,2-b:2',3'-d]silole)-2,6-diyl-alt-(2,1,3-benzothiadiazole)-4,7-diyl] : [6,6]-phenyl C71-butric acid methyl ester (PSBTBT:PC70BM) with an extended absorption to the infrared. In order to account for different illumination situations such as bright sunlight or cloudy skies we investigated different light sources shining through the semi-transparent device. The transmitted light exhibits remarkable color rendering properties making this polymer/fullerene combination and the respective solar cells suitable for real-life window applications. These properties are moreover tunable by the incorporation of suitable dyes and organic absorbers into the device architecture.
