Conference 9160: Metamaterials, Metadevices, and Metasystems 2014

Sunday - Thursday 17–21 August 2014

Part of Proceedings of SPIE Vol. 9160 Metamaterials: Fundamentals and Applications 2014

9160-1, Session 1

Coherent control in metamaterials for device and system applications *(Keynote Presentation)*

Nikolay I. Zheludev, Univ. of Southampton (United Kingdom) and Nanyang Technological Univ. (Singapore); Kevin F. MacDonald, Eric Plum, Xu Fang, Univ. of Southampton (United Kingdom)

Harnessing the coherent interaction of optical waves on photonic metamaterial nanostructures provides for ultrafast all-optical control, at arbitrarily low intensity, of a wide variety of optical phenomena, from absorption and refraction to optical activity and anisotropy. We introduce this new coherent control concept and explore device and systems application potential in spectroscopy and all-optical data processing through a number of experimental demonstrations.

9160-2, Session 1

Actively tunable metadevices *(Invited Paper)*

Mark L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Many conventional optoelectronic devices consist of thin, stacked films of metals and semiconductors. In this presentation, I will demonstrate how one can improve the performance of such devices by nano-patterning the constituent layers at length scales below the wavelength of light. The resulting metafilms and metasurfaces offer opportunities to dramatically modify the optical transmission, absorption, reflection, and refraction properties of devices. This is accomplished by encoding the optical response of nanoscale resonant building blocks into the effective properties of the films and surfaces. To illustrate these points, I will show how nanopatterned metal and semiconductor layers can be used to enhance the performance of photodetectors, solar cells, and enable new imaging technologies. I will also illustrate how metadevices with actively switchable materials can be used to create active components capable of dynamically manipulating light.

9160-3, Session 1

Natural computing with cognitive photonic networks *(Invited Paper)*

Cesare Soci, Nanyang Technological Univ. (Singapore)

We provide proof-of-principle demonstrations of natural computing using simple fiber networks. Thanks to the fast propagation speed of optical signals and to the inherent parallelism of optical networks, linear networks can efficiently solve polynomial (e.g. the matrix inversion) and nondeterministic polynomial (e.g. the Hamiltonian path) mathematical problems. Moreover, nonlinear Erbium doped or chalcogenide fibers can be used to implement metaheuristic optimization, such as the famous ant colony algorithm, or to realize all-optical neuromorphic systems that effectively mimic axon and synapse functionalities. We argue that this framework may be readily extended to integrated silicon photonics or plasmonic waveguide networks to tackle problems of greater complexity.

9160-4, Session 1

Image quality assessments of metamaterial-based microwave remote sensing systems

Steve T. Kacenjar, Lockheed Martin Corp. (United States); David Thomas Crouse, The City College of New York (United States); Igor Bendoym, Tamelia Ali, Phoebus Optoelectronics, LLC (United States); Paul Okun, Lockheed Martin Corp. (United States)

With the advent of lightweight, low cost and spatially stationary metamaterial-based microwave scanning/imaging systems, key questions remain as to their imaging quality effectiveness relative to current beam directing and shaping methods. Methods such as varactor-controlled metamaterials and metasurfaces provide distinctive approaches in steering and shaping the microwave radiation, yet their robustness to operational bandwidth and off-axis deployment may limit their utility in various operational setting such as in portal remote sensing, radar and communication systems. This paper compares the beam shaping performance of two metamaterial approaches under extended bandwidth and off-axis deployment operations to that of near-diffraction limited operational systems.

The first approach, metamaterial stacks, has a split-ring resonator (SRR) multi-layer geometry with varactor shunts between each two-ring unit cell comprising the metamaterial lattice. These varactors provide local control of the phase profile of the beam along the metasurface. The second approach, metasurfaces, rely on a mode-lock laser to temporarily write “chevon” shaped latent image structures onto a semiconductor surface. These structures are areas of excited charge carriers that make these areas of the semiconductor pseudo-metallic. The shape and location of these structures induce local phase changes of the beam. With both approaches, the phase-profile control can be used for beam focusing and steering.

The High Frequency Structural Simulator (HFSS) will model both approaches to estimate the Modulation Transfer Function (MTF) performance across the operational band for both on-axis and off-axis source configurations. These results are then compared with theoretical diffraction-limited performance and current operational systems.

9160-5, Session 2

Gap plasmon-based metasurfaces: fundamentals and applications *(Invited Paper)*

Michael G Nielsen, Sergey I. Bozhevolnyi, Univ. of Southern Denmark (Denmark)

Plasmonic metasurfaces, i.e., nm-thin surface metal nanostructures with subwavelength-sized lattice units, have recently attracted considerable attention due to their abilities to efficiently control both phase and amplitude of transmitted and reflected radiation. We have recently shown that metal nanostructures, in which the bottom metal layer is covered with a thin dielectric layer while the top layer consists of a periodic array of metal nanobricks, thus supporting gap surface plasmon (GSP) resonances, offer improved control of the phase and amplitude of the reflected light. Astutely choosing the thickness of a dielectric spacer, one can realize various operational regimes: from efficient broad or narrowband light absorption that can be exploited for black gold effect or color printing to efficient reflection with the adjustable phase that can be used for phase-gradient metasurfaces. In this talk, the underlying physical mechanisms involved in the process of light reflection by GSP structures are elucidated. Various designs of GSP resonator arrays are considered that are tailored for specific applications, including realization of independent phase gradients in the reflected light for different polarizations, polarization controlled coupling to propagating surface plasmon-polariton modes and other optical functionalities.

9160-6, Session 2

Nonlocal polarization approach to metasurfaces *(Invited Paper)*

Viktor A. Podolskiy, Christopher M. Roberts, Sandeep Inampudi, Univ. of Massachusetts Lowell (United States)

Over last several years new diffraction-based platforms for manipulating the flow of light emerges as a viable tool for ultra-compact photonics. This platform, known as metasurfaces, is based on arrays of planar optical resonators, fabricated at the interface between two dielectrics, arranged to produce diffracted waves of a pre-designed amplitude and direction. Since the majority of light-matter interactions happen within the near-field proximity of the interface, metasurfaces are an optical analog of two-dimensional graphene.

Optics of metasurfaces are fundamentally different from optics of volumetric composite materials. Although finite-difference and finite-element tools can, in principle, be used to characterize the optics of metasurfaces, these techniques require volumetric meshes of a large structure with subwavelength resolution. Due to their two-dimensional nature, metasurfaces cannot be characterized by an effective permittivity or effective index, rendering conventional effective medium techniques useless to describe optics of diffractive structures. Here we propose an analog of effective medium techniques for metasurfaces by characterizing metasurfaces by two-dimensional polarizability. Since the typical spatial profiles of metasurfaces are inhomogeneous on the wavelength scale, polarizability becomes strongly nonlocal (dependent on the wavevector). Nonlocality is known to enable propagation of multiple waves in volumetric structures. Similarly, nonlocal polarization yields diffraction in two-dimensional metasurfaces. We develop the set of boundary conditions that can be used to quantitatively describe diffraction by metasurfaces and compare the predictions of the developed formalism to full-wave solutions of Maxwell equations. The developed formalism can be used as a new convenient tool for understanding, designing, and optimization of metasurface optics.

9160-7, Session 2

Broadband phase delay and frequency conversion with metasurfaces

Vincent Ginis, Vrije Univ. Brussel (Belgium); Philippe Tassin, Chalmers Univ. of Technology (Sweden); Thomas Koschny, Ames Lab. (United States); Costas M. Soukoulis, Iowa State Univ. (United States) and Foundation for Research and Technology-Hellas (Greece)

Metasurfaces—or sheet metamaterials—have revolutionized the manipulation of optical signals through the interaction with a nanostructured surface whose unit cells consist of subwavelength antenna structures. These metasurfaces can reproduce several three-dimensional optical devices, including lenses, mirrors and wave plates, by imposing phase discontinuities across optically flat surfaces. To date, these phase shifts remain limited between 0 and 2π, intrinsically limiting the operational bandwith of metasurfaces. In this contribution, we demonstrate metasurfaces whose bandwidth of operation can be broadened by way of a specific constellation of coupled Lorentzian resonators and we discuss how the bandwidth depends on the number of implemented resonances. Finally, we extend the scope of these metasurfaces and introduce a mechanism that allows for the frequency conversion of optical signals.

9160-8, Session 2

Performance and stability analysis of nonlocal polarization approach to the optics of metasurfaces

Christopher M. Roberts, Sandeep Inampudi, Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States)

Metasurfaces, optically thin structure with engineered diffraction, have gained attention in the past few years as new platform for ultra-compact photonics. Due to the quasi-two dimensional nature of metasurfaces results in the majority of light-matter interaction near-field the interfaces of dielectrics and metasurface. Therefore, conventional techniques for calculating light interaction with composite systems (metamaterials), that have been developed with volumetric material in mind, are typically inefficient in understanding the optics of metasurfaces. Moreover, since the optics of metasurfaces are more akin to the two dimensional structure graphene than to the traditional optics of volumetric composites, traditional effective medium theories cannot be used to describe the diffractive optics by characterizing the metasurface as an effective index or an effective permittivity/permeability.

A new technique for calculating diffraction by the metasurfaces has been recently proposed. In contrast to the majority of computational or analytical technique, the proposed formalism does not require introduction of effective index to describe interaction of light with metasurface. Instead, we treat the metasurface as a two-dimensional sheet with finite (nonlocal) polarizability, and relate the amplitudes of transmitted and reflected beams to each other via boundary conditions. We show that adequate treatment of optics of metasurfaces requires discontinuity of both normal and tangential components of electric fields, and present a comprehensive comparison between conventional techniques for solving Maxwell equations and the proposed nonlocal polarization model. This presentation focuses on analysis of convergence, stability, and memory/time performance of the proposed formalism.

9160-9, Session 2

High-transmittance all-dielectric Huygens' metasurfaces

Isabelle Staude, Manuel Decker, The Australian National Univ. (Australia); Matthias Falkner, Friedrich-Schiller-Univ. Jena (Germany); Jason Dominguez, Sandia National Labs. (United States); Dragomir N. Neshev, The Australian National Univ. (Australia); Igal Brener, Sandia National Labs. (United States); Thomas Pertsch, Friedrich-Schiller-Univ. Jena (Germany); Yuri S. Kivshar, The Australian National Univ. (Australia)

Metamaterial Huygens' surfaces - reflectionless surfaces that can be realized by two-dimensional subwavelength arrays of polarizable particles with both electric and magnetic response [1,2] - have been suggested for efficient beam steering [1,2], beam shaping [1], and focusing [2] in the microwave [1] and mid-infrared spectral range [2]. However, existing realizations [1] and proposed designs [2] are based on plasmonic meta-atoms, and cannot be directly transferred to near-infrared or even visible frequencies because of the high dissipative losses of plasmonic structures at optical frequencies.

Here we demonstrate, for the first time, metamaterial Huygens' surfaces for near-infrared frequencies by replacing the plasmonic meta-atoms by high-permittivity all-dielectric nanoparticles with tailored Mie-type resonances [3]. We experimentally measure both amplitude and phase of light transmitted through a fabricated metasurface exhibiting spectrally overlapping electric and magnetic dipole-type modes in the near-infrared spectral range. We observe 360 degrees phase variation of the transmitted light in combination with high transmittance values. Our experimental measurements are in excellent agreement with numerical simulations and analytical coupled-dipole calculations which further indicate that near-unity transmittance can be achieved for an optimized experimental structure. This high transmittance in combination with the simultaneously observed strong phase response that provides complete phase coverage is key for the realization of a wide range of applications including efficient wavefront shaping, dispersion control devices, and holograms.

9160-10, Session 2

Metasurfaces inner symmetries: from square lattices to quasicrystalline layouts

Sergey S. Kruk, The Australian National Univ. (Australia); Alexander Poddubny, Ioffe Physico-Technical Institute (Russian Federation); Christian Helgert, Friedrich-Schiller-Univ. Jena (Germany); Manuel Decker, Isabelle Staude, The Australian National Univ. (Australia); Christoph Menzel, Christoph Etrich, Carsten Rockstuhl, Friedrich-Schiller-Univ. Jena (Germany); David A. Powell, The Australian National Univ. (Australia); Thomas Pertsch, Friedrich-Schiller-Univ. Jena (Germany); Dragomir N. Neshev, Yuri S. Kivshar, The Australian National Univ. (Australia)

Metamaterials and metasurfaces rely on the ability to design and fabricate nanoparticles of various shapes – meta-atoms - and to place them in a user-defined arrangement. This allows for the creation of composite metamaterials optimized for a desired operation and functionality with respect to their interaction with electromagnetic radiation. The properties of metamaterials are commonly defined by the response of the individual meta-atoms, usually at normal incidence [1]. However, different types of meta-atom arrangements as well as different directions of excitation lead to different coupling conditions among meta-atoms, and as a result, to different optical responses [2]. Here we study and exploit an extra degree of freedom in metamaterial design – symmetry of their inherent arrangement.

Theoretically we use two complimentary approaches. First, we utilized the advanced Jones calculus [3] to describe qualitatively influence of the inherent symmetries on the optical properties. Second, we use coupled dipoles approach, applicable for quantitative analysis of the power of symmetry-dependant metamaterial response. In our experiments, we employ rotationally symmetric metal-dielectric meta-atoms sustaining both electric and magnetic artificial response. The use of symmetric meta-atoms allows detecting the optical effects dependant on the lattice symmetry only, including circular dichroism and optical activity. All the analytical predictions and experimental measurements are in a good agreement and are fully supported by full-wave numerical calculations.

Our findings allow for the first time the quantitative analysis of the impact of inter-element coupling and lattice symmetry on the optical properties of metamaterials, and they constitute an important step towards the design of metasurfaces with desired optical properties.

9160-11, Session 3

Single-photon source based on NV center in nanodiamond coupled to TiN-based hyperbolic metamaterial *(Invited Paper)*

Vladimir M. Shalaev, Mikhail Y. Shalaginov, Purdue Univ. (United States); V. V. Vorobyov, Photonic Nano-Meta Technologies (Russian Federation); A. V. Akimov, Russian Quantum Ctr. (Russian Federation); Alexei Lagutchev, Purdue Univ. (United States); Vasily V. Klimov, P.N. Lebedev Physical Institute (Russian Federation); Alexander V. Kildishev, Alexandra Boltasseva, Purdue Univ. (United States)

We experimentally demonstrate both the lifetime reduction and the enhancement of single-photon emission from nitrogen-vacancies in nanodiamonds coupled to a hyperbolic metamaterial (HMM) based on TiN/AlScN superlattice. Our results pave the way towards future CMOS-compatible integrated quantum sources. Coupling NV centers to HMM allows for the spontaneous emission efficiency of single-photon emitters to be engineered over a broad spectral range. This enhancement is a result of a drastic increase in the photonic density of states within an HMM, providing numerous extra radiative channels to the emitter. In addition, our superlattice structures make use of CMOS compatible materials, thereby opening new highways for the fabrication of integrated CMOS compatible single-photon sources.

9160-12, Session 3

Nonlinear vortex and solitonic behaviour in hyperbolic metamaterial applications *(Invited Paper)*

Allan D. Boardman, Peter Egan, Univ. of Salford (United Kingdom)

The fascinating world of structured material sustaining structured light, such as spinning light beams, is investigated with the aim of revealing new and exciting pathways to applications in modern digital control of our environment. Vortex generation and propagation properties have a beautiful history, and the possibility of generating them together with magnetooptic control in hyperbolic metamaterials offers some important new horizons and they will be discussed in detail. An emphasis will be placed on the fact that certain members of the soliton family have a lot of application possibilities, especially when placed into the context of materials being used in a light-controlling-light environment. The latter phenomenon is suitable for optical chips of the future. Both spatial and temporal solitons will be invoked with an emphasis upon narrow beams and extremely short pulses. It will be pointed out, very strongly, that detailed control of light-packets can also be introduced especially by the deployment of the anisotropy offered by hyperbolic metamaterials in the optical frequency range. In order to stimulate the main features of this kind of metamaterial activity, an exact study of wave propagation in anisotropic waveguides is required. It is an added advantage to be able to use magnetooptics, which is a, globally, very advanced technology and is now being carefully assessed, globally, to combat any integration difficulties into optical circuitry. All the complex structures that will be examined will include the kind of soliton-like channels available from modern experimental facilities and a special consideration will be given to neighbouring interface interactions. A wide range of metamaterials, will be examined, showing that the outcomes of the investigations presented here will lead to a new range of exotic optical switching.

9160-13, Session 3

Photonic hyper-crystals *(Invited Paper)*

Evgenii Narimanov, Purdue Univ. (United States)

In this talk, I introduce a new “universality class” of artificial optical media - the photonic hyper-crystals. These hyperbolic metamaterials with a periodic spatial variation of dielectric permittivity on a subwavelength scale, combine the features of optical metamaterials and photonics crystals within the same medium, and allow for an unprecedented degree of control of light propagation.

Metamaterials and photonic crystals currently represent the primary building blocks for novel nanophotonic devices. With the goal of ultimate control over the light propagation, an artificial optical material must rely on either the effect of a subwavelength pattern that changes the average electromagnetic response of the medium, or on Bragg scattering of light due to a periodic variation that is comparable to the wavelength. By virtue of this inherent scale separation, the corresponding metamaterial- and photonic crystal paradigms, while complementary, are generally considered mutually exclusive within the same environment.

The situation is however very different in the world of hyperbolic metamaterials, where the opposite signs of the dielectric permittivity components in two orthogonal directions lead to a hyperbolic dispersion of TM-polarized propagating waves, with the wave numbers unlimited by the frequency. As a result, a periodic variation in the dielectric permittivity, regardless of how small is its period, will necessarily cause Bragg scattering of these high-k waves, leading to the formation of photonic bandgaps in both the wavenumber and the frequency domains, with profound consequences on wave propagation and scattering in these photonic hyper-crystals.

9160-14, Session 3

Self-assembled tunable photonic hyper-crystals

Vera N. Smolyaninova, Bradley Yost, David Lahneman, Towson Univ. (United States); Evgenii Narimanov, Purdue Univ. (United States); Igor I. Smolyaninov, Univ. of Maryland, College Park (United States); Thomas Gresock, Towson Univ (United States)

We demonstrate a novel artificial optical material, a “photonic hyper-crystal”, which combines the most interesting features of hyperbolic metamaterials and photonic crystals. Similar to hyperbolic metamaterials, photonic hyper-crystals exhibit broadband divergence in their photonic density of states due to the lack of usual diffraction limit on the photon wave vector. On the other hand, similar to photonic crystals, hyperbolic dispersion law of extraordinary photons is modulated by forbidden gaps near the boundaries of photonic Brillouin zones. Three dimensional self-assembly of photonic hyper-crystals has been achieved by application of external magnetic field to a diluted cobalt nanoparticle-based ferrofluid. Unique spectral properties of photonic hyper-crystals lead to extreme sensitivity of the material to monolayer coatings of cobalt nanoparticles, which should find numerous applications in biological and chemical sensing.

9160-15, Session 4

Hyperbolic metamaterials: Kronig Penney approach *(Invited Paper)*

Jacob B. Khurgin, Johns Hopkins Univ. (United States)

Hyperbolic optical metamaterials is an interesting class of extremely artificial materials that exhibit metallic or dielectric properties depending on the polarization. Effective medium approach predicts that the wavevectors can be infinitely high, although in practicability they are limited by the periodicity of the metamaterials (often referred to as “nonlocality”). In this talk we examine a different approach, based on Kronig Penney modal and show how one can obtain dispersion, group velocity, density of states, and the loss of hyperbolic metamaterial without reverting to extensive numerical calculations. Our approach shows that hyperbolic materials can be interpreted as coupled arrays of gap plasmons, and also reveals an interesting fact, missing form effective medium model) that elliptical and hyperbolic dispersions can coexist in the material at certain frequencies.

9160-16, Session 4

Enhanced spontaneous emission from the inside of a multilayer hyperbolic metamaterial

Lorenzo Ferrari, Dylan Lu, Dominic Lepage, Zhaowei Liu, Univ. of California, San Diego (United States)

Hyperbolic metamaterials (HMMs) allow the engineering of spontaneous emission (SE), with broadband and tunable features. However, in the current configurations the emitters are dispersed on top of the HMM, which does not maximize the radiation-matter coupling.

The present study optimizes the SE enhancement of a point source, modeled as a dipole, by including it inside a multilayered silver (Ag)/silicon (Si) HMM. Two figures of merit quantify the performance of the emitter, with respect to its behavior in a homogeneous environment: the Purcell factor (PF), which describes the decay speed enhancement, and the radiative enhancement (RE), which represents the far-field increase of emitted power. First, we demonstrate the tunability of the PF for an outer point source by varying the percentage of Ag in a single period of the multilayer. Then we move the dipole inside each individual Si layer and compute the respective Purcell enhancements. We observe a significant enlargement in bandwidth, with spectral features dependent on the dipole polarization. The PF inside the structure reaches a value of almost 300, 3 times larger than that achieved outside. To scatter into the far field the radiation trapped in the HMM, we implement a triangular grating with a pitch of 300 nm, and rectangular grating with a pitch of 200 nm and a slit width of 40 nm. The emitter is embedded in a layer of polymethyl methacrylate (PMMA), a host material commonly used in fabrication. A 10-fold and 6-fold RE are obtained in the triangular and rectangular grating respectively.

9160-17, Session 4

Experimental realization of broadband super absorber based on rainbow trapping in hyperbolic metamaterials

Dengxin Ji, Haomin Song, Xie Zeng, Hai-feng Hu, Kai Liu, Nan Zhang, Qiaoqiang Gan, Univ. at Buffalo (United States)

Thin-film perfect absorbers are important optical/thermal components required by a variety of on-chip applications, including photon/thermal-harvesting, thermal energy recycling, and vacuum heat liberation. Recently, researches on metal-insulator-metal (MIM) metamaterials based perfect absorber and trapped “rainbow” storage of light have attracted considerable interests. However, these researches are limited by either narrow absorption band or relatively low coupling efficiency. In this work, we experimentally realize a patterned hyperbolic meta-film with engineered and freely tunable absorption band from near-IR to mid-IR spectral regions based on multilayered metal/dielectric hyperbolic metamaterial (HMM) waveguide taper. By cascading resonant MIM perfect absorber elements with gradually tuned widths along the vertical direction, the absorption band of the patterned HMM film is extended significantly. As the incident light is coupled into the HMM waveguide taper, the group velocity of the waveguide mode at different wavelength can be reduced significantly at their corresponding critical widths, resulting in the enhanced light-matter interaction [1]. In addition, multi-patterned HMM metafilms is also demonstrated to reduce the required number of metal/dielectric layers, and therefore simplifying the sample preparation and experimental realization of on-chip broadband super absorbers. The ability to efficiently produce broadband, highly confined and localized optical fields on a chip is expected to create new regimes of optical/thermal physics, which holds promise for impacting a broad range of energy technologies ranging from photovoltaics, to thin-film thermal absorbers/emitters, to optical-chemical energy harvesting.

9160-18, Session 4

Optical characterization of multilayered hyperbolic metamaterials

Thejaswi U. Tumkur, Yuri A. Barnakov, Mikhail A. Noginov, Norfolk State Univ. (United States); Vladimir Liberman, MIT Lincoln Lab. (United States)

We compare two different methods designed to determine the dielectric permittivity components and the ENZ (Epsilon-Near-Zero) wavelength in lamellar Au and Ag-based metal/dielectric metamaterials with hyperbolic dispersion. The first measurement method utilizes polarized angular reflectance measurements. The second measurement technique relies on generalized ellipsometry in an anisotropic measurement mode. The experimental data obtained with the two techniques are in reasonable agreement with the permittivity values calculated using effective medium predictions for a two-component uniaxial medium. It is shown that the extracted permittivity values are sensitive to imperfections in fabrication and chemical oxidative degradation due to ambient storage effects.

9160-19, Session 4

Design of hyperbolic metamaterials by genetic algorithm

Ian A. Goforth, Hossein Alisafaee, Daniel B. Fullager, Christopher Rosenbury, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

Based on the unique optical characteristics and applications of Hyperbolic Metamaterials (HMM), we consider a design method to find the optimal performance of such structures. We employ a powerful optimization approach, called genetic algorithm (GA), to “naturally” find HMM structures that are globally optimized for specific applications. To do this, we investigate the effectiveness of a few fitness functions incorporated within the GA and evaluate their results based on the degree of convergence and computation times and also the tolerances of the final structures. Moreover, we discuss and compare the possible fabrication challenges in realizing the HMMs based on these designs. Further, we try to optimize the performance of conventional HMMs using GA to obtain improvements in the spectral features of these structures. We then compare the results of these three cases: 1) conventional design, 2) GA-assistedconventional design, and 3) full-GA optimization. Finally, we make conclusions about the advantages and disadvantages of using GA for optimization purposes in HMMs.

9160-20, Session 4

Non-elastic light scattering in hyperbolic medium *(Invited Paper)*

Alexander Poddubny, Ioffe Physico-Technical Institute (Russian Federation) and National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Ivan V. Iorsh, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Pavel Ginzburg, Anatoly V. Zayats, King’s College London (United Kingdom); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Yuri S. Kivshar, The Australian National Univ. (Australia)

We present a theoretical study of the non-elastic light scattering in the hyperbolic medium. Hyperbolic medium is a uniaxial medium where the two main components of the dielectric tensor have opposite signs. This leads to the hyperbolic surface of wave vectors corresponding to the given frequency, which, in turn, enhances the density of photonic states. Such effect is known to strongly modify the light-matter interaction with the most notable example being the Purcell effect. However, most of the current studies are limited to the coherent optical processes.

Here, we investigate non-elastic scattering of the light in the hyperbolic medium when photon energy is transferred to the quasiparticles, such as electrons (Compton scattering) or phonons (Brillouin or Raman scattering). We demonstrate, that the scattering selection rules are drastically changed in the hyperbolic regime due to the modified photon dispersion. We also perform a rigorous quantum mechanical analysis of the scattering problem using the Huttner-Barnett local quantization scheme, which allows us to account for the losses. Our study indicates, that the Compton scattering cross section in the visible spectral range and the Compton shift are strongly enhanced as compared to that in vacuum and this effect can be observed experimentally.

9160-500, Session Plen

Non-Covalent Interactions of Carbon Nanotubes in Polymer Composites

Eva M. Campo, Bangor Univ. (United Kingdom)

Despite much effort to control dispersion, alignment, and overall processing of Carbon Nanotubes, both their surface chemistry and distribution in polymer matrices remain an active topic of research. Growth and processing can yield local defects along the graphitic structure to become effective latching sites conducive to polymeric interaction; a prelude to dispersion. With all, the possibility of controlled surface chemistry paves the way of CNTs towards supramolecular chemistry. In this scheme, π-π and CH-π interactions play an important role in time-evolved bonding dynamics; which in turn, is exhorted by both chemistry and processing. We will engage in an exploration that provides insights into bonding in nanocomposites, offering invaluable information towards the synthesis-structure-property paradigm.

9160-501, Session Plen

Nanoscale Silicon as an Optical Material

Philippe M. Fauchet, Vanderbilt Univ. (United States)

As the material at the core of all microelectronic devices, silicon has fueled most technological revolutions in the 20th century. It is abundant and, among inorganic materials, inexpensive. Due to extremely large industrial investments over the past decades, it was tamed like no other material before. However, with the possible exception of the photovoltaic industry, silicon has until recently been used by a single industry. The situation started changing over 20 years ago when advances in the manufacture of nanometer-size objects (e.g., quantum dots, wires, sheets) and devices with deep submicron features (e.g., photonic crystals) allowed researchers to manipulate the properties of bulk silicon and to exploit the unusual optical properties of nanoscale silicon structures. In this presentation, the history, including the most recent developments, of nanoscale silicon as an optical material will be reviewed with a special emphasis on active and biosensing structures.

9160-502, Session Plen

Nanoscale Engineering Optical Nonlinearities and Nanolasers

Shaya Fainman, Univ. of California, San Diego (United States)

Dense photonic integration requires miniaturization of materials, devices and subsystems, including passive components (e.g., engineered composite metamaterials, filters, etc.) and active components (e.g., lasers, modulators, detectors). This paper discusses passive and active devices that recently have been demonstrated in our laboratory, including monolithically integrated short pulse compressor utilized with silicon on insulator material platform and design, fabrication and testing of nanolasers constructed using metal-dielectric-semiconductor resonators confined in all three dimensions.

9160-22, Session 5

Graphene enabled nanoantenna based opto-electro-mechanical biosensor *(Invited Paper)*

Ertugrul Cubukcu, Univ. of Pennsylvania (United States)

Graphene as a monolayer of carbon atoms in a honeycomb lattice has attracted significant interest for its unique optical, electrical, mechanical properties for a range of applications. Metal based plasmonic devices and sensors can capitalize on graphene for unprecedented new functionalities if synergistically integrated. One such intriguing property of graphene that plasmonics can benefit from is its impermeability to gas molecules even as small as a single He atom. Capitalizing on this we demonstrated that nanoantennas made of silver, the ideal plasmonic material that tends to oxidize due to sulfur containing ambient gases, can be effectively passivated with a monolayer graphene. Due to its atomic thickness, graphene also does not perturb nanoantenna near-fields significantly maintaining the full potential of silver nanoantennas in sensing applications.

Graphene is also a very promising material as a bioactive layer due to its ability to effectively adsorb biomolecules through pi-pi stacking interactions. If graphene is used as a monolayer functionalization layer, lengthy sensor surface modification steps will not be necessary. We studied the binding affinities between several different proteins and graphene and found that adsorption can be as strong as that of a specifically binding antigen-antibody pair.

We will also discuss a new multimodal opto-electro-mechanical device that synergistically combines a graphene field effect transistor based nanoelectronic sensor and a nanoantenna based photonic sensor on a mechanical resonator sensor. This hybrid approach combining electrochemical, refractive index, and mass sensing functions on the same device footprint opens up new directions in nano-bio-sensors with unprecedented features. This proof-of-concept nanosensor experimentally achieves sub-picomolar label-free detection limits across all three independent sensing modes, and possesses a dynamic range that is 2-3 orders of magnitude larger than that of any single mode nanosensor.

Graphene in electromagnetic metamaterials *(Invited Paper)*

Philippe Tassin, Chalmers Univ. of Technology (Sweden); Nian-Hai Shen, Ames Lab. (United States) and Iowa State Univ. (United States); Maria Kafesaki, Foundation for Research and Technology-Hellas (Greece); Thomas Koschny, Iowa State Univ. (United States); Costas M. Soukoulis, Iowa State Univ. (United States) and Foundation for Research and Technology-Hellas (Greece) and Ames Lab. (United States)

Graphene is a two-dimensional material system consisting of carbon atoms arranged in a honeycomb lattice. It is just one atom thick and exhibits many unusual mechanical, electrical and optical properties. In this contribution, we present the results of our studies on how graphene can be useful to create metamaterials in the terahertz, infrared, and visible ranges of the electromagnetic spectrum. Graphene is potentially useful for use in metamaterials, because (1) it allows for miniaturization down to the atomic length scale; (2) its tunable Fermi level allows for unprecedented tunability of electromagnetic structures made of this material; (3) it has a highly reactive response, resulting in strongly localized, deeply subwavelength plasmons and deep subwavelength resonators; and (4) it may provide broadband gain. At optical frequencies, the conductivity of graphene is too small to obtain useful metamaterial response from patterned graphene sheets, but it can provide tunability when combined with metallic metamaterials [Opt. Express 20, 12198 (2012)]. In the near-infrared, graphene offers highly confined surface plasmons, which are plagued by considerable dissipative loss, though [Nature Photon. 6, 259 (2012)]. At terahertz frequencies, we compare a series of experimental measurements for the dynamic terahertz conductivity of graphene with recently proposed terahertz graphene metamaterial structures metamaterials made from patterned graphene [Science 341, 620 (2013)]. In addition, we compare split-ring resonators made from graphene versus gold and discuss the properties of the electric and magnetic dipole resonances of such split-ring resonators, as well as applications in tunable metamaterials.

9160-24, Session 5

Infrared nano-imaging and nano-spectroscopy of graphene plasmons

Zhe Fei, Univ. of California, San Diego (United States); Aleksandr S. Rodin, Boston Univ. (United States); Wenzhong Bao, Univ. of Maryland, College Park (United States); Zeng Zhao, Univ. of California, Riverside (United States); Martin Wagner, Siyuan Dai, Mengkun Liu, Alexander S. McLeod, Univ. of California, San Diego (United States); Gerardo Dominguez, California State Univ., San Marcos (United States); Alex Zettl, Univ. of California, Berkeley (United States); Antonio H. Castro Neto, National Univ. of Singapore (Singapore); Mark Thiemens, Univ. of California, San Diego (United States); Fritz Keilmann, Ludwig Maximilian Univ. of Munich (Germany); Chun Ning Lau, Univ. of California, Riverside (United States); Michael M. Fogler, Dimitri N. Basov, Univ. of California, San Diego (United States)

Graphene was predicted to be a candidate material for plasmonics and metamaterials since years ago. But this remains a prediction other than an established fact only until recently, when our groundbreaking experimental works were reported. In this talk, we present first nano-imaging and nano-spectroscopy studies of graphene plasmons using scattering-type scanning near-field microscope –a unique technique allowing efficient excitation and high-resolution imaging of graphene plasmons. With this technique, we were able to show that common graphene/SiO2/Si back-gated structure support propagating surface plasmons in the infrared frequencies. The observed plasmons are highly confined surface modes with a wavelength around 200nm that are conveniently tunable by the back gate voltages [Nature 487, 82–85 (2012)]. In addition, we performed nano-spectroscopy of graphene over a broad range of mid-infrared frequencies, which provides evidence of strong coupling between graphene plasmons and SiO2 optical phonons [Nano Lett. 11(11), 4701-4705 (2011)]. Finally, we were able to map and characterize various types of line defects inside CVD graphene film by exploring real space patterns of propagating surface plasmons. These line defects, including cracks, wrinkles, and even grain boundaries, trigger distinct plasmonic features due to plasmon interference [Nature Nanotech. 8, 821–825 (2013)]. Further modeling and analysis unveiled unique electronic properties associated with these line defects.

9160-25, Session 6

Functional optical metamaterials employing spatial dispersion and absorption *(Invited Paper)*

Andriy Shevchenko, Patrick Grahn, Matti Kaivola, Aalto Univ. School of Science and Technology (Finland)

Non-trivial metamaterials are often composed of anisotropic and asymmetric metamolecules of a size that is only a few times smaller than the wavelength of visible light. This results in a significant spatial dispersion making the wave characteristics dependent not only on the polarization, but also on the propagation direction. Due to spatial dispersion, the material can, for example, show “optical magnetism” even if the magnetic dipole moments of the constituent metamolecules are equal to zero. In addition to spatial dispersion, most functional optical metamaterials exhibit considerable absorption, such that only thin metamaterial films can be considered as transparent. The wave characteristics, such as refractive index (n) and impedance (Z) or electric permittivity and magnetic permeability, in such a material will depend on the orientation of the material's entrance facet, which determines the wave attenuation direction.

We present a relatively simple semianalytical method to theoretically treat and design spatially dispersive and absorptive optical metamaterials. The approach enables one to calculate the parameters n and Z for any polarization and incidence angle of light analytically in terms of the reflection and transmission coefficients of a single layer of metamolecules. We also discuss ways in which the spatial dispersion and absorption can be used to control optical beams. As an example, a metamaterial slab can be designed to provide divergence-free propagation of an optical beam independently of the beam's transverse profile and angle of incidence or to reflect light differently by the different facets of the slab.

9160-26, Session 6

Light filaments based free space metamaterial components *(Invited Paper)*

Natalia M. Litchinitser, Zhaxylyk A. Kudyshev, Scott Will, Univ. at Buffalo (United States); Martin C. Richardson, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

The development of ordered structures of filaments opens the possibility of creating conductive filament structures capable of guiding microwaves or terahertz frequency radiation. In this talk we discuss a fundamentally new approach for manipulating microwaves in air based on unique physical properties of hyperbolic metamaterials formed of plasma filaments in air. We show that filament-based hyperbolic metamaterials can be used for focusing, guiding and steering radar signals to facilitate new degrees of freedom in the detection of such signals in realistic environments. Further, we theoretically and numerically demonstrate that by variation of realistically available parameters of virtual hyperbolic metamaterials, such as fill-fraction of plasma filaments and recombination rate of free electrons with positive ions inside the filament channels, it is possible to design various metamaterial components in the free space for increasing the angular and range resolution of microwave radar systems, and show that they can survive in adverse environments.

9160-27, Session 6

Plasmonic and metamaterial devices based on opto-mechanical interactions

Pavel Ginzburg, Alexey V. Krasavin, King's College London (United Kingdom); Alexander S. Shalin, Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Yuri S. Kivshar, The Australian National Univ. (Australia); Anatoly V. Zayats, King's College London (United Kingdom)

Optical forces are of significant interest from both fundamental and applicative points of view. Typical optical forces achievable with reasonable light intensities are, in nano-to-pico Newton range. One of the approaches for optical forces enhancement relies on the increase of the fields plasmonic nanostructures. In this talk we will demonstrate several novel effects, related to classical and quantum opto-mecanical effects inspired by plasmonic nano-structures and metamaterial assembly [1, 2].

One of the intriguing effects, that will be presented, emerges from novel quantum-mechanical self-induced torques acting on an emitter situated in structured material environment. We further demonstrated, that dipole situated within hyperbolically anisotropic metamaterial applies giant self-induced torque and deterministically aligns itself in the prescribed direction. The magnitude of the torque is order of magnitudes larger than in any other anisotropic materials existing in nature.

Other interesting opto-mechanical phenomenon that will be discussed in this contribution relies on sub-diffractional confinement of guided plasmonic modes and the ability to enhance and engineer forces on nano-scale. Here we propose and demonstrate the concept of force-induced nonlinear optical interactions. In general light beams of different frequencies cannot interact directly, however they could if a mediating material object is present. Nonlinear materials are commonly used for this purpose. Here we propose a new approach to control light with light, based on a nano-opto-mechanical system integrated in a plasmonic waveguide is proposed. Opto-mechanical motion of a free-floating resonant nanoparticle in a subwavelength plasmonic V-groove waveguide is used in the prototype.

9160-28, Session 6

Tailoring dispersion by strong coupling

Thejaswi U. Tumkur, Guohua Zhu, Devon Courtwright, Mikhail A. Noginov, Norfolk State Univ. (United States)

We study the strong coupling of dye molecules to surface plasmons polaritons of thin silver films. The dispersion splits into three branches and demonstrates avoided crossing, characteristic of strong coupling. The dispersion is further modified, when gain is introduced, by strongly pumping the dye molecules. In a series of complementary experiments, we also show that dye molecules can be strongly coupled to localized plasmons modes of rough silver films and also multilayered hyperbolic metamaterials. Our preliminary results could pave the way for a new class of hybrid plasmonic materials and metamaterials.

9160-29, Session 6

Extraordinary optical transmission in the scope of nonlocality

Johan Christensen, Christin David, N. Asger Mortensen, DTU Fotonik (Denmark)

Plasmons in metals can oscillate on a sub-wavelength length scale and this large-k response constitutes an inherent prerequisite for fascinating effects such as perfect imaging, ENZ super squeezing, etc., just to name a few. Nonlocal response has previously been found to pose limitations to field-enhancement phenomena. Accounting for nonlocal hydrodynamic response in thin perforated metal film, we present a detailed study into the properties and influences of the extraordinary optical transmission.

9160-30, Session 6

On the electrodynamics of moving permanent dipoles in external electromagnetic fields

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

Whereas Maxwell's macroscopic equations relate the electric and magnetic fields to their material sources (i.e., charge, current, polarization and magnetization), Poynting's theorem governs the flow of electromagnetic energy and its exchange between fields and material media, while the Lorentz law regulates the back-and-forth transfer of momentum between the media and the fields. The close association of momentum with energy thus demands that the Poynting theorem and the Lorentz law remain consistent with each other, while, at the same time, ensuring compliance with the conservation laws of energy, linear momentum, and angular momentum. This paper shows how a consistent application of the aforementioned laws of electrodynamics to moving permanent dipoles (both electric and magnetic) brings into play the rest-mass of the dipoles. The rest mass must vary in response to

external electromagnetic fields if the overall energy of the system is to be conserved. The physical basis for the inferred variations of the rest-mass appears to be an interference between the internal fields of the dipoles and the externally applied fields. We use two different formulations of the classical theory in which energy and momentum relate differently to the fields, yet we find identical behavior for the rest-mass in both formulations.

9160-31, Session 7

Plasmonic vibrational sensing in the mid-infrared *(Invited Paper)*

Frank Neubrech, Harald Giessen, Univ. Stuttgart (Germany)

Infrared spectroscopy is ideally suited for a label-free and direct characterization of molecular species. Inconveniently, the analysis of small amounts of molecules, which is of large interest for sensing applications, is hampered by their relative low extinction cross-sections. One possibility to overcome this limitation is to use surface-enhanced infrared spectroscopy (SEIRS), where large electromagnetic near-fields provided by plasmonic excitations of metal nanoparticles are employed to enhance signals from molecular vibrations. Such strongly enhanced fields are of great interest for sensing applications, e.g., the detection of molecules by their vibrational fingerprints in the infrared with applications in analytical science, medicine, explosive detection, etc. However, this principle of nanoantenna-assisted SEIRS has been proved for example to detect self-assembled monolayers of molecules with attomolar sensitivity but can also applied to detect more complex molecules, like organic molecules, biologically relevant peptides or proteins.

As a first demonstration of infrared vibrational sensing of biomolecules we covered nanoantennas with a specially designed collagen peptides. To do so, a flow cell was used giving us the unique possibility to control the collagen adsorption on the nanostructures and to perform in-situ SEIRS in aqueous solutions. For antennas with different lengths the plasmonic resonance fairly coincides with the amide I and amide II bands of the collagen peptide. Depending on the ratio of the vibrational and plasmonic excitation we observe differently enhanced vibrational signal with Fano-type line shapes. In comparison to conventional infrared spectroscopy such vibrational signals are enhanced by up to four orders of magnitude.

9160-32, Session 7

Experimental verification of heat flux bending in multilayered thermal metamaterials

Krishna K. Vemuri, Prabhakar Bandaru, Univ. of California, San Diego (United States)

We demonstrate heat flux bending in a multilayered composite considering an effective medium approximation. We show that when the orientation of the composite is physically rotated with respect to the applied temperature gradient , the resultant thermal conductivity tensor can be modified to be anisotropic, with non-zero off- diagonal elements. The resultant anisotropy was found to be dependent on the angle of rotation as well as of the ratio of the thermal conductivities of the constituent materials.

We experimentally demonstrate the bending of the heat flux in three such multilayered composites made by alternately stacking 2mm thick layers of copper ~ 391 W/mK and alloy steel ~ 42 W/mK respectively with three different rotation angles. Temperature profiles in the composites were imaged using an infrared camera (FLIR A320) and agreed closely with the simulations [1]. We show that the resultant heat flux vectors in the composites are oriented at an angle with the applied temperature gradient , due to anisotropy in the thermal conductivity.

Our experiments and analysis indicate that heat flux does not have to be collinear with the applied temperature gradient, e.g. the temperature gradient in a particular direction can drive heat flux in an orthogonal direction. Our studies have implications in thermal energy management with possible utility in portable electronics, nano-combustible systems, solar energy utilization etc.

Infrared absorption by coupled surface plasmon modes in an ultra-thin metamaterial

Peter A. Hobson, QinetiQ Ltd. (United Kingdom); Piers Andrew, Nokia Research Ctr. (United Kingdom); Benny T. Hallam, Imerys Minerals Ltd. (United Kingdom); Chris R. Lawrence, QinetiQ Ltd. (United Kingdom)

We report infrared reflectivity measurements from an ultra-thin metamaterial system supporting a textured top mirror spaced above a perfect electrical conductor by a subwavelength dielectric spacer. The surface texturing causes the structure to diffractively couple to free radiation. Furthermore, the structure supports flat-band, surface plasmon absorption modes at discrete intervals across the infrared spectrum.

The nature of the band structure is different depending on whether the incident field is transverse electric (TE) or transverse magnetic (TM) polarized. The TE data shows three distinct modes, each of which maintain coupling over all angles of incidence. The TM data shows a more complex band structure; with modes positioned at the wavenumbers corresponding to TE modes and additional modes spaced at frequencies midway in-between. The fundamental TM mode mirrors the TE mode and maintains coupling for all angles of incidence, but higher order TM modes exhibit an angle-dependent coupling. We also observe a sub-fundamental TM mode that is due to phonon absorption within the dielectric spacer layer of the structure.

The nature of the electromagnetic modes, their mutual interactions and the device band structure haves been characterized by finite element and other numerical modelling of the experimental data. With the exception of the phonon mode, the analyzed modes show that absorption of incident radiation predominantly occurs in the metal layers of the structure, at frequencies dictated by the geometry of the patterned top surface and shown to be a series of odd and even standing wave solutions.

Vanadium dioxide: a tunable disordered metamaterial and applications *(Invited Paper)*

Federico Capasso, Mikhail A. Kats, Shriram Ramanathan, Harvard School of Engineering and Applied Sciences (United States)

In VO_2 thin films, the Insulator-to-Metal transition occurs gradually with increasing temperature: Nanoscale inclusions of the metallic phase emerge in the surrounding insulating-phase VO2, which grow and connect in a percolation process, eventually leading to a fully metallic state at the end of the transition.The unique temperature-dependent dispersion of this effective medium was used to demonstrate that a film of VO2 , with thickness (~150 nm) much smaller than the wavelength, deposited on sapphire can operate as a temperature tunable absorber; in particular, nearly perfect absorption was achieved at a particular temperature for a narrow range of infrared wavelengths. The reflectivity of such a device varies dramatically and non-monotonically across the phase transition, with the strong absorption feature appearing during an intermediate state of VO2 as a result of coupling to an ``ultra-thin-film resonance. Since the emissivity of an object is equal to its frequency-dependent absorptivity (Kirchoff's law) such a thin-film VO2 -sapphire structure is expected to have an emissivity that also depends strongly and non-monotonically on temperature. This structure displays ``perfect" blackbody-like thermal emissivity over a narrow wavelength range (approximately 40 cm-1, surpassing the emissivity of our black-soot reference. We observed large broadband negative differential thermal emittance over a > 10 C range: Upon heating, the VO -sapphire structure emits less thermal radiation and appears colder on an infrared camera.

9160-36, Session 7

Thermal instability in plasmonics

Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Alexei L. Bogdanov, Western Digital Corp. (United States); Gennady Tartakovsky, Advanced Systems & Technologies, Inc. (United States); Sergey Vergeles, L.D. Landau Institute for Theoretical Physics (Russian Federation); Vladimir Parfenyev, Ilya A. Fedorov, Moscow Institute of Physics and Technology (Russian Federation)

Plasmon nanolasers, also known as SPASERs, attract much attention in recent years due to the numerous potential applications in the plasmonics. We consider thermal effects in the metal nanoresonator immersed in the active medium. The size of the resonator is much less than the wavelength. The plasmon field inside the nanoresonator operates as a quantum object. Due to the nanosize of the resonator the internal plasmon electric field is on the order of the atomic field even for few plasmon quants. The coupling between the plasmon field and plasmon resonator is anomalous strong. We develop the quantum dynamics of the plasmon field and show that the SPASER may be the subject of thermal instability. When number of the plasmon is maintained at the stationary level the loss increases with increasing the temperature of the SPASER. Therefore, the heat generation increases with the increasing the temperature. We have positive feedback and corresponding thermal instability. When the energy, accumulated in the plasmon nanoresonator, exceeds the instability threshold the temperature increases exponentially. We find the increment of the temperature growth and lifetime as function of the loss in metal and the structure of the plasmon resonator. We consider how the thermal instability influence the luminescence and find how the lasing threshold is changed. The coherence of the light emitted by the plasmon laser is also considered. The thermal stability of the nanolaser is important for many

9160-37, Session 8

Manipulating phase and power flow with electromagnetic metamaterials *(Invited Paper)*

Anthony Grbic, Gurkan Gok, Univ. of Michigan (United States)

Transformation electromagnetics (EM) has provided an entirely new approach to designing electromagnetic devices. In transformation EM, a targeted field distribution is derived from an initial one through a coordinate transformation. The form invariance of Maxwell's equations under coordinate transformations is then exploited to calculate the transformed material parameters needed to support the targeted field distribution. However, finding the coordinate transformation that yields a desired electromagnetic field distribution is not always straightforward and may not be possible.

Here, an alternative electromagnetic design approach is introduced. Material parameters are defined in terms of desired distributions of phase progression and power flow direction. First, spatial distributions of the wave vector and direction of Poynting vector are stipulated within the medium. From these two distributions, the required anisotropic and inhomogeneous material parameters needed to support such propagation are found. The material parameters are then implemented using metamaterials. Such spatial control of phase and power flow allows the phase and amplitude of a field profile to be arbitrarily tailored. The proposed synthesis method will find use in the design of antennas and beamforming networks, as well as in scattering control. In addition, the methodology could provide a novel approach to signal routing, the design of mode conversion devices, and the generation of extreme radiating apertures and exotic beams.

9160-38, Session 8

Guiding, switching, and sensing with nanorod metamaterials *(Invited Paper)*

Gregory A. Wurtz, Wayne Dickson, Pavel Ginzburg, Alexey V. Krasavin, Anatoly V. Zayats, King's College London (United Kingdom)

Invited talk: Controlling photonic processes on length scales below the diffraction limit requires structural elements with dimensions much smaller than the wavelength. Recently, novel plasmonic metamaterial has been developed based on arrays of aligned plasmonic nanorods which can be designed to exhibit hyperbolic dispersion or epsilon-near-zero behaviour. This metamaterial provides a flexible platform with tuneable optical properties across the visible and telecom spectral range. Such metamaterials can be used instead of conventional plasmonic metals for designing plasmonic waveguides, plasmonic crystals, label-free bio- and chemo-sensors, for development nonlinear plasmonic structures with the enhanced nonlinearities, and controlling emitters. In this talk, we will overview fundamentals and applications of plasmonic nanorod metamaterial for designing new types of nanostructured plasmonic platforms, bio- and chemical sensing components, and nonlinear optical devices.

9160-39, Session 8

Voltage tunable mid-infrared metamaterials based on strong light-matter coupling

Alexander Benz, Ines Montano, John F. Klem, Igal Brener, Sandia National Labs. (United States)

Metamaterials provide excellent characteristics for optical filters covering the entire range from visible to radio frequencies. Their optical reflectance and transmittance depend primarily on the geometry of the individual sub-wavelength resonators and not on bulk material properties. However, realizing an actively tunable metamaterial that can be used as an optical filter or modulator remains challenging.

Here we present the design and experimental realization of an electrically tunable metamaterial at mid-infrared wavelengths. Our devices operate in the strong light-matter coupling regime where energy is periodically exchanged between the metamaterial (the optical cavity) and intersubband transitions (the two-level system). We can tune the intersubband energy continuously from 28.5 THz (at zero bias) to 34.1 THz (at 5 V) by applying a bias across the quantum-well stack. Due to the strong coupling between two-level system and metamaterial cavity, we also tune the spectral device response. We can shift the upper polariton frequency continuously over 2.5 THz (corresponding to 8% of the center frequency or one full linewidth) by changing the external bias from zero to 5 V.

This work was performed, in part, at the Center for Integrated Nanotechnologies, a U.S. Department of Energy, Office of Basic Energy Sciences user facility. Portions of this work were supported by the Laboratory Directed Research and Development program at Sandia National Laboratories. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

9160-40, Session 8

Mechanical tuning of metasurface made from stand-up split ring resonators

Fan Zhou, Chen Wang, Biqin Dong, Xiangfan Chen, Cheng Sun, Northwestern Univ. (United States)

Recently, many efforts have been made toward creating metasurfaces based on the static local tuning of electrical response of material to the light. However, very limited study has been conducted for the response to the magnetic component of incoming light, which shows substantial effect in metasurfaces by generating a non-unity or even negative permeability that does not exist in nature, especially extending the metasurfaces with mechanical tunability to modulate optical properties in the visible or near-infrared range. In this project, we firstly demonstrate the tunable metasurface subject to the external dynamic excitation. A novel route is developed to fabricate the metasurface composed of vertically aligned split ring resonator (SRR) array with U-shaped cross-section using nanotransfer printing process. Such a metasurface allows for full coupling of the magnetic field component at all angles of incidence, leading to much higher excitation efficiency with respect to the excitation of the planar SRR array. As the U-shaped SRR faces upwards rather than in plane, two beams of the SRR are free standing and thus can be driven by the force induced by the electromagnetic resonance. When the circulating current in the coil is excited by a pulse TM polarized light, strong magnetic field at resonant frequency concentrates inside the SRR gap and induces forces to actuate the beams to their mechanical resonance modes. Using a narrow-band laser source, the measured resonance shift caused by the change of the gap distance matches with simulation result.

9160-21, Session 9

Extreme plasmonics in atomically thin materials *(Keynote Presentation)*

Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain); Alejandro Manjavacas, Rice Univ. (United States)

Plasmons in graphene feature several advantages with respect to more conventional materials, including a large electro-optical tunability and extreme optical-field enhancement, which are suitable building blocks to produce complete optical absorption, extreme light modulation, and ultra sensitive response down to the single-molecule level. Other atomically thin materials also exhibit similar properties. We will discuss here the challenges and opportunities introduced by these types of materials, including their application to quantum optics, electro-optical devices, and sensing.

9160-42, Session 9

Localized surface phonon polariton resonances in cuboidal silicon carbide nanopillar arrays

Chase T. Ellis, Joseph G. Tischler, Orest J. Glembocki, U.S. Naval Research Lab. (United States); Francisco J. Bezares, U.S. Naval Research Lab. (United States) and American Society for Engineering Education (United States); Richard Kasica, National Institute of Standards and Technology (United States); Loretta Shirey, Joshua D. Caldwell, U.S. Naval Research Lab. (United States)

Polar dielectrics, such as silicon carbide, are capable of supporting plasmonic-like effects through the excitation of phonon-mediated collective charge oscillations (Surface phonon polaritons, SPhP). The absence of free carriers in these materials provides a low-loss alternative to metal-based plasmonic materials that exhibit high optical losses. In this study, we investigate the optical response of localized SPhP resonances in fixed-height (950nm), fixed-length (400nm) 4H-SiC, cuboidal nanopillars that vary in width (400nm-6,400nm), and thus aspect ratio. We find that these low-loss nanostructures yield high Q-factor, polarization-dependent, localized SPhP resonances that can be tuned over a wide spectral range. FTIR reflectance measurements using incident light polarized parallel or perpendicular to the width of the cuboidal nanostructure were performed to measure the various localized SPhP resonances. Overall, more than 4 distinct localized SPhP resonances are excited by each polarization, including a monopole resonance that is excited by both polarizations. By changing the nanopillar aspect ratio (AR=width/length), we demonstrate that these localized SPhP resonances can be tuned over a broad spectral range. All resonances exhibit narrow linewidths (3cm^-1 to 30 cm^-1) that correspond to high quality factors in the 30-300 range. The elongated cuboid geometry is of particular interest, since each polarization can stimulate SPhP resonances that span different spectral ranges; thus, yielding a spectral response that is tunable via polarization control.

9160-43, Session 9

Non-steady-state organic plasmonics and its application to optical control of Coulomb blocking in nanojunctions

Guangqi Li, Northwestern Univ. (United States); Boris D. Fainberg, Holon Institute of Technology (Israel) and Tel Aviv Univ. (Israel)

Purely organic materials characterized by low losses with negative, near-zero, and smaller than unity dielectric permittivities can be easily fabricated [1]. Here we develop a theory of non-steady-state organic plasmonics with strong short laser pulses [2] that enable us to obtain near-zero dielectric permittivity during a short time only. Our consideration is based on the model of the interaction of strong (phase modulated) laser pulse with organic molecules, Ref.[3], extended to the dipole-dipole intermolecular interactions in the condensed matter [4].

We have proposed to use non-steady-state organic plasmonics for the enhancement of intersite dipolar energy-transfer interaction in the quantum dot wire that influences on electron transport through nanojunctions [5]. Such interactions can compensate Coulomb repulsions for particular relationships between their values [6]. We propose the exciton control of Coulomb blocking in the quantum dot wire based on the non-steady-state near-zero dielectric permittivity of the organic host medium using chirped laser pulses.

9160-45, Session 9

Superdirective dielectric resonator antenna

Alexandr E. Krasnok, Dmitry S. Filonov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Constantin R. Simovski, Aalto Univ. School of Electrical Engineering (Finland); Yuri S. Kivshar, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and The Australian National Univ. (Australia); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

We propose and demonstrate experimentally a simple approach for achieving superdirectivity of emitted radiation for electrically small antennas based on a spherical dielectric resonator with a notch. Superdirectivity is achieved without using complex antenna arrays and for a wide range of frequencies. We also demonstrate the steering effect for a subwavelength displacement of the source. In contrast to conventional superdirective antennas, our design has significantly smaller losses, radiation efficiency up to 80 %, and matching in 3% frequency band.

9160-46, Session 10

Is there a metamaterial route to high temperature superconductivity? *(Invited Paper)*

Igor I. Smolyaninov, BAE Systems (United States); Vera N. Smolyaninova, Towson Univ. (United States)

Superconducting properties of a material, such as electron-electron interactions and the critical temperature of superconducting transition can be expressed via the effective dielectric response function of the material. Such a description is valid on the spatial scales below the superconducting coherence length (the size of the Cooper pair), which equals ~100 nm in a typical BCS superconductor. Searching for natural materials exhibiting larger electron-electron interactions constitutes a traditional approach to high temperature superconductivity research. Here we point out that recently developed field of electromagnetic metamaterials deals with somewhat related task of dielectric response engineering on sub-100 nm scale. We argue that the metamaterial approach to dielectric response engineering may considerably increase the critical temperature of a composite superconductor-dielectric metamaterial.

9160-47, Session 10

Visualizing catalytic reactions and light-matter interactions in plasmonic materials and metamaterials with sub-nanometer-scale resolution *(Invited Paper)*

Jennifer A. Dionne, Stanford Univ. (United States)

We present new electron-beam spectroscopic techniques that enable visualization of nanoparticle phase transitions in reactive environments and light-matter interactions in three dimensions. We focus particular attention on plasmonic materials and metamaterials that could form the basis for future meta-devices and meta-systems. First, we directly monitor hydrogen absorption/desorption in individual palladium nanocrystals with sizes ranging from tens of nanometers down to just a few nm. Our approach is based on in-situ electron energy-loss spectroscopy (EELS) in an environmental transmission electron microscope. By probing hydrogen-induced shifts of the palladium plasmon resonance, we find that hydrogen loading and unloading isotherms are characterized by abrupt phase transitions and macroscopic hysteresis gaps. These results suggest that alpha and beta phases do not coexist in single-crystalline nanoparticles, in striking contrast with conventional first-order phase transitions and ensemble measurements of Pd nanoparticles. Then, we then extend these techniques to monitor nanoparticle reactions in a liquid environment. By constructing a flow chamber, we directly monitor growth and assembly of colloidal plasmonic metamaterial constituents induced by chemical catalysts. Lastly, we introduce a novel tomographic technique, cathodoluminescence spectroscopic tomography, to probe optical properties in three dimensions with nanometer-scale spatial and spectral resolution. Particular attention is given to reconstructing a 3D metamaterial resonator supporting broadband electric and magnetic resonances at optical frequencies. Our tomograms allow us to locate regions of efficient cathodoluminescence across visible and near-infrared wavelengths, with contributions from material luminescence and radiative decay of electromagnetic eigenmodes. The experimental signal can further be correlated with the radiative local density of optical states in particular regions of the reconstruction. Our results provide a general framework for visualizing chemical reactions and light-matter interactions in plasmonic materials and metamaterials, with sub-nanometer-scale resolution, and in three-dimensions.

9160-48, Session 10

Settling the controversy of Forster energy transfer (FRET)

Cristian L. Cortes, Zubin Jacob, Univ. of Alberta (Canada)

Control of energy transfer in nanophotonic environments is important for applications in organic photovoltaics, OLEDs, as well as molecular imaging and sensing devices. Specifically, short-range intermolecular energy transfer such as Forster resonance energy transfer (FRET) occurs when molecules are less than 10nm apart. Engineering the spontaneous emission lifetime of molecules is achieved through control of the local density of states (LDOS) ?(r,?). It has been assumed that the LDOS can also govern processes like the FRET rate between molecules [1-2]. From this premise, recent experimental work has concluded that the FRET rate is unaffected by the nanophotonic environment. Here, we show that the non-local spectral density function See(r,r',?) should be used as the correct physical quantity governing intermolecular energy transfer rates. We also show that the FRET rate can be engineered in specific nanophotonic environments.

Generally the density of states is defined through the dyadic Greens function at a point i.e. G(rD, rD,?) . From its definition, it is clear that the LDOS is a local quantity that only depends on the location of the donor molecule rD. To describe a non-local process like intermolecular energy transfer, we define the non-local spectral density See(rA, rD, ?)= |nA·G(rA, rD,?)·nD, based on semi-classical theory [3] or quantum theory of energy transfer [4]. Note that it depends on the location of the donor molecule as well as the location of the acceptor molecule within the inhomogeneous environment. To confirm that this quantity correctly describes the physical process of energy transfer, we have reproduced the experimental results from [1]. We define this as the non-local dipole spectral density which is a physical quantity equivalent to the Purcell factor used to characterize spontaneous emission From our simulations, we found excellent agreement between the predictions using SEE and their observed results. Briefly, [1] studied the effect of the environment by placing different donor-acceptor pairs a specific distance away from a silver mirror. The observed constant FRET rate was a result of the relatively large separation distance ranging from 60-200nm away from the mirror, as compared to the intermolecular separation distance of 7nm. We found that if the donor-acceptor pairs were placed closer to the mirror (1-20nm) then there would be a noticeable change in the energy transfer rate. Of course, this prediction would only be valid so long as the local medium and weak-coupling approximation remain valid as well.

To conclude, we have proposed using the non-local spectral density function See to describe FRET rates within inhomogeneous environments. We have found that this quantity demonstrates that it is possible to engineer FRET in nanophotonic environments, despite recent experimental work. This work should impact future experimental studies as well as engineering applications like FRET-based imaging, sensing, and solar harvesting.

Effect of rotation symmetry on the optical activity using planar meta-nanostructures

Eng Huat Khoo, Yew Li Hor, A*STAR Institute of High Performance Computing (Singapore); Eunice Leong, Yanjun LIu, IMRE (Singapore)

In this paper, we design layered composite meta-structures to investigate its' effect on the optical activity and circular dichroism (CD). The layered composite meta-structures consist of thin gammadion nanostructure with thickness lamda/10, where lamda is the incident wavelength. The layered meta-structures are alternate between a dielectric and gold (AU) material. Each layered composite meta-gammadion is arranged together in an array of pitch 700 nm. In the first case, 3 layers of meta-gammadion, with metal-insulator-metal (MIM) and insulator-metal-insulator (IMI) configuration are simulated with material properties from optical hand book. There are 3 modes in the CD spectrum, which can be characterized into Bloch CD mode and hybrid CD modes. Compared with the CD spectrum of whole structure of gammadion in gold with same total height, the CD of the MIM layered composite are larger. When the number layer increase to 5, it is observed that the CD is reduced by 30% and there is a red shift in the Bloch CD mode and a slight blue shift in the hybrid CD modes. By further increasing the number of layers to 7, we observed further CD increment and larger wavelength shift in the CD modes. The layered composite meta-gammadion is fabricated using template stripping method. Experimental results also show excellent agreement with the simulation results for CD and wavelength shift. We submerge the layered meta-gammadion into a solution of chiral molecules. The CD spectrum of the meta-gammadion shows a larger wavelength shift compared to pure metal structures. This indicate a more sensitive and robust detection of chiral molecules.

9160-51, Session 10

Demonstration of the magnetic Purcell effect in wire metamaterials

Alexey P. Slobozhanuk, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Alexander Poddubny, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and Ioffe Physical-Technical Institute (Russian Federation); Alexandr E. Krasnok, Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

In our contribution, we present experimental study of the magnetic Purcell effect in the finite array of wires in the microwave frequency range and reveal the full spatial-frequency map of the Purcell factor. We investigate Purcell effect in the stationary regime of source feeding where Purcell factor determines a change of time average power emitted by a subwavelength source. In our case, source represents a subwavelength loop probe.

To provide experimental investigation, we designed a wire metamaterial resonator as an 14?14 array of brass wires. Wire length, radius and lattice period are equal to 20 cm, 0.1 cm and 1 cm, respectively. The probe presented a small loop with the diameter 1.2 cm, connected by the coaxial cable to the vector network analyzer. The loop probe was fixed in the precise coordinate scanner, oriented parallel to the metamaterial surface. The scanner moved along the wires at the height h = 0.2 cm above the metamaterial. This allowed us to measure the Purcell factor in dependence on the coordinate along wires.

The Purcell factor has peaks at the frequencies, corresponding to the subwavelength-volume Fabry-Perot modes of the wire medium resonator. The Purcell factor enhancement is most brightly manifested for the low order modes. Thus, tailoring of the subwavelength-volume Fabry-Perot modes, which are very different from those of the conventional dielectric resonators, allows one to obtain the independent control over the density of states and the spatial distribution of the electromagnetic field.

9160-41, Session 11

Linear and nonlinear properties of all-dielectric metamaterials *(Invited Paper)*

Dragomir N. Neshev, Isabelle Staude, The Australian National Univ. (Australia); Maxim Shcherbakov, Lomonosov Moscow State Univ. (Russian Federation); Andrey E. Miroshnichenko, Manuel Decker, The Australian National Univ. (Australia); Andrey A. Fedyanin, Lomonosov Moscow State Univ. (Russian Federation); Igal Brener, Sandia National Labs. (United States); Yuri S. Kivshar, The Australian National Univ. (Australia)

For more than a decade, optical metamaterials have relied on plasmonic nanoparticles to achieve a number of unique properties, such as artificial magnetism. However plasmonic structures inherently suffer from strong dissipative losses at optical frequencies, which are critically hampering their performance. A new route to overcome this key problem has been opened by the experimental observations of electric and magnetic Mie-type resonances in high-permittivity all-dielectric nanoparticles [1]. Such nanoparticles exhibit very low losses at optical frequencies and for non-spherical particles the magnetic and electric resonances can be individually engineered to tailor both magnetic and electric polarizabilities. When combined together, such high-permittivity nanoparticles can form a new class of lossless metamaterials and metasurfaces, thus opening novel applications in nanophotonics, including wavefront engineering or advanced light sources.

This talk will overview our activities on all-dielectric metasurfaces based on silicon nanodisks [2], which allow for individual tuning of their electric and magnetic resonances. The possibility to engineer the resonances enables us to achieve unique linear and nonlinear optical properties of the metasurfaces. In particular, we show the suppression of backward scattering in the case of spectral mode overlap [2], as well as the efficient spectral shaping of emission of quantum dots in close proximity to the metasurface. Finally we study experimentally third harmonic generation in our structures and investigate the possibility to enhance the nonlinear optical response by realising nano-clusters of silicon disks.

Developing ceramic materials for practical plasmonics *(Invited Paper)*

Alexandra Boltasseva, Nathaniel Kinsey, Urcan Guler, Jongbum Kim, Purdue Univ. (United States); Gururaj V. Naik, Stanford Univ. (United States); Vladimir M. Shalaev, Purdue Univ. (United States)

The field of plasmonics has long been dominated by noble metals, which lack both tunability of their optical properties and CMOS-compatibility. Alternative plasmonic materials, such as transition metal nitrides and transparent conducting oxides (TCOs), offer a solution to these problems and enable consumer plasmonic devices across many fields including

localized surface plasmon resonance (LSPR), integrated optical circuitry, and metamaterials. Among the transition metal nitrides, titanium nitride (TiN) has shown promise as a plasmonic material in the visible and near infrared (NIR). For LSPR applications, TiN nanoparticles exhibit resonances that overlap with the biological transparency window, thus enabling nanoscale medical applications. In addition, TiN has a similar optical efficiency to gold, is chemically stable, thermally stable, and is bio-compatible. TiN has also recently been demonstrated as a successful material for integrated plasmonic applications, with waveguiding structures achieving surface plasmon polariton (SPP) propagation lengths exceeding 5 mm. Such structures can easily be integrated with plasmonic modulators, which use the tunability of TCOs to attenuate a SPP wave. Electro-optic plasmonic modulators have achieved an extinction ratio of 46 dB/um, with a coupling loss of 1 dB. In this talk, various plasmonic ceramic materials will be discussed for plasmonic devices with enhanced flexibility and performance across many avenues of nanophotonic research.

9160-53, Session 11

Manufacturing of bulk nanoplasmonic materials and metamaterials by micro-pulling down method *(Invited Paper)*

Dorota A. Pawlak, Katarzyna Sadecka, Marcin Gajc, Karolina Korzeb, Pawel Osewski, Andrzej Klos, Barbara Surma, Institute of Electronic Materials Technology (Poland); Alessandro Belardini, Grigore Leahu, Concita Sibilia, Univ. degli Studi di Roma La Sapienza (Italy)

Two novel bottom-up manufacturing methods of nanoplasmonic materials and metamaterials will be presented utilizing the crystal growth techniques: (i) directional solidification of eutectic composites [1], and (ii) direct doping of dielectric matrices with plasmonic nanoparticles (NanoParticles Direct Doping - NPDD) [2]. Eutectics are simultaneously monolithic and multiphase materials forming self-organized micro/nanostructures, which enable: (i) the use of various component materials including oxides, semiconductors, metals, (ii) the generation of a gallery of geometrical motifs and (iii) control of the size of the structuring, often from the micro- to nanoregimes. On the other hand, the novel method of direct doping of dielectric matrices with nanoparticles utilizing directional solidification provides three-dimensional nanoplasmonic materials enabling doping with nanoparticles of various chemical composition, various size and shape, as well as co-doping with other chemical agents. Materials with plasmonic resonances at visible and IR wavelengths, as well as materials with enhanced photoluminescence and up-conversion as well as with anomalous refraction [3] will be presented. Our new approach may lead to novel manufacturing solutions for photonic applications in areas photonics, optoelectronics, photovoltaics.

Principles of vortex light generation from nanoscale arrays *(Invited Paper)*

David L. Andrews, Mathew D Williams, David S Bradshaw, Univ. of East Anglia (United Kingdom); Ruifeng Lui, David B Phillips, Sonja Franke-Arnold, Miles J Padgett, University of Glasgow (United Kingdom)

Light beams with unusual forms of wavefront offer a host of useful features to extend the repertoire of those developing new optical techniques. Complex, non-uniform wavefront structures offer a wide range of optomechanical applications, from microparticle rotation, traction and sorting, through to contactless microfluidic motors. Beams combining transverse nodal structures with orbital angular momentum, or vector beams with novel polarization profiles, also present new opportunities for imaging and the optical transmission of information, including quantum entanglement effects. Whilst there are numerous well-proven methods for generating light with complex wave-forms, most current methods work on the basis of modifying a conventional Hermite-Gaussian beam, by passage through suitably tailored optical elements. Based on symmetry arguments, the direct generation of complex beams by spontaneous emission was until recently considered impossible. However, newly emerging principles indicate that nanofabricated emitter arrays, cast in an appropriately specified geometry, can overcome the obstacles. This presentation introduces the methods and reports on the latest advances, which are potentially paving the way for new laser sources.

9160-55, Session 11

Tunable linear and nonlinear optical properties of transparent conductive oxides for Si-compatible active nanoplasmonics

Antonio Capretti, Boston Univ. (United States) and CNR-SPIN (Italy); Yu Wang, Boston Univ. (United States); Nader Engheta, Univ. of Pennsylvania (United States); Luca Dal Negro, Boston Univ. (United States)

Transparent Conductive Oxides (TCOs) are emerging as a promising platform for silicon-compatible plasmonic nanostructures and active metamaterials for a variety of different device applications ranging from compact nano-sensors and light sources to energy harvesting components. The electric permittivity of TCOs is negative in the near-infrared spectral range enabling the excitation of plasmonic resonances with sub-wavelength localized electric field and dramatically reduced dissipative losses compared to traditional metal-based plasmonic and metamaterials systems.

In the present work we demonstrate controlled fabrication of Aluminum Zinc Oxide (AZO) and Indium Tin Oxide (ITO) thin films with tunable plasmonic response across the 1-2um spectral range, deposited using magnetron sputtering. In addition, we demonstrate light-emitting rare-earth doped TCOs with negative permittivity for novel light-emitting plasmonic devices based on Si-processing. The fabricated samples are investigated using spectroscopic ellipsometry, photoluminescence, scattering spectroscopy, and nonlinear second harmonic generation spectroscopy. Our numerical and experimental results demonstrate tunability of the epsilon-near-zero condition for the fabricated materials and an increased electric field concentration leading to significantly enhanced second-harmonic generation.

In conclusion, our work paves the way to the engineering of tunable active metamaterials based on the widespread Si technology for applications to linear and nonlinear optical devices.

9160-56, Session 11

Experimental demonstration of negative refractive index in principally homogeneous materials (magnetic semiconductors) *(Invited Paper)*

Adil-Gerai Kussow, Alkim Akyurtlu, Yassine Ait El Aoud, Hamzeh M. Jaradat, Univ. of Massachusetts Lowell (United States)

Homogeneous negative refractive index materials are introduced as an alternative to normally utilized inhomogeneous metamaterials. The theory of such materials was developed several years ago (A. Kussow and A. Akyurtlu, PRB 78, 205202 (2008)), and the effect is due to the coexistence of the spin-wave mode with the plasmonic mode, and both modes are activated by the electromagnetic field with simultaneous negative permittivity and permeability responses within the narrow frequency band close to the ferromagnetic resonance. To justify this theory, the thin films of ferromagnetic semiconductor, Cr-doped indium oxide, were fabricated, with clearly measured ferromagnetism at high saturation magnetization and a Curie temperature which is much higher than room temperature. The refractive index, within mid-IR, was extracted from combined transmittance and reflectance data and was compared with theoretical prediction. Also, a direct standard beam displacement method validates the effect of negative refraction in this material.

9160-57, Session 12

Field effect frequency tunable metamaterials *(Invited Paper)*

Harry A. Atwater Jr., Victor W. Brar, Georgia T. Papadakis, Ho Wai Lee, Michelle Sherrott, California Institute of Technology (United States)

The carrier density and optical properties of dielectric and plasmonic materials are typically fixed at the time of fabrication. However field effect tuning of the electrochemical potential in semimetallic materials such as graphene and conducting oxide nanoresonators enables the plasmon and phonon dispersion to be measured. We demonstrate the design of a tunable ENZ metamaterial based on metal and transparent conductive oxide (TCO) multilayers, using the field effect to tune the permittivity of the TCO across thin gate dielectric layers. Gated field effect modulation of the carrier density in graphene nanoresonators in a'perfect absorber' geometry allows for strong modulation of the absorbance. Electrochemical and carrier density modulation in metals yields tunable resonances in metal nanostructures and reveals the plasmoelectric effect, a newly-discovered photoelectrochemical potential. By tuning the permittivity and index to near-zero values, expands the length scale over which coherent quantum emitter phenomena (e.g., concurrence, superradiance) can be observed in epsilon-near-zero media.

9160-58, Session 12

Materials and fields at the nanoscale: design and engineering of active photonic-plasmonic nanostructures *(Invited Paper)*

Luca Dal Negro, Boston Univ. (United States)

The ability to tailor light-matter interactions in metal-dielectric nanostructures is at the heart of nano-optics technology. The exquisite control of propagating and non-propagating electromagnetic fields made possible by the engineering of optical nanomaterials enables innovative approaches for nanoscale electromagnetic field enhancement, concentration and manipulation. In particular, the manipulation of the photonic-plasmonic regime in Fano-coupled active nanomaterials has recently led to broadband linear and nonlinear optical nano-antennas, nanoscale energy concentrators, biosensors, as well as novel types of resonant nano-cavity structures of interest to sub-wavelength light sources and photodetectors with dramatically enhanced emission/absorption optical cross sections.

In this talk, I will present our results on the design, nanofabrication and optical characterization of active nanostructures and metamaterials for on-chip device applications to light sources and nonlinear nano-optics based on the widespread silicon platform. In particular, I will discuss nonlinear and polarization switchable optical nanoantennas as well as our work towards the engineering of low-loss dielectrics with tunable negative permittivity in the near-infrared spectral range. Rare-earth doped conductive oxide nanostructures and active epsilon-near-zero (ENZ) materials are fabricated and their tunable polaritonic responses across the 1-2?m spectral range demonstrated using scattering, photoluminescence and second harmonic generation spectroscopy. Finally, our work on broadband Purcell enhancement of radiation rates in rare earth coupled hyperbolic media will be discussed.

9160-60, Session 12

Bilayer four-fold rotationally symmetric subwavelength nanostructures for chirality switching

Yew Li Hor, A*STAR Institute of High Performance Computing (Singapore)

Chirality effect has been reported from the interaction of light with chiral plasmonic nanostructures. Such nanostructure enhances the chirality response of the chiral molecules and provides a good platform for biochemical sensing and molecular structure manipulation. The ability to detect chiral molecules has been a long term goal of biologists and chemist because chirality is inherent in macromolecules such as proteins and DNA in human body. One of the challenging problems is manipulation of the CD spectrum. Here, we investigate the switchable chiral effects of subwavelength nanostructures array with each of the unit cell. It consists of two layers of gold nanostructures sandwiching a thin layer of SiN with thickness of 50 nm in four-fold rotationally symmetric arrangement. Different nanostructures such as nanorods and nanostripe are investigated. The switchable chirality effect is observed in both plasmonic and Bloch modes when the mutual angle between the first layer and second layer rotates with respect to each other. The magnitude of chirality changes from positive to negative when the mutual angle rotates from 0° to 90°. In the order hand, the nanostructures change from right-handed to left-handed structures without altering the polarization of incident light, or vice versa, upon the mutual rotation angles. Thus, by manipulating the mutual rotation angle, the handedness of the nanostructure will switch and cause the reversal of the outgoing light.

9160-61, Session 13

Guiding waves around the corners: topologically protected photonic transport *(Invited Paper)*

Gennady B. Shvets, Tzuhsuan Ma, S. Hossein Mousavi, The Univ. of Texas at Austin (United States); Alexander B. Khanikaev, Queens College (United States)

We propose a novel and easily realizable platform for making photonic topological insulators. The platform is based on a simple "bed of nails" photonic structure. Our numerical simulations and analytic theory demonstrate the existence of topologically protected surface waves that are conceptually different from the standard surface Tamm states. We will discuss the significance of such topological protection and the possibility of guiding surface waves along sharp zigzag-like trajectories.

9160-62, Session 13

Anisotropic metamaterials to enhance ring imaging Cherenkov detection

Vincent Ginis, Vrije Univ. Brussel (Belgium); Philippe Tassin, Chalmers Univ. of Technology (Sweden); Thomas Koschny, Iowa State Univ. (United States); Costas M. Soukoulis, Iowa State Univ. (United States) and Foundation for Research and Technology-Hellas (Greece)

Cherenkov radiation is a peculiar form of electromagnetic radiation emitted by charged particles that propagate at a velocity larger than the phase velocity of light. In addition to several applications, including the development of novel light sources and the detection of labeled biomolecules, this type of radiation is widely utilized in so-called Ring Imaging Cherenkov (RICH) detectors in high-energy physics experiments. Indeed, at fixed momentum, the Cherenkov cone, which is a measure of the particle's velocity, can be used for the determination of the mass and the identification of the unknown particle. Unfortunately, there exists a trade-off in RICH detectors between the intensity of the generated Cherenkov beam and the accuracy of the velocity measurement. Using the tools of transformation optics, we derive a covariant description of Cherenkov radiation and demonstrate how the Cherenkov intensity and the velocity resolution can be decoupled in a metamaterial radiator. We show that the detector sensitivity is determined by the permittivity of the medium in the perpendicular direction, whereas the intensity of the Cherenkov beam depends on the permittivity in the longitudinal direction. Finally, we show how realistic anisotropic metamaterials, composed of thin metallic cylinders embedded in a dielectric matrix, can enhance the intensity of the generated Cherenkov beam more than a factor two in comparison with state-of-the-art detectors.

9160-63, Session 13

Fluctuational forces in metamaterials

Cristian L. Cortes, Zubin Jacob, Univ. of Alberta (Canada)

In this work we present the first unified approach to understanding Casimir, Casimir-Polder and Van Der Waals interactions in hyperbolic metamaterials. It is seen that inspite of the absorption, dispersion and finite unit cell size significant modifications in the force are exhibited that can be experimentally isolated. We consider a practical thin film structure and use a macroscopic theory of fluctuations to analyze the arising forces.

Our theoretical approach uses Rytov's theory of fluctuational electrodynamics which later led to Lifshitz theory of Casimir Forces. We show how the approach also can be used for Casimir-Polder and Van-Der-Waals interactions and adapted to hyperbolic media. We also show the equivalence of our results to macroscopic quantum electrodynamic approaches.

We take into account experimental non-idealities such as absorption, dispersion and finite unit cell size to obtain the magnitude of the forces in experimental scenarios. This work paves the wave for engineering vacuum and thermal fluctuational forces with metamaterials.

Optical spin Hall effect in two-dimensional phase gradient complementary metasurface

Jeong-Weon Wu, Yeon Ui Lee, Ewha Womans Univ. (Korea, Republic of)

Two-dimensional phase gradient metasuface is designed where V-shape antennas are arrayed in a square lattice. In a phase gradient metasurface, the presence of a gradient in refractive index allows for an optical spin Hall effect even for a normally incident light. Spatial separation of two orthogonal circularly polarized lights in the direction vertical to the gradient direction is already reported in the literature. In a two-dimensional phase gradient surface, the gradient direction is determined by the vector sum of each phase gradient, which leads to a spatial separation of two orthogonal circularly polarized lights in the direction newly defined. Focused ion beam is adopted to fabricate a complementary metasurface. First the extraordinary refraction satisfying the generalized Snell's law is examined by experiment, and an FDTD simulation is carried out to compare the experimental results with the theory. Second optical spin Hall effect is examined by a polarization-selective measurement.

9160-66, Session 13

Optical phenomena in multi-periodic plasmonic multilayers

Alexey A. Orlov, Anastasia K. Krylova, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Sergei V. Zhukovsky, Viktoriia E. Babicheva, Technical Univ. of Denmark (Denmark); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Optical properties of plasmonical multilayers of a special type are thoroughly studied. We call a nanostructured multilayer plasmonic when it is comprised of alternating metal and dielectric layers allowing surface plasmon-polaritons (SPPs) to be excited at the metal-dielectric interfaces. It is conventional to consider only two layers that forms the unit cell of the multilayer. In this study we double the number of layers in the unit cell and choose different constitutive materials thus introducing bi-periodicity in our structures. We analyze in details how bi-periodicity transmutes optical properties of plasmonic multilayers and demonstrate phenomena of anomalous tri-refringence, wideband all-angle negative refraction, and nontrivial Dirac-like points.

9160-67, Session 14

Direct laser writing: principles, materials, and applications *(Invited Paper)*

Alexandros Selimis, George Kenanakis, Angelos Xomalis, Maria Kafesaki, Maria Farsari, Foundation for Research and Technology-Hellas (Greece)

We summarize the principles of Direct Laser Writing Microfabrication, and present our recent work in materials processing and functionalization of 3D structures. We also discuss the future applications and prospects for the technology.

9160-68, Session 14

Design, fabrication, and characterization of plasmonic and dielectric metamaterials *(Invited Paper)*

Uriel Levy, Meir Grajower, Boris Desiatov, Liron Stern, Avner Yanai, The Hebrew Univ. of Jerusalem (Israel)

In this talk we present the design, fabrication and experimental characterization of plasmonic and dielectric metamaterials. In particular, we compare metal and dielectric metasurfaces, and show that the latter may be the preferable choice for applications involving transmission optics. Furthermore, we demonstrate significant heating of metallic and metallo-dielectric structures by probing the structures with scanning thermal microscopy in the near field. Finally, we present a new approach for achieving super lensing based on longitudinal modes in the vicinity of the plasma frequency.

9160-69, Session 14

High-throughput nanofabrication of planar chiral metamaterials fabricated using nanospherical-lens lithography *(Invited Paper)*

Yun-Chorng Chang, Academia Sinica (Taiwan) and National Cheng Kung Univ. (Taiwan); Chang-Han Wang, Yu-Min Huang, Fu-Tian Tseng, National Cheng Kung Univ. (Taiwan)

Nanospherical-Lens Lithography (NLL) is an economic fabrication technique that is capable of fabricating nanodisk arrays that cover large area. It utilizes polystyrene nanospheres as focusing lenses to focus the incoming ultraviolet light and exposure the underlying photoresist layer. Photoresist hole arrays form after developing. Metal nanodisk arrays can be fabricated following metal evaporation and lifting-off process. Nanodisk arrays with diameter less than 100 nm and cover an area as large as 1 cm2 are being fabricated regularly using NLL in our research group.

In this study, NLL is used to fabricate nano-ellipse arrays by replacing the light source with a commercial ultraviolet lamp. The UV light from the lamp is propagating differently between the directions perpendicular and parallel to the lamp and therefore demonstrates different focusing behavior. We can control the orientation of the nano-ellipse since the long-axis is found to be parallel to the lamp direction. The Localized Surface Plasmon Resonance (LSPR) of the nano-ellipse arrays is in infrared region when the long-axis length exceeds 1000 nm, which can be used as platforms for surface-enhanced infrared absorption (SERIA). We can also vary the exposure duration, the angle between exposures, and the sample location to fabricate more complicated metamaterials after multiple exposure conditions. In addition, we also demonstrated the fabrication of much smaller patterns, whose LSPR is in the near-infrared. We believe this proposed method is a powerful tool to fabricate multiple metamaterials in large-scale, which will be very useful for various metamaterial applications.

9160-70, Session 14

Layer-by-layer assembled colloidal silver nanoparticle films for SERS applications

Hung-Ying Chen, Meng-Hsien Lin, Shangjr Gwo, National Tsing Hua Univ. (Taiwan)

Surface enhanced Raman spectroscopy (SERS) has received much attention due to its great potential for ultrasensitive detection. However, quantitative SERS measurements are still restricted by the poor uniformity of available SERS substrates. Here, we demonstrate that colloidal Ag nanoparticle films can be utilized as uniform SERS substrates. The close-packed Ag nanoparticles in theses films allow the formation of regular dense arrays of “hot-spots”, which can dramatically enhance the Raman signal in “hot-areas”. We find that this bottom-up method for fabricating tunable SERS substrates is quite simple, robust, and scalable. Therefore, it can become an attractive approach for quantitative SERS applications.

Recently, we have reported that layer-by-layer assembled colloidal noble-metal (Au and Ag) nanoparticle films exhibit strong and tunable plasmonic responses. Here, we experimentally demonstrate that tunable plasmonic metamaterials formed by using colloidal Ag nanoparticle films have the potential to be used as uniform SERS substrates. In this work, the analytes, such as self-assembled monolayers with designated functional groups, are placed on “hot-areas”, which are composed of dense “hot-spots” between close-packed colloidal nanoparticles with tunable coupling strength controlled by nanoparticle surface ligands. We find that the Raman signals from the analytes can be greatly enhanced. Moreover, the spatial mapping of SERS signal is performed to demonstrate the uniformity of SERS signal. It is shown that quantitatively SERS measurement of analyte concentration is feasible.

9160-71, Session 14

Temperature dependent surface modification of silica spheres with methacrylate

Kwang-Sun Kang, Kyungil Univ. (Korea, Republic of)

Temperature dependent surface modification of silica spheres with 3-(Trimethoxysilyl)propylmethacrylate (TMSPM) has been performed. Although the surface of the silica spheres is tried to modify at room temperature, no evidence of the surface modification is observed. The reaction temperatures were varied from 60 to 80°C with various reaction periods. Small absorption shoulder of the C=O stretching vibration showed at approximately 1700 cm-1 for the spheres reacted at 60°C. The clear absorption peak representing the C=O stretching vibration of the ester appeared at 1698 cm-1 for the spheres reacted for 80 min and shifted toward 1720 cm-1 with the increase the reaction time for the spheres modified the surface at 70°C. Strong absorption peak at 1698 cm-1 showed for the spheres modified the surface at 80 °C after 180 min and the absorption peak shifted to 1725 cm-1. The FESEM image shows clear evidence of the modified spheres.

Realization of negative index in second-order dispersive metamaterials using standard dispersion models for electromagnetic parameters

Tarig A. Algadey, Monish R. Chatterjee, Univ. of Dayton (United States)

Electromagnetic velocities offer a convenient route to predicting optical refraction in a material as a function of frequency and specific material parameters. Thus, it is known that in domains where the (real parts of) permittivity and permeability of the medium are positive, the resulting phase index is also positive. Conversely, if both these parameters have negative real parts, the material begins to exhibit negative index characteristics. Negative index may be shown to occur when the group and phase velocities in the material become counter-propagating. To examine whether and when this might happen, a spectral approach involving slowly time-varying phasors and chiral constitutive relations was recently developed, and the velocities for dispersive permittivity, permeability and chirality were derived up to first and second order. For both cases, it is found that the presence of chirality automatically makes a propagating plane wave devolve into circular polarizations. Additionally, it is found that the energy velocity is not generally expressible independent of field amplitude for second-order dispersion, unless specific assumptions are made regarding dispersive coefficients for the three parameters of interest. However, phase and group velocities may still be expressed in terms of coefficients only (independent of field amplitude) even for second-order. In this paper, we incorporate in the derived equations physical models (including Debye, Lorentz and Condon) for material dispersion in permittivity, permeability and chirality in order to further examine the consequences of second-order dispersion leading to negative index for practical cases, and also evaluate the resulting phase and group indices.

Acoustic metamaterial with negative parameter

Hongwei Sun, Fei Yan, Jiangsu Automation Research Institute (China); ying li, Nanjing University of Science and Technology, Nanjing 210094, China (China)

This paper presents modeling, analysis techniques and experiment of metamaterial panel for invisible using. For a unit cell of an infinite metamaterial panel, governing equations are derived using the extended Hamilton principle. The concepts of negative effective mass and stiffness and how the spring-mass-damper subsystems create a stopband are explained in detail. Numerical simulations reveal that the actual working mechanism of the proposed metamaterial panel is based on the concept of conventional mechanical vibration absorbers. It uses the incoming elastic wave in the panel to resonate the integrated membrane-mass-damper absorbers to vibrate in their optical mode at frequencies close to but above their local resonance frequencies to create shear forces and bending moments to straighten the panel and stop the wave propagation. Moreover, a two-dimension acoustic metamaterial panel consisting of lumped mass and elastic membrane is proposed in the lab. We do experiments on the model and The results validate the concept and show that, for two-dimension acoustic metamaterial panel do exist two vibration modes. For the wave absorption, the mass of each cell should be considered in the design. With appropriate design calculations, the proposed two-dimension acoustic metamaterial panel can be used for absorption of low-frequency waves and hence expensive micro-manufacturing techniques are not needed for design and manufacturing of such metamaterial panel for low-frequency waves absorption/isolation .

Anderson localization for discretely disordered metamaterials: effect of polarization and off-axis incidence

Glen J. Kissel, Univ. of Southern Indiana (United States)

We consider polarization and off-axis incidence effects for one-dimensional photonic bandgap structures consisting of alternating layers of positive and negative index materials (PIM/NIM), with one or more parameters discretely disordered. Such long randomly disordered systems exhibit Anderson localization, whose effects can be studied using the Lyapunov exponent of the product of independent identically distributed random transfer matrices modeling the structure. We use Furstenberg's integral formula to calculate Lyapunov exponents for s and p polarizations, and for a range of angles of incidence for these random matrix models. Furstenberg's integral formula requires integration with respect to the probability distribution of the randomized layer parameters, and integration with respect to the so-called invariant probability measure of the direction of the vector propagated by the long chain of random matrices. This invariant measure can rarely be calculated analytically, so some numerical technique must be used to produce the invariant measure for a given random matrix product model. Here we use the method of Froyland-Aihara, especially suited for discretely disordered parameters, to calculate the invariant measure. This method produces the invariant measure from the left eigenvector of a certain sparse row-stochastic matrix. This sparse matrix represents the probabilities that a vector in one of a number of discrete directions will be transferred to another discrete direction via the random transfer matrix. The Froyland-Aihara method results in a dramatic reduction in computation time to calculate Lyapunov exponents compared to traditional layer or vector iteration methods.

Design of periodic plasmonic photocoupler for infrared optoelectronics

Zhenghua An, Fudan Univ. (China)

Similar to the antenna in microwave regime, plasmonic resonances of periodic metal structures are favorable for coupling electromagnetic energy or photons efficiently into optoelectronic devices and therefore boost their performance, thanks to the surface electromagnetic waves or surface plasmon polariton. In this work, we demonstrate that a plasmonic cavity consisting of a periodically perforated metal film and a flat metal sheet separated by a semiconductor spacer is particularly suitable for multicolor infrared light detection, due to the excellent spectral tunability, spatially distinct field distributions and absorption enchancement. Three different types of optical modes are clearly identified --- the propagating and localized surface plasmons on the perforated metal film and the Fabry-Perot modes inside the cavity. Interactions among them lead to a series of hybridized eigenmodes exhibiting excellent spectral tunability and spatially distinct field distributions, which cannot be achieved by convential grating photocoupler. As an example, we design a two-color detector protocol with calculated photon absorption efficiencies enhanced by more than 20 times at both colors, reaching ~42.8% at 15μm (in wavelength) and ~46.2% at ~10.2 μm for a 1 μm total thickness of sandwiched quantum wells. The rich plasmonic-photonic hybridization effects discovered here provide plenty of opportunities to optimize light harvesting efficiencies for modern ultra-small infrared optoelectronic devices with subwavelength dimensions.

Reflected metasurface for polarization-controlled hologram application

Pin Chieh Wu, Wei Ting Chen, Kuang-Yu Yang, National Taiwan Univ. (Taiwan); Chih-Ming Wang, National Dong Hwa Univ. (Taiwan); Yao-Wei Huang, National Taiwan Univ. (Taiwan); Greg Sun, Univ. of Massachusetts Boston (United States); Shulin Sun, Lei Zhou, Fudan Univ. (China); Ai Qun Liu, Nanyang Technological Univ. (Singapore); Din Ping Tsai, National Taiwan Univ. (Taiwan)

Holograms are the optical devices that are able to reconstruct pre-designed images and show many applications in our daily life. However, applications of hologram are always limited by the constituent materials and pixel sizes resulting in the working range are forbidden at particular wavelength region. In recent years, the metasurfaces, an array of plasmonic antenna with varying geometric sizes showing the abilities to manipulate both amplitude and phase of incident electromagnetic wave in a wide electromagnetic region. Here, we present a hologram composed of reflected metasurface (called meta-hologram) which is designed and fabricated for visible wavelength. Also, both experimental and simulation results show the meta-hologram working in a very high efficiency. Using gold cross nano-antennas as building pixel to construct our meta-hologram devices, the reconstructed images of meta-hologram show polarization-controlled dual images with high contrast for both coherent and incoherent light sources. Moreover, such meta-hologram not only shows a broad spectral working range but also under a wide range of incidence angles. The flexibility demonstrated here for our meta-hologram paves the road to a wide range of applications related to holographic images at arbitrary electromagnetic wave region.

Calculating magnetic permeability response from a conducting square ring structure

Ahmad Khayyat Jafari, Jiangfeng Zhou, Univ. of South Florida (United States)

Recently, there have been some suggestions to utilize the non-resonant elements to get a diamagnetic response with permittivity less than one over a wide frequency range. Actually, enhancing the diamagnetic interactions between theses loops leads to a rise of the magnitude of the mutual inductance and in turn the magnitude of the magnetic susceptibility of the system. In this paper, the properties of an arrangement of periodically conducting square rings have been characterized. The core of this numerical work is to analyze the inductive interactions between the building blocks. A lattice model has been introduced in order to determine the magnetic permeability of the structure from the microscopic quantities which are the total mutual inductance and capacitance of the entire construction plus the self-inductance of individual cells. Frequency dispersion of the magnetic permeability is due to the self-inductance of individual square ring. Despite the fact that this effect is not as dominant as resonant processes in split-ring resonators, this approach introduces a magnetic response with a broad-band frequency.

It is also demonstrated that the general behavior of the circular and square ring architecture is the same. However, in order to obtain the closest packing pattern, which leads to stronger mutual inductance, the square ring formation is the best choice. As a matter of fact, square pattern has no magnetic flux loss if its thickness is ignored (ideal case).

Nonreciprocal manipulation of light propagation in 2D-photonic crystals with cylindrical metamaterials consisting of arrayed SWNTs with helical DC

Koichi Fukushima, Osaka Prefecture Univ. (Japan); Tatsuya Nakajima, Tohoku Univ. (Japan); Atsushi Syouji, Yamanashi Univ. (Japan); Hajime Ishihara, Osaka Prefecture Univ. (Japan)

The nonreciprocal manipulation of light propagation is an invaluable ingredient in a next-generation optical networking. However, it is challenging to bend a photon's path rapidly even by using magnetized dielectrics which is only natural nonreciprocal materials. The purpose of this contribution is to introduce a novel material structure to achieve the above mentioned challenging goal.

First, we demonstrate the TE light propagation in nonreciprocal cylindrical 2D-photonic crystals whose dielectric tensor has real parts of off-diagonal terms. In whispering gallery mode (WGM) in each unit element, light goes around one-way direction of the circumference of a cylinder, and resonates nonreciprocally with the periodic array of cylinders. As a result, the direction of light propagation becomes round and the nonreciprocal degree is dominated by the real parts of off-diagonal terms of the dielectric tensor.

On the other hand, the real parts of off-diagonal elements are always associated with the large imaginary parts of diagonal terms, which ensures no energy divergence. However, this spoils the effect of WGM.

Then, we introduce a novel phenomenon to overcome the above problem, i.e., rotational Doppler shift in helical conducting SWNTs. If the angular frequency of electrons of helical currents is larger than the light frequency, the amplitude of one circular polarization is intensified. So the effective-dielectric tensor has large real parts of off-diagonal terms.

As a result, 2D-photonic crystals with cylindrical metamaterials consisting of arrayed SWNTs with helical DC enable us to manipulate light propagation in a drastic way.

Scattering and coupling between subwavelength resonators

Morteza Karami, Steven Kitchin, Michael A. Fiddy, The Univ. of North Carolina at Charlotte (United States)

Understanding the mechanisms behind novel electromagnetic properties of metamaterials is crucial to design better structures; so we study how meta-atoms interact with each other depending on the periodicity of the structure. We investigate how energy coupling occurs between different resonant frequencies of our designed subwavelength meander type resonators and how it defines the bulk properties. To do this, we start with numerical simulations of a small number of meta-atoms to see how coupling changes by changing the number of subwavelength resonators. In addition, we compare the simulation results with experiments done in the microwave region. Furthermore, we study some of bulk properties such as negative refraction where how periodicity and scattering of subwavelength elements influence it, whether there is negative index or not. A prism made out of our designed S-resonator was simulated to show the existence of negative refraction and to understand its relation with negative index.

Enhanced radiation from dipolar sources in proximity of subwavelength hyperbolic metamaterial resonators

Caner Guclu, Univ. of California, Irvine (United States); Ting-Shan Luk, George T. Wang, Michael B. Sinclair, Sandia National Labs. (United States); Filippo Capolino, Univ. of California, Irvine (United States)

Hyperbolic material (HM) substrates are shown to increase dramatically the power emitted by dipolar emitters in their proximity due to the increased local density of states. In general most of the emitted power by a dipolar source is coupled to the HM substrate and dissipated there as heat. This fact can be used for engineering the decay rate of emitters whereas the emitted power into the free space is not enhanced necessarily and the radiation efficiency of such systems remains low. On the other hand, for many applications such as solid-state lighting, the main goal is to achieve the enhancement of radiative emission, instead of just boosting the total emission. In this study we utilize three-dimensional HM resonators with subwavelength size for enhancing not only the Purcell factor, but also the radiative emission of a quantum emitter positioned close to the resonator. Resonators are made of silver-silica layers. Our findings indicate that the total emission is enhanced mainly due to the increased radiation into free space showing that HM resonators are efficient radiators and suitable for utilization as nano-antennas. Various dipole positions and orientations are investigated and at the resonance wavelength in the visible spectrum we report up to 100-fold enhancement of radiative power emission with respect to the power emitted by a dipole in free space. Finally we elaborate on the impact of using a finite array of HM resonators stressing the role of inter-element spacing. In summary, we report that a dense array of subwavelength HM resonators can be used for enhancing radiative emission of quantum emitters.

Characterization of ferromagnetic/dielectric systems for metamaterials applications

Brittany Bates, Nicole Greene, Natalia Noginova, Norfolk State Univ. (United States)

Incorporation of ferromagnetic materials into metamaterial systems provides an opportunity to tune microwave permeability with an external magnetic field, strongly affecting wave propagation. We characterize microwave properties of several soft magnetic materials with high permeability as possible candidates for such applications. In the range of the ferromagnetic resonance, the permeability of ferromagnetic/dielectric composites varies from positive to negative values. In addition, a low field absorption peak is observed in mu-metal and metglas systems. This feature can be ascribed to the domain mode resonance, which provides an additional possibility of tuning with low fields.

Anisotropy modeling of polarization dependent terahertz metamaterials

Hyunseung Jung, Hojin Lee, Soongsil Univ. (Korea, Republic of)

There have been substantial progresses in engineering the resonance properties of metamaterials by manipulating the size, pitch, or shape of their meta-atoms to be utilized for the terahertz and optical applications such as filters, detectors, sensors, and absorbers. It is well known that most of metamaterials have different resonance properties depending on the polarization of incident waves. However, any comprehensive study for understanding the resonance mechanism by the anisotropy of metamaterials has never been reported so far. In this study, we propose a novel anisotropy modeling of the polarization dependent meta-atoms at terahertz frequencies. The proposed anisotropic metamaterials are composed of metallic microstructures combined with various numbers of H-shaped meta-atoms and fabricated onto the flexible polyimide substrate by conventional photolithography process. We confirm that the proposed metamaterials successfully realize the unique properties that can modulate the resonance frequency for the specific polarization of an incident wave, while can keep one identical resonance frequency for their orthogonal polarization direction, simultaneously. Moreover, the experimental results show that regardless of the number of H-shaped meta-atoms as well as the polarization direction, their individual bandwidth can stay unchanged by coupling effects between adjacent meta-atoms and their excited electric dipole moments. Since the complementary structure has the opposite properties due to Babinet's principle, the proposed design methods are expected to be utilized not only for the reflective type, but also for the transmissive type metamaterial filters.

Excitation of surface waves in the photonic crystal / graphene structure for terahertz frequency range

Alaudi K. Denisultanov, Mikhail K. Khodzitskiy, Solveyga E. Azbite, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Photonic crystals are one of the most remarkable metamaterials for electromagnetic waves manipulation for last decades, therefore they can be used as filters, waveguides, polarization changers, superlenses, superprisms, etc [1]. As well today graphene has attracted considerable attention due to the unusual properties such as perfect thermal and electric conductivities etc. [2]. A periodic stack of equally spaced parallel layers of graphene has the properties of a 1D photonic crystal, with narrow stop bands that are nearly periodic in frequency, and that may be used as spectral-selective mirror [3]. In this paper the excitation of surface waves in the photonic crystal bounded by graphene layer was investigated for terahertz frequency range. Peaks of transmissivity in band-gaps of photonic crystal that caused by excitation of surface waves were obtained. The control of frequency position of peaks by temperature and magnetic field was demonstrated in the frequency range from 0.1 to 1 THz.

Titanium nitride as nonmetallic metamaterial component: gyroidal self-assembly and nonlinear optical response

Srujana Prayakarao, Norfolk State Univ. (United States); Spencer Robbins, Cornell Univ. (United States); Nathaniel Kinsey, Purdue Univ. (United States); Devon Courtwright, Norfolk State Univ. (United States); Alexandra Boltasseva, Vladimir M. Shalaev, Purdue Univ. (United States); Ulrich B. Wiesner, Cornell Univ. (United States); Vladimir I. Gavrilenko, Carl E. Bonner Jr., Mikhail A. Noginov, Norfolk State Univ. (United States)

Titanium Nitride (TiN) is considered to be a non-metallic alternative to traditional (gold and silver) plasmonic materials. In this work, we have studied (1) nonlinear chi3 optical response of TiN thin films (using z-scan technique) as well as (2) optical properties of the gyroidal metamaterial assembled of TiN nanoparticles. Despite of relatively low plasmonic response of TiN gyroidal metamaterial, some of its properties (e.g. bright multi-color reflection observed in optical microscopy) resemble those of gyroidal metamaterial composed of Au nanoparticles.

Microwave interaction with visible light

Alexey P. Slobozhanuk, Polina V. Kapitanova, Dmitry S. Filonov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); David A. Powell, Ilya V. Shadrivov, The Australian National Univ. (Australia); Mikhail Lapine, The Univ. of Sydney (Australia); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Ross C. McPhedran, The Univ. of Sydney (Australia); Yuri S. Kivshar, The Australian National Univ. (Australia)

We report an arrangement allowing interaction between waves of arbitrary frequencies, which is achieved by introducing an additional coupling mechanism to impose artificial interaction between otherwise independent elements.

We provide a scheme where split-ring resonators (SRRs) are actively involved in the optical control, serving as both receivers and sources of optical radiation. Our design comprises two varactor-loaded SRRs, which are arranged to be orthogonal to each other. With this geometry, the symmetry of the arrangement ensures there is no electromagnetic coupling between the two resonators. However, one of the SRRs is controlled by a photodiode (PD), and the other is equipped with a light-emitting diode (LED), positioned so as to provide efficient optical interaction between the LED and the PD. At low power of the electromagnetic signal launched into the LED-SRR, there is insufficient voltage rectified by the varactor to light up the LED, so there is no interaction between the SRRs. At higher power, the LED is lit and the emitted light is absorbed by the PD, providing a voltage across the varactor, thus changing its capacitance, which directly affects the resonance frequency of the PD-SRR. Thus, the resonant frequency of the PD-SRR is directly controlled by the signal power in the LED-SRR, despite having no direct electromagnetic coupling between the two.

We report a prototype fabrication and experimental confirmation of the above ideas, demonstrating a remarkable resonance shift and polarisation dependence.

9160-73, Session 15

Backward phase matching for second harmonic generation in negative index materials

Wenshan Cai, Georgia Institute of Technology (United States)

The phase-matching condition, resulting from the conservation of photon momentum, is among the foremost vital aspects to consider in harmonic generation and wave-mixing. The exotic electromagnetic parameters made possible by metamaterials provoke us to reevaluate the established rules of phase-matching for nonlinear optical interactions. When a metamaterial possesses a positive index of refraction at the fundamental frequency and a negative index for the harmonic wave, phase-matched frequency doubling requires that the indices for the fundamental and harmonic waves have the same magnitude but opposite signs. Since the Poynting vector and the wave vector in a negative-index medium are antiparallel to each other, the harmonic output will travel towards the source of the fundamental wave. This new type of phase-matching condition, known as "backward phase-matching," has been predicted for years but an experimental verification at optical frequencies is still lacking.

Here we report the experimental demonstration of backward phase matching in a negative index material. The unconventional phase matching condition is achieved by exploiting two distinct modes in a plasmonic waveguide, where the real parts of the refractive indices is 3.4 and -3.4, respectively, for the fundamental wave at 770nm and the harmonic at 385nm. The effective, nonvanishing second-order nonlinear susceptibility is enabled by applying a bias voltage across half of the dielectric layer in the waveguide. The observed peak conversion efficiency at the excitation wavelength of ~770nm indicates the backward phase matching, where the phase-matched harmonic wave propagates along a direction opposite to that of the incoming fundamental wave.

9160-74, Session 15

From unidirectional scattering to nonlinear unidirectional generation: leveraging magneto-electric interference

Ekaterina Poutrina, Air Force Research Lab. (United States); Alec Rose, Duke Univ. (United States); Dean Brown, Air Force Research Lab. (United States); David R. Smith, Duke Univ. (United States); Augustine M. Urbas, Air Force Research Lab. (United States)

We analyze the resonant electromagnetic response of sub-wavelength plasmonic dimers formed by two metal strips separated by a thin dielectric spacer. We demonstrate that the off-resonant electric and resonant, geometric shape-leveraged, magnetic polarizabilities of the dimer element can be designed to have close absolute values in a certain spectral range, resulting in a predominantly unidirectional scattering of the incident field due to pronounced magneto-electric interference. Switching between forward and backward directionality can be achieved with a single element by changing the excitation wavelength, with the scattering direction defined by the relative phases of the polarizabilities.

We consider further the nonlinear response of dimers to electromagnetic excitation. We demonstrate that, similar to the linear case, a unidirectional nonlinear generation is possible by leveraging magneto-electric interference in the nonlinearly produced field, without phase-matching requirements being involved. The nonlinear regime gives an additional advantage of achieving unidirectional generation for the total (nonlinearly produced) field, rather than just for the scattered portion of the field. Moreover, a proper choice of the crystalline properties of the spacer material can lead to nonlinear generation predominantly in the direction orthogonal to that of the original excitation, in case of a single isolated dimer.

We next extend the analysis to some periodic configurations, including the specific case of a perforated metal film, and discuss the differences between the observed unidirectional scattering and the extraordinary transmission effect. The unidirectional response can be preserved and enhanced with periodic arrays of dimers and can find applications in nanoantenna devices and integrated optic circuits.

9160-75, Session 15

Second harmonic generation from asymmetric plasmonic nanoparticle dimers

Augustine M. Urbas, Vitaliy N. Pustovit, Richard Vaia, Sushmita Biswas, Kyoungweon Park, Dhriti Nepal, Air Force Research Lab. (United States)

In this paper we explore the second-order nonlinear response of the pairs (dimers) of plasmonic nanoparticles possessing a localized surface plasmon resonance (LSPR). Significant effort has been devoted to exploring the interaction between plasmonic nanoparticle assemblies and strongly interacting nanoparticles. The linear properties of such systems have been the focus of much recent work. Following on this, we focus on the nonlinear response of interacting particle assemblies both theoretically and experimentally. In these assemblies, despite even-order nonlinear processes being forbidden in bulk centro-symmetric medium like metals, we predict a high degree of resonant enhancement for pairs of spherical shaped nanoparticles where inversion symmetry is broken by an asymmetry in particle size. Recent experiments demonstrate a significant second-harmonic surface nonlinear response from the local fundamental field distribution and enhancement present in dimer assemblies. We explore different configurations of nanoparticle dimers ranging over shape, size and separation by performing calculations on experimentally relevant systems. This allows us to draw from and compare existing studies of particle pairs and target new studies on high second harmonic yield configurations. Nonlinear measurements of second harmonic yield from selected configurations prepared by directed self-assembly techniques will be presented. Our calculations, carried out accounting for high multipolar orders of interaction, demonstrate that the optical response of dimers exhibits a periodic dependence on the distance between nanoparticles, and that this becomes more pronounced for more asymmetric pairs.

9160-76, Session 15

Electrically controlled nonlinear optical phenomena in photonic metamaterials *(Invited Paper)*

Wenshan Cai, Georgia Institute of Technology (United States)

The past decade has witnessed the emergence and explosive development of optical metamaterials that afford exotic light manipulations. In addition to the continued investigation of these artificially structured optical media with unorthodox properties not found in nature, there has been an ever-growing interest in the study of metamaterials beyond the conventional, linear regime. Two particularly compelling directions are active metamaterials, where the optical properties can be purposely tailored by external stimuli in a reversible manner, and nonlinear metamaterials, which enable intensity-dependent frequency conversion of light waves. By exploring the interaction of these two directions, in this work we leverage the electrical and optical functions simultaneously supported in nanostructured metals and experimentally demonstrate electrically-controlled nonlinear optical processes from a metamaterial absorber. Both the second harmonic generation and the optical rectification, enhanced by the light concentrating ability in the tri-layered metal-dielectric structure, are shown to follow the resonance behavior in the metamaterial and are modulated externally with applied voltage signals. Our results reveal the potential of metamaterials as customized nonlinear media with engineered and intercorrelated linear and higher-order properties. These results also demonstrate the grand opportunity to exploit optical metamaterials as a self-contained, dynamic electrooptic system with intrinsically embedded electrical functions and optical nonlinearities.

9160-77, Session 15

Subpicosecond relaxation of the third-order nonlinear susceptibility in fishnet metamaterials

Alexander Shorokhov, Maxim Shcherbakov, Lomonosov Moscow State Univ. (Russian Federation); Jörg Reinhold, Friedrich-Schiller-Univ. Jena (Germany); Andrey A. Fedyanin, Lomonosov Moscow State Univ. (Russian Federation); Thomas Pertsch, Friedrich-Schiller-Univ. Jena (Germany)

To date, much effort was put in experimental studies of optical properties of fishnet metamaterials. However, experiments on their nonlinear-optical properties are largely limited to the optical harmonic generation spectroscopy. In this work, we study the temporal dynamics of the third-order nonlinear susceptibility in fishnet metamaterials on the subpicosecond time scale using the pump-probe technique.

The sample was made by e-beam-lithography and lift-off techniques. It represents a multilayer Au-MgO-Au heterostructure. The structure has a period of 500 nm in both lateral directions. The thicknesses of the Au films and the intermediate dielectric film are 20 nm and 35 nm, respectively. Transient properties of third-order optical nonlinearity are probed using the pump-probe technique. Two femtosecond laser pulse trains from an Er-doped passively mode-locked fiber laser are focused by an objective lens onto the sample. The third harmonic generation signal is collected behind it by a photon-multiplier tube. Inducing a time delay between the pulses makes it possible to observe non-stationary states of the nonlinear susceptibility of the sample.

Experimental data indicate existence of a delay in the nonlinear response of the metamaterial attributed to subpicosecond relaxation of gold characterized by a time constant of approximately 1 ps. Estimated modulation of the third-order nonlinear susceptibility is equal to 5% for a pump pulse energy of 120 fJ.

Our results disclose the possibilities of tailoring the nonlinear-optical properties of the fishnet metamaterials on the subpicosecond time scale.

9160-78, Session 16

THz polarization control using chiral metamaterials *(Invited Paper)*

Maria Kafesaki, Foundation for Research and Technology-Hellas (Greece) and Univ. of Crete (Greece); George Kenanakis, Eleftherios N. Economou, Costas M. Soukoulis, Foundation for Research and Technology-Hellas (Greece)

Chiral metamaterials, due to their giant chirality values, orders of magnitude larger than the chirality of natural chiral materials, can provide unique possibilities for the control of electromagnetic wave polarization. Such a control is extremely useful in the THz regime, where there is a serious lack of optical components. In this talk we will present a variety of different chiral metamaterials operating in the THz regime and we will demonstrate, both theoretically and experimentally, very large optical activity values and/or large circular dichroism and/or negative refractive index response, verifying thus the unique capabilities of our metamaterials to control the THz-wave polarization. Moreover, incorporating properly in our metamaterial structures photoconducting Si, we demonstrate optically switchable chiral response, which gives to our structures a unique potential to create dynamic polarization control components, like switchable polarization filters, modulators, wave plates and others.

9160-79, Session 16

Theory and modeling of self-induced transparency in Terahertz graphene metamaterials *(Invited Paper)*

Sang Soon Oh, Joachim M. Hamm, Andreas Pusch, Ortwin Hess, Imperial College London (United Kingdom)

The optical conductivity of graphene can be described as a sum of intraband and interband conductivities. When doped, graphene will have a non-zero Fermi level such that the intraband conductivity is dominant at terahertz frequencies, but it can be significantly reduced by strong incident electromagnetic waves allowing high transmission. Undoubtedly, this induced transparency of graphene can be modified by changing the gate voltage or by overlaying metamaterials on graphene. However, it is not straightforward to explain the induced transmission change – self-induced transparency – of graphene metamaterials for different incident field intensities, since a modified optical conductivity and an associated non-uniform field distribution are present and involved simultaneously. To understand the underlying physics of induced transparency of graphene metamaterials at terahertz frequencies, we performed numerical simulations based on the finite-difference time-domain method incorporated with an analytical model for the optical conductivity of graphene. Our simulation results confirm that the induced transparency of graphene metamaterial is strongly dependent on both the gate voltage and the geometry parameters of meta-atoms. We show that the resonant nature of graphene metamaterials significantly modifies the induced transparency of graphene. In particular, the sign of the modulation depth (T/dT) is reversed at the resonant frequencies of metamaterials. We employed a simple RLC model to explain the reversed sign and this is supported by FDTD simulation results. In addition, the effect of non-uniform electric field on the induced transparency is investigated. We believe that our model will provide a simple way of understanding the nonlinear response of graphene metamaterials.

9160-80, Session 16

Manipulating terahertz waves with photo-imprinted diffraction gratings

Philippe Tassin, Chalmers Univ. of Technology (Sweden); Ioannis Chatzakis, Liang Luo, Iowa State Univ. (United States); Nian-Hai Shen, Ames Lab. (United States); Lei Zhang, Iowa State Univ. (United States); Jigang Wang, Ames Lab. (United States); Thomas Koschny, Costas M. Soukoulis, Iowa State Univ. (United States)

The terahertz spectral range of the electromagnetic spectrum—loosely defined from about 100GHz to 10THz—has long been an inaccessible region in between the successful realms of electronics and photonics, because of the lack of efficient and compact sources and detectors for terahertz radiation. Developments in the past decade, however, have enabled the exploration of terahertz science and the rapid rise of terahertz imaging and spectroscopy for, amongst others, biomedical and security applications. Here we explore a route towards reconfigurable terahertz devices. We demonstrate the possibility of creating photonic structures for terahertz waves by projecting the optical image of a metal mask onto a thin GaAs substrate using a femtosecond pulsed laser source [Appl. Phys. Lett. 103, 043101 (2013)]. This creates a pattern of illuminated and dark regions on the substrate. We show that the conductive pattern of free carriers created in this way behaves like a diffraction grating for terahertz waves and we present examples of one- and two-dimensional gratings. The experimental results are confirmed by computer simulations. The demonstrated photo-imprinted diffractive elements could be made reconfigurable by replacing the fixed metal mask employed in our study by a device with spatially controlled transmission for the optical pump beam, e.g., a digital micromirror device.

9160-81, Session 16

Design, simulation, and fabrication of a novel reconfigurable graphene terahertz filter

Kai Yang, Sara Arezoomandan, Berardi Sensale-Rodriguez, The Univ. of Utah (United States)

Graphene is an allotrope of carbon atoms arranged in a two-dimensional honeycomb lattice structure. Single-layer graphene has excellent electrical, thermal, mechanical, and optical properties, which makes it attractive for many terahertz applications. Terahertz waves can be employed in diverse areas such as astronomy, security, high speed communications, biomedicine, spectroscopy, etc. However, up until recently, there has been a lack of practical terahertz active devices such as reconfigurable terahertz filters. Many of these applications require the development of simple reconfigurable terahertz filters to control and manipulate terahertz waves. Taking advantage of the extraordinary properties of graphene, we propose and discuss a novel micro-machined reconfigurable graphene-based terahertz filter. The key components are the periodic metal rings with several gaps where active graphene strips are placed. We can easily adjust the resonance frequency of the terahertz filter by varying a couple of parameters such as the inner and outer radius of the metal ring, the gap, the number of graphene layers, and by (dynamically) varying the conductivity of each graphene layer. This work explains the principle of operation of the device, its design based on numerical simulations, its fabrication process, and also presents experiment results. The simulation results show that the resonance frequency is a monotonically decreasing function of the graphene electrical conductivity. The active area is also an important parameter in graphene terahertz devices as reducing it can boost the speed of the device. This device's active area is >100X smaller than that of other devices proposed in the literature.

9160-82, Session 16

Tunable frequency converter for terahertz frequency range based on space-time transformation

Egor A. Gurvitz, Anna V. Vozianova, Mikhail K. Khodzitskiy, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Recently, special interest is being shown to developments of media with space-time dependent dispersion of constitutive parameters. The physical principals of such media [1] can be effectively described in the frame of transformation optics theory [2]. In general, potential applications of such media can be found in laser system devices, fiber optics transmission lines, radars and detection systems, integrated and planar optics and etc. In this paper, tunable frequency convertor medium on basis of transformation optics theory was considered. It can be used as a source of tunable frequency generation in radar, spectroscopy and imaging systems. The tunable frequency convertor can be realized by using metamaterials with time dependent permittivity and permeability which are modulated by high speed arbitrary signal form generator. In this work we present analytical and numerical investigation of such device and consider metamaterial constitutive parameters for conversion of infrared radiation into terahertz one.

9160-83, Session 17

Polarization controlled colorful images reconstructed by reflective meta-hologram *(Invited Paper)*

Din Ping Tsai, Academia Sinica (Taiwan); Pin Chieh Wu, Wei Ting Chen, National Taiwan Univ. (Taiwan); Kuang-Yu Yang, Academia Sinica (Taiwan); Chih-Ming Wang, National Dong Hwa Univ. (Taiwan); Yao-Wei Huang, National Taiwan Univ. (Taiwan); Greg Sun, Univ. of Massachusetts Boston (United States); Shulin Sun, Lei Zhou, Fudan Univ. (China); Ai Qun Liu, Nanyang Technological Univ. (Singapore)

Holograms are the optical devices to reconstruct images by recovering amplitude and phase of light, which show many applications in our daily life. Recently, the metasurfaces, an array of sub-wavelength antenna, show the abilities to exhibit extraordinary light-manipulation abilities to overcome the limitations of conventional holograms, such as the absorption of photo-sensitive material or the pixel size of hologram. Here, we performed a high-efficiency broadband reflected metasurface and meta-hologram in 4-level phase by reflected metasurface made of subwavelength 6x6 gold cross nano-antennas of 16 different shapes which is designed and fabricated in optical frequencies. As a result, the reconstructed images of meta-hologram exhibit far more efficient (reaches 18% for 780 nm illumination), polarization-controlled dual colorful images with high contrast, functioning for both coherent and incoherent light sources within a broad spectral range (bandwidth ?880 nm) and under a wide range of incidence angles. The reflective hologram has a number of advantages such as simple fabrication process, low metal absorption, broad working spectral range, and greater tolerance to variation of incident angle and light incoherence. By combining with the techniques of tunable metasurfaces, meta-hologram can potentially be used to realize the active hologram that works at arbitrary electromagnetic wave region.

9160-84, Session 17

Numerically stable reconstruction of wavelength-scale objects with sub-wavelength resolution

Sandeep Inampudi, Univ. of Massachusetts Lowell (United States); Nicholas A. Kuhta, Oregon State Univ. (United States); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States)

Significant developments in materials and fabrication techniques require development in imaging systems in order to resolve sub-wavelength details of objects. So far the only reliable technique to provide nano-scale resolution is near field scanning optical microscopy (NSOM) which relies on point-by-point scanning and has other complications. In contrast, engineered meta-grating structures (optically thin gratings with sub-wavelength periodicity) have the ability to couple and transmit information about the sub-wavelength features of the near-field object to propagating waves have shown promising results in resolving sub-wavelength features with far-field measurements. Implementation of this technique relies on computational image reconstruction using multiple far-field measurements and requires a parametric representation of spatial spectrum of the object. However, classic expansions including Taylor and orthogonal-function-based series result in substantial instabilities in recovery of higher wavevector part of the spectrum. Here we present a highly stable and accurate image recovery process using physically meaningful expansion into "pixel" basis. In this expansion, the area covered by the illumination beam is divided into a finite number of regions (pixels) and the intensity produced by the object at the location of each pixel is numerically recovered. Our results indicate that in ideal situation with higher signal-to-noise ratio the technique can provide resolutions of the order of wavelength/50, while in a more realistic setting

the technique can achieve stable image recoveries with resolution of the order of wavelength/20, far better than resolutions of any far-field imaging techniques to date.

9160-85, Session 17

Invisibility cloaking in the diffusive-light limit *(Invited Paper)*

Robert Schittny, Muamer Kadic, Martin Wegener, Karlsruher Institut für Technologie (Germany)

Albert Einstein's theory of relativity imposes stringent limitations to making macroscopic objects invisible with respect to electromagnetic light waves propagating in vacuum. These limitations are not relevant though for propagation of light in diffusive media like fog or milk because the effective energy speed is significantly lower than in vacuum due to multiple scattering events. Here, by exploiting the close mathematical analogy between the electrostatic or near-field limit of optics on the one hand and light diffusion on the other hand, we design, fabricate, and characterize simple core-shell cloaking structures for diffusive light propagation in cylindrical and spherical geometry.

In our experiments, a hollow metallic core with few-centimeters radius and effectively zero diffusivity isolates its interior from the outside. To make this core appear like the diffusive surrounding, we add a shell with higher diffusivity than that of the surrounding. Formulas connecting the required radii and diffusivities can immediately be translated from the electrostatic limit of optics. The shell is implemented by a polydimethylsiloxane (PDMS) coating, doped with dielectric melamine-resin microparticles. The surrounding is water with some milk or other scattering medium added. Following white-light illumination from one side, we image the light emerging on the other side. While the obstacles alone cast a significant diffusive shadow, the cloaks nearly appear like the homogeneous surrounding without anything inside.

9160-86, Session 17

Design of homogeneous coatings for the cloaking of arbitrarily-shaped objects

Carlo Forestiere, Luca Dal Negro, Boston Univ. (United States); Giovanni Miano, Univ. degli Studi di Napoli Federico II (Italy)

We present a novel theory for the cloaking of arbitrarily-shaped objects and demonstrate electromagnetic scattering cancellation through designed homogeneous coatings. Our approach is based on the quasi-electrostatic approximation and on its first and second order radiative corrections, obtained through the perturbation theory. By expanding the dipole moment of a coated object in terms of its resonant modes, we perform the direct calculation of the permittivity values of the coating layer that cancel the net dipole moment and abates the total scattered power. In particular, this is accomplished by finding the the zeros of a polynomial, whose degree depends on the number of bright modes of the system. We also show that, by using the radiative corrections, our approach leads to an accurate design of the cloaking not only in the Rayleigh limit, but in the whole regime in which the dipolar scattering is dominant. Finally, we present several examples of the cloaking of arbitrarily-shaped object, of particles lying on a substrate, and of multi-coated objects. The developed approach paves the way to the the design of ``invisibility cloaks" for irregularly-shaped devices such as complex sensors and detectors.

9160-87, Session 17

Optimization of aberrations in transformation optics inspired lenses

Saul Wiggin, Queen Mary, Univ. of London (United Kingdom)

A new optical lens is designed using metamaterials and transformation optics based on the Cooke triplet. The original lens system was defined using ray tracing in standard optical design software, while a single lens has been constructed to 'mimic' its performance. We find the proposed lens has preserved properties from its triplet counterpart with improved RMS wavefront.

9161-2, Session 1

A new and fast numerical method for the determination of the optical properties of quantum structures

François Thierry, Judikaël Le Rouzo, Institut Matériaux Microélectronique Nanosciences de Provence (France); François R. Flory, Institut Matériaux Microélectronique Nanosciences de Provence (France) and Ecole Centrale Marseille (France); Gérard Berginc, Thales Optronique SA (France); Ludovic Escoubas, Institut Matériaux Microélectronique Nanosciences de Provence (France)

We present a novel numerical method to determine the optical properties of nanostructures. The structures under study are quantum wells (QWs), circular cross-section quantum wires (QWRs) and spherical quantum dots (QDs). The properties that we focus on are absorption, photoluminescence and effective refractive index. We calculate the energy levels with a new formulation of a shooting method under the envelope function and effective mass approximations with a band nonparabolicity correction. Although the effective mass approximation has been proven to diverge for small sizes and low-bandgap materials, we show that we can achieve great correlation with results of semiempirical methods such as pseudopotential (PP), tight-binding (TB), k.p or even ab-initio calculations such as local-density approximation (LDA) taken from the literature. This allows a more accurate determination of the optical properties that derive from electronic ones. We especially study the impact of the size on confinement effects. The model that we use is fast, that is why it has a great interest for optimization procedures. This could be used to estimate the power conversion efficiency of next generation solar cells that incorporate nanostructures and find the best combination of components and structural geometries to get the optimum device design.

9161-3, Session 1

Influence of core-shell interfaces in exciton and multi-exciton dynamics of CdSe-CdZnS quantum dots

Alessandro Minotto, Francesco Todescato, Raffaella Signorini, Univ. degli Studi di Padova (Italy); Jacek J. Jasieniak, Commonwealth Scientific and Industrial Research Organisation (Australia); Renato Bozio, Univ. degli Studi di Padova (Italy)

Semiconductor quantum dots (QDs) possess attractive optical properties that fulfill different tasks in photonics. Thanks to the evolution of core-shell colloidal synthesis[1], QDs exhibit almost ideal emitting properties. Their employment in optoelectronic devices is encouraged by their size-tunable emission as well as by their high absorption cross-sections and high photoluminescence (PL) quantum yields (QYs)[2,3]. In this work, starting from the archetypal CdSe based systems, the influence of shell thickness and composition on exciton dynamics in CdSe-CdxZn1-xS core-shell QDs is investigated. By means of steady-state (Uv-Vis absorption, PL, amplified PL) and transient optical spectroscopy (PL and pump-probe), single- and multi-exciton creation and recombination processes are characterized and correlated with different core-shell interfaces, previously studied with a Raman experiment4. Surface trap states are responsible for single QD PL blinking and Auger non-radiative recombination, which strongly hamper the generation and the radiative recombination of excitons and multi-excitons, respectively. The variety of spectroscopic techniques employed permit to explore the interaction between exciton and trap-states from picosecond to hundreds of nanoseconds time scale. The present study clarifies why graded core-shell CdSe-CdS-Cd0.5Zn0.5-ZnS represent the best performing hetero-structure, since such QDs combine the high radiative rates of CdS, the efficient de-trapping process of Cd0.5Zn0.5S and the superior confinement potential of ZnS in a single dot.

9161-4, Session 1

Investigation of CdS nanowire lasing emission

Robert Röder, Max Riediger, Friedrich-Schiller-Univ. Jena (Germany); Daniel Ploss, Arian Kriesch, Robert Buschlinger, Ulf Peschel, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Carsten Ronning, Friedrich-Schiller-Univ. Jena (Germany)

Nanophotonic on-chip integrated components are a promising approach to face forthcoming limitations of electronic integrated circuits by new all optical concepts using optical data transmission and processing. Exploiting semiconductor nanowires, which offer efficient waveguide properties and mark the lower size limit of photonic laser systems, builds a possible route to overcome these challenges. High quality cadmium sulfide nanowires open therefore up the green spectral range around 2.4 eV acting as Fabry-Pérot laser resonators with a remarkable low threshold of 10 kW/cm^2 at room temperature [Geburt et al, Nanotechnology 23, 365204 (2012)] and operating even in cw emission mode [Röder et al, Nano Letters 13, 3602 (2013)]. Since optical processing is depending on the emission characteristics of the future device, a "head-on" setup was developed to investigate the light output originating out of the end facet of a single nanowire laser. This setup is suited to investigate super luminescence (ASE) as well as lasing emission as a function of the polarization of the optical pump beam. Furthermore, the angular distribution of nanowire lasing emission as well as the polarization can be determined.

9161-5, Session 1

Engineering bright sub-10-nm upconverting nanocrystals for single-molecule imaging *(Invited Paper)*

Emory Chan, The Molecular Foundry (United States)

Lanthanide-doped nanocrystals can be utilized as low-background biological imaging probes due to their ability to convert infrared excitation into visible emission – a process known as upconversion. These unique upconverting probes do not photobleach or decompose under intense excitation, enabling their use in long-term studies and single-molecule assays. The brightness of these lanthanide-doped particles, however, has been limited by a poor understanding of energy transfer within the nanocrystal and an unavoidable trade-off between brightness and size. Here, we describe the use of a high-throughput computational package to simulate the spectrum and energy transfer pathways of arbitrary compositions of NaYF4 nanocrystals doped with multiple lanthanide ions. Using this in silico combinatorial method, we screened for nanocrystal compositions that exhibit high luminescence intensity and high spectral purity. These hits were then experimentally refined using a high-throughput nanocrystal synthesis robot and a laser-scanning plate reader. Finally, we used single-nanoparticle upconversion microscopy to investigate the effects of surfaces on the upconverted emission of a size series of nanocrystals. This combined theoretical and experimental approach allowed us to predict and experimentally verify new compositions of upconverting nanocrystals that are brighter and more spectrally pure than previous nanoparticles, enabling the imaging of single upconverting nanoparticles as small as fluorescent proteins.

9161-6, Session 2

Novel materials and nanostructures for near-field engineering *(Invited Paper)*

Luca Dal Negro, Boston Univ. (United States)

The development of novel Si-compatible materials and nanostructures that support optical resonances with strongly enhanced local fields enables the control of propagating and non-propagating electromagnetic fields for the engineering of plasmonics and metamaterials components that can be easily integrated within the current CMOS technology. In this talk, I will present our results on the materials development and nanofabrication of active nanostructures based on low-loss conductive oxides with tunable negative permittivity in the near-infrared spectral range. In particular, I will discuss our recent work on rare-earth doping of conductive oxide nanostructures and metamaterials that boost polaritonic responses across the 1-2 µm spectral range on a Si compatible platform.

In this talk, I will present our results on the materials development and nanofabrication of light emitting and strongly nonlinear active nanostructures based on low-loss conductive oxides with tunable negative permittivity in the near-infrared spectral range. Surface-enhanced infrared spectroscopy using metal oxide plasmonic nanoantennas

Otto L. Muskens, Yudong Wang, Martina Abb, Cornelis H. de Groot, Univ. of Southampton (United Kingdom)

Metal oxides are technologically important materials for use in catalysis, electronics, and sensors. We demonstrate strong surface enhanced infrared spectroscopy (SEIRS) using metal oxide plasmonic nanoantennas. Using a deposition process compatible with e-beam lithography and lift-off, we have fabricated of indium-tin oxide antennas of varying length ranging between 0.2 - 4.0 micrometers [1]. FTIR spectroscopy of antenna arrays was used to demonstrate effective the wavelength scaling and a fourfold reduction of the plasmon wavelength, enabling ultracompact antennas and extremely subwavelength metamaterials. The SEIRS signal of a 50-nm thin film of PMMA spincoated over the antennas was used to demonstrate the near-field enhancement associated with the plasmonic antennas [1]. The response of the ITO arrays was of comparable strength as equivalent arrays of gold antennas. We subsequently demonstrate extremely high density integration of ITO and gold antennas with spacings as small as 100nm, entering the range of plasmonic near field coupling. The plasmonic functionality of doped metal oxides complements existing applications of these versatile materials and may open up new applications in mid-IR spectroscopy and sensing.

9161-8, Session 2

Facile synthesis of Cu_2S nanoarchitectures in application of surface enhanced Raman scattering

Shih-Yu Fu, Hao-Syuan Jhang, Yu-Kuei Hsu, National Dong Hwa Univ. (Taiwan); Yan-Gu Lin, National Synchrotron Radiation Research Ctr. (Taiwan)

Surface plasmon resonance (SPR) is one of the main mechanisms of surface Raman enhance scattering (SERS) and it will depend on the morphology and free carrier density of substrates, in many of discussions have been proved. Recently, the semiconductor copper(I) sulphide (Cu_2S), the natural p-type semiconductor, exhibits remarkable SPR in the near-infrared region and can be regards as best candidate for active SERS substrates. In this report, the successive ionic layer absorbance and reaction (SILAR) process will be used to synthesis Cu_2S nanotubes from ZnO nanorods as template deposited by electrochemical reaction. To further manipulate the different carrier densities of Cu_2S nanotubes, the adjustment of Cu vacancy in Cu_2S can be accomplished by exposure under oxygen ambiance. Taking 4-aminothiophenol (4-ATP) as probe molecule to measure the SERS performance by Cu_2S nanotubes made in this fabrication and also examines the effect on SERS by changing Cu vacancy under an exciting wavelength of 632.8 nm and light power of 15 mW. In fact, the modulation of Cu vacancy will positively correlate to the SPR frequencies and so could get the best enhancement factor under the limited condition of exciting source. Therefore, our results could provide a new opportunity to use SERS to explore the molecule-semiconductor interaction, a fundamental but essential question for designing novel devices.

9161-9, Session 2

Plasmon-enhanced optical properties of Au/TiO_2 core-shell nanowires studied by finite difference time domain calculation

Jubok Lee, Sun-Hee Lee, Min Su Kim, Hyungjung Shin, Jeongyong Kim, Sungkyunkwan Univ. (Korea, Republic of)

Recently various kinds of TiO_2 nanostructures hybridized with metal nanomaterials have been designed and shown to increase the power conversion efficiency and photocatalytic reaction by the enhancement of charge separation and broadening the spectral response into the visible wavelength regime. In this study, we fabricated the Au/TiO_2 core shell nanowires (NWs) and investigated optical properties of them such a photoluminescence (PL), Raman, and dark field scattering spectra in single NW level using high resolution laser confocal microscope. The results showed that PL of hybrid structures were greatly quenched due to the efficient charge separation occurring on the Au interface of hybrid structures. On the contrary, the scattering efficiency increased up to 3 times over plain TiO_2 nanowires by having hybrid structures with Au nano core and/or Au nanoparticles. The results were consistent with FDTD calculation that showed the increase of light scattering and field intensity on Au/TiO_2 core shell NW in the total magnitude and the spectral coverage. The actual photocatalytic efficiency of Au/TiO_2 NW was also measured to be superior to that of the plain TiO_2 NWs

9161-10, Session 2

Self-assembled nanoplasmonic structures with symmetry-breaking

Sui Yang, Xiaobo Yin, Boubacar Kante, Peng Zhang, Jia Zhu, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

The ability to light-matter interactions has been the driving force for the recent advancement of plasmonic materials whose subwavelength spatial structure and symmetry design enables unprecedented optical properties with possible applications ranging from sensing to imaging and information technology. Plasmonic structures with designed symmetries that can be realized by using traditional top-down approaches such as e-beam lithography only lead to strongly anisotropic and small-scale materials. In contrast, bottom-up approaches based self-assembly may offer advantages of large scalability and cost effectiveness, but often result in simple structures with high degree of symmetry because of the fact that complex and symmetry-breaking structures are often not thermodynamically favorable. A key challenge is how to overcome this limitation to build nanoplasmonic structures with broken symmetries that are essential to materials properties. Here we propose and experimentally demonstrate a novel plasmon guided self-assembly route to scalable synthesize this new class of symmetry-breaking nanoplasmonic strucutres with selectable optical magnetism. Through the study of symmetric effects of nanocomposites together with judicious nanoscale chemical binding control, we achieved symmetry breaking assemblies of two side-by-side gold nanorod dimer with a longitudinal offset, which defines the degree of symmetry-breaking that gives rise of intriguing optical modes. More importantly, we use structure-dependent plasmonic properties of gold nanodimers as their own structure guide to reshape the magnitude of symmetry interplays and structure homogeneity that led to realization of desired magnetic resonances. In conclusion, our research provides a novel optically selective self-assembly route to engineer symmetry-breaking nanophotonic materials with unique functionalities.

9161-11, Session 3

Hybrid materials: a bottom-up approach for nanotechnology applications *(Invited Paper)*

Giovanna Brusatin, Univ. degli Studi di Padova (Italy)

Engineered organic-inorganic hybrid materials, HyMat, offer new opportunities for the easy, fast and cheap development of optical devices. Integration of inorganic networks, organic functional groups and optically active molecules or nanoparticles allows to obtain combinations of properties and structures otherwise impossible with traditional material.

In particular, a simple and highly versatile synthesis platform is presented enabling preparation of HyMat, built up by a bottom-up sol-gel approach at low process temperatures. A few types of key building blocks constitute the way for accessing HyMat and make up their formulation, providing a means to synthetize innovative materials enabling to get:

- Optical active micro and nanostructures
- Miniaturized sensors for analytes in gaseous or liquid media
- Direct patternability with a range of lithographic techniques
- Variable inorganic and organic compositions and controlled porosity

Examples of micro and nano structures based on these spin-on materials with ceramic (i.e. GeO_2, TiO_2, ZrO_2, HfO_2, Al_2O_3) or silica based hybrid compositions will be presented for different applications including plasmonic or fluorescent sensors, high refractive index, etching masks, bio functionalization.

9161-12, Session 3

Enhanced stimulated emission in ZnO thin films using microdisk top-down structuring

Komla Nomenyo, Univ. de Technologie Troyes (France); Abde-Sattar Gadallah, Univ. de Technologie de Troyes (France) and Cairo Univ. (Egypt); Sergei Kostcheev, Univ. de Technologie Troyes (France); Dave J. Rogers, Nanovation (France); Gilles Lerondel, Univ. de Technologie Troyes (France)

Despite the absence of an effective p-ZnO junction and although ultraviolet lasers and LEDs based on GaN are readily available, ZnO is still interesting due to its large exciton binding energy, efficient radiative recombination and simpler crystal-growth processes which are significant for lower costs ZnO-based devices. On the other hand, ZnO structuring in order to realize photonic structures, has proved to be a critical issue that is faced up by the strong mechanical properties of ZnO, making of lithography one of the main challenges to confront for the fabrication of efficient ZnO lasers and LEDs.

In this work, ZnO microdisks were fabricated in planar thin film using a top-down approach combining electron beam lithography and reactive ion etching. These microdisk structured thin film exhibit a stimulated surface emission between 7 to 3 times higher than the reference film depending on the excitation power density. Narrowing, reduction in lasing threshold and blue shifting of the emission wavelength were observed along with the enhancement in the emitted intensity. Results clearly demonstrate that the light enhancement comes from the increase of the thin film internal quantum efficiency and the amplification of the stimulated emission. An analysis in terms of waveguiding is presented in order to explain these effects. These results are of great interest demonstrating that significant gain can be obtained using microstructured thin film which remains easier to fabricate than nanostructured ones.

9161-13, Session 3

Synthesis of high purity metal oxide nanoparticles for optical applications

Colin Baker, Woohong R. Kim, E. Joseph Friebele, Guillermo Villalobos, Jesse Frantz, L. Brandon Shaw, Bryan Sadowski, Jas S. Sanghera, U.S. Naval Research Lab. (United States)

In this paper we present our recent research results in synthesizing metal oxide nanoparticles for use as laser gain media and transparent ceramic windows via two separate techniques, co-precipitation and flame spray pyrolysis. The synthesis of high purity rare earth doped sesquioxide nanoparticles by a co-precipitation technique was performed by using highly purified nitrates of corresponding oxides. The nanoparticles were pressed into ceramic discs that exhibited superior optical properties. These transparent ceramics typically exhibited optical transmission approaching the theoretical limit and showed very high optical-to-optical lasing slope efficiency.

We have also synthesized sexquioxide nanoparticles using a Flame Spray Pyrolysis (FSP) technique. We present data demonstrating that the FSP system can be used to control the material phase of the nanoparticles, leading to the synthesis of a metastable phase of sesquioxide which has never been reported using this technique. Significantly, the presence of the metastable phase enables the ceramic powders to be hot pressed at lower temperatures resulting in excellent optical quality transparent windows with very fine grain sizes.

Finally, we present our research in the synthesis of rare earth doped Boehmite nanoparticles by Co-precipitation. The nanoparticles structure is chemically engineered so that the rare-earth ion is encased in a cage of Boehmite to prevent ion-ion proximity and energy transfer and they serve as precursors for fabricating high power fiber lasers. The nanoparticles are synthesized using precise pH control and ligand stabilization, allowing them to be doped into optical fiber preforms. The preforms have been drawn into fibers exhibiting long lifetimes and high laser efficiencies.

9161-14, Session 3

Ultrafast dynamics of coherent exciton-polaritons in ZnO/ZnMgO multiple quantum wells

Minfeng Chen, Academia Sinica (Taiwan); Yia-Chung Chang, Academia Sinica (Taiwan) and National Chiao Tung Univ. (Taiwan); Ja-Hon Lin, Yi-Kai Shen, Hsuan-Ching Lin, National Taipei Univ. of Technology (Taiwan); Wei-Ren Liu, Chia-Hung Hsu, National Synchrotron Radiation Research Ctr. (Taiwan); Chin-Chia Kuo, Wen-Feng Hsieh, National Chiao Tung Univ. (Taiwan)

We found striking time-dependent behavior of the carrier-induced change in transmission coefficient ($\Delta T/T$) through ZnO/ZnMgO multiple quantum wells (QWs) observed by femto-second pump-and-probe experiment. Instead of single (electron-hole plasma) EHP excitation (which decays exponentially) for bulk ZnO material as reported in the literature, multiple transient peaks of $\Delta T/T$ were observed and their behavior can be explained by the dynamic behavior of coherent exciton-polaritions in ZnMgO and their decay into electro-hole pairs in ZnO QWs.

A theoretical framework to investigate the ultrafast dynamics of coherent exciton-polaritons in ZnO/ZnMgO is developed. The Maxwell's equations coupled with polarization fields associated with excitons are used to model the dynamics of coherent exciton-polaritons. The following mechanism is proposed: 1) the first steep rise in (transient differential transmittance) TDT is attributed to the occupation of photo-excited EHPs in ZnO QWs that quenches the absorption of the probe beam by the (band filling) BF effect. After elapsing of the pump pulse, the non-radiative decay of EHPs weakens the BF effect that causes the exponential decay. The revivals of TDT evidence refueling of EHPs by coherent exciton-polaritons stored in barrier regions. The barrier polaritons could scatter into well EHPs while they tunnel through the ZnO QWs that were then observed by the probe pulse.

Based on the finite-difference time-domain modeling with physical phenomenological parameters, the subtle underlying physics is captured and we obtained good explanation of the experimental results, which illustrates a mechanism to monitor the dynamic behavior ofexciton-polaritons in ZnMgO.

9161-15, Session 3

Effect of annealing on the structural and optical properties of ZnO and AZO films prepared by sol-gel spin coating method

Sanjeev Kumar, Anil Kumar, Univ. of Delhi South Campus (India); Poonam Shokeen, Department of Electronic Science, University of Delhi South Campus, New Delhi - 110021 (India); Udaibir Singh, Univ. of Delhi (India); Fouran Singh, Inter Univ. Accelerator Ctr. (India); Avinashi Kapoor, Univ. of Delhi (India)

Zinc oxide (ZnO) and aluminum doped ZnO (AZO) thin films were fabricated on glass substrate by low cost sol–gel spin coating technique. ZnO thin films have the potential in the emerging thin-film technologies, which can be employed in thin-film solar cells, transistors, sensors and other optoelectronic devices. The influences of annealing temperature on the structural and optical properties of ZnO and AZO thin films were investigated. The structural properties of the ZnO films such as surface morphology and crystallinity were determined using atomic force microscopy (AFM) and X-ray diffraction (XRD), respectively. Our result shows an increase in the grain size and RMS surface roughness of the films with increasing annealing temperature from 200°C to 400°C. The optical properties of the ZnO films were characterized by the ultraviolet–visible (UV–vis) spectroscopy and Tauc method was adopted to explore the optical band gap. We get the optical band gap of ZnO films ranges from 3.26±0.01 eV to 3.34±0.01 eV and AZO films ranges from 3.28±0.01 eV to 3.32±0.01 eV. These values were very close to the band gap of intrinsic ZnO which is 3.37 eV. The reduction of the optical band gap with increasing annealing temperature can be due to the improved crystallinity and decreased defects of the films with higher annealing temperature. ZnO thin film with optical transmittance more than 90% was obtained with annealing temperature of 400°C. This could be the optimum annealing temperature for ZnO and AZO thin films to be employed in transparent conductive oxide (TCO) applications on glass and plastic substrates

9161-16, Session 4

Monitoring interfacial charge dynamics via FSRS *(Invited Paper)*

Adam M. Schwartzberg, Lawrence Berkeley National Lab. (United States); David Hoffman, Univ. of California, Berkeley (United States); Sibel Liblibici, The Molecular Foundry (United States); Richard A. Mathies, Univ. of California, Berkeley (United States)

Most of the efficiency losses in organic photovoltaic (OPV) systems result from charge carrier recombination which pre- vents charges from being transported to and collected by the electrodes. Recombination in these complex mesoscopic systems is poorly understood, thus making the engineering of materials with low recombination rates, and therefore high efficiency, very difficult. Additionally, OPV systems are distinct from traditional semiconductor PVs because of their molecular nature; in these systems molecular motions become extremely important

This project is aimed at gaining a more complete understanding of the vibrational motions that facilitate charge separation and transport within bulk heterojunction OPVs as well as the structural responses that occur during exciton migration, charge separation and charge transport. This knowledge will allow for intelligent design of chemical (i.e. structural) modifications of existing OPV materials, or synthesis of new ones, that will have lower charge carrier recombination rates leading to higher efficiency solar energy devices.

Highly crystalline urchin-like ordered arrays of ultra-thin zinc oxide nanowires: towards solar cell fabrication

Anisha Gokarna, Romain Parize, Hind Kadiri, Komla Nomenyo, Univ. de Technologie Troyes (France); Gilles Patriarche, Lab. de Photonique et de Nanostructures (France); Patrice Miska, Univ. of Lorraine (France); Gurpreet S. Selopal, Riccardo Milan, Isabella Concina, Alberto Vomiero, Univ. degli Studi di Brescia (Italy); Gilles Lerondel, Univ. de Technologie Troyes (France)

Well-ordered periodic arrangement of nanostructures with controllable enhanced surface morphology and advanced Light-matter Interaction control i.e. absorption and emission enhancement has recently become extremely relevant in terms of application. Flower or sea-urchin like ZnO nanostructures, grown by low temperature chemical processes on periodic 2D or 3D templates are one of the best candidates. The aim of this work is to demonstrate selective, patterned growth of ZnO using low cost, easy-to-fabricate templates by the bottom-up approach. This approach combines the fabrication of self-organized templates of functionalized polystyrene (PS) beads or silica beads followed by the growth of ZnO using low temperature chemical bath deposition method. ZnO nucleation layer is deposited on the PS beads prior to the synthesis of ZnO NWs. Formation of highly crystalline, luminescent ultra narrow NWs with diameter lower than 10 nm are observed to be formed around the PS beads leading to a new kind of urchin-like ZnO. The structural and optical properties of these urchin-like structures will be presented. These urchin-like ZnO structures have been successfully integrated as photoanodes in dye sensitized solar cells. Preliminary results will be discussed.

9161-18, Session 4

Nanocavity enhanced absorption of ultra-thin films

Haomin Song, Univ. at Buffalo (United States); Luqing Guo, Zhejun Liu, Fudan Univ. (China); Kai Liu, Xie Zeng, Dengxin Ji, Nan Zhang, Univ. at Buffalo (United States); Hai-feng Hu, Northeastern Univ. (China); Suhua Jiang, Fudan Univ. (China); Qiaoqiang Gan, Univ. at Buffalo (United States)

In most thin-film energy harvesting/conversion applications, there is a long-existing trade-off between optical absorption and thickness of semiconductor materials. For instance, ultrathin-film photovoltaic devices and photocatalysis platforms may lead to the enhanced carrier extraction/transportation but insufficient light absorption. Particularly, when the absorptive materials are scaled down to atomically thin dimensions, their light-matter interactions are inherently weak. Consequently, absorption enhancement strategies will introduce revolutionary advances to these ultra-thin-film materials/devices. Here we propose a design by placing a predesigned lossless spacer layer between an ultra-thin absorptive material and a metal reflector to realize

spectrally tunable resonances absorbed in the top ultra-thin layer. As the incident light is coupled into this structure, the reflected components will cancel the incident light at the top surface, resulting in a destructive interference absorber. Since the bottom metal reflector does not absorb much light, most energy will dissipate in the top ultra-thin layer resulting in the significant absorption enhancement. By tuning the thickness of the spacer layer, the destructive interference resonance is spectrally tunable for ultra-thin absorptive materials down to atomic thickness, and therefore overcoming the conflict between the optical absorption and film thickness. This principle exploits the wave property of light and will pave the way towards the spectrally tunable absorption enhancement of ultra-thin materials.

9161-19, Session 4

Aluminum and copper plasmonics for enhancing internal quantum efficiency of core-shell and core-multishell nanowire photoelectrodes

Sarath Ramadurgam, Chen Yang, Purdue Univ. (United States)

One of the most critical challenges for achieving solar-to-hydrogen (STH) efficiency greater than 10% (100 W/m2), especially in metal oxide photoelectrodes, is the poor internal quantum efficiency (IQE) arising from high, bulk and surface, recombination and insufficient light absorption. For instance, the theoretical STH efficiency of hematite photoelectrodes is about 15.5%, but the best studies employing various strategies such as nanowire geometry, doping, co-catalyst, surface state passivation, ‘dual absorber’ systems and plasmonic nanostructures demonstrated limited efficiencies between 5-6%. Plasmonics for light trapping particularly has emerged as a promising strategy to address this challenge. However, most designs are photocatalyst specific and employ precious metals, making large scale applications infeasible.

To address these challenges, we present metal-photocatalyst core-shell and semiconductor-metal-photocatalyst core-multishell nanowires as a novel class of multi-functional plasmonic photoelectrodes. Specifically, we explore aluminum and copper as plasmonic materials to ensure scalability of the photoelectrodes. We theoretically demonstrate that the size dependant localized plasmon resonances in such nanowires can be tuned to enhance absorption within ultrathin photocatalyst layers irrespective of the photocatalyst material choice. Such enhanced absorption ensures the photo-charges are preferentially generated very close to the photocatalyst-electrolyte interface and can effectively drive the reaction forward, thereby improving the IQE. We show that the absorption predicted in core-multishell nanowires employing aluminum come remarkably close to that of silver based core-multishell nanowires. Finally, we validate the generality of this approach by demonstrating absorption enhancement in nanowires with, and not limited to, Fe_2O_3, Cu_2O, CoO, WS_2 and MoS_2 as the photocatalyst.

9161-20, Session 4

Mixed ZnO nanoparticles as buffer layers of organic solar cells

Young-Kuk Kim, Kyu-Chae Choi, Youn-Kyung Baek, Eun-Jin Lee, Korea Institute of Materials Science (Korea, Republic of)

We demonstrate that mixture of nanoparticles of ZnO having different shapes can improve the photovoltaic performance of the inverted organic solar cells (IOSC) having blend of poly(3-hexylthiophene) and Phenyl-C61-butyric acid methyl ester as their active layer. In this study, we have synthesized ZnO spherical nanodots (NDs) and nanorods (NRs) from zinc acetate dihydrate (ZnOAc) with addition of strong bases dissolved in methanol and Transparent colloidal solutions having uniformly dispersed ZnO NDs or NRs were prepared by controlling solvent composition. Application of ZnO NRs as electron transporting layers for IOSC improved its short circuit current density (Jsc) compared with ZnO NDs-based buffer layers resulted from modification of energy barriers between electrode and active layers. However, insufficient surface coverage of ZnO NRs owing to agglomeration lowered fill factor and open circuit voltage (Voc) of the solar cell. Then, mixed buffer layers containing both ZnO NDs and ZnO NRs were applied and resulted in highly enhanced PCEs up to 4.12% due to improvement in Jsc by ZnO NRs and conservation of good surface coverage by ZnO NDs.

Impact of hydrogen bonding in solvent for dispersion of ZnO nanocrystals on photovoltaic properties of organic solar cells

Young-Kuk Kim, Kyu-Chae Choi, Youn-Kyung Baek, Eun-Jin Lee, Korea Institute of Materials Science (Korea, Republic of)

We demonstrate that the morphology of ZnO buffer layers for the inverted organic solar cells (IOSC) was improved by controlling the molecular interaction in solvents to disperse of ZnO nanoparticles (NPs). Dispersion of ZnO NPs in non-polar solvent usually resulted in turbid or semi-transparent solution. In this study, uniform dispersion of ZnO NPs were achieved through applying mixed solvents composed of both non-polar and polar solvents without assistance of organic surfactant. From the analysis based on Hansen solubility parameter theory, this improvement was mainly associated with hydrogen bonding interactions between the two components of solvents. Smooth ZnO buffer layers were deposited using the colloidal solution based on the binary solvent mixture and the photovoltaic performance of the IOSC was highly improved by optimizing solvent mixtures.

Highly transparent and conducting graphene embedded ZnO films with enhanced photoluminescence fabricated by aerosol synthesis

Sung Jin An, Kumoh National Institute of Technology (Korea, Republic of); Jong-Young Kim, Korea Institute of Ceramic Engineering and Technology (Korea, Republic of)

Recently, mechanically exfoliated single-layer graphene sheets, transferred on top of ZnO film without chemical bonding, was reported to enhance ultraviolet photoluminescence (PL) of the ZnO due to a resonant excitation of a graphene plasmon. Low resistance and transparency are also crucial for improving the current injection and light extraction efficiency for the realization of solid-state lighting using LEDs. For these reasons, in the present work, we attempted to fabricate a transparent, conducting, and luminescent ZnO/graphene hybrid thin film using surface plasmon (SP) mediated photoluminescence.

For the hybridization of ZnO with graphene, an aerosol synthetic method: ultrasonic-assisted spray pyrolysis (UASP), was applied. One of the advantages of UASP is that multiple components can be incorporated into an aerosol droplet to serve different purposes. By adding additional components to the starting graphene precursor, inorganic particles wrapped by graphene nanoplatelets can be obtained. This aerosol synthetic route allows us to have a continuous mode of operation and readily scalable synthesis of large-area graphene-embedded thin film, or nano-composite particles.

The resulting ZnO/graphene thin film exhibits enhanced PL approximately three times greater than bare ZnO film. We have also shown that such PL enhancement can be achieved in a quasi-core-shell-type ZnO/graphene composite with reduced graphene oxide exhibits a larger PL enhancement than conventional reduced graphene oxide. Moreover, high optical transmittance (>80%) and increased electrical conductivity (>2 orders of magnitude) of the ZnO/graphene composite films show that the present composites are promising as transparent, conducting, and luminescent materials for use in optoelectronic devices.

Coatable chromonic liquid crystal polarizer

Yu-Jin Choi, Dae-Yoon Kim, Pureun Im, Won-Jin Yoon, Ji-Tae Kim, Hui-Su Kim, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

A chromonic liquid crystal (CLC) polarizer was fabricated from Sunset Yellow FCF (H-SY) Macroscopic molecular orientation was achieved by bar-coating the self-assembled lyotropic CLCs and the oriented structure was frozen by the subsequent photo-polymerizing processes. Their molecular packing structures and optical behaviors were further investigated using the combined techniques of microscopy, scattering and spectroscopy. The polymer-stabilized H-SY films showed good mechanical and chemical stabilities without sacrificing a high polarizability. Therefore it can allow us to develop the smart optical and electrical devices. This work was mainly supported by the Human Resource Training Project for Regional Innovation, Converging Research Center Program, Basic Science Research Program (2013R1A1A2007238), Global Ph.D Fellowship Program (2013H1A2A11033907), and BK21 PLUS Program, Korea.

Fullerene patterns in the elastically anisotropic cholesteric liquid crystals

Won-Jin Yoon, Pureun Im, Dong-Gue Kang, Yu-Jin Choi, Ji-Tae Kim, Hui-Su Kim, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

Fullerene-based reactive molecule (C60RM) was newly designed and synthesized. Its chemical structure and phase behavior were investigated with spectroscopic, scattering and microscopic techniques. In addition, the self-assembled striped C60RM pattern was successfully fabricated via the one-dimensional pattern-forming state of an elastically anisotropic cholesteric LC medium. This work was mainly supported by the Human Resource Training Project for Regional Innovation, Converging Research Center Program (2013K000404), Basic Science Research Program (2013R1A1A2007238), and BK21 PLUS Program, Korea.

9161-37, Session PWed

Surface-induced phase transition behaviors of the rod-disc molecule

Won-Jin Yoon, Dae-Yoon Kim, Yu-Jin Choi, Sang-A Lee, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

Rod-disc liquid crystal (LC) molecule (RD12) was newly designed and synthesized for characterizing and understanding of surface-induced phase transition behaviors of RD12 by changing the surface chemistry and the physical interactions. Upon varying the width of the LC cells and changing their surface chemical and physical states, the phase transition behavior of RD12 was rapidly changed. The nematic phase of RD12 in the LC cell with a low cell gap and polyimide rubbed surface could be preserved and the crystallization of RD12 was thoroughly controlled. It was concluded on the systematic experimental investigations that the glassy nematic phase was formed because of the fact that the surface anchoring force is bigger than the crystallization force. This work was mainly supported by the Converging Research Center Program (2013K000404), Global Ph.D Fellowship program (2013H1A2A1033907), and BK21 PLUS Program, Korea.

Reversible actuation of an azobenzene-based photochromic liquid crystalline polymer

Yu-Jin Choi, Dae-Yoon Kim, Won-Jin Yoon, Sang-A Lee, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

We have newly synthesized a novel photochromic polymer (PLCP) via the acrylic diene metathesis polymerization. From the combined the techniques of DSC, POM and 2D WAXD, it was realized that PLCP formed a nematic (N) LC ordered phase containing the cynclinically tilted SmC-type cybotactic clusters, in which molecular packing structure is related to the head-to-side connected PLCP chemical structure. Additionally, we demonstrated the rewritable micro-patterned PLCP film by using light and/or heat. Due to the wireless remote controllability of reversible actuating and patterning behaviors of PLCP, it can be applied as a key material in opto-electronic and bio-mimetic devices. This work was mainly supported by the Human Resource Training Project for Regional Innovation, Basic Science Research Program (2013R1A1A2007238), Global Ph.D Fellowship Program (2013H1A2A11033907), and BK21 PLUS Program, Korea.

Synthesis and characterization of highly luminescent CuInS2/ZnS quantum dots for near-infrared bio-imaging

Hyung Seok Choi, Jae Chul Park, Youngsun Kim, Mi Hwa Oh, Duk Young Jeon, Yoon Sung Nam, KAIST (Korea, Republic of)

Near-infrared (NIR) luminescent quantum dots (QDs) have been intensively investigated for in vivo bio-imaging applications. In particular, CuInS2/ZnS core-shell QDs (CIS/ZnS QDs) have received much attention for bio-imaging because of their high absorption coefficient, photostability, possible emission in the NIR spectra, and a relatively low level of cytotoxicity compared to cadmium-based QDs. In this study, we report a new synthesis method to prepare highly luminescent, NIR-emitting CIS/ZnS QDs with a diameter of about 3 nm at various emission spectra from visible to NIR region (570-730 nm). A simple heating-up method is employed using 1-dodecanethiol as a multi-functional agent, i.e., as a reaction medium, a sulfur source, and a capping ligand. In addition, by utilizing off-stoichiometry effects, the emission spectrum is controlled as the Cu/In ratio of the CIS core changes from 1/4 to 2/1. The synthesized CIS/ZnS QDs with a Cu/In ratio of 1.8 show a high photoluminescence quantum yield (PLQY) up to about 60 % at a maximum emission wavelength of 726 nm. The CIS/ZnS QDs are encapsulated within poly(methyl methacrylate) (PMMA) microspheres and dispersed in an aqueous solution. In vivo feasibility tests for deep-tissue bio-imaging applications are performed by intramuscular injection of the QD-loaded PMMA microspheres into a mouse model. Our results demonstrate that highly luminescent, NIR-emitting CIS/ZnS QDs are very attractive materials for deep tissue bio-imaging applications. Further investigation on size control up to the excitonic Bohr diameter (about 8.2 nm) and characterization of defect structures is now under way to increase PLQY in the NIR window.

Luminescence studies on solid and nanostructured SiO_2:Eu^{3+} spheres obtained by sol-gel route

Jorge A. Garcia-Macedo, Univ. Nacional Autónoma de México (Mexico); Estrella Terán-Hinojosa, Univ. Nacional Autónoma de Mexico (Mexico); Afredo Franco, Univ. Tecnológica Fidel Velázquez (Mexico)

Rare earths in confined systems are studied because their possible imaging applications. In this work we studied the optical properties of Eu3+ inside nanoporous spheres. Their properties were compared with these from europium in solid SiO2 spheres prepared by sol-gel method. Nanoporus channels were produced by using a surfactant. The last one was removed by chemical procedure. Then, europium was incorporated into the channels. XRD reveals the hexagonal structure of the pores. That was confirmed by HRTEM that shows the channels, clearly. N2 adsorption- desorption isotherm Type IV, characteristic of mesoporous materials, was obtained by BET. The I(5D0→7F2)/I(5D0→7F1) asymmetry ratio from Eu3+ transitions was obtained by photoluminescence. It had a value of 2.65 in the solid spheres and 1.65 in the nanoporous ones. That means Eu3+ is in an asymmetric site in both systems, and asymmetry is bigger in the solid spheres. Because the differences, we can use this parameter to distinguish between both systems, easily. Photoluminescence lifetimes were obtained for the 5D0→7F2 emission. It was shorter in the solid spheres than in the nanoporous ones, confirming there is a more asymmetric site for the rare earth in the first case. IR spectra shows Eu3+ is not incorporated as part of the SiO2 network.

Type-I InAs quantum dots covered by GaAsSb strain reducing layer

Martin Pokorný, Martin Kozák, Frantisek Trojánek, Charles Univ. in Prague (Czech Republic); Jirí Pangrác, Alice Hospodková, Institute of Physics of the ASCR, v.v.i. (Czech Republic)

This work is focused on examining ultrafast photoluminescent properties of InAs quantum dots (QDs) grown on GaAs substrate and covered by GaAs1-xSbx strain reducing capping layer (SRL). The samples were prepared by Stranski-Krastanow growth method. The aim is to understand the processes occurring inside the QDs and wetting layer (WL) and how the SRL influences the energy levels inside the QDs. It was already proven that the SRL of this composition can decrease energies of transitions inside these QDs to the IR range, which makes these structures promising candidate for devices emitting near infrared radiation. It is possible to shift the luminescence wavelength towards 1.3 and even 1.55 µm, which are widely used in telecommunications.

Using upconversion method we measured luminescence dynamics of two samples with different concentration of Sb in the SRL with sub-picosecond time resolution. We investigated the effect of temperature, as well as the intensity and wavelength of the excitation pulse. We also compared the properties of the samples after excitation by λ=760 nm pulse and 850 nm pulse – the former one is energetically above the GaAs substrate band gap; in the second case we excited only the QDs and the WL. We consequently derived recombination and relaxation processes occurring inside InAs QDs and also proved that the transport of charge carriers from the substrate and from the WL into the QDs is efficient.

Three-dimensional branched nanowire heterostructures as efficient light-extraction layer in light-emitting diodes

Jeong Min Baik, Joonmo Park, Byeong-Uk Ye, Ulsan National Institute of Science and Technology (Korea, Republic of)

We report a facile method to fabricate three-dimensional branched ZnO/MgO nanowire heterostructures and their application as the efficient light-extraction layer in light-emitting diodes. The branched MgO nanowires are produced on the hydrothermally-grown ZnO nanowires with a small tapering angle towards the tip (~ 6 o), by the oblique angle flux incidence of MgO. The structural evolution during the growth verified the formation of the MgO nanoscale islands with strong (111) preferred orientation on very thin (5~7 nm) MgO (110) layer. The MgO nanobranches, are then grown on the islands, are polycrystalline consisting of many grains oriented in specific directions of <200> and <220>, supported by the nucleation theory. The LEDs with the branched ZnO/MgO nanowire arrays show a remarkable enhancement in the light output power by 21 % compared with that of LEDs with pristine ZnO nanowires. Theoretical calculations using a finite-difference time-domain method reveal that the nanostructure is very effective in breaking the wave-guiding mode inside the ZnO nanowires, extracting more light especially in radial direction through the MgO nanobranches.

Optical attenuation of plasmonic Au-PDMS nanocomposite thin-film devices

Gregory T. Forcherio, Donald K. Roper, Univ. of Arkansas (United States)

Compact description of far-field optical interactions between plasmonic nanocomposites and adjacent media permits facile a priori design of devices for light manipulation. Limited tractability of nanoscale descriptions at device-architectures previously limited development of plasmonic devices. Optical interactions between nanocomposites and adjacent optical elements, a simple device, are describable using infinite linear algebraic sums. Influence of plasmonic absorption and non-linear phenomena on device performance are distinguishable from measured transmission, reflection, and attenuation (resonant and non-resonant losses) of nanocomposites featuring nanoparticles in multiple dimensions. Two- and three-dimensional distributions of gold nanoparticles supported by silica and poly(dimethylsiloxane) substrates, respectively, are considered. A unique ternary map of transmission, reflection, and attenuation correlates far-field optical behavior to nanoparticle density and opacity of the adjacent element. Intuitive, visual specification of nanoparticle density and adjacent media needed to obtain a desired optical behavior is possible using the ternary map. The compact model and ternary map provide useful tools for the design and integration of plasmonic nanocomposites into photonic devices for sustainable energy and biomedical applications.

Optical properties of solutions and thin films of silver and gold nanoparticles with hyaluronic acid

Vasyl J. Syrvatka, Yurij I. Slyvchuk, Ivan I. Gevkan, Ivan I. Rozgoni, Iryna O. Matyukha, Oksana V. Shtapenko, Institute of Animal Biology NAAS (Ukraine)

Silver and gold nanoparticles have recognized importance in laboratory settings for colorimetric detection of proteins and DNA because of their unique optical, electrical and photothermal properties. Currently such nanoparticles have wide applications in diagnostic and therapeutic area. The main purpose of the study was to investigate optical properties of solutions and thin films of silver and gold nanoparticles with hyaluronic acid and they change under influence of different chemicals and modification procedure. We explored physicochemical properties of nanoparticles with size from 1 to 100 nm with prospect of their use as signal enhancers, optical sensors and biomarkers. For this purpose we synthesized silver and gold nanoparticles with size from 1 to 100 nm. Hyaluronic acid was used as composite agent. Thin films of nanoparticles were done by evaporation method. Ultraviolet-visible spectroscopy we used for study of optical and physical properties of silver and gold nanoparticles at all stages of the experiment. All structural changes of nanoparticles under influence of different chemicals and modification procedure were controlled by scanning and transmission

electron microscopy. The results showed that solutions and think films of silver and gold nanoparticles with hyaluronan have strong optical properties. Furthermore different chemicals lead to structural changes of nanoparticles and modification of their optical properties. Therefore, the solutions and thin films of silver and gold nanoparticles with hyaluronan have distinctive optical and physicochemical properties and can be applied as signal enhancers, optical sensors and biomarkers.

Fabrication of chromonic nanofiber embedding self-assembled discotic sunset-yellow FCF dyes

Dong-Gue Kang, Dae-Yoon Kim, Pureun Im, Won-Jin Yoon, Yu-Jin Choi, Ji-Tae Kim, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

Chromonic nanofibers with the self-assembled Sunset-Yellow FCF nanocolumns were fabricated by electrospinning method. Based on the thermal, microscopic and scattering experiments, it was verified that Sunset-Yellow FCF molecules formed a glassy columnar nematic (N) phase in the PVP/H-SSY nanofiber. When the PVP/H-SSY nanofiber was annealed above the Tg of PVP, the H-SSY nanocolumns further self-organized into three-dimensional ordered crystals. The uniaxially oriented nanofiber mats embedding assembled nanocolumns may open the new doors for the practical applications of the spun fibers in optical, electronic and optoelectronic devices. This work was mainly supported by the Human Resource Training Project for Regional Innovation, Basic science Research Program (2013R1A1A2007238), Global Ph.D Fellowship Program (2013H1A2A1033907), and BK21 PLUS Program, Korea.

Synthesis and characterization of a tetrathiafulvalene-based polymer

Pureun Im, Dong-Gue Kang, Ji-Tae Kim, Min-Wook Park, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

A photovoltaic polymer (6TTF-polymer) containing tetrathiafulvalene (TTF) was newly designed and synthesized via condensation polymerization. Furthermore, 6TTF-polymer containing fullerene (C60) is also polymerized to obtain both electron donor and electron acceptor moieties in the polymer chain. Electron-rich TTF can act as an electron donor and electron-deficient C60 can work as an electron acceptor. The chemical structure of 6TTF-polymer was characterized by utilizing FT IR, proton and carbon NMR spectroscopes and its thermal behavior was monitored by DSC. Furthermore, optical and electrochemical properties of the 6TTF-Polymer was investigated by using cyclic voltammetry, photoluminescence, and UV-Vis. The highest occupied molecular orbital level (EHOMO = -4.79eV) and band-gap energy (Eg = 1.91 eV) of the 6TTF-polymer suggested that TTF-based polymer could act as a good electron donating material for the optoelectronic applications. This work was mainly supported by the Human Resource Training Project for Regional Innovation, Basic Science Research Program (2013R1A1A2007238), and Converging Research Center Program (2013K000404), and BK21 PLUS Program, Korea.

Hierarchical structures from the asymmetric amphiphilic tetrathiafulvalene molecule

Pureun Im, Dae-Yoon Kim, Soon-Chun Park, Sang-A Lee, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

A novel amphiphilic molecule (amph-7TTF14) containing tetrathiafulvalene (TTF) was newly designed and synthesized. From the 2D WAXD pattern of the oriented amph-7TTF14 film, the crystal structure was identified to be a monoclinic unit cell. The main driving forces for the self-assembly of amph-7TTF14 were the face-to-face pi stacking interaction between TTF groups and the nanophase separation between rigid TTF groups and flexible hydrophobic alkyl and hydrophilic tri(ethylene oxide) tails. The morphological structure observed by using TEM, AFM, and POM indicated that the amph-7TTF14 formed not only flat ribbons but also scrolls and helixes. Based on the experimental results, it was realized that the scrolls and helices were induced by the unbalanced surface stresses generated during the crystallization process. This work was mainly supported by the Human Resource Training Project for Regional Innovation, Basic Science Research Program (2013R1A1A2007238), and Converging Research Center Program (2013K000404), Global Ph.D Fellowship Program (2013H1A2A1033907), and BK21 PLUS Program, Korea.

Characteristics of YAG-doped ZnO/ITO deposited by spraying methed

Wun Wei Lin, National Taipei Univ. of Technology (Taiwan)

This study presents a novel white light device consisted of a yttrium aluminum garnet (YAG) phosphor-doped zinc oxide (ZnO) (ZnO:YAG) thin film deposited on a indium tin oxide (ITO) glass substrate by ultrasonic spray pyrolysis(USP).

Growth of YAG phosphor-doped zinc oxide (ZnO) film was deposited by an USP method on ITO substrates. First step the ZnO:YAG film samples at 500°C and atmospheric pressure in nitrogen (N2) gas flow fixed rate of 100 sccm for one hour. Second step the samples at 400°C in air for 10 min. Characteristics of the ZnO:YAG film on ITO glass substrates. The ZnO solution sources of Zn(CH3COO)2•2H2O (0.5 M) and CH3COONH4•2H2O (0.5 M) with 1:3 proportional ratio, and the phosphor powder (NYAG4156 phosphor, INTEMATIX) was added into the ZnO solution source solution to form the spraying aqueous solution. The YAG phosphor at 0, 1, 5 and 10 wt.%. were examined by x-ray diffraction (XRD) pattern, hall measurement, and photoluminescence (PL) pattern spectra. The color of the PL spectra of the yttrium-aluminum garnet (YAG) phosphor-doped zinc oxide (ZnO) thin films under excitation of He-Cd laser with wavelength of 325 nm is nearly white.

Nonlinear properties of IGZO thin films prepared by RF magnetron sputtering

Sanal K. Kozhiparambil, Vishnu K., Shijeesh M. R., Madambi K. Jayaraj, Cochin Univ. of Science & Technology (India)

ABSTRACT

Transparent conducting indiuim galium zinc oxide (IGZO) films were successfully grown on glass substrates at room temperature by RF magnetron sputtering. Structural, optical, morphological and electrical properties of IGZO films deposited at different RF power were investigated. Composition of the film was analysed by EDAX measurement which shows that percentage of Zn increased with the RF power. Surface morphology of the IGZO film measured from AFM analysis showed that the roughness of the film was increased with increase in RF power. The average transmission in the visible range was greater than 80% and the transmission in the higher wavelength region decreased with increase in RF power. The carrier concentration in IGZO films could be controlled by controlling RF power due to the increase of Zn/(Ga+In+Zn) ratio. Nonlinear properties of IGZO thin films were measured using z-scan technique. Increase in free electron co concentration of IGZO thin films lead to a decrease of the corresponding nonlinear optical absorption response.

Sensors based on facet dielectric metamaterial

Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Andrey N. Lagarkov, Institute for Theoretical and Applied Electromagnetics (Russian Federation); Ilya A. Ryzhikov, Alexander V. Vaskin, Konstantin N. Afanasiev, Irina A. Boginskaya, Igor V. Bykov, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Ilya S. Kurochkin, Lomonosov Moscow State Univ. (Russian Federation); Igor A. Budashov, N.M. Emanuel Institute of Biochemical Physics (Russian Federation)

The sensors for the detecting and analyzing bio and chemical substances is the important application for the modern metamaterials. We suggest the new dielectric metamaterial with facet structure, where the local electromagnetic field is much enhanced in comparison with the amplitude of the incident light. Each facet operates as a micro resonator of Fabry-Perot type. The incident light excites these micro resonators that have various resonance frequencies. The em field oscillations in the facets interact and form the collective modes that are spatially localized in hot spots, where local field has maxima. The incident light pumps energy in the localized modes increasing to giant values the local em field. The planar metamaterial with facet structure were prepared by electron-beam deposition of the cerium dioxide on the special alumina ceramics. The internal stress accumulates in the process of the deposition. We found the parameters of the deposition process when the relaxation of the stress results in the formation the facet structure. The elementary cell of the facet structure has hexagonal shape and it is separated from the other facets by the nano-gaps which thickness is much less than the average size ~ 3 mic of the facets. To detect the field enhancement we deposit the gold nanoparticles on the surface of the metamaterial. The surface concentration was about few particles per one cell. The organic acid known as DTNB was adsorbed on the surface of the gold particles. The giant enhancement of the Raman signal from DTNB is detected.

9161-23, Session 5

High temperature ceramics based nanophotonic structures

Manfred Eich, Technische Univ. Hamburg-Harburg (Germany)

The talk will present our research on novel high temperature hierarchical nanomaterials concepts which are a focus of our collaborative research program on taylor made multiscale materials systems. We will report on titania and zirkonia based ordered and also disordered 3D structures which are designed and fabricated in order to very effectively reflect heat radiation in high temperature environments (T>1000 degC). The theoretical and experimental photonic properties and the fabrication details and thermal properties of thin layers of such 3D structures will be discussed. Due to their porosity these structures also employ a very small thermal conduction and thus can replace conventional thermal barrier coatings in air craft and power generation gas turbines. In addition, the presentation will cover high temperature stable structures that can be designed to show narrow band thermal far field emission properties as well as can enhance near field thermal transport via their hyberbolic optical properties.

9161-24, Session 5

Direct printing of planar photonic circuits with high refractive index

Carlos A. Pina-Hernandez, abeam Technologies, Inc. (United States); Aleksandr Polyakov, Lucas Digianantonio, The Molecular Foundry (United States); Giuseppe Calafiore, Sergey Babin, abeam Technologies, Inc. (United States); Stefano Cabrini, The Molecular Foundry (United States); Christophe Peroz, abeam Technologies, Inc. (United States); Alexander Koshelev, Alexey Bugrov, Alexander Goltsov, Nano-Optic Devices (United States)

The nanopatterning of high refractive index optical films promises the development of novel photonic nanodevices such as optical integrated circuits or imaging sensors. As a first step, we report here for the first time a printable photonic circuit fabricated by direct imprinting of inorganic films with high refractive index.

Hybrid organic/inorganic printable materials based on TiO_2 were developed for crack free films with high transparency. Printed nanophotonic devices with sub-10 nm resolution were achieved in a single UV-imprinting step by applying low pressure (<3 bar) [1]. The imprinting was performed with flexible PDMS and hard Ormostamp templates. The patterned films were annealed at high temperatures to transform the hybrid material into inorganic TiO_2 with high refractive index. The optical properties of the fabricated nanostructures can be easily tuned by controlling the post-annealing conditions; for instance, a refractive index higher than 2.0 and an extinction coefficient close to zero can be achieved in the visible wavelength range. We will present and discuss material characterization as well as the optical properties of the first printable planar optical circuits. The printed circuit is composed of curved multi-mode ridge waveguides (RWG), wavelength demultiplexers based on digital planar holograms (DPH) and directional light couplers.

Our technology opens an original route for fabricating novel printable photonic devices at low cost and high throughput.

9161-25, Session 5

Block copolymer assisted refractive index engineering of metal oxides for applications in optical sensing

Zsolt L. Poole, Univ. of Pittsburgh (United States); Paul R. Ohodnicki Jr., National Energy Technology Lab. (United States); Michael Buric, National Energy TEchnology Laboratory (United States); aidong yang, Univ of Pittsburgh (United States); Shaymaa Riyadh, Univ. of Bagdhad (Iraq); Yuankun Lin, Univ. of North Texas (United States); Kevin P. Chen, Univ. of Pittsburgh (United States)

We demonstrate in this paper that the refractive indices of important sensory metal oxides (TiO_2, SnO_2, ZnO, etc.) can be altered “at will” to meet the on-fiber refractive index compatibility requirements for optimal sensory integration. The tailoring of the refractive indices is accomplished by controlled 3D nanostructuring in the sub-100nm (sub-wavelength) domain using the method of block-copolymer templating combined with the sol-gel approach. Metal oxides are an important class of functional materials in chemical and biosensing due to the charge transfer interactions that take place at the surface with a chemisorbed species. The inert nature of silica, which at the same time permits its operation in a wide array of extreme conditions, limits its sensory capability. The integration of these highly developed sensory metal oxides with the optical fiber platform has seen limited success due to the large refractive index incompatibility (n_{silica} ~ 1.46, $n_{metal-oxide}$ > 2). Some thin film coatings have been shown to function but their functionality

has not been well developed and their sensory responses not well explored. Therefore, we present three novel advances in regards to the integration of functional metal oxides with the fiber platform. First, that the refractive indices can be tailored to meet the on-fiber compatibility requirements. Second, we demonstrate the type of the optical response by incorporating a high temperature stable fiber Bragg grating. And third, we present numerical modeling results that well describes the operation of metal oxide coatings, whether refractive index adjusted thick films or high refractive index thin films.

9161-26, Session 6

Polymer based nanocomposites with tailorable optical properties *(Invited Paper)*

Roberto Simonutti, Univ. degli Studi di Milano-Bicocca (Italy); Annalisa Colombo, Univ. degli Studi di Milano-Bicocca (Italy) and Fondazione CIFE (Italy)

A recurring challenge in the field of polymeric nanocomposites is the control of the spatial distribution of nanoparticles (NPs) in the polymer matrix. It is well-decreed that a specific NP dispersion state is necessary to obtain the desired property of polymer nanocomposites. In particular, there is considerable interest in dispersing luminescent or high refractive index NPs into transparent and uncolored polymer matrices, with the final goal of obtaining a solar concentrator or increasing the polymer's dielectric constant. Important for these materials is that scattering needs to be minimized, a requirement that is met by ensuring that the NPs are uniformly well-dispersed in the polymeric matrix. Different approaches have been developed in order to reduce the particle-particle attraction, that causes segregation between the inorganic and polymeric phases, like the brush-induced steric stabilization. In this case the surface of the NP is modified in such a way to be covered by a brush of organic molecules, the good dispersion conditions are to be find balancing the enthalpic and entropic terms of the interaction among the NPs surface brushes and the polymer chains. Two main applications will be described. The first is the fabrication and characterization of a luminescent solar concentrator based on giant CdSE/CdS quantum dots (QDs). It will be shown that the incorporation of the QDs in the polymer matrix does not cause any degradation of their emission efficiencies. Finally, polymer nanocomposites, based on acrylic polymers and TiO2 NPs, with refractive index as high as 1.89 will be presented.

9161-27, Session 6

Multi-physics modeling of photonic and excitonic properties of DNA-based nanostructures

Étienne Boulais, Massachusetts Institute of Technology (United States); Nicolas Sawaya, Harvard Univ. (United States); Keyao Pan, Massachusetts Institute of Technology (United States); Alán Aspuru-Guzik, Harvard Univ. (United States); Mark Bathe, Massachusetts Institute of Technology (United States)

Precise spatial organization of chromophores and inorganic materials at the nanometer-scale yields unique optical properties that are important to the discovery and development of novel photonic systems. In particular, natural photosynthetic apparatus present in bacteria provide inspiration for biomimetic nanoassemblies of dye molecules that may yield highly efficient synthetic light-harvesting complexes.

Programmed self-assembly of DNA uniquely enables the precise construction of such complex nanometer-scale architectures. The scaffolded DNA origami approach utilizes 'staple strands' of single-stranded DNA that hybridize to a complementary target 'scaffold strand' in solution to form megadalton-scale 3D molecular architectures. These assemblies act as molecular pegboards to assemble dye molecules with angstrom-level precision.

In this work we present a multi-physics computational procedure that enables exploring, designing and characterizing novel emergent photonic and excitonic properties of such scaffolded dye assemblies. Atomic-level solution DNA nanostructures are predicted using the finite element based framework CanDo (http://cando-dna-origami.org) that uses DNA sequence design to predict the 3D solution shape and mechanical properties of megadalton-scale DNA-based architectures. Atomic reconstruction of DNA assemblies with scaffolded dyes is subsequently generated as input to molecular dynamics simulation of DNA-dye complex conformational dynamics. Dye positions and orientations are used to compute energy transfer, using the Förster theory for dilute systems, and a hybrid classical/quantum approach for densely packed dye assemblies, when quantum coherence and excitonic coupling become significant. Quantitative prediction of experimental structures and optical properties of DNA-dye architectures verifies our approach. This framework promises to be of major importance for the discovery of next-generation DNA-based nanophotonic materials.

9161-28, Session 6

Spatially adjusted spontaneous emissions from photonic crystals embedded light-emitting diodes

Yu-Feng Yin, Yen-Chen Lin, National Taiwan Univ. (Taiwan); Yi-Chen Liu, Hai-Pang Chiang, National Taiwan Ocean Univ. (Taiwan); Jian-Jang Huang, National Taiwan Univ. (Taiwan)

In this work, the angular light output enhancement of LEDs was investigated from the spontaneous emission and light scattering of devices with different photonic crystal (PhC) geometries. The emitted photon coupled into a leaky mode is differentiated by the manipulation of quality factor in various spatial frequencies. Therefore, light extraction in this light-emitting device is determined by the modal extraction lengths and the quality factors obtained from the measured photonic bands. Furthermore, the higher- and lower-order mode spontaneous emissions are affected by the nonradiative process in the PhC structures with different lattice constants. In our cases, the photonic crystal device with the largest period of 500 nm exhibits the highest low-order mode extraction and quality factor. As a result, a self-collimation behavior toward the surface normal is demonstrated in the 3D far-field pattern of such a device. We conclude that, with the coherent light scattering from the PhC region, the spontaneous emission of the material and spatial behavior of the extracted mode can be both managed by the proper design of the device.

9161-29, Session 6

Ultrahigh-contrast and large-bandwidth thermal rectification in near-field electromagnetic thermal transfer between nanoparticles

Linxiao Zhu, Clayton R. Otey, Shanhui Fan, Stanford Univ. (United States)

We exploit the unique properties of optical waves in nanophotonic structures to enhance the capabilities for active control of electromagnetic thermal transfer at nanoscale. We show that the near-field electromagnetic thermal transfer between two nanospheres can exhibit a thermal rectification effect with very high contrast and large operating bandwidth. A thermal rectifier, is a two-body device that operates in a nonequilibrium condition so that for a given temperature bias, the magnitude of heat flow between the bodies depends on the direction of the temperature bias. In this work, we consider near-field electromagnetic thermal transfer between two nanospheres, made of same type of SiC. Since these spheres are much smaller than the free-space wavelength for the relevant resonance modes, it is known that their resonances are scale invariant, i.e., the resonance frequencies are independent of the radius of the sphere, whereas the spatial distribution of the resonance modal field scales directly with the radius of the sphere. We show that such a scale invariance property results in a significant asymmetry in the relevant coupling constants between the modes in the spheres, and hence provides a rectification mechanism that is distinctly different from all previous works. For a photon-based thermal rectifier, such a mechanism significantly enhances its performance. We also show that the three-dimensional nanoscale modal confinement in these systems directly enables high-speed operation of the device. Our work shows that the unique modal properties of nanophotonic structures can be exploited to create a powerful mechanism for achieving new thermal functionalities.

9161-30, Session 6

Heating processes in plasmonic resonances: a non-linear temperature dependent permittivity model

Alessandro Alabastri, Francesco De Angelis, Remo Proietti Zaccaria, Istituto Italiano di Tecnologia (Italy)

Heating processes in plasmonics are essential every time the interaction with electromagnetic fields induces dissipation within metallic nanostructures. In particular the capability to predict the final temperature reached by a system (e.g. an ensemble of nanoparticles within a host medium) can be crucial when dealing with electronic, medical or chemical applications. Here we present a dispersive model of the dielectric function of a metallic medium which depends on temperature. Since temperature, in turn, depends on the intensity of the electromagnetic source and on the optical response of the medium itself, the model expresses non-linearity features. The model, which does not require any fitting parameter, can be utilized whenever the impact of temperature on the optical response of a system needs to be clarified and/ or when non-linearities might play a major role.

9162-1, Session 1

Purcell factors and other interesting quantum optical effects with nanoplasmonic resonators *(Invited Paper)*

Stephen Hughes, Queen's Univ. (Canada)

No Abstract Available

9162-2, Session 1

Modal representation of light-matter interactions in plasmonic nanoresonators *(Invited Paper)*

Christophe Sauvan, Jean-Paul Hugonin, Philippe Lalanne, Institut d'Optique Graduate School (France)

We have developed a self-consistent electromagnetic theory of light-matter interactions in nanoresonators. The theory that relies on the concept of quasinormal modes with complex frequencies is capable of accurately handling any photonic or plasmonic resonator with strong radiation leakage, absorption and material dispersion. We use the modal formalism to revisit Purcell's factor. The new formula substantially differs from the usual one; in particular, we predict that a spectral detuning between the emitter and the resonance does not necessarily result in a Lorentzian response in the presence of dissipation. More generally, we derive a modal expansion of the imaginary part of the Green tensor. This modal representation provides a powerful tool to calculate and understand the degree of spatial coherence in complex photonic or plasmonic systems.

9162-3, Session 1

Interaction of a quantum emitter with a meta--surface

Didier Felbacq, Univ. Montpellier 2 (France)

Metasurfaces are the two-dimensional analogue of metamaterials. They are made of thin resonant structures deposited on a surface. They allow for the control of phase, wavefront, polarization or refracted energy of light. A metasurface made of ultrathin resonant wires was considered. Confined Bloch modes arise due to resonances and form a natural basis to characterize the spontaneous and stimulated decays of a quantum emitter placed near the surface.

The dispersion relation for the Bloch modes was obtained by of an asymptotic theory for each scatterer, coupled to a multiple scattering theroy.

Computing typical quantum properties such as the spontaneous or stimulated emission rates requires the knowledge of the density of electromagnetic states, a classical quantity. For the resonant metasurface under study, the crossed density of states of the system was calculated in terms of the continuum of scattering states as well as the Bloch modes. This requires a deformation of the integral over plane waves in the complex planes of wavevectors. This makes possible to specify a probability of de-excitation over the different open channels and the engeneering of the coupling over localized modes. In particular the various regimes of strong and weak coupling were investigated with the aim of studying the coupling of energy between localized Bloch modes and a quantum emitter.

9162-4, Session 1

Spontaneous emission dynamics of quantum emitters coupled to epsilon-near-zero metamaterials

Ruzan Sokhoyan, Georgia T. Papadakis, Ho Wai Lee, Harry A. Atwater Jr., California Institute of Technology (United States)

Coherently coupled quantum emitters are likely to constitute important elements of future quantum computing and communication systems. In free space, interactions between quantum emitters drastically diminish when the inter-emitter spacing is comparable to half a resonant wavelength. Coupling quantum emitters to an environment with carefully tailored local density of optical states (LDOS) could dramatically increase their interaction range. Within the framework of macroscopic quantum electrodynamics [1], we articulate here how coupling quantum dipole emitters to an epsilon-near-zero (ENZ) metamaterial enables the observation of quantum cooperative effects, focusing on the collective decay of emitters. In the present work, we consider ENZ metamaterials composed of multilayer metal-dielectric stacks, which have shown to exhibit ENZ behavior for a small range of wavelengths [2]. First we analyze the spontaneous emission enhancement of a dipole emitter for the cases when the emitter is in the proximity of the metamaterial or is embedded into the layered metamaterial structure, and we compare our results with those from the homogenized effective-medium approach [3]. Further, by scanning over different resonant frequencies of the quantum emitters, we investigate how inter-emitter interactions vary when approaching the ENZ regime of the metamaterial. We calculate the collective decay rate and the dipole-dipole coupling parameter as a function of positions and resonant frequencies of the emitters and investigate the superradiant behavior of quantum emitters in the ENZ regime.

9162-5, Session 1

Advanced emission manipulation in quantum-dot metamaterials *(Invited Paper)*

Manuel Decker, Isabelle Staude, Sergey S. Kruk, Dragomir N. Neshev, Yuri S. Kivshar, The Australian National Univ. (Australia)

Plasmonic nanoparticles have proven to provide a very effective way to control and enhance the photoluminescence properties of quantum emitters due to their ability to confine light to ultra-small volumes and, therefore, have large potential for applications in the field of solar-energy harvesting, efficient photodetection, and biosensing [1,2]. Particularly more complex-shaped nanoparticles that can be incorporated as meta-atoms in metamaterials can be used to specifically tailor the spontaneous emission of semiconductor quantum dots (QDs) beyond the mere enhancement of the photoluminescence (PL) signal.

Here, we report on our experimental investigations to answer the question how the energy of QDs is distributed when several metamaterial modes of very different characteristics - like electric and magnetic metamaterial modes - are present [3]. By superimposing two orthogonal modes of equal strength at the wavelength of QD-PL, we demonstrate a sharp difference in their interaction with the magnetic and electric metamaterial modes. We also demonstrate that the polarization-state of emission is critically dependent on the multipolar properties of the metamaterial resonances. We propose the novel concept of manipulation of the polarization state of light emission in a system of QDs coupled to a multipolar resonance in metamaterials. In particular, we show that the superposition of several resonant multipolar contributions (e.g. electric/magnetic dipole moments, quadrupole moments etc.) leads to the emission of chiral light of opposite handedness.

9162-6, Session 2

Fabrication of InGaN quantum dots for use as active photonic emitters *(Invited Paper)*

Arthur J. Fischer, Xiaoyin Xiao, Ganapathi S. Subramania, Jeffrey Y. Tsao, Daniel D. Koleske, Ping Lu, Jeremy B. Wright, Sheng Liu, George T. Wang, Sandia National Labs. (United States)

Fabricated quantum dots (QDs) are desired for a wide variety of applications including emitters for full-color compact projectors, optical data storage, solid state lighting, and single photon sources. InGaN QDs are particularly promising for solid state lighting applications where strain relaxation allows for more In incorporation and efficient emission at yellow and red wavelengths. InGaN material grown by metalorganic chemical vapor deposition is fabricated into QDs using post-growth etch processing. Atomic force microscope measurements show InGaN QDs in the size range from 2 to 10 nm with a density of ~10^11 dots/cm2. Transmission electron microscopy x-ray analysis shows clear evidence of InGaN QDs on the surface of the GaN template layer. Micro-photoluminescence measurements with 266 nm pumping and a 1 micron pump spot size show emission at ~420 nm. The InGaN photoluminescence peak shifts by ~20 nm showing that we can increase the quantum confinement via etch processing. InGaN material with a GaN capping layer also showed a 2 to 4 times increase in PL efficiency compared to uncapped InGaN material demonstrating the need for passivation of InGaN QDs. With further development work, the fabrication method used here to demonstrate InGaN QDs has the potential for demonstrating single QDs at deterministic locations inside photonic crystal structures. Sandia National Laboratories is a multiprogram laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04–94AL85000.

9162-7, Session 2

Physics of local quantum states in carbon nanotubes for photonic applications *(Invited Paper)*

Yuhei Miyauchi, Kazunari Matsuda, Kyoto Univ. (Japan)

Single-walled carbon nanotubes (SWNTs) are extremely thin cylinders of hexagonal carbon networks with diameters on the order of 1 nm, and can be metal or semiconductor depending on their chiral structure. Semiconducting SWNTs exhibit near infrared luminescence, and their emission wavelengths (~900-1600 nm for SWNTs with diameters of ~ 1 nm) are suitable for photonic applications in telecommunication and bio-imaging. Here we will review our recent studies on exciton physics of local quantum-dot-like states embedded in SWNTs. We will discuss the advantages and limitations of using SWNTs as near-infrared light emitters, and how the local states affect the optical properties of SWNTs. Then we will give an overview of the impacts and benefits of embedding the local quantum-dot-like states in quasi-one-dimensional SWNTs for their applications as near infrared light emitters. Especially, we have recently found a drastic enhancement of the luminescence quantum yield of excitons due to the dimensionality modification of excitons in the local states; the detailed mechanism of the enhancement will be discussed. We will also review our recent efforts towards understanding universal exciton dynamics in one-dimensional nanostructures with sparse zero-dimension-like states through nonlinear luminescence spectroscopy on the local states in SWNTs with different density and origins.

9162-8, Session 2

Yellow single-photon emission from nitrogen impurity centers in AlAs *(Invited Paper)*

Masafumi Jo, RIKEN (Japan) and National Institute for Materials Science (Japan); Takaaki Mano, Takashi Kuroda, Yoshiki Sakuma, Kazuaki Sakoda, National Institute for Materials Science (Japan)

Isolated impurity centers in semiconductors are attractive as quantum light sources because of their superior homogeneity and scalability. Nitrogen (N) has a large electronegativity and a small atomic radius compared with other V-column elements, and the substitutional N atoms in III-V formed isoelectronic impurity centers around the position where the excitons were localized. The aim of this study was to demonstrate the visible single-photon generation from N impurities in AlAs.

Nitrogen delta-doped AlAs was grown on a GaAs(001) substrate using a molecular beam epitaxy machine equipped with a radio-frequency nitrogen plasma source. Optical properties of the individual centers were investigated by steady-state and time-resolved photoluminescence. The electronic states for the N impurities in AlAs were calculated using the valence-force-field and tight-binding methods.

Sharp emission lines from excitons bound to the N impurities were observed at 2.1–2.2 eV, below the X conduction band minima in AlAs. The quadratic increase in the photoluminescence intensity with the N concentration indicated that the nitrogen impurity centers consisted of NN pairs. In contrast, the emission associated with isolated N impurities was not observed. The calculations showed that an isolated N atom formed a resonant state above the conduction band edge in AlAs. In contrast, NN1[110] and NN4[220] pairs formed bound states inside the band gap. Photon correlation measurement produced the second-order correlation function $g^{(2)}(0) = 0.33$. This demonstrates the generation of non-classical light in the yellow wavelength range from an NN pair in AlAs.

9162-9, Session 3

Realizing a quantum transistor using a quantum dot strongly coupled to a cavity *(Invited Paper)*

Edo Waks, Hyochul Kim, Ranojoy Bose, Tao Cai, Shuo Sun, Univ. of Maryland, College Park (United States); Glenn S. Solomon, National Institute of Standards and Technology (United States)

Two dimensional photonic crystals have been recognized as a highly promising device platform for compact integrated photonics. They can also localize and trap light to spatial volumes on the order of a cubic wavelength, resulting in large electromagnetic intensities. By embedding a single quantum dot (QD) in the high field region of photonic crystal cavities it becomes possible to achieve strong light-matter interactions at the single photon/single atom level. These unprecedented interaction strengths open up the possibility for creating nonlinear optical effects approaching the single photon level. In addition, they can be exploited to engineer unique quantum mechanically entangled states of light and matter that enable scalable quantum networks. In this talk, I will discuss our work on coupling indium arsenide (InAs) QDs to photonic crystal structures in order to realize a quantum transistor, where the quantum state of the dot conditionally rotates the state of an incident photon. This device applies a universal quantum CNOT gate to a photon, which is the basic building block for universal quantum computation. We demonstrate the coherence of the transistor via the observation of Rabi oscillations, which show that we are directly controlling the quantum state of the device. Our results provide a step towards scalable quantum networks and distributed quantum computers implemented in a compact nanophotonic device platform.

9162-10, Session 3

Large-alphabet quantum key distribution using time-energy entangled photons

Dirk R. Englund, Catherine Lee, Jacob Mower, Zheshen Zheng, Franco N. C. Wong, Jeffrey H. Shapiro, Massachusetts Institute of Technology (United States)

Quantum key distribution (QKD) enables two parties, Alice and Bob, to establish a private cryptographic key at a distance. Practically, the rate of key generation is limited by experimental constraints, such as the rate of generating photons or the repetition rate of single photon detectors. However, Alice and Bob can increase the amount of shared information per detected photon by using of high-dimensional photon correlations. Here, we will describe a QKD protocol that employs time-energy correlations between entangled photons[1,2]. The security analysis of this protocol relies on estimating the time-frequency covariance matrix of Alice's and Bob's measurements, which enables Alice and Bob to bound Eve's maximum obtainable information. We have implemented high-dimensional time-energy QKD protocols using commercially available telecom dispersion emulation systems, enabling high generation rate and photon information capacity in excess of 3 bits per detected photon coincidence.

9162-11, Session 3

Generation of photon pairs with reconfigurable entanglement on a nonlinear chip *(Invited Paper)*

Andrey A. Sukhorukov, James G. Titchener, Che Wen Wu, Alexander S. Solntsev, Dragomir N. Neshev, The Australian National Univ. (Australia)

Integrated quantum optical circuits have the potential to produce and control entangled photons far more efficiently than traditional bulk optics. Spontaneous parametric down-conversion (SPDC) can provide an 'on-chip' source of entangled photons in structures with quadratic nonlinearity, so that there is no need to generate entanglement externally to the quantum circuit. Engineering the properties of the photonic structure can enable us to control the photon propagation within the integrated circuit.

We show that biphotons with any desired complex spatial entanglement can be generated in nonlinear waveguide arrays (WGA) with specially optimized characteristics. This photon source can be integrated on a chip for processing of the generated path-encoded qudits.

The propagation of biphotons in a waveguide array is governed by a linear Schrödinger-type equation, so driving all three waveguides simultaneously will produce a linear superposition of the output states that would be produced if the waveguides were driven individually. Hence altering the amplitude and phase of the driving lasers allows switching between the states spanned by the set of single waveguide outputs.

In order to manipulate the biphoton generation within the WGA, we engineer the sign of the effective quadratic susceptibility along the length of each waveguide. This can be achieved in practice by altering the domain structure through electric poling, representing a feasible route towards an 'on chip' reconfigurable source of spatially entangled photons.

We also show that by employing adiabatic waveguide coupling, we can generate spatially entangled photon pairs while simultaneously providing spatial pump filtering and keeping photon-pair states pure. We estimate the performance of the pump filtering to be of the order of 72 dB. Moreover the proposed method is highly tolerant to fabrication inaccuracies.

9162-12, Session 4

Quantum dots with engineered multi-carrier interactions for light-emitting diodes *(Invited Paper)*

Victor I. Klimov, Los Alamos National Lab. (United States)

Lighting consumes almost one-fifth of all electricity generated today. A dramatic improvement in lighting efficiency is possible by replacing traditional incandescent bulbs by light-emitting diodes (LEDs) in which current is directly converted into photons via the process of electroluminescence. The focus of this presentation is on the emerging technology of LEDs that use solution-processed semiconductor quantum dots (QDs) as light emitters. QDs are nanosized semiconductor particles whose emission color can be tuned by simply changing their dimensions. They feature near-unity emission quantum yields and narrow emission bands, which results in excellent color purity. These properties make QDs attractive for applications in lighting and display technologies. This presentation overviews spectroscopic studies of QDs that address the problem of nonradiative carrier losses in QD-LEDs, and approaches for its mitigation via the appropriate design of QD emitters. We consider processes such as carrier recombination via surface defects including hot-electron trapping, discussed in the context of QD emission intermittency ("blinking"). We also analyze nonradiative Auger recombination in the presence of extra charges, and specifically, the asymmetry between recombination pathways in positively and negatively charged QDs. Finally, we provide evidence for the direct relation of Auger recombination to the problem of LED efficiency roll-off (known also as a "droop" effect") at high driving currents, suggesting that the realization of high-performance LEDs might require a new generation of "Auger-decay-engineered" QDs that in addition to being efficient single-exciton emitters would also show high emission efficiency in the multicarrier regime.

9162-13, Session 4

Positioning of single quantum dots on nanoscale areas of metal-free substrates

Isabelle Staude, The Australian National Univ. (Australia); Varun K. A. Sreenivasan, Macquarie Univ. (Australia); Ivan Shishkin, Kirill Samusev, Ioffe Physico-Technical Institute (Russian Federation) and National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Manuel Decker, Dragomir N. Neshev, The Australian National Univ. (Australia); Andrei V. Zvyagin, Macquarie Univ. (Australia); Yuri S. Kivshar, The Australian National Univ. (Australia)

The coupling of colloidal semiconductor quantum dots (QDs) to subwavelength nanophotonic structures remains an active field of research [1]. For enhanced control over the optical properties of the coupled system, the positioning of QDs at specific locations of the photonic nanostructures is crucial. In particular, selective binding of QDs to the feed elements of plasmonic (metallic) nanoantennas has been demonstrated to allow for tailoring the directionality of QD emission [2]. However, the precise and controlled placement of single colloidal QDs with respect to metal-free all-dielectric photonic nanostructures by a scalable lithographic process still poses a major challenge. The demand for such a process is rapidly growing, driven by emerging research efforts into all-dielectric nanoantennas and all-dielectric metamaterials [3].

Here, we demonstrate a novel process for selective binding of single semiconductor core-shell quantum dots (QDs) to transparent all-dielectric (glass) substrates with nanoscale precision. This is accomplished by defining a mask via electron-beam lithography (EBL) followed by functionalization of only the exposed areas of the substrate with a heterobifunctional linker, while applying a binding inhibitor to

all other areas. Single QD blinking is clearly observed for several QD functionalized sites. Our approach is compatible with standard two-step EBL nanofabrication schemes and it does not rely on the presence of metals, making it suitable for coupling QDs to various nanoresonators, including dielectric-only systems.

9162-14, Session 4

Photons-on-demand: synthesis and integration strategies for non-blinking giant quantum dots *(Invited Paper)*

Jennifer A. Hollingsworth, Han Htoon, Krishna Acharya, Niladri S. Karan, Mathew R. Buck, Farah Dawood, Hue M. Nguyen, Aaron M. Keller, Los Alamos National Lab. (United States)

Bright, stable emitters are needed for the range of applications from bio-imaging and molecular tracking to solid-state lighting and single-photon sources for quantum information processing. We have previously demonstrated ultrastable single-emitter level photoluminescence in non-blinking and non-photobleaching thick-shell CdSe/CdS [1] and InP/CdS [2] core/shell colloidal quantum dots. The remarkable properties of these nanoscale emitters were initially attributed to an unusually thick CdS shell, inspiring the designation of "giant" quantum dots.[3] We have since shown that in addition to shell thickness, core size, electronic structure and/or core/shell interfacial properties can strongly influence the processes that impact blinking behavior – charging and nonradiative Auger recombination. With these various 'design parameters' in mind, we are synthesizing a range of quantum dot heterostructures targeting similar single-dot stability across the visible and into the near-infrared. I will review our recent progress in meeting the strict requirements for single-dot photostability for green, red and near-infrared emitting quantum dots. I will also discuss how we are coupling these 'active' photonic materials with plasmonic or dielectric components to enhance or modify exciton recombination processes. Specifically, we have developed synthetic methods to fabricate semiconductor giant quantum dot-metal hybrid heterostructures, while we have used a 'direct-write' nanolithography approach to integrate colloidally synthesized quantum dots with pre-fabricated structured photonic materials. In both cases, we can achieve nanoscale integration for enhanced or modified emission properties.

9162-15, Session 5

Isotropic band gaps, optical cavities, and freeform waveguides in hyperuniform disordered photonic solids *(Invited Paper)*

Marian Florescu, Univ. of Surrey (United Kingdom); Weining Man, San Francisco State Univ. (United States); Ruth Ann Mullen, Etaphase Inc. (United States); Milan M. Milosevic, Timothy Amoah, Univ. of Surrey (United Kingdom); Paul M. Chaikin, New York Univ. (United States); Salvatore Torquato, Paul Steinhardt, Princeton Univ. (United States)

Hyperuniform disordered solids are a new class of designer photonic materials with large isotropic band gaps comparable to those found in photonic crystals. The hyperuniform disordered materials are statistically isotropic and possess a constrained randomness such that density fluctuations on large scales behave more like those of ordered solids, crystals or quasicrystals, than like those of conventional amorphous materials. The hyperuniform disordered network structures are designed by employing a centroidal tessellation of a hyperuniform point pattern to generate a "relaxed" dual lattice, whose vertices are necessarily trihedrally coordinated. Our simulations show that slab architectures of Si based hyperuniform disordered networks display photonic bad gaps of at least 20%. Optical cavities introduced in these materials support localized modes with high quality factors and a variety of symmetries. The isotropy of the PBG unique to hyperuniform disordered structures, enables designer waveguides of essentially arbitrary shape, along which the light can be guided through the excitation of localized resonances similar to the ones that we found in the point-like defects. Using standard electron beam lithography and inductively-coupled plasma reactive ion etching we have fabricated hyperuniform disordered structures with an average lattice constant of 500nm and wall thickness of 100nm. Furthermore, our experiments demonstrate photonic band gaps and low-loss wave-guiding in submicron scale Si-based hyperuniform structures operating at in the 1550nm wavelength range and open the way for the realization of highly flexible, disorder-insensitive optical micro-circuit platforms.

9162-16, Session 5

Qualitative models in nanophotonics

Arkadi Chipouline, Friedrich-Schiller-Univ. Jena (Germany)

Recent technological advancements allowing creation of nanoobjects/metamaterials in the optical domain has forced the revisiting of basics electrodynamic principles and assumptions. A large amount of new experimental and theoretical data has to be structured within the framework of a new unified approach, in order to distinguish the really fundamental knowledge from various applications and particular cases. A unified approach appears to be extremely important for educational courses in the area of nanophotonics/optical metamaterials. In particular it allows us to present a self-consistent physical picture, which in turn minimizes the amount of educational material to be memorized to the crucial physics.

The results of analytical, numerical, and experimental investigations of the resonantly coupled dynamics of the classical system (strip resonator, plasmonic nanoresonator) and quantum systems (Josephson Junction (JJ), quantum dots, dye molecules, etc.) are presented. The wide range of the physical phenomena appearing in these coupled system, is analysed in the frame of the unified approach. The following problems will be considered:

1. Regular and stochastic characteristics (radiation linewidth) of the nanolasers (such as the spaser).

2. It is shown that direct application of Schawlow-Townes expression overestimates the linewidth and has to be avoided at the description of the nanolaser. Analytical results are compared with ones obtained from the direct numerical simulation of the dynamics of the laser equations.

3. A model for anapole laser will be presented.

4. Propagation of the plane wave in a metamaterial with gain (metaatoms in form of spasers) is considered using the developed earlier multipole model and the results of the spaser dynamics. It is shown that the stable propagation is possible if ratio of the coupled and uncoupled active molecules is chosen carefully.

5. The problems of the luminescent enhancement and life time shortening are analysed in the frames of the developed approach and compared with the experimental data.

9162-17, Session 5

Beam shaping and manipulation in photonic crystal structures *(Invited Paper)*

Anna C. Tasolamprou, Foundation for Research and Technology-Hellas (Greece); Lei Zhang, Iowa State Univ. (United States); Maria Kafesaki, Foundation for Research and Technology-Hellas

(Greece); Thomas Koschny, Costas M. Soukoulis, Iowa State Univ. (United States)

Photonic crystals (PCs) are well known materials mostly due to their band gap properties. Additionally is has been shown, both theoretically and experimentally, that PCs support the propagation of surface waves, provided that they are properly terminated. This termination consists of a corrugated outer periodic layer which may differ in shape and/or lattice constant from the bulk material. Introducing a line defect acting as a waveguide in a bulk photonic crystal structure and properly designing the corrugated layer enables the excitation of the surface states within the band gap. The surface layer alone leads to reduced transmission efficiency along the waveguide axis; nevertheless an additional grating like-layer may facilitate the coupling of the surface waves to outgoing propagating waves. The surface energy radiation results in enhanced transmission and directionality of the beam. The key feature of this configuration is the grating layer which under specific conditions, leads to constructive interference of the diffracted waves and beaming. This work investigates and demonstrates how the proper design of the grating layer allows for selective interference and provides control over the beam shape and emission angle. Apart from the PCs, it has been discovered that even a single dielectric layer can support surface states, whereas a surface and grating bilayer may couple the surface states to outgoing propagating waves. Here we also demonstrate both experimentally and theoretically, that such a bilayer dielectric structure allows for the collimation and enhanced transmission of a Gaussian incident beam, while a system of multiple cascading bilayers can sustain the beam for large propagation distances.

9162-18, Session 6

CMOS integrated plasmonics: interconnects and modulators *(Invited Paper)*

Alexandra Boltasseva, Nathaniel Kinsey, Marcello Ferrera, Purdue Univ. (United States); Viktoriia E. Babicheva, DTU Fotonik (Denmark); Gururaj V. Naik, Stanford Univ. (United States); Alexander V. Kildishev, Vladimir M. Shalaev, Purdue Univ. (United States)

During the last decade, numerous designs have been proposed for the fabrication of fundamental nanophotonic devices such as waveguides, modulators, amplifiers, and photodetectors. All of which require high mode localization and the low propagation losses to maximize their performances. However, most of these structures use noble metals such as gold or silver, which are not CMOS-compatible, limiting their applicability. Recently, a great effort has been given in the search of alternative plasmonic materials. According to these studies, transition metal nitrides and transparent conducting oxides (TCOs) could represent promising platforms for future plasmonic devices. Among these materials, titanium nitride (TiN) is one of the best candidates because of its chemical stability, bio-compatibility and resistance to mechanical stress. In addition, it can be grown epitaxially on many substrates. TCOs offer the ability to vary their complex refractive indices over a broad range by modulating the carrier concentration with an external electric field. In this work, by using potentially CMOS-compatible plasmonic materials, we investigate a novel design for an ultra-compact modulator. Our modulator can achieve an extinction ratio of 46 dB/µm, an off-state mode size as small as 1.3 µm, and 3 dB modulation in just 65 nm of propagation length. The experimental characterization of TiN-based waveguides is also presented as the first step towards an integrated plasmonic modulator. Our guiding structures show propagation losses < 0.79 dB/mm. Both the modulator and waveguide are potentially CMOS compatible. These results demonstrate the ability of future CMOS compatible nanophotonic devices

9162-19, Session 6

Printing high-quality tunable porous silicon microcavities *(Invited Paper)*

Paul V. Braun, Neil A. Krueger, Hailing Ning, Univ. of Illinois at Urbana-Champaign (United States)

Porous silicon (PSi) became a material of interest in the early 1990's with its ability to emit visible light. Since that time, PSi has demonstrated potential beyond light emission and gained an identity as a versatile optical material because of its inherent refractive index modulation capabilities achieved by either porosity variation or porosity infiltration. Porosity variation produces high-quality optical superlattices (e.g. microcavities), which feature optical resonances that control the light-matter interaction of light-emitters located inside the cavity and can simultaneously be tuned by pore infiltration. However, all such attempts with PSi monolithic microcavities have been fundamentally limited to emitters integrated into the porous network. Hybrid microcavities could extend the scope of compatible emitters, but grafting fragile, free-standing PSi films without damage has been an obstacle to realizing high-quality structures. Here, we demonstrate that PSi photonic components, when coupled with a modified transfer-printing technique, enable the formation of high-quality hybrid microcavities that are compatible with all forms of external emitters. Further, we provide a means to utilize PSi's refractive index modulation capabilities in the hybrid microcavity, allowing us to both globally tune and spatially modulate the resonant mode of the resulting structure.

9162-20, Session 6

Metal oxides as tunable photonic materials *(Invited Paper)*

Otto L. Muskens, Univ. of Southampton (United Kingdom)

Highly doped metal oxides behave like Drude metals in the infrared and transparent dielectrics in the visible. We show that a wide range of optical properties can be achieved of interest for applications in photonics, ranging from tunable dielectrics for hybrid plasmonic devices [1], to epsilon-near-zero response [2] and plasmonic behavior in the infrared [3]. Epsilon-near-zero behavior includes total external reflection and air guiding of light using metal oxide cladded waveguides. Ultrafast control of metal-oxide hybrid photonic structures, exploiting picosecond modulation of the free carrier density, is demonstrated which opens up avenues for new active photonic devices.

9162-21, Session 6

Strong coupling of delocalized and localized resonances in voltage tunable terahertz 2D plasmonic crystals *(Invited Paper)*

Gregory C. Dyer, Sandia National Labs. (United States); Gregory R. Aizin, Kingsborough Community College (United States) and The City College of New York (United States); S. James Allen Jr., Univ. of California, Santa Barbara (United States); Albert D. Grine, Don Bethke, John L. Reno, Eric A. Shaner, Sandia National Labs. (United States)

Low dimensional plasmonic systems based on III-V compound semiconductor heterostructures and graphene have garnered significant attention for their application in terahertz (THz) detectors, mixers, oscillators and modulators. Of particular interest is the broad tunability of underdamped plasma excitations in these two-dimensional (2D) plasmonic systems. Here we illustrate the rational design of voltage tunable THz plasmonic crystals using sequential coupled GaAs/AlGaAs 2D plasmonic resonators as the basic building block. Much like a metamaterial element, the studied structures are subwavelength, yet nonetheless Bragg scatter plasma waves from a repeated crystal unit cell.

We electronically detect the spectrum of coupled 2D plasmonic micro-resonator structures at cryogenic temperatures. Using a plasmonic homodyne mixing mechanism to downconvert the near field of plasma waves to a DC signal, a 50% in situ tuning of the plasmonic crystal band edges is observed. Breaking of a plasmonic crystal's translational symmetry introduces localized plasmonic resonances to the measured spectra. Due to the coupling of localized defect modes with crystal surface states known as Tamm states and the inherent asymmetries in the device structures, we observe an induced transparency-like phenomenon. These experimental results are interpreted and validated using an equivalent circuit formulism where the field effect tunable kinetic inductance of quantum confined electrons has a dominant contribution. The active control of coupled plasmonic resonators demonstrated in this work suggests new paths for the development of ultra-sensitive direct and heterodyne THz detectors, planar metamaterials, and slow-light devices.

9162-22, Session 7

Dielectric and metallic nanosuspesions with tunable optical nonlinearities *(Invited Paper)*

Zhigang Chen, Nankai Univ. (China) and San Francisco State Univ. (United States); Demetrios N. Christodoulides, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

In recent years, the development of artificial materials exhibiting novel optical properties has become one of the major scientific endeavors. Of particular interest are soft-matter systems, which play a central role in numerous fields ranging from life sciences to chemistry and physics. In this talk, we will present two types of soft-matter systems with tunable optical nonlinearities. The first one is the colloidal dielectric suspensions while the second is the metallic suspension. In both systems, by appropriately engineering the polarizability of the nanosuspensions, we can alter at will the nonlinear light-matter interactions in order to overcome the effects from diffraction and scattering, hence to achieve deep beam penetration through the colloids. In particular, we have deliberately synthesized colloidal suspensions with negative polarizabilities by suspending polytetrafluoroethylene (PTFE) particles in a diluted glycerin-water solution, and we have observed robust propagation and enhanced transmission of self-trapped light through such scattering media. In addition, we show that plasmonic nanoparticles provide a versatile platform for controlling the flow of light in soft-matter systems. Due to resonant nature of the light-matter interaction in metallic nanosuspensions, we have observed self-trapping and robust soliton propagation of light over distances up to 25 diffraction lengths, which would have been otherwise impossible in conventional dielectric settings. Our findings may bring about solutions to overcome large scattering loss and to pave the avenue for engineering various soft matter systems with tunable nonlinearities, promising for various applications including optical trapping and manipulation as well as initiation of chemical reactions.

9162-23, Session 7

Ultrafast reconfigurable photonic devices using dynamic wavefront shaping

Otto L. Muskens, Thomas Strudley, Roman Bruck, Univ. of Southampton (United Kingdom)

Wavefront shaping has enabled the use of opaque scattering media as versatile and reconfigurable optical elements. Here we demonstrate ultrafast control of a shaped light field exploiting a combination of wavefront shaping and ultrafast nonlinearity of the host medium. We identify a new regime of ultrafast phase control, which can be used to effectively dephase the shaped wavefront, resulting in a modulation of up to 63%. This phase dynamics can be partially inverted to produce a dynamical reshaping of the light field and a transient increase of the peak intensity of an optimized wavefront by as much as 20%.

9162-24, Session 7

Nonlinear frequency generation from Si/Chalcogenide glass hybrid waveguides by degenerate four wave mixing

Jörg Schilling, Martin-Luther-Univ. Halle-Wittenberg (Germany); Peter W. Nolte, Martin-Luther-Univ. Halle-Wittenberg (Germany) and Fraunhofer-Institut für Werkstoffmechanik (Germany); Georg von Freymann, Technische Univ. Kaiserslautern (Germany); Mark McMillen, Queen's Univ. Belfast (United Kingdom)

Recent successes in the area of efficient four wave mixing (FWM) in SiN- and Hydex-waveguides have triggered a plethora of further work on frequency comb generation and the applications for ultrashort pulses. However due to the limited third order nonlinearity (n2) of SiN and Hydex, the structures have a large footprint and a high power input is necessary. The chalkogenide glass As2S3 on the other hand promises a nearly 10 times larger n2 and a nonlinear figure of merit (FOM) of 215 for telekom wavelengths, although the fabrication of low loss As2S3-waveguides still presents a challenge.

Here we demonstrate the combination of the superior waveguiding properties of Si with the high nonlinear FOM of As2S3 in form of an infiltrated Si slot waveguide, applying standard CMOS technology and a subsequent nano-injection molding process to infiltrate the 100nm wide slot with As2S3. Several race track resonators are formed to create a structure of small footprint and efficiently enhance the degenerate four wave mixing process. NIR radiation is supplied by two tunable cw-lasers via lensed fibres which are butt-coupled to the Si feeding waveguide.

From low power transmission measurements Q-factors of 10^5 were obtained for the race track resonators. An evaluation of the free spectral range yields a group index of ng=3.4 and a group velocity dispersion of -3300ps/(nm km). Feeding a pump power and signal power of 10mW and 5mW in neighbouring resonances, degenerate four wave mixing within the race track resonators was observed leading to the formation of idler waves with a conversion efficiency of -40dB. A frequency sweep of the signal wave emphasizes the importance of a vanishing group velocity dispersion for enhanced efficient FWM. Furthermore alternative waveguide designs (Bragg-waveguides) and possibilities for quasi phase matching within the resonator are discussed.

These results represent an important step towards hybrid active photonic devices combining the optical nonlinearity of chalcogenide glasses with silicon photonics.

9162-25, Session 7

Medium-dependent resonance energy transfer: a controlling role for three-centre upconversion

Jamie M. Leeder, David L. Andrews, Univ. of East Anglia (United Kingdom)

Upconversion (UC) generally refers to any nonlinear optical process that facilitates conversion of low energy radiation into higher energy emission. Typically achieved in materials incorporating rare-earth ions, exploiting their rich density of available electronic state transitions, non-parametric UC systems are often placed in categories including excited state absorption (ESA), photon avalanche (PA) and energy transfer (ET). The latter, energy transfer upconversion (ETUC) achieves nonlinear excitation of a chromophore as a consequence of one or more non-radiative resonance energy transfer (RET) events, through coupling with neighbouring sensitizer ions. Being susceptible to the local electromagnetic environment, the mechanism of RET is known to be influenced by surrounding matter, underscoring the importance of similar channels for media control within ETUC materials.

Developing the principles of two-centre RET, a fully quantized representation of local electronic structure and electrodynamics is extended by the introduction of a mediator species – a vicinal, non-absorbing chromophore. This theory underpins a new application of the medium-modified energy transfer theory to three-centre RET. The present report focuses on upconversion in which two identical donors transfer energy to an acceptor, promoting two-photon excitation and shorter wavelength emission. The mechanism for this three-centre system proves to be significantly influenced by a fourth, essentially passive chromophore. Investigations of the influence of this mediator, in improving or inhibiting RET, determine parameters that can be optimized to improve the UC efficiency. The results provide insight into factors that might assist the optimization of laser active media, and the improvement of optical characteristics in novel designer materials.

9162-26, Session 8

Novel phenomena in nano-photonic systems of macroscopic sizes *(Invited Paper)*

Marin Soljacic, Massachusetts Institute of Technology (United States)

Nanophotonic techniques can enable numerous novel and exciting phenomena. However, in order to make use of these opportunities for many applications of interest (e.g. energy, or displays), one has to have the ability to implement nanophotonic structures over large scales. In this talk, I will present some of our recent theoretical and experimental progress in exploring these opportunities.

9162-27, Session 8

Nanophotonics with nanomaterials: a route for functional photonic integration *(Invited Paper)*

Atsushi Yokoo, M. D. Birowosuto, Masaya Notomi, NTT Basic Research Labs. (Japan)

To realize low-power photonic-integration, it is important to implement functional materials with small volume because the active size determines the power consumption. However, such heterogeneous integration is difficult. One possible way is to employ nanomaterials for building blocks for photonic integration, but. they are usually less efficient because their size is much smaller than the wavelength of light. In this talk, we show that a combination of nanomaterials with well-designed nanophotonic systems enables strong interaction between nanomaterials with photons. We demonstrate a high-Q nanocavity consisting of an sub-wavelength III/V nanowire coupled with a Si photonic crystal, which realizes unprecedented strong light confinement in a nanowire. We discuss related technologies and possible impacts for future photonic integration.

9162-28, Session 8

Fabrication and characterization of optical cavities and integrated photonics structures on GaN-based photonic crystal membranes grown on silicon for visible and near infra-red applications *(Invited Paper)*

Romuald Houdré, Noelia Vico Triviño, Ulagalandha Dharanipathy, Jean-François Carlin, Nicolas Grandjean, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

The development of waveguides and photonic crystal (PhC) waveguides has been a topic of intense research effort during the past few years. Most of conventional waveguides are fabricated on Si using silicon-on-insulator technology. However, it is intrinsically limited to near infrared applications. Owing to its near-UV bandgap, GaN is transparent in the visible range, and is an ideal candidate for visible range applications such as bio-photonics and fluorescence-based systems. III-nitrides are also potentially suitable for operation around 1.5 µm. They offer low free carrier absorption and negligible two-photon absorption. They also exhibit a considerable mechanical hardness and a high thermal stability of the refractive index, which is one order of magnitude larger than that of InP. Furthermore, III-nitride epilayers have already been grown on silicon substrates with device quality, as shown by the fabrication of high-efficiency blue light emitting diodes. Actually, GaN on silicon may offer a unique template for integrated photonics.

The fabrication and characterization of freestanding hybrid GaN photonic structures operating at 1.55 µm or in the visible range will be discussed. The structures are self-supported by tethers and coupled to photonic crystal waveguides and cavities. The fabrication process is based on the growth of GaN on Si, e-beam lithography and dry etching. W1 PhC waveguides and L3 cavities are investigated. The cavities exhibit quality factors as high as ~ 5400. In the visible range, L7-type cavity with InGaN/GaN quantum wells exhibit modes with Q factors up to 5200 at ~ 420 nm at 10 K.

9162-29, Session 8

Diamond photonics *(Invited Paper)*

Marko Loncar, Harvard School of Engineering and Applied Sciences (United States); Michael J. Burek, Birgit M. Hausmann, Harvard Univ. (United States); Vivek Venkataraman, Harvard School of Engineering and Applied Sciences (United States)

In my talk I will review recent advances in nanotechnology that have enabled fabrication of nanoscale optical devices and chip-scale systems in diamond. Applications ranging from quantum optics and nonlinear optics, to optomechanics will be discussed.

9162-30, Session 9

Graphene plasmons: properties and applications *(Invited Paper)*

Phaedon Avouris, Damon B Farmer, Marcus Freitag, IBM Thomas J. Watson Research Ctr. (United States); Yielei Li, Columbia Univ. (United States); Tony Low, Hugen Yan, Han Wang, IBM Thomas J. Watson Research Ctr. (United States)

I will discuss the optical properties and possible applications of graphene in photonics and plasmonics. I will review the basics of the single particle and collective excitations of graphene, discuss the mechanisms of photocurrent generation in graphene and the design and characteristics of graphene-based photodetectors. I will show that the coupling of light to localized graphene plasmons provides an excellent way of enhancing the strength of graphene-light interaction. Plasmon excitations

in graphene micro- and nano-structures and their use in graphene devices in the infrared and terahertz ranges of the EM spectrum will be discussed. The interactions of graphene plasmons with intrinsic graphene and substrate phonons and their implications will also be analyzed.

9162-31, Session 9

2D nano-optoelectronics *(Invited Paper)*

Thomas Mueller, Andreas Pospischil, Marco M. Furchi, Technische Univ. Wien (Austria)

Two-dimensional (2D) atomic crystals, such as graphene and atomically thin transition metal dichalcogenides (TMDCs), are currently receiving a lot of attention. They are crystalline, and thus of high material quality, even so, they can be produced in large areas and are bendable, thus providing opportunities for novel applications. In this talk, a 2D p-n junction diode based on an electrostatically doped tungsten diselenide (WSe2) atomic monolayer will be presented. As p-n diodes are the basic building block in a wide variety of optoelectronic devices, our demonstration constitutes an important advance towards 2D optoelectronics. Applications as photovoltaic solar cell, photodiode, and light emitting diode will be discussed.

9162-32, Session 9

Short-pulse fiber lasers mode-locked by carbon nanotube and graphene *(Invited Paper)*

Shinji Yamashita, The Univ. of Tokyo (Japan); Sze Y Set, Bo Xu, Alnair Labs Corporation (Japan)

We review the optical properties of carbon nanotubes (CNTs) and graphene and describe how those properties have been used for the implementation of various nonlinear fiber optic applications. Early studies on the optical properties of CNTs in the late 90s revealed that these materials exhibit high third order susceptibility and a broadband saturable absorption with a sub-picosecond response time. Recent discovery of similar nonlinear optical properties in graphene attracts much attentions in this field. Such ultrafast, highly nonlinear optical response means that they can be employed for noise suppression and for the mode-locking of fiber lasers, and in addition, their high third order nonlinearity holds great promise for the implementation of various other nonlinear fiber optic devices such as wavelength converters based on four wave mixing. In this paper, we will discuss the various methods that have been considered thus far for the integration of CNTs and graphene in optical systems and highlight the advantages and limitations of using the saturable absorption of CNTs and graphene for the passive mode-locking of fiber lasers, and the current status of CNT and graphene saturable absorbers in the state of art fiber laser technologies.

9162-33, Session 10

Quantum plasmonics: plasmon induced processes *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Plasmon energies can be tuned across the spectrum by simply changing the geometrical shape of a nanostructure. Plasmons can efficiently capture incident light and focus it to nanometer sized hotspots which can enhance electronic and vibrational excitations in nearby structures.[1] For narrow plasmonic junctions, quantum mechanical effects can play an important role: the large field induced in the junction can facilitate electron tunneling and charge transfer[2] and also lead to nonlinear optical response.[3] Another important but still relatively unexplored effect is production of hot energetic electrons which can transfer into nearby structures and induce a variety of processes. This process is a quantum mechanical effect: the decay of plasmon quanta into electron-hole pairs. I will discuss how plasmon induced hot electrons can be used in various applications: such as to induce chemical reactions in molecules physisorbed on a nanoparticle surface;[4] to inject electrons directly into the conduction band of a nearby substrate;[5] and to induce local doping of a nearby graphene sheet.[6]

Hybrid graphene-silicon photonic integrated circuits *(Invited Paper)*

Dirk R. Englund, Ren-Jye Shiue, Cheng Peng, Massachusetts Institute of Technology (United States)

There has been a rapidly growing interest in graphene-based optoelectronics. This exceptional material exhibits broadband optical response, ultrahigh carrier mobility and more importantly, potential compatibility with silicon complementary metal-oxide semiconductor (CMOS) technology. We describe our recent results on integrated hybrid graphene-silicon photonic systems. One of the central advantages of such nanophotonic structures, such as cavities and waveguides, is the ability to greatly enhance the absorption into graphene, from the low single-pass value of 2.3% to nearly 100%. In particular, by coupling graphene to an optical cavity, we demonstrated an efficient electro-optic modulator that features a modulation depth of 10 dB and a switching energy of just 300 fJ. High-speed modulators now reach rates beyond the GHz mark. We will also describe the implementation of graphene photodetectors on silicon waveguide. These show a responsivity beyond 300 mA/W. Data transmission rates in excess of 12 Gbps and response times above 20 GHz are achieved. These results show the feasibility of graphene as a building block for silicon photonic integrated circuits. In particular, on-chip graphene active devices such as modulators and photodetectors are promising for their broadband response, high-speed operation, low power consumption and ease-to-fabrication.

9162-35, Session 10

Plasmon-phonon coupling in graphene nanostructures *(Invited Paper)*

N. Asger Mortensen, DTU Fotonik (Denmark)

Nanostructured graphene on SiO2 substrates pave the way for enhanced light-matter interactions and explorations of strong plasmon-phonon hybridization in the mid-infrared regime. In particular, the structural control over localized graphene plasmons can be used to map out the hybridization of plasmon and phonon modes. Unprecedented large-area graphene nanodot and antidot optical arrays are fabricated by nanosphere lithography, with structural control down to the sub-100 nanometer regime. The interaction between graphene plasmon modes and the substrate phonons is experimentally demonstrated and variation of the nanodot diameter is used to map out the hybridization of plasmons and phonons, showing coupling energies of the order 20 meV. Our findings are further supported by theoretical calculations and numerical simulations.

9162-36, Session 10

2D materials for strong light-matter interactions at nanometer lengthscales and ultra-fast timescales *(Invited Paper)*

Frank H. Koppens, ICFO - Institut de Ciències Fotòniques (Spain)

Optics and opto-electronics of graphene is one of most vibrant, rapidly developing and exciting areas which has already led to some commercial applications. Rather than being just another new photonic material, it combines a wide palette of unique aspects which promise breakthroughs in several outstanding problems of nanophotonics and optoelectronics, including broadband photodetection and sensing, on-chip manipulation of nanoscale optical fields and lasing.

In this talk, the most recent developments of graphene nano-photonics, plasmonics and photoconversion for near-infrared and infrared frequencies are being reviewed. Strong interactions between graphene and nanoscale light-emitters are actively controlled and detected by tuning graphene from an absorbing to plasmonic material. Graphene plasmons, which allow for strong confinement of optical fields are visualized in real space and gate-tunability and long propagation lengths are demonstrated by employing high mobility graphene.

9162-37, Session 11

Molecular bond Fano resonances in organic thin films enhanced by (A)SRR arrays *(Invited Paper)*

Richard M. De La Rue, Ifeoma G. Mbomson, Saima I. Khan, Graham J. Sharp, Basudev Lahiri, Nigel P. Johnson, Univ. of Glasgow (United Kingdom); Henrique Vilhena, Scott G. McMeekin, Glasgow Caledonian Univ. (United Kingdom)

This presentation will be concerned with nanophotonic structures, in particular asymmetric split-ring resonator (ASRR) structures, that may be exploited in sensing applications. In particular, these applications include bio-medical sensing, organic material sensing more generally - and environmental sensing. Specific attention will be paid to identification of specific molecules of interest via their bond Fano-resonance signatures.

9162-38, Session 11

Spectrally selective chiral silicon metasurfaces based on infrared fano resonances *(Invited Paper)*

Gennady B. Shvets, The Univ. of Texas at Austin (United States)

Metamaterials and metasurfaces represent a remarkably versatile platform for light manipulation, biological and chemical sensing, and nonlinear optics. Many of these applications rely on the resonant nature of metamaterials, which is the basis for extreme spectrally selective concentration of optical energy in the near field. In addition, metamaterial-based optical devices lend themselves to considerable miniaturization because of their sub-wavelength features. This additional advantage sets metamaterials apart from their predecessors, photonic crystals, which achieve spectral selectivity through

their long-range periodicity. Unfortunately, spectral selectivity of the overwhelming majority of metamaterials that are made of metals is severely limited by high plasmonic losses. Here, we propose and demonstrate Fano-resonant all-dielectric metasurfaces supporting optical resonances with quality factors that are almost an order of magnitude sharper than those supported by their plasmonic counterparts. We also demonstrate that these silicon-based metasurfaces exhibit extreme planar chirality, opening exciting possibilities for efficient ultra-thin circular polarizers and narrow-band thermal emitters of circularly polarized radiation.

9162-39, Session 11

Complex chiral colloids for visible and ultraviolet plasmonics *(Invited Paper)*

David J. Norris, ETH Zürich (Switzerland)

Because nanoparticles have properties strongly influenced by their shape, various routes to complex geometries have been developed. Despite these advances, chiral shapes, those not superimposable on their mirror image, remain challenging. Aggregates and helices with chirality are possible, but not other shapes critical for sensing, catalysis, and nonlinear optics. Solid particles with strong optical chirality at ultraviolet wavelengths could also enhance detection of chirality in biomacromolecules. Here, we will discuss recent efforts to prepare chiral nanoparticles. We have been exploiting anisotropic etching of silicon wafers to create solid chiral plasmonic nanopyramids of a specific handedness. The resulting particles, which are dispersed into liquids as colloids, present chiral pockets for molecular binding whilst their tips allow exploration of superchiral electromagnetic fields. Made from gold, they exhibit record circular dichroism at red wavelengths. From aluminum, ultraviolet chirality resonant with biomolecules is obtained. Thus, in addition to other applications, they allow new routes to detecting structural chirality in chemistry and biology.

Shear ordering of densely packed core-shell spheres in super viscoelastic medium for making 3D photonic crystals

Qibin Zhao, Andrew I. Haines, David R. E. Snoswell, Univ. of Cambridge (United Kingdom); Chris E. Finlayson, Aberystwyth Univ. (United Kingdom); Christian Schaefer, Darmstadt Univ. of Technology (Germany); Peter Spahn, CACI International, Inc. (United States); Lars O. Herrmann, Jeremy J. Baumberg, Univ. of Cambridge (United Kingdom)

Making photonic crystals on large scale remains highly problematic, despite their great utility for manipulating light. We have been developing routes to polymer opals, which are stretchable 3D photonic crystals comprised of densely-packed ordered core-shell spheres. Here we demonstrate their fabrication on the kilometre-scale using a novel bottom-up bending-induced oscillatory shearing (BIOS) process.

Shearing has been widely studied yet not fully understood in both granular physics and colloidal science. Compared to most granular or colloidal systems which use a liquid inter-particle medium with low viscosity which thus has little influence, our shearing assembly works with densely-packed polymer spheres in a highly viscoelastic medium. The spheres, with a hard polystyrene core and a low Tg soft sticky polyethylacrylate shell, are pressed into thin films sandwiched between two rigid plastic foils, then sheared in the solid phase using BIOS technique. By banding the sandwiched film onto heated rollers and driving the film backward and forward repeatedly, oscillatory lateral is applied homogeneously across the whole film, and high quality flexible 3D photonic crystal films of length scale up to 1km are obtained. Optical reflection and transmission properties of the photonic crystals show the influence of processing in one direction (uni-axial BIOS) or two directions (bi-axial BIOS, 30° with respect to each other) for different numbers of passes. This is confirmed by using micro-radian x-ray scattering, which demonstrates how the in-plane and inter-plane arrangements of spheres evolves. Such polymer photonic crystals have a wide range of uses in healthcare, coatings and security applications.

9162-40, Session 12

Light trapping and solar energy harvesting in thin-film photonic crystals *(Keynote Presentation)*

Sajeev John, Univ. of Toronto (Canada)

We describe designs of 3D photonic crystal silicon-based solar cells that enhance the overall absorption of sunlight using architectures consisting of less than 1 micron (equivalent bulk thickness) of silicon. This arises from light-trapping in the higher bands of a photonic crystal, where the electromagnetic density of states is enhanced rather than suppressed. This enables unprecedented strong absorption of sunlight in a material with weak intrinsic absorption.These crystals trap light through a parallel-to-interface negative refraction (PIR) effect and other optical resonances that occur over a broad angular and frequency range. These 3D photonic crystals exhibit slow group velocity modes, in which the flow of energy is transverse to the depth of a thin film of material. In the case of a modulated nano-wire photonic crystal solar cell, it is possible to absorb roughly 75% of all available sunlight in the wavelength range of 400-1100 nm, using one micron of silicon. In the case of conical nano-pore silicon photonic crystal, roughly 85% of all available sunlight is absorbed and power conversion efficiency in the range of 17.5%-22.5% is predicted. With combined plasmonic and photonic crystal light trapping, the fraction of absorbed sunlight exceeds 90%. The power conversion efficiencies of these sub-micron photonic crystals rival those of present-day solar cells using up to 300 microns of silicon. These photonic crystals offer additional opportunities for solar spectral reshaping to rival and possibly surpass the Shockley-Queisser power conversion efficiency limit.

9162-41, Session 12

Absorption in photonic crystals: from order to disorder *(Invited Paper)*

Christian Seassal, Loic Lalouat, He Ding, Emmanuel Drouard, Guillaume Gomard, Romain Peretti, Thierry Deschamps, Institut des Nanotechnologies de Lyon (France); Fabien Mandorlo, Régis Orobtchouk, INL-CNRS-INSA Lyon (France); Alain Fave, Institut National des Sciences Appliquées de Lyon (France)

The maturity of nanophotonics has triggered the emergence of novel concepts for light trapping in photovoltaic solar cells. Such novel approaches are based on various promising nanostructures, including planar 2D photonic crystals, and their abilities to control light propagation and photon capture.

While strictly mono-periodic photonic crystals enable to achieve high absorption in limited spectral ranges, introducing a controlled degree of disorder offers an efficient way to substantially increase the integrated absorption, and finally the generated photocurrent. In this communication, we will first introduce the nanophotonic engineering concepts, and the methodologies used to design and fabricate photonic crystal assisted solar cells, based on thin or ultra-thin c-Si and a-Si:H layers. Then, we will discuss on the potential of absorption increase using multi-periodic and pseudo-disordered photonic crystals. The enhanced absorption in such complex structures is achieved thanks to the optimized coupling of the incident light into a large number of modes in the spectral range of interest.

The use of such nanophotonic concepts is thus expected to greatly increase the efficiency of moderate cost thin film solar cells. Additionally, when combined with up- or down-conversion processes, these concepts can also be at the basis of ultra-high efficiency 3rd generation solar cells.

In this communication, we will present an overview of these nanophotonic concepts. This will be illustrated by examples, with a particular focus on the emergence of photonic crystals-assisted thin film silicon solar cells.

9162-42, Session 12

All-semiconductor IR broadband superabsorbers

G. Chinna R. Devarapu, Stavroula Foteinopoulou, Univ. of Exeter (United Kingdom)

Traditional absorbing architectures involves sandwiching the absorbing medium between an anti-reflector that enhances the in-coupling of the impinging light and a back-reflector that enhances the interaction between light and the absorbing matter. Current research directions in absorption management involve impedance-matched metamaterials for antireflection or plasmonic resonances for harnessing strong interaction between light and absorber. Here we demonstrate an all-semiconductor one-step superabsorber paradigm that is judiciously structured to simultaneously facilitate both a strong in-coupling and interaction of light with the semiconductor absorber leading to a near-perfect absorption over a broad IR spectral range.

9162-43, Session 12

Multi-dielectric stacks as a platform for giant optical field *(Invited Paper)*

Aude L. Lereu, Myriam Zerrad, Institut Fresnel (France); Marlène Petit, Frédérique De Fornel, LICB, UMR CNRS 5209 (France); Claude Amra, Institut Fresnel (France)

Multi-dielectric thin films can be analytically optimized with the admittance formalism to reach 100% absorption despite the low imaginary indices (some 10-5) of dielectric materials. Such optimization hence provides large optical field enhancements [1]. Theoretically, the enhancement should not be bounded if one does not consider non-linear aspects or optical damage. Indeed the field enhancement is conversely proportional to the imaginary part of the index of refraction. However this enhancement requires drastic illumination spectral and angular bandwidths [2], which constitutes a key limitation. Such multi-dielectric stacks were produced; one was optimized to be resonant with an enhancement factor equal to 1000, for a 633 nm illumination with an incidence of 45° and a TE polarization. Near field and far field measurements were then carried out to experimentally characterize the field enhancement [3, 4]. The differences with the predicted enhancement are explained by the experimental illumination conditions. We numerically evaluate the losses as a function of the light source spectral bandwidth and angular divergence [2].

We will first present our design method leading the fabrication of such multi-dielectric stacks, which can be optimized for arbitrary wavelengths, indices or polarizations. We will then report on our experimental characterization in near and far field, using a photon scanning tunneling microscope and scattering optical setup, respectively. Finally, we will numerically demonstrate the spectral and angular bandwidths essential to achieve the predicted field enhancement. This investigation may find applications for ultra-sensitive optical sensors or integrated light sources to mention a few.

9162-46, Session 13

Controlling and creating plasmonic absorption processes in graphene nanostructures

Victor W. Brar, California Institute of Technology (United States) and Kavli Nanoscience Institute (United States); Min S. Jang, Seoul National Univ. (Korea, Republic of); Michelle Sherrott, Seyoon Kim, Laura Kim, California Institute of Technology (United States); ManSoo Choi, Seoul National Univ. (Korea, Republic of); Harry A. Atwater Jr., California Institute of Technology (United States)

Behaving as an extraordinarily thin waveguide, graphene has been recently shown to support electronically tunable ,Mid-IR plasmons with optical mode volumes that are 107 times smaller than freespace, and plasmon wavelengths more than 100 times shorter. In this presentation, it will be shown that the plasmonic absorption of a graphene sheet can be enhanced and perturbed in controllable ways by controlling the thickness and permittivity of the supporting substrate. We will show the results of recent experiments where 25% absorption is achieved in the plasmonic modes of a graphene sheet by carefully selecting the properties of an underlying silicon nitride substrate. We also demonstrate how additional absorption pathways can be created by modifying the surrounding dielectric environment to have optical resonances that can couple to the graphene plasmons. By placing graphene nanoresonators on a single layer boron nitride (BN) sheet new surface phonon plasmon polariton (SPPP) modes arise due to a strong coupling effect between the graphene plasmons and a BN optical phonon. We map the wavevector and doping dependence of these modes, and show that they display an anti-crossing behavior that indicates the strength of the coupling effect.

9162-47, Session 13

Plasmoelectric potentials in Au nano-hole arrays

Matthew T. Sheldon, California Institute of Technology (United States); Jorik van de Groep, FOM Institute for Atomic and Molecular Physics (Netherlands); Ana M. Brown, California Institute of Technology (United States); Albert Polman, FOM Institute for Atomic and Molecular Physics (Netherlands); Harry A. Atwater Jr., California Institute of Technology (United States)

The resonant plasmonic properties of metallic nanostructures depend strongly on charge carrier density. Stemming from this dependence, we have recently reported a theoretical framework and provided experimental evidence for a 'plasmoelectric effect', a newly described mechanism for generating electrochemical potentials in plasmonic nanostructures. Our initial work with Au colloid nanoparticles has shown that, unlike the more familiar thermoelectric or photovoltaic effects, the magnitude and sign of the plasmoelectric potential depends on the frequency difference between the plasmon resonance and incident radiation.

Here, we report measurements on lithographically patterned samples with a design that has been optimized via iterative full wave simulations to maximize plasmoelectric potentials. The structure consists of lithographically defined square-lattice arrays of 100nm diameter holes in a 20nm thick Au film. The plasmonic resonance is very sensitive to the inter-hole spacing, allowing sharp and highly tunable absorption peaks to be defined across the visible spectrum by varying the hole pitch. Scanning Kelvin probe force microscopy (KPFM) determined the surface potential of device structures while varying the incident wavelength. Under 30mW cm^-2 monochromatic illumination, we measure induced potentials of ± 150mV from hole arrays, with a characteristic sign change for illumination blue or red of the absorption maximum. This is a 2-order of magnitude increase compared with Au colloid particles, and consistent with our theoretical framework. Our findings guide the development of solid-state power conversion devices based on the plasmoelectric effect, as our devices generate electrochemical potentials 1000x larger than comparable thermocouples under equivalent optical power.

9162-48, Session 13

Theory of absorption-induced transparency *(Invited Paper)*

Sergio G. Rodrigo, Centro Univ. de la Defensa (Spain) and Instituto de Ciencia de Materiales de Aragón (Spain); Luis Martín-Moreno, Instituto de Ciencia de Materiales de Aragón (Spain)

Absorption induced transparency (AIT), roughly speaking, is a peak seen in the transmission spectrum of a holey metal film when a molecular dye is deposited on top of it [1]. An AIT peak appears unexpectedly close to one of the absorption energies of the molecules, hence its name. Tentative explanations of AIT pointed to strong-coupling interactions between Surface-Plasmon-Polaritons (SPPs) and molecules, when they are close by the metal surface (not inside the holes) [1]. However, we recently demonstrated the actual physical mechanism behind AIT [2]. This takes place through a strong modification of the propagation constant of holes, kz, so the holes must be at least partially filled. The spectral position of an AIT peak, its intensity and full width is mainly controlled by the spectral features of kz, AIT having thus a localized character, which also explains that it occurs in single holes.

In addition, we demonstrated that hole arrays in the AIT regime behave like a metamaterial characterized by a dielectric constant composed by a Drude plasma term (of geometric origin) plus a Lorentz term due to the molecules. We shown that AIT peaks are nonplasmonic in character, so they are expected at frequency regimes other than the optical, what opens the door for detection spectroscopy of chemical compounds with sharp absorption lines in the THz or microwave regimes.

Meta-detectors for 4th generation infrared imagers *(Invited Paper)*

Sanjay Krishna, Ctr. for High Technology Materials (United States)

Mid infrared imagers are poised for the 4th generation of imagers. There is an increased emphasis on obtaining detectors with enhanced dynamic functionality at the pixel level. Meta-infrared detectors in which infrared detectors are combined with meta-structures are a promising way to realize this. The infrared region is appealing due to the low metallic loss, large penetration depth of the localized field and the larger feature sizes compared to the visible region. We will discuss approaches to realize multicolor detectors using these approaches.

Design of highly directional and narrowband infrared emitters

Christopher H. Granier, Louisiana State Univ. (United States); Francis O. Afzal, Truman State Univ. (United States) and Louisiana State Univ. (United States); Changjun Min, Nankai Univ. (China) and Louisiana State Univ. (United States); Jonathan P. Dowling, Georgios Veronis, Louisiana State Univ. (United States)

Bulk thermal emittance sources possess incoherent, isotropic, and broadband radiation spectra that vary from material to material. However, these radiation spectra can be drastically altered by modifying the geometry of the structures. In particular, several approaches have been proposed to achieve narrowband, highly directional thermal emittance based on photonic crystals, gratings, textured metal surfaces, metamaterials, and shock waves propagating through a crystal. Here we present optimized aperiodic structures for use as narrowband, highly directional thermal infrared emitters for both TE and TM polarizations. One-dimensional layered structures without texturing are preferable to more complex two- and three-dimensional structures because of the relative ease and low cost of fabrication. These aperiodic multilayer structures designed with alternating layers of silicon and silica on top of a semi-infinite tungsten substrate exhibit extremely high emittance peaked around the wavelength at which the structures are optimized. Structures were designed by a genetic optimization algorithm coupled to a transfer matrix code which computed thermal emittance. First, we investigate the properties of the genetic-algorithm optimized aperiodic structures and compare them to a previously proposed resonant cavity design. Second, we investigate a structure optimized to operate at the Wien wavelength corresponding to a near-maximum operating temperature for the materials used in the aperiodic structure. Finally, we present a structure that exhibits nearly monochromatic and highly directional emittance for both TE and TM polarizations at the frequency of one of the molecular resonances of carbon monoxide (CO); hence, the design is suitable for a detector of CO via absorption spectroscopy.

Unusual thermal emission from a 3D metallic photonic crystal: quasi-equilibrium limit *(Invited Paper)*

Mei-Li Hsieh, National Chiao Tung Univ. (Taiwan); Rajeev V. Shenoi, Shawn-Yu Lin, Rensselaer Polytechnic Institute (United States)

We report the observation of unusual thermal radiation at elevated temperatures (T=400-900K) from a three-dimensional metallic photonic-crystal composite that includes a micro-cavity. Upon thermal excitation, its emissive power at selective wavelengths does not correlate with its absorptivity - a deviation from the postulate of Kirchhoff law at thermodynamic equilibrium. The ratio of its emissive power to that of a black body at nominally the same surface temperature also far exceeds one- a deviation from Planck's radiation law. The excitation of photon gas in the photonic-crystal composite beyond the equilibrium Bose-Einstein distribution is suggested as a possible explanation.

9162-52, Session 14

Tensilely strained germanium nanomembranes for direct-bandgap infrared light emission *(Invited Paper)*

Roberto Paiella, Cicek Boztug, Boston Univ. (United States); Jose Sanchez-Perez, University of Wisconsin - Madison (United States); Jian Yin, Boston Univ. (United States); Max G Lagally, University of Wisconsin - Madison (United States)

The development of practical light sources based on group-IV semiconductors is a major outstanding goal of optoelectronics research, as a way to enable the continued integration of electronic and photonic functionalities on a CMOS compatible platform. However, this goal is severely complicated by the indirect energy bandgap of silicon, germanium, and related alloys. A possible solution is provided by the ability of biaxial tensile strain in Ge to lower the conduction-band edge at the direct (Gamma) point relative to the L-valley minima, until at a strain of about 1.9% the fundamental bandgap becomes direct.

Here we show that, by virtue of their ultrasmall thicknesses, Ge nanomembranes under externally applied mechanical stress are capable of accommodating such relatively high strain levels (up to over 2%). With this approach, we have demonstrated strong strain-enhanced Ge photoluminescence accompanied by a large strain-induced red shift in emission wavelength. A theoretical model of the emission properties of tensilely strained Ge has also been developed and applied to the measured high-strain luminescence spectra, providing evidence of population inversion. Finally, mechanically flexible photonic-crystal cavities have been developed on these nanomembranes, and used to demonstrate particularly large (20?) strain-induced enhancements in radiative efficiency, together with the observation of luminescence signatures associated with band-edge cavity modes. These results are promising for the development of group-IV semiconductor lasers for the technologically important short-wave infrared spectral region.

9162-53, Session 15

Recent progress in photonic crystals and their applications *(Invited Paper)*

Susumu Noda, Kyoto Univ. (Japan)

In this conference, I will report on the recent progress in photonic crystals. The examples include (i) ultrahigh-Q nanocavities, (ii) all-Si Raman nanolasers, (iii) broad-area high-power coherent photonic-crystal lasers, (iv) thermal-emission control for environmental sensing and thermo-photovoltaic power generation system, and (v) on-demand 3D optical control. Such a broad-range of progress in photonic crystals indicates that photonic crystal research has now entered advanced phases towards realization of ultimate control of photons.

9162-54, Session 15

Multi-color nanowire photonic crystal laser pixels *(Invited Paper)*

Ganapathi S. Subramania, Jeremy B. Wright, Sheng Liu, George T. Wang, Qiming Li, Alexander Benz, Daniel D. Koleske, Ping Lu, Sandia National Labs. (United States); Huiwen Xu, Luke F. Lester, The Univ. of New Mexico (United States); Ting-Shan Luk, Igal Brener, Sandia National Labs. (United States)

Emerging applications such as solid-state lighting and display technologies require micro-scale vertically emitting lasers with controllable distinct lasing wavelengths and broad wavelength tunability arranged in desired geometrical patterns to form “super-pixels”. Conventional edge-emitting lasers and current surface-emitting lasers do not produce a viable solution as they require abrupt changes in semiconductor bandgaps or cavity length. Here, we successfully address these challenges by introducing a new paradigm that extends the laser tuning range additively by employing multiple monolithically grown gain sections each with a different emission center wavelength. Using broad gain-bandwidth III-nitride multiple quantum well (MQW) heterostructures and a novel top-down nanowire photonic crystal nanofabrication we obtain single-mode lasing in the blue-violet spectral region(Sci. Rep,3,2982(2013)). This has a remarkable 60 nm of tuning (or 16% of the nominal centre wavelength) that is determined purely by the photonic crystal geometry. This approach can be extended to cover the entire visible spectrum.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-AC04-94AL85000.

9162-55, Session 15

Active nanophotonics technology *(Invited Paper)*

Yeshaiahu Fainman, Univ. of California, San Diego (United States)

Achieving the most compact footprint for photonic components is an important factor in the design of integrated optical devices. Like most other photonic components, the minimum size for a laser is ultimately governed by ?0, the free space wavelength of the laser emission. As the size of a conventional dielectric semiconductor laser is decreased towards ?0, three effects adversely influence the lasing process. Firstly, the roundtrip path of the optical wave in the gain medium is shortened, secondly radiative losses are increased and finally the field confinement inside the resonator is reduced, resulting in less overlap of the optical mode with the gain medium. All of these effects serve to increase the lasing threshold, so that lasing cannot be achieved below a certain size limit. The ultimate challenge is to reduce the size of the laser resonator in all three dimensions.

We introduced a new family of 3-D nanolaser resonators, developed design and fabrication methodology as well as testing and characterization procedures. The example devices experimentally validate our approaches and demonstrated lasers action at room temperatures. We also demonstrated a new family of scalable plasmonic nanoresonators exploiting coaxial structures and used these nanolasers to demonstrate thresholdless operation. There are a number of very important research directions that are still in initial stages and will need to be investigated further in the future.

Light self-trapping in an array of sub wavelength waveguides

Gregorio Mendoza González, Erwin A. Martí Panameño, Benemérita Univ. Autónoma de Puebla (Mexico)

Based in the numerical experiment techniques, we study the propagation dynamics of an optical beam in an one-dimensional array of parallel subwavelength waveguides, possessing Kerr nonlinearity. In our problem we consider the plane wave and monochromatic approximations. The numerics are based in Finite Difference Time Domain (FDTD) method. With a constant Kerr coefficient, and selecting the array parameters (diameter and separation of the waveguides) as well as the incident radiation properties (wavelength, field amplitude, etc.), we are able to observe the self-trapping of the light in one single waveguide. The radiation self-trapping can be observed for different incidence angles.

9162-72, Session PWed

Third-harmonic generation enhancement in polymer-dispersed liquid crystal grating

Surawut Wicharn, Prathan Buranasiri, King Mongkut’s Institute of Technology Ladkrabang (Thailand)

In this paper, the enhancement of third-harmonic generation in one-dimensional periodic grating structure with low-index contrast, which is produced by holographic illuminated liquid crystal droplets and called polymer-dispersed liquid crystal grating, with near-infrared pumping has been demonstrated. The observed enhancement process is theoretically explained and modeled with a multiple-scale perturbation analysis and split-step Fourier transform technique, respectively. We show that the third-harmonic generation has been enhanced by setting the fundamental frequency wavelength to the long-wavelength band-edge of the first photonic band-gap of this periodic structure and satisfying band-edge phase-matched condition. The numerical results show that a dramatic enhancement of the third-harmonic field is observed near the long-wavelength band-edge of the second photonic band-gap. Furthermore, the total energy output of third-harmonic field is more than the energy that produced by a phase-matched nonlinear crystal.

9162-73, Session PWed

Cooperative behavior of quantum emitters coupled to plasmonic waveguides near frequency cutoff

Ruzan Sokhoyan, Harry A. Atwater Jr., California Institute of Technology (United States)

Future quantum computing and communication systems are likely to exploit coherently coupled quantum emitters. In free space, dipole-dipole interactions between quantum emitters drastically diminish when the inter-emitter spacing is comparable to half a resonant wavelength. Coupling quantum emitters to plasmonic structures could dramatically increase their interaction range, due to the small mode volume characteristic to plasmonic fields. Within the framework of

quantum electrodynamics, we articulate here how coupling quantum dipole emitters to a plasmonic waveguide could enable observation of quantum cooperative effects, focusing on the emitter entanglement and collective decay. We consider a single-mode plasmonic rectangular waveguide with a dielectric core and metal cladding which is known to mimic behavior of an epsilon-near-zero metamaterial at the frequency cutoff [1]. Assuming different resonant frequencies of the quantum emitters we investigate how the inter-emitter interactions are varied when approaching the cutoff frequency of the fundamental plasmonic mode supported by the waveguide. We calculate Purcell factor, collective decay and coupling parameters as a function of the spatial position and resonant frequencies of the emitters. We show that coupling emitters to an ?-near-zero waveguide allows one to relax the constraint on precision positioning of emitters which is crucial for other solid state based entanglement generation schemes and extend the spatial scale at which the superradiance can be observed.

Gold nanoplates can serve as mirrors to enhance nanoparticle electrodynamics

Zijie Yan, Ying Bao, Uttam Manna, Raman Shah, Norbert F. Scherer, The Univ. of Chicago (United States)

Mirrors are ubiquitous components of modern optical experiments, where they define laser cavities, serve as essential elements for beam steering and beam shaping (e.g., spatial light modulators), and play key roles in light-emitting and harvesting devices. Chemically synthesized single-crystalline Au nanoplates have atomically flat surfaces over micron length scales, representing “perfect” mirrors to reflect (near-) infrared laser beams with negligible distortion. Here we show that such Au nanoplates can serve as transmissive mirrors that enhance optical detection and electrodynamic interactions. We demonstrate enhanced optical trapping and optical binding of Ag nanoparticles in interferometric optical traps created by the Au plate mirrors. Moreover, in dark-field microscopy, the Au nanoplates behave analogously to extraordinarily transmissive substrates that improve the imaging of Ag nanoparticles near a nanoplate surface by enhancing the scattering of light from nanoparticles that are in close proximity (~100 nm) to the Au nanoplate. Our results show that Au nanoplates can serve as unique platforms as active photonic materials for optical manipulation and for the investigation of plasmonic interactions between different metallic nanostructures.

Nonlinear optical phononics: Inducing and harnessing stimulated Brillouin scattering in nanoscale photonic circuit waveguides *(Invited Paper)*

Benjamin J. Eggleton, The Univ. of Sydney (Australia)

We review recent progress in inducing and harnessing stimulated Brillouin scattering (SBS) in integrated photonic circuits. Exciting SBS in a chip-scale device is challenging due to the stringent requirements on materials and device geometry. We discuss these requirements, which include material parameters, such as optical refractive index and acoustic velocity, and device properties, such as acousto-optic confinement. Recent work on SBS in nano-photonic waveguides and micro-resonators is presented, with special attention paid to photonic integration of applications such as narrow-linewidth lasers, slow- and fast-light, microwave signal processing, Brillouin dynamic gratings, and nonreciprocal devices.

9162-59, Session 16

PT-symmetric synthetic materials and structures *(Invited Paper)*

Demetrios N. Christodoulides, Mohammad-Ali Miri, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

We provide an overview of recent developments in parity-time symmetric optical materials and structures. As it will be shown, PT-symmetry can be directly realized in optics through a judicious intermixing of optical gain, loss, and index guiding. The properties and possible optical functionalities that could emerge from this symmetry will be also discussed in this talk.

9162-60, Session 16

Single mode PT symmetric large area lasers

Hossein Hodaei, Mohammad-Ali Miri, Matthias Heinrich, Demetrios N. Christodoulides, Mercedeh Khajavikhan, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

In the last few years, compact high-power single-mode semiconductor lasers have been the focus of considerable attention for integrated photonic applications. Despite the intense activity in this area, the realization of such sources in a fully integrated fashion still remains a challenging task. Various strategies to preferentially encourage lasing in the fundamental mode have so far been suggested including spatial filtering by which one aims to increase the losses (or at least lower the gain) experienced by the undesirable modes, without unduly influencing the lasing threshold of the fundamental mode. However, the resulting laser devices tend to be significantly more sensitive to longitudinal and lateral perturbations.

Quite recently, a new approach has been proposed to resolve these issues by utilizing parity-time (PT) symmetry. When the refractive index of an optical arrangement is described by an even profile, while its gain/loss obeys an anti-symmetric distribution, the corresponding eigenvalue spectrum may be entirely real-valued. As a consequence, the modes experience zero net gain or loss, unless PT symmetry is spontaneously broken. Within the context of large-mode-area lasers, this phase transition can be judiciously tuned to present substantial gain to the fundamental mode, while appearing neutral to all the higher order modes. Here we demonstrate a novel class of large-area single-mode semiconductor distributed feedback lasers in which notions from parity-time symmetry is employed to reliably suppress higher-order

spatial modes while the DFB structure ensure single longitudinal mode operation. Our work provides an important step towards harnessing PT symmetry to enforce single-mode operation in intense large mode-area lasers.

9162-61, Session 16

Unidirectional lasing emerging from frozen light in nonreciprocal cavities *(Invited Paper)*

Hamidreza Ramezani, Univ. of California, Berkeley (United States); Tsampikos Kottos, Wesleyan Univ. (United States); Ilya Vitebskiy, Air Force Research Lab. (United States)

We introduce a class of unidirectional lasing modes associated with the frozen mode regime of nonreciprocal slow-wave structures. Such asymmetric modes can only exist in cavities with broken time-reversal and space inversion symmetries. Their lasing frequency coincides with a spectral stationary inflection point of the underlying passive structure and is virtually independent of its size. These unidirectional lasers can be indispensable components of photonic integrated circuitry.

9162-62, Session 17

Isotropic Dirac cones in the Brillouin-zone center of photonic crystals and metamaterials *(Invited Paper)*

Kazuaki Sakoda, National Institute for Materials Science (Japan) and Univ. of Tsukuba (Japan); Hiroyuki Takeda, National Institute for Materials Science (Japan)

The isotropic linear dispersion relation in the Brillouin zone of optical periodic structures, which is often called (photonic) Dirac cones, has been attracting considerable interest, since it can realize interesting optical phenomena such as unidirectional propagation of surface modes and optical simulation of Zitterbewegung. In particular, Huang et al. (Nature Mater., 2011) clarified that isotropic Dirac cones in the Brillouin-zone center can be created by accidental degeneracy of two modes for two-dimensional square- and triangular-lattice dielectric photonic crystals.

On the other hand, we showed by the tight-binding approximation for metamaterials characterized by well-defined electro¬magnetic resonant states localized in their unit structures that the particular combination of the symmetry of the two modes results in the Dirac cone (Opt. Express, Vol. 20, p.3898 (2012)) and the double Dirac cone (Opt. Express, Vol. 20, p.9925 (2012)). Later we extended this discussion to general cases by developing a degenerate perturbation theory for the vector electromagnetic field combined with the group theory (Opt. Express, Vol. 20, p.25181 (2012)) and proved the presence of the Dirac cones and double Dirac cones in the square, triangular, and cubic systems.

In this presentation, we extend our calculation to photonic crystals and metamaterials of different spatial symmetries and examine the method to realize and detect Dirac cones in optical frequencies. In particular, we discuss the possibility of their creation in photonic crystal slabs by numerical examination of their dispersion relation.

9162-63, Session 17

Photonic analog of graphene: novel functions inspired by condensed matter physics *(Invited Paper)*

Tetsuyuki Ochiai, National Institute for Materials Science (Japan)

Conical dispersion in 2d and 3d physical systems attracts growing interests recently.

Graphene, monolayer of Carbon atoms arranged in a honeycomb lattice, is a typical example that exhibits the so-called Dirac cone around the Brillouin zone corners. Honeycomb-lattice photonic crystals (PhCs) composed of parallel cylinders also exhibit the Dirac cone whose mass gap is controllable with the symmetry of the structures.

We thus refer to the honeycomb-lattice PhCs as photonic analog of graphene.

The controllability enables us to design various novel light transports in the bulk, edge, and interface, inspired by notions developed in condensed-matter physics.

I will present fundamental properties of the photonic graphene and their possible applications.

9162-64, Session 18

Nonlinear evolution of slow light pulses *(Invited Paper)*

Kobus Kuipers, FOM Institute for Atomic and Molecular Physics (Netherlands)

One of the advantages of slow light in photonic crystals is that the slowdown of the light propagation enhances nonlinear processes. Investigation of these processes is however far from trivial. As is always the case in nonlinear optics, the sequence of components in a device matters to the overall nonlinear response of the composite device. As a consequence it is hard from input-output measurements to determine how each individual component contributes to the overall evolution of slow light pulses. In order to solve this we demonstrate, following the electrical analogue, nanoscale photonic point-to-point measurements characterizing a single component inside a composite device. We perform spectrally resolved near-field scanning optical microscopy on ultrashort pulses propagating inside a slow light photonic crystal waveguide, which is part of a composite sample. A power study reveals a reshaping of the pulse's spectral density, which we model using the nonlinear Schrödinger equation. With the model, we are able to identify the various physical processes governing the nonlinear pulse propagation. Finally, we contrast the near-field measurements with transmission measurements of the complete composite sample to elucidate the importance of gaining local information about the evolution of the spectral density.

9162-65, Session 18

Slow-light metawaveguides

Stavroula Foteinopoulou, Univ. of Exeter (United Kingdom)

We demonstrate the strong coupling between backward and forward guided modes in a left-handed material(LHM)-right-handed material (RHM) heterostructure waveguide leading to a slow light mode that can extended over a wide modal-index bandwidth. Our dynamic simulations in time-domain reveal that the latter is a most crucial feature for effectively achieving ultra-slow propagation of EM energy. We further show with our paradigm that strong temporal compression leads to a mesoscopic intensity enhancement, covering areas of the order of the free space wavelength without the need for a strong spatial compression.

9162-66, Session 18

Optically induced indirect photonic transitions in a slow light photonic crystal waveguide *(Invited Paper)*

Manfred Eich, Michel Castellanos Munoz, Alexander Y. Petrov, Technische Univ. Hamburg-Harburg (Germany); Liam O'Faolain, Univ. of St. Andrews (United Kingdom); Juntao Li, Univ. of St. Andrews (United Kingdom) and Sun Yat-Sen Univ. (China);

Thomas F. Krauss, Univ. of St. Andrews (United Kingdom) and The Univ. of York (United Kingdom)

The presentation will cover our work on indirect photonic transitions in a silicon slow light photonic crystal waveguide. The transitions are driven by an optically generated refractive index front that moves along the waveguide and interacts with a signal pulse copropagating in the structure. The structure described is genuinely nonreciprocal, as it provides different frequency shifts for co- and counterpropagating signal and index fronts.

9162-67, Session 18

Theory and experimental demonstration of enhanced gain in slow light photonic crystal waveguides *(Invited Paper)*

Jesper Mørk, Yaohui Chen, Per Lunnemann Hansen, Sara Ek, Elizavetta S. Semenova, Kresten Yvind, Technical Univ. of Denmark (Denmark)

In this talk we experimentally demonstrate that by the use of slow light effects, the gain coefficient of a semiconductor waveguide can be enhanced beyond the value given by the material gain. The device investigated is a photonic crystal membrane structure with embedded layers of quantum wells or quantum dots. Furtermore, an effective model in terms of propagating Bloch waves is derived and fundamental limitations to the gain enhancement are discussed.

9162-76, Session 18

True stopping of light: a new regime for nanophotonics *(Invited Paper)*

Kosmas L. Tsakmakidis, Xiang Zhang, Univ. of California, Berkeley (United States); Ortwin Hess, Imperial College London (United Kingdom)

The extremely large speed of light is a tremendous asset but also makes it challenging to control, store or shrink beyond its wavelength. Particularly, reducing the speed of light down to zero is of fundamental scientific interest that could usher in a host of important photonic applications, some of which are hitherto fundamentally inaccessible. These include cavity-free, low-threshold nanolasers, novel solar-cell designs for efficient harvesting of light, nanoscale quantum information processing (owing to the enhanced density of states), as well as enhanced biomolecular sensing. We shall here present nanoplasmonic-based schemes where time-dependent sources excite “complex-frequency” modes in uniform (plasmonic) heterostructures, enabling complete and dispersion-free stopping of light pulses, resilient to realistic levels of dissipative, radiative and surface-roughness losses. Our theoretical and computational results demonstrate extraordinary large light-deceleration factors (of the order of 15,000,000) in integrated nanophotonic media, comparable only to those attainable with ultracold atomic vapours or with quantum coherence effects, such as coherent population oscillations, in ruby crystals.

9162-68, Session 19

Generation and control of vortex beams using twisted nonlinear photonic crystals *(Invited Paper)*

Ady Arie, Tel Aviv Univ. (Israel)

Twisted nonlinear photonic crystals can be realized by introducing an edge dislocation into an otherwise periodically poled quadratic nonlinear crystal. In this case, the second order nonlinear coefficient has a fork-shaped form. By sending a pump beam transversely to the plane of the dislocation, a vortex beam is generated at the second harmonic, whose orbital angular momentum is determined by the crystal. Furthermore, when the pump beam travels longitudinally, in the plane of the dislocation, the parity of the dislocation’s topological charge governs the transfer of energy between an input wave and its second harmonic.

9162-69, Session 19

The topological photonic states in gyrotropic microstructured materials *(Invited Paper)*

Yanfeng Chen, Minghui Lu, Cheng He, Nanjing Univ. (China)

The topology of electronic systems has recently attracted much attention in condensed matter physics research because of its unique properties including robust unidirectional chiral edge (surface) states and fermionic time-reversal symmetry protected momentum-dependent spin polarization of such edge (surface) states in quantum spin Hall (topological insulator) system. In this talk, we propose some quasi-particle counterparts of the quantum spin Hall effect (topological insulator) in two-dimensional photonic or phononic crystals. For photonic analogy, two linear electromagnetic polarizations (transverse electric and transverse magnetic waves) can propagate in one-way with opposite directions at the edge of photonic crystal composed of a gyrotropic medium exhibiting both gyroelectric and gyromagnetic properties simultaneously. Two circular polarizations (left-circular and right-circular waves) can be used to realize photonic topological insulator by piezo-electric and piezo-magnetic superlattices as well. Such photonic topological systems show unidirectional polarization-dependent transportation of photonic topological edged states, which is robust against certain disorders and impurities. Analyzing the symmetry in these systems, we find that some bosonic time-reversal invariant chiral impurities would invalidate such topological states, indicating that the conventional bosonic time-reversal symmetry is not valid to protect their robustness. Instead, the robustness is rather protected by a new symmetry, which might be the general requirement for topological photonic crystals. Thus, we find that this unique property is not protected by conventional time-reversal symmetry of photons obeying the bosonic statistics with T2=1 but rather by the same symmetry, T2=-1, as electron’s time-reversal symmetry. Based on the tight-binding approximation approach, we construct an effective Hamiltonian for these photonic structures, which have a similar form to that of an electronic system. Furthermore, the Z2 invariant of such models is calculated in order to unify their topological non-trivial character. Our finding provides a viable way to exploit the topological property of quasi-particles, and also can be used to develop a platform to mimic the spin properties of electrons.

9162-70, Session 19

Topological feature in silicon photonics *(Invited Paper)*

Mohammad Hafezi, Joint Quantum Institute (United States)

We investigate the effect of synthetic gauge fields on various photonic transport properties. In particular, we demonstrate the robustness of topological edge states in a photonic system of coupled microring resonators. Using direct imaging and transmission analysis, we show that the edge states are less susceptible to lattice disorders than bulk states.

9163-1, Session 1

Bringing metamaterials to real applications *(Invited Paper)*

Vladimir M. Shalaev, Alexander V. Kildishev, Alexandra Boltasseva, Purdue Univ. (United States)

Basic requirements and challenges for brining metamaterials (MMs) to real-life applications will be discussed. We also review the recent progress in developing tunable and active MMs, nanolasers, and a new means for engineering the photonic density of states with MMs. Novel plasmonic materials with superior properties based on transparent conducting oxides and ceramics will be outlined. Finally, we consider a new approach for controlling light by using 2D meta-surfaces.

9163-2, Session 1

Graphene plasmonics and nanophotonics *(Invited Paper)*

Harry A. Atwater Jr., California Institute of Technology (United States)

Field effect tuning of the electrochemical potential in graphene nanoresonators enables the plasmon and phonon dispersion to be measured. We experimentally demonstrate a method of efficiently coupling long-wavelength freespace light into nanoscale graphene plasmonic resonators. Despite the large wavelength mismatch and the thinness of the graphene sheet, we show that nearly 25% of incident radiation at 7.2 microns can be coupled into 40nm graphene nanoresonators - an order of magnitude improvement over conventional silicon dioxide/Si-based graphene devices. This large enhancement of absorption is achieved by employing a “Salisbury screen”-type geometry, where a back reflector is held in the vicinity of the graphene nanoresonators to create a destructive interference effect. Our calculations show that this simple geometry allows for the impedance of the graphene plasmonic modes to be matched to the freespace impedance, which results in the efficient absorption that we observe. We can further tune the metasurface impedance to modulate this effect, either by electrostatically varying the carrier density in situ, or by patterning the graphene nanoresonators to different lengthscales. Those controls allow us to electronically tune the absorption from 0 to 25%, and demonstrate at least 22% absorption over 100cm-1 of bandwidth.

9163-3, Session 2

Topological insulator for broadband switchable metamaterials *(Invited Paper)*

Jun-Yu Ou, Jin-Kyu So, Univ. of Southampton (United Kingdom); Giorgio Adamo, Zilong Wang, Jun Yin, Venkatram Nalla, Stefano Vezzoli, Azat Sulaev, Lan Wang, Handong Sun, Cesare Soci, Nanyang Technological Univ. (Singapore); Nikolay I. Zheludev, Optoelectronics Research Ctr. (United Kingdom) and Nanyang Technological Univ. (Singapore)

Topological Insulator BiSbTeSe (BSTS) is introduced as a broadband plasmonic material ranging from mid-IR to UV. Dielectric constants derived from ellipsometric measurements are in excellent agreement with first principle DFT calculations showing two regions of anomalous dispersion due to the combination of bulk interband transitions and surface contribution of the topologically protected states in the UV and the bandgap region (~5 ?m). Metamaterials and gratings are fabricated on the BSTS crystal showing strong plasmonic response from UV to NIR. This, combined with ultrafast (t>100 fs) modulation of its optical response, shows the potential of Topological Insulators as platforms for high-frequency switchable metamaterials.

9163-4, Session 2

Yttrium hydride nanoantennas for active plasmonics

Nikolai Strohfeldt, Andreas Tittl, Martin Schäferling, Frank F. Neubrech, Univ. Stuttgart (Germany); Uwe Kreibig, RWTH Aachen (Germany); Ronald Griessen, Vrije Univ. Amsterdam (Netherlands); Harald W. Giessen, Univ. Stuttgart (Germany)

A key challenge for the development of active plasmonic nanodevices is the lack of materials with fully controllable plasmonic properties. In this work, we demonstrate that a plasmonic resonance in top-down nanofabricated yttrium antennas can be completely and reversibly turned on and off using hydrogen exposure. We fabricate arrays of yttrium nanorods and optically observe in extinction spectra the hydrogen-induced phase transition between the metallic yttrium dihydride and the insulating trihydride. Whereas the yttrium dihydride nanostructures exhibit a pronounced particle plasmon resonance, the transition to yttrium trihydride leads to a complete vanishing of the resonant behavior. The plasmonic resonance in the dihydride state can be tuned over a wide wavelength range by simply varying the size of the nanostructures. By modifying the dielectric function of yttrium dihydride from literature to include nanofabrication-specific effects, we are also able to perfectly reproduce our experimental extinction spectra in numerical simulations, what allows us to make quantitative predictions about the resonance width and position of any yttrium-based plasmonic nanodevice. Furthermore, we develop an analytical diffusion model to explain the temporal behavior of the hydrogen loading and unloading trajectories observed in our experiments and gain information about the thermodynamics of our device. Thus, our nanorod system serves as a versatile basic building block for active plasmonic devices ranging from switchable perfect absorbers to active local heating control elements.

9163-5, Session 2

Electrodynamic description of spasers: multipolar modes, universal figures of merit, and minimal gain threshold

Nikita Arnold, Calin Hrelescu, Thomas A. Klar, Johannes Kepler Univ. Linz (Austria)

Although a spaser is in principle a quantum-mechanical system, we demonstrate that it can be conveniently described within a purely electrodynamic framework. Both spasing threshold and post-threshold operation are in some respect conceptually similar to a conventional laser, where an electrodynamic framework can also be applied as long as gain saturation is included in the dielectric constant close to and beyond threshold.

We find universal expressions for the necessary threshold-gain for small (unretarded) particles of arbitrary shape. The minimal required gain at a specific wavelength depends only on the optical materials constants of the metal and the gain matrix, and is independent of the particle shapes. With realistic non-restrictive assumptions about the gain medium, this wavelength is close to the spectral minimum of the ratio -Im(eps_met)/Re(eps_met) , which therefore represents the universal figure of merit for a given metal. When Ag is used as a metal and a typical polymer as a host matrix, spasing can be expected at -Im(eps_gain)=0.026, which corresponds to a realistic dye concentration of some 10^19 cm^3.

Nevertheless, once the minimally necessary gain at a specific frequency

is determined via the materials constants, the specific geometric parameters, such as aspect ratios of rods or shells can be determined which allow for spaser operation at this minimal gain.

These general considerations are illustrated with two examples: (i) retarded calculations for dipolar modes of finite sized silver rods and (ii) semi-analytical simulations for spherical shells, both submerged in gain medium.

9163-6, Session 2

Active plasmonic devices *(Invited Paper)*

Uriel Levy, Liron Stern, Boris Desiatov, Meir Grajower, Alexandros Emboras, The Hebrew Univ. of Jerusalem (Israel)

In this talk we demonstrate the role of metal optics in enhancing the performances of active devices. This includes the demonstrations of various concepts and devices ranging from plasmonic enhanced silicon Schottky detectors for the near IR, resistive memory devices based on the platform of silicon plasmonics. Finally, we will demonstrate our recent results related to a coupled plasmonic-atomic system which provides the capability of controlling the resonant lineshape at will.

9163-7, Session 2

Plasmonic black metal polarizers for ultra-short laser pulses

Thomas M. Sondergaard, Esben Skovsen, Aalborg Univ. (Denmark); Christoph Lemke, Christian-Albrechts-Univ. zu Kiel (Germany); Tobias Holmgaard, Mekoprint A/S (Denmark); Till Leißner, Christian-Albrechts-Univ. zu Kiel (Germany); René L. Eriksen, Jonas Beermann, Univ. of Southern Denmark (Denmark); Michael K. Bauer, Christian-Albrechts-Univ. zu Kiel (Germany); Kjeld Pedersen, Aalborg Univ. (Denmark); Sergey I. Bozhevolnyi, Univ. of Southern Denmark (Denmark)

This paper considers theoretically and experimentally a range of plasmonic-black-metal polarizers suitable for ultra-short pulses. The polarizers consist of a metal surface being nanostructured with a periodic array of ultra-sharp grooves with periods of 250-350 nanometers, and groove depths around 500 nanometers. The surfaces can be designed such that practically all incident light with electric field perpendicular to the groove direction is absorbed. The efficient absorption is due to incident light being coupled into gap-plasmon polaritons that propagate downwards in the gaps between groove walls towards the groove bottom, where it is then subsequently absorbed during propagation. Reflection is largely avoided due to an adiabatic groove taper design. The other polarization, however, is very efficiently reflected, and the main point of this paper is that the reflection is (both theory and experiments) with negligible dispersive stretching even for ultra-short pulses of 5-10 femtoseconds temporal width in the visible and near-infrared. For comparison pulse propagation through 1-mm silica glass can cause a pulse to increase from 5 femtoseconds to more than 20 femtoseconds. Temporal pulse shapes after reflection are calculated by decomposing the incident laser pulse into temporal Fourier components, calculating the reflection coefficient in the frequency domain, and then Fourier-transforming the reflected pulse back to the time-domain. Reflection of pulses is compared for polarizers based on different metals (gold, nickel, chromium) with a range of groove-array designs and directions of light incidence, a range of center wavelengths and pulse widths for the incident pulse.

9163-8, Session 3

Giant nonlinear response from plasmonic metasurfaces coupled to intersubband transitions *(Invited Paper)*

J. Lee, M. Tymchenko, Christos Argyropoulos, Pengyuan Chen, Feng Lu, The Univ. of Texas at Austin (United States); Frederic Demmerle, Gerhard Böhm, Markus-Christian Amann, Walter Schottky Institut (Germany); Andrea Alu, Mikhail A. Belkin, The Univ. of Texas at Austin (United States)

Ultrathin metamaterials with giant nonlinear optical response may enable applications including super-resolution imaging, efficient frequency conversion and optical control with greatly-relaxed phase-matching conditions, as well as for optical switching and memories at the nanoscale. Current efforts to enable giant nonlinear response in metamaterials were focused mostly on using the natural nonlinear response of plasmonic metals or by enhancing the nonlinearity of optical crystals using plasmonic nanoantennas. These approaches failed, however, to create structures with nonlinear response many orders of magnitude higher than that of bulk nonlinear materials.

In this work, we demonstrate that by coupling of a quantum-engineered multi-quantum-well semiconductor layer with electromagnetically-engineered plasmonic elements we may produce ultrathin planarized metasurfaces with giant nonlinear response. Our approach allows creating large-area metasurfaces in which virtually any element of the effective nonlinear susceptibility tensor may be engineered.

We experimentally prove the concept by designing and fabricating 400-nm-thick metasurfaces for second harmonic generation at lambda~8um. The effective nonlinear susceptibility over 50 nm/V was measured for second-harmonic generation under normal incidence, which is 3-4 orders of magnitude larger than that provided by traditional nonlinear crystals or nonlinear metasurfaces reported to date. The practical impact of the nonlinear metasurfaces proposed here may be extended to a variety of fields, including THz generation and detection, phase conjugation, and other nonlinear processes.

This work was supported by the AFOSR YIP awards FA9550-10-1-0076 (to MB) and FA9550-11-1-0009 (to AA), the NSF ECCS-1348049 award, and the ONR MURI grant N00014-10-1-0942.

9163-9, Session 3

High accuracy models of sources in FDTD computations for subwavelength photonics design simulations

James B. Cole, Univ. of Tsukuba (Japan); Saswatee Banerjee, Sumitomo Chemicals Co., Ltd (Japan)

The finite difference time domain (FDTD) algorithm is popular tool for photonics design, but the error of conventional second-order FDTD is about h**2/12, where h is the grid spacing, and the errors due to the source model further increase it. Even with supercomputers many practical design problems are too large to solve. Nonstandard (NS) FDTD, based on a superposition of second-order finite differences, has been demonstrated to give much higher accuracy than conventional FDTD for the sourceless wave equation and Maxwell's equations (h**6 / 24192).

We can analytically compute the field due to a point source in an unbounded homogeneous medium. This analytical solution is inserted into the NS finite difference (FD) model and the parameters of the source model are adjusted so that the FDTD solution very nearly matches the analytical one. To derive the scattered field source model, we use the NS-FD model of the total field and of the incident field to deduce the correct source model.

Sources that generate a scattered field must be modeled differently from ones radiate into free space. We demonstrate the high accuracy of our source models by comparing with analytical solutions. This approach yields a significant improvement inaccuracy, especially for the scattered field, where we verified the results against Mie theory. The computation time and memory requirements are about the same as for conventional FDTD.

We apply these developments to model such sources as quantum dots in optical circuits and systems, and to solve design and propagation problems in subwavelength structures.

9163-10, Session 3

Plasmonic nanoparticle strings: threading nanoparticle chains with light *(Invited Paper)*

Lars O. Herrmann, Ventsislav K. Valev, Univ. of Cambridge (United Kingdom); Christos Tserkezis, Centro de Fisica de Materiales (Spain); Jonathan S. Barnard, Univ. of Cambridge (United Kingdom); Setu Kasera, Melville Lab. for Polymer Synthesis (United Kingdom); Oren A. Scherman, Univ. of Cambridge (United Kingdom); Javier Aizpurua, Centro de Fisica de Materiales (Spain); Jeremy J. Baumberg, Univ. of Cambridge (United Kingdom)

Light-matter interactions in the nanoscale can be efficiently controlled by novel plasmonic materials. One particularly attractive approach to fabricate and tailor such nanomaterials is by using light itself. Here we demonstrate an efficient way to exploit light for threading plasmonic nanoparticle strings, that is, creating chains of gold nanospheres conductively connected via gold threads with well-controlled dimensions. Gold nanosphere clusters are first self-assembled with use of appropriate rigid organic molecular linkers, namely cucurbiturils, which fix the interparticle gaps at precisely 0.9 nm. In such self-assemblies the excitation of collective plasmonic modes (called Capacitive Chain Plasmons, CCP) along linear and quasi-linear nanoparticle chains within the clusters leads to long-wavelength extinction resonances, accompanied by huge near-field enhancement at the interparticle gaps. The near-field enhancement is then exploited for threading, which is achieved by illuminating with ultrafast lasers whose wavelength coincides with that of the CCP mode, thus enabling non-thermal melting of gold at the gaps. This formation of plasmonic threads allows charge transfer within the entire nanoparticle strings, leading to the appearance of new, hybrid chain/rod modes in the infrared, called Threaded Chain Plasmons (TCP). The evolution and optical properties of the TCP modes, and their dependence on string length and thread width are analysed both experimentally and theoretically. Finally, we show that the nanoparticle size, chain length, and laser power offer unique control of the thread widths, which can be identified with a precision significantly exceeding that of electron microscopy by comparing experimental and simulated extinction spectra.

9163-11, Session 4

Graphene as a platform for dynamically controlled plasmonics *(Invited Paper)*

Alexandra Boltasseva, Naresh K. Emani, Ting-Fung Chung, Alexander V. Kildishev, Yong P. Chen, Vladimir M. Shalaev, Purdue Univ. (United States)

Graphene exhibits several remarkable optical properties like large optical transparency, saturable absorption and broadband nonlinear response which can have wide ranging applications in light harvesting and detection, touchscreens and ultrafast lasers. The main challenge in translating this remarkable potential to real applications is enhancing the interaction of light with graphene. Graphene being a single layer of carbon atoms absorbs only 2.3% of incident radiation. This can be enhanced by integrating plasmonic nanostructures in the vicinity of graphene, and also by patterning graphene leading to excitation of its intrinsic plasmons. The intrinsic plasmons in graphene are not efficient in confining light below 6 μm wavelength due to rapid decay by optical phonons. In this talk we focus on graphene antenna hybrid devices and specifically on controlling the optical properties of plasmonic structures operating at near-IR and mid-IR frequencies with graphene. The optical properties of graphene exhibit strong dependence on the sheet carrier density which can be dynamically controlled by a gate voltage. Therefore when plasmonic antennas are fabricated on top of graphene, their optical properties can be tuned by modulating charge density in underlying graphene. Dynamic modulation in bow-tie and Fano resonant plasmonic antennas will be presented. Additionally, need for novel doping techniques like ion-gel gating and reduction in work function mismatch between antennas and graphene will be discussed. Finally the current prospects and future directions for improvements will be identified

9163-12, Session 4

Mid-infrared nanosplasmonics on graphene: broadband antennas, detectors, and modulators *(Invited Paper)*

Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

By incorporating suitable MIM structures in optical antenna designs, we demonstrate an electrically tunable coupled antenna array on graphene with a large tuning range (1100 nm, i.e. 250 cm-1, nearly 20% of the resonance frequency) of the antenna resonance at mid-ir wavelengths (6-7 μm), almost twice the bandwidth than previously reported using gratings of linear coupled Au optical antennas on graphene. Using doubly-resonant antenna arrays, mid-ir intensity modulation has been demonstrated with maximum modulation depth of more than 30% and a bandwidth of 600 nm. Much higher on-off ratio can be achieved by designing a critically coupled structure. Our devices exhibit a 3dB cut-off frequency of 30 MHz, which can be further increased into the GHz range.

Applications to graphene detectors so far are still limited by low responsivity due to the weak optical absorption (only 2.3% in the monolayer graphene sheet) and short photo-carrier lifetime (< 1 ps). We will report on an investigation of closely-coupled metallic antenna structures on graphene and show that they can be utilized to simultaneously improve both the light absorption and photo-carrier collection. We have demonstrated room temperature mid-infrared (mid-IR) antenna-assisted graphene detectors with more than 200 times enhancement of responsivity (~0.4 V/W) compared to devices without antennas (<2 mV/W).

9163-13, Session 4

Deep modulation of mid-infrared light using plasmonic fano-resonant meta-surfaces integrated with graphene *(Invited Paper)*

Gennady B. Shvets, The Univ. of Texas at Austin (United States)

Plasmonic metasurfaces enhance light-matter interaction by focusing light into extremely subwavelength dimensions. These carefully designed structures have been used in extremely thin optical component which can mold the wavefront, with exciting applications in optical lenses, beam steering, and biosensing applications. Adding dynamic tunability to these devices opens up the possibility for new application in single pixel detection and 3D imaging as well as optical modulators and switches. However the existing approaches for designing active optical devices in infrared, are either slow or have small refractive index change. Plasmonic antennas integrated with single-layer graphene (SLG) was recently utilized for high-speed modulation, but with modest modulation depth (MD). In this work, we take advantage of SLG integration with Fano-resonant metasurface to achieve an order of magnitude MD.

We made two samples with two different gap sizes (Sample 1: G=70nm, Sample 2: G=100nm). The free carrier density N is proportional to ΔV=V_g-V_CNP which is the gate voltage relative to the charge neutrality point voltage. The modulation depth (MD) defined as MD(N=x,λ)=R(N=0,λ)/(R(N=x,λ)) for these two samples was

experimentally measured to reach 500 % and 1000 % for Samples 1 and 2 respectively at around λ≈7μm as N increases from zero to N=4.8e12 (cm)^(-2). Our simulation indicate that reflection phase changes by about 90 degrees at λ≈7.2μm as N varies between 1.6e12< N<4.8e12 (cm)^(-2).

In conclusion, we demonstrate that graphene integration with a Fano-resonant metasurface is a promising platform for strong modulation of amplitude and phase of infrared light. The high modulation rate of graphene charge carriers promises the next generation of high-speed modulators and beam steering photonic platforms.

This work is supported by the Office of Naval Research (ONR) through the grant N00014-13-1-0837

9163-14, Session 4

Exciton-plasmon interactions in graphene-semiconductor structures *(Invited Paper)*

Tigran V. Shahbazyan, Jackson State Univ. (United States); Kirill A. Velizhanin, Los Alamos National Lab. (United States)

Doped monolayer graphene with Fermi energy in the range 0.2-0.6 eV exhibits a stable in-plane plasmon wave in the infrared frequency range with gate-tunable wavelength well the below radiation wavelength at the same frequency. A large local density of states of graphene plasmons as compared to that of surface plasmon polaritons on metal surfaces ensures a very efficient graphene plasmon coupling to excitons in semiconductor nanostructures such as quantum dots (QD) and quantum wells (QW) situated at a close distance to the graphene sheet. We present our recent results on both weak and strong coupling between plasmons and excitons in graphene-semiconductor structures. In the former case, we discuss highly efficient long-range energy transfer between excitons in QDs mediated by graphene plasmons over distances far exceeding the Forster radius. In the latter case, we discuss excitations in narrow gap semiconductor QW separated from graphene by a potential barrier and show that Coulomb interactions between QW excitons and graphene plasmons lead to mixed states characterized by Rabi splitting of about 100 meV for small graphene-QW separations.

9163-15, Session 4

Plasmons in inhomogeneously doped graphene nanostructures

Iván Silveiro, Francisco Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

Doped graphene has emerged as a promising plasmonic material at THz and IR frequencies due to its peculiar electronic band structure. The plasmonic response of this material has been generally studied under a uniform doping configuration. However, realistic geometrical configurations produce inhomogeneities in the doping charge distribution. We study the effect of inhomogeneous doping in extended graphene, as well as in nanodisks and ribbons. For a periodically doped graphene sheet we predict 100% light absorption [1], which is accompanied by high levels of enhancement of the energy-transfer rate between an optical emitter and the graphene sheet [2]. We also study plasmons in graphene nanodisks including the effect of inhomogeneity in the distribution of the doping charge. Specifically, we discuss the following two configurations: charged disks containing a fixed amount of additional carriers, which are self-consistently distributed along its surface to produce a uniform voltage; and neutral disks exposed to a neighboring external point charge. For charged disks, we find dipolar plasmons similar to those of uniformly doped graphene structures, with the plasmon induced charge piling up near the edges [3]. In contrast, neutral disks exhibit a p-n junction at a certain distance from the disk center, giving rise to plasmon modes that are strongly localized at that particular radius. We further illustrate how axially symmetric graphene dark-plasmons can be excited by coupling to a neighboring metallic element. Our results provide an in-depth understanding of graphene behavior under these doping conditions.

9163-16, Session 5

The spasing and loss compensation in plasmonic nanoshell laser *(Invited Paper)*

Vitaliy N. Pustovit, Air Force Research Lab. (United States); Arkadi Chipouline, Friedrich-Schiller-Univ. Jena (Germany); Dean P. Brown, Air Force Research Lab. (United States); Tigran V. Shahbazyan, Jackson State Univ. (United States); Augustine M. Urbas, Air Force Research Lab. (United States)

We here presents the first unified theory of the response of plasmonic nanoshells assisted by optical gain media. Our approach combines rigorous Mie scattering equations for the plasmonic structure and the density matrix formalism, which is well known in laser physics, allowing a correct description of different relaxation and energy exchange channels in the system. We derive a fundamental equation for calculation of SPASER frequency which we claim to be valid for any type of SPASER physical geometry. We demonstrate that ONLY radiative losses are responsible for the spasing and loss compensation process in the laser resonator.

Plasmonic waveguide filter based on metal-insulator-metal structure and its slow light effects

Jicheng Wang, Lin Sun, Yueke Wang, Jiangnan Univ. (China)

The plasmonic waveguides optical selective filters with double-groove shaped metal-insulator-metal(MIM) structure is proposed in theory. It was found that the transmission characteristics of such structures depend on the phase relationship between the plasmonic wave passing through the groove and the one returning to the waveguide from the groove, which can be interpreted by the interference theory. The simulation shows that transmission characteristics in the surface plasmon waveguide are changed as width of the double-groove increasing. In addition, we can find the phenomenon of slow light when the light passes through this structure.

9163-19, Session 5

Lossless surface plasmon polariton guiding in electrically driven nanowaveguides

Dmitry Y. Fedyanin, Moscow Institute of Physics and Technology (Russian Federation); Alexey V. Krasavin, King's College London (United Kingdom); Aleksey V. Arsenin, Moscow Institute of

Physics and Technology (Russian Federation); Anatoly V. Zayats, King's College London (United Kingdom)

Implementation of optical components in microprocessors can boost their performance by orders of magnitude. However, the size of optical elements is fundamentally limited by diffraction, while miniaturization is one of the essential concepts in the development of high-speed and energy-efficient electronic chips. Surface plasmon polaritons (SPP) could be an efficient solution of this problem offering a unique opportunity to localize energy and guide signals at the nanoscale, but ohmic losses in the metal limit the SPP propagation length to a few tens of micrometers and suppress utilization of plasmonic waveguides in semiconductor chips. Realization of compact and energy-efficient loss compensation scheme eliminates this drawback, allowing the implementation of the plasmonic approach into numerous applications.

Recently, full loss compensation has been experimentally demonstrated with optical pumping, but low efficiency, operation only in the pulse regime and inability to integrate it on a chip makes electric pumping much more favourable.

In this work, we propose a novel SPP amplification scheme based on an Au/InAsP/InGaAs/AlInAs double-heterostructure tunneling Schottky-barrier diode in a waveguiding geometry with deep-subwavelength mode confinement.

The proposed scheme is shown to fully compensate SPP propagation loss at a moderate current density of about 20kA/cm2 in a steady-state regime under room-temperature conditions. Furthermore, the threshold current is reduced by one order of magnitude, as the temperature decreases down to 150K. The estimated power consumption of interconnects based on the proposed active waveguides is comparable with silicon photonics, which creates the backbone for the implementation of plasmonic components in on-chip circuits.

9163-20, Session 6

Isotropic infrared metamaterials *(Invited Paper)*

Takuo Tanaka, RIKEN (Japan); Atsushi Ishikawa, Okayama Univ. (Japan); Che-Chin Chen, Instrument Technology Research Ctr. (Taiwan); Din Ping Tsai, National Taiwan Univ. (Taiwan)

An isotropic infrared (IR) metamaterial consisting of three-dimensional (3D) metallic nanostructures is experimentally demonstrated by a newly-developed metal-stress driven self-folding method. Metamaterials have introduced a new paradigm over the last decade to create unprecedented optical functionalities using sub-wavelength resonant structures, i.e. meta-atoms. Since meta-atom is an analog of antenna that asymmetrically interacts with light, the resultant optical responses of metamaterials are inevitably anisotropic, severely limiting their practical applications. Isotropic responses of metamaterials have been achieved at microwave frequencies by employing 3D symmetric alignment of meta-atoms, but their optical versions are still elusive due to the challenge of 3D nanofabrication. Here, we present the first experimental realization of an isotropic IR metamaterial using fourfold-symmetric 3D configuration of metallic nanostructures. Mass-productive formation of the assembled 3D stereostructures was achieved by a metal-stress driven self-folding method. Systematic transmission spectroscopy demonstrated unambiguous isotropic characteristics for any lateral rotation, polarization, and incident angle up to 40º. The corresponding numerical simulations well re-produced the experimental results, revealing that the interplay of electric and magnetic interactions of the 3D meta-atom plays a crucial role for the bi-anisotropic responses. Our results demonstrated a promising method to manufacture highly symmetric metamaterials, leading to isotropic optical responses. We anticipate our technique to be a breakthrough for introducing the concepts of metamaterials to real-components, especially at optical frequencies.

9163-22, Session 6

Three-dimensional metamaterials: from split ring resonator to toroidal metamolecule *(Invited Paper)*

Yao-Wei Huang, Wei Ting Chen, Pin Chieh Wu, Chun Yen Liao, National Taiwan Univ. (Taiwan); Vassili A. Fedotov, Vassili Savinov, Nikolay I. Zheludev, Univ. of Southampton (United Kingdom); Din Ping Tsai, National Taiwan Univ. (Taiwan)

Split ring resonator (SRR) has attracted wide attentions since the discovery of negative refraction in 2002. In 2010, the toroidal resonance, a fundamental resonance mode that differ from electric or magnetic multi-dipole expansion, has found with the higher quality factor in its spectral response in compared to that of magnetic dipole resonance in microwave region. In this paper, we experimentally designed and fabricated three-dimensional SRR arrays and toroidal metamolecule by using double exposure e-beam lithography with precise alignment technique, and then their resonance behaviours are studied in optical region. We proposed a three-dimensional toroidal structure that supported toroidal resonance under normal incidence with large incident angle tolerance for more efficient electromagnetic energy harvesting. The electric as well as magnetic energy are effectively confined within the toroidal structure, these properties have promising applications in the field of plasmonics, such as integrated 3D plasmonic metamaterials, plasmonic biosensor and lasing spaser.

9163-23, Session 6

Where is next metamaterials moving forward? *(Invited Paper)*

Ai Qun Liu, Nanyang Technological Univ. (Singapore); Din Ping Tsai, National Taiwan Univ. (Taiwan); Nikolay I. Zheludev, Univ. of Southampton (United Kingdom)

Meta-fluidic-materials aim at manipulating light and metal-liquid flow in the microchannel, and exploiting their interaction to create highly versatile devices has received significant scientific interests in many areas. The novelties of the integrated meta-fluidic-material are two-fold. First, metal-fluids can be used to carry substances for analysis in highly sensitive optical micro-devices. Second, metal-fluids can also be exploited to control light, making them tunable, reconfigurable and adaptive. In this paper, the state-of-the-art of meta-fluidic-material research is reviewed with breakthrough innovations in optical and photonic devices, including the high potential applications of meta-fluidic-material in biophysical, biochemistry and biomedical studies.

Meta-fluidic-materials represent a new paradigm for designing light-manipulating devices, such as cloaks, transformation optics and field concentrators, through the engineering of electromagnetic space using materials with spatially variable parameters. We demonstrate that a laminar metal-liquid flow in microfluidic channel exhibits spatially variable dielectric properties that support novel wave-focusing and interference phenomena. This work provides new insight into the unique optical properties of meta-fluidic devices and their potential applications.

Meta-fluidic-material is not only to change the material properties through tuning or reconfiguring the unit element structure size or shapes, which is changed by the metal-liquid flow in the microchannel. It is significant breakthrough research for the meta-fluidic-material to demonstrate new materail with new physics phenomena that are never been observed before. In the paper, the different types of meta-fluidic-material will be presented with some future industry applications.

9163-25, Session 7

Mode control and loss compensation of propagating surface plasmons *(Invited Paper)*

Zhili Jia, Deng Pan, Hong Wei, Hongxing Xu, Institute of Physics (China)

Nanophotonic plasmon circuits may play important roles in next-generation information technology as semiconductor-based electronics is approaching the physical limit. The functions of such circuits rely on the rigorous control of plasmon propagation. One important aspect of such control is controlling the conversion of different plasmon modes for designed plasmon routing in complex nanophotonic networks. Here, we experimentally prove that the conversion of plasmon modes occurs widely in metallic nanowire waveguides, the basic components of plasmonic circuits, by introducing local structural symmetry breaking. In further simulations for the structure of a nanowire with a particle in its proximity, it is shown that the mode conversions originate from the redistribution of electric field in the wave front which is caused by the scattering of localized modes in the nanogap and on the nanoparticle. The different spin of incident photons can also control different plasmon modes in metal nanowires. This mode conversion and spin effect can be applied to flexibly control the plasmon propagation behavior in plasmonic nanowire networks.

9163-26, Session 7

Confined Tamm plasmons lasers *(Invited Paper)*

Joel Bellessa, Clementine Symonds, Guillaume L'Heureux, Univ. Claude Bernard Lyon 1 (France); Jean-Jacques Greffet, Jean-Paul Hugonin, Institut d'Optique Graduate School (France); Pascale Senellart, Aristide Lemaître, Lab. de Photonique et de Nanostructures (France)

Plasmonic Tamm states are interface modes formed at the boundary between a distributed Bragg mirror and a metallic layer. Their optical properties lie in between surface plasmons and microcavity photonic modes. In particular, the losses are reduced compared to a conventional plasmon. We will describe some features of semiconductor quantum wells coupled to extended Tamm modes, like strong coupling with the excitons and lasing. The main advantage of the Tamm modes lies in the easy confinement of the mode which can be obtained only by structuring the metallic part of the structure. The reduction of the mode volume leads to an efficient control of the spontaneous emission (increased beta factor), making Tamm confined structures well suited for single photon emitters and lasers. We demonstrate that confined Tamm plasmon modes can be advantageously exploited for the realization of new kind of metal/semiconductor lasers. Laser emission is studied for Tamm structures with various diameters of the metallic disks which provide the confinement. A reduction of the threshold with the size is observed. The competition between the acceleration of the spontaneous emission and the increase of the losses leads to an optimal size, which is in good agreement with calculations. Polarization effects in asymmetrical Tamm structures will also be discussed.

9163-27, Session 7

Surface Plasmon Mediated Inverse Polarization Transmission through Metallic Gratings in Deep Ultraviolet Band

Guoguo Kang, Chi Quan, Xiaodi Tan, Beijing Institute of Technology (China)

Inverse polarization transmission of light, with the TE transmittance ηTE largely exceeding the TM transmittance ηTM, through subwavelength metallic gratings at certain wavelength in deep ultraviolet band is theoretically investigated. By using the Fourier modal method and the planar waveguide theory, we show that the light transmission involves both the surface plasmon and the low-loss waveguide modes. Strong coupling of the incident wave to surface plasmon polariton results in the minimum in TM transmittance, whereas the coupling to the low-loss mode leads to the TE transmittance maximum. The established physical mechanism is sufficient to explain the inverse polarizing phenomenon observed in aluminum grating at the wavelength of 193nm, which may lead to important applications such as effective and compact polarizer used in DUV lithography.

9163-28, Session 7

Highly tunable ultra-narrow-resonances with optical nanoantenna phased arrays in the infrared

Shiqiang Li, Robert P. H. Chang, Northwestern Univ. (United States)

We report our recent development in pursuing high Purcell-Factor plasmonic resonances, with vertically aligned 2-D periodic nanorod arrays. Due to the freely tunable antenna resonances of the nanorod, through material properties (I.e. Plasma frequency and damping factor), the length of the nanorod, and the orthogonal polarization direction to the lattice surface, the 2-D vertically aligned nano-antenna array can have high-Q resonances tunable from near infrared to THz regime (Markel-Zou-Schatz resonance). The Q-factor in combination with the small mode volume gives a Purcell factor which could potentially be applied to various enhanced nonlinear photonics or optoelectronic devices. The 'hot spots' around the nanorods can be freely harvested as no index-matching is necessary. The resonances maintain its Q-factor with the change of refractive index, which is of great interest for molecular sensing. We also present a proof-of-concept realization of the proposed structure and it's optical measurement, which agree extremely well with theory and simulations. The demonstrated Q factor is above 400 and the field intensity enhancement is about four orders of magnitude.

9163-29, Session 7

Controlling the optics of sub-nanometer plasmonic cavities with graphene and other 2D atomic-sized layers

Christos Tserkezis, Centro de Fisica de Materiales (Spain); Jan Mertens, Daniel O. Sigle, Anna L. Eiden, Univ. of Cambridge (United Kingdom); Fumin Huang, Queen's Univ. Belfast (United Kingdom); Antonio Lombardo, Univ. of Cambridge (United Kingdom); Zhipei Sun, Aalto Univ. (Finland); Ravi S. Sundaram, Univ. of Cambridge (United Kingdom); Alan Colli, Nokia Research Ctr. UK (United Kingdom); Silvia Milana, Andrea C. Ferrari, Univ. of Cambridge (United Kingdom); Javier Aizpurua, Centro de Fisica de Materiales (Spain); Jeremy J. Baumberg, Univ. of Cambridge (United Kingdom)

Metallic nanoparticle dimers are particularly attractive plasmonic units, both from a theoretical and an experimental point of view. While recent advances in nanofabrication push rapidly towards minimising the interparticle distance, achieving sub-nanometer gaps, for which exciting quantum or nonlocal phenomena become relevant, is still challenging. An alternative, easier route is to consider a metallic nanoparticle placed on a metallic substrate, and study its interaction with its mirror image. Appropriate spacers between metallic interfaces prevent conductive contact. Here we propose the use of novel two-dimensional materials such as graphene as spacers. A single graphene monolayer acts as a very thin spacer (0.34 nm), while increasing the number of graphene layers leads to controllable, reproducible "quantised" sub-nanometer

gaps. By illuminating the system at large angles of incidence we show that an optical response similar to that of a metallic nanoparticle dimer is reproduced. For relatively thick spacers, a bonding dipole-like mode is excited in the near-infrared range of the spectrum, redshifting as the spacer thickness decreases. Reducing the thickness of the spacer to a single graphene monolayer leads to strong interaction that allows for the bonding quadrupole-like mode to distinctively appear in the scattering spectra. Finally, we show that additional control of the optical response of such dimers can be achieved by using different spacers, such as MoS2 or CdSe, and/or by generating flat facets at the contact of the nanoparticles with the substrate.

9163-30, Session 7

Helium-ion beam modification and tunable gap loading of plasmonic nanoantennas *(Invited Paper)*

Otto L. Muskens, Univ. of Southampton (United Kingdom)

Control over the resonances of plasmonic antennas is of considerable interest for their applications in nonlinear optics, sensing and spectroscopy. We show that helium-ion beam milling allows achieving extreme control over nanometer-sized gaps, including 30-nm deep gaps with widths below 5 nm, and vertically milled partial gaps [1]. The linear and nonlinear optical response of antennas with partially conducting bridges is investigated using single-particle spectroscopy, revealing that a bridge of nanometer height is sufficient to change the loading from capacitive to inductive type. Additionally, we demonstrate conductive antenna loading using transparent conductive oxides as active medium with unusual properties.

9163-31, Session 8

Voltage-controlled strong coupling with metamaterial nanocavities: fundamentals and applications *(Invited Paper)*

Igal Brener, Alexander Benz, Sandia National Labs. (United States)

A single metamaterial resonator can act as very powerful "nanocavity" that allows for exquisite control over the magnitude and polarization of the optical fields near the resonator traces. We recently used these nanocavities to show strong coupling to optical excitations in semiconductors that can be designed and tailored through most of the infrared: i) intersubband transitions in quantum wells and ii) "epsilon near zero" (ENZ) modes. In both cases, these excitations can be influenced by the application of an electric field. This effect can be used for controlling the optical coupling and thus the overall spectral response of the metamaterial. I will present several examples of active, tunable metamaterials based on these effects.

9163-32, Session 8

Comparison of third-order nonlinear optical properties of colloidal gold nanoshells and nanorods

Marta Gordel, Wroclaw Univ. of Technology (Poland) and Ecole Normale Supérieure de Cachan (France); Joanna Olesiak-Banska, Radoslaw Kolkowski, Katarzyna Matczyszyn, Marek J. Samoc, Wroclaw Univ. of Technology (Poland); Malcolm Buckle, Ecole Normale Supérieure de Cachan (France)

We present a detailed comparison of the third-order nonlinear optical properties of colloidal gold nanoshells and gold nanorods in water suspensions, determined using the open- and closed-aperture Z-scan measurements performed with femtosecond laser pulses, in a broad range of wavelengths. The studies were carried out with attention being paid to having laser pulse energies well below the threshold of nanoparticle melting, so gold nanoshells and gold nanorods were stable during the laser irradiation [1]. The two-photon absorption coefficient (?2), the nonlinear refractive index (n2), the two-photon absorption cross-section (?2) and the saturation intensity for one-photon absorption (ISat) were evaluated in the 530-1200 nm wavelength range. [2]

For both gold nanorods and nanoshells the nonlinear absorption is dominated by absorption saturation, however, two-photon absorption is also clearly seen in some wavelength ranges. For the nanorods the longitudinal surface plasmon (l-SPR) range is dominated by saturated absorption while in the transverse surface plasmon resonance (t-SPR) range the two-photon absorption (2PA) properties dominate [2]. The gold nanoshells with the thinnest shell show two-photon absorption in the range between 530-600 nm, the estimated value of two-photon absorption cross-section ·2 is 5.12 ·1010 GM/cm2, longer wavelengths are dominated by absorption saturation We have found that the reciprocals of saturation intensities are the highest in the maximum of one-photon absorption (1PA) range for all studied nanoshells, however they decrease with the increase of a shell thickness.

The value of the merit factor ·2/M (two-photon absorption cross section scaled by the molecular weight) for gold nanorods (10nm x 35 nm) is equal to 7.5 (GM ·mol/g) at 530 nm [2], for the gold nanoshells it is markedly lower: 1.9 (GM ·mol/g) at 530 nm and 2.6 (GM ·mol/g) at 600 nm.

We have proved that gold nanorods are more efficient in absorbing light than gold nanoshells. Additional features such as: low cytotoxicity, facile immunetargeting, nonsusceptibility to photobleaching or denaturation makes them excellent probe for bioimaging.

9163-33, Session 8

Field enhanced plexitonic coupling between InAs quantum dot and silver film: highly sensitive plasmonic composite

Venus Dillu, Preeti Rani, Ravindra K. Sinha, Delhi Technological Univ. (India)

Plasmonics has become de facto dominating technology with important applications such as nano scale wave guidance, nano-circuitry, sensing, spectroscopy, imaging, lasing, solar cells etc. These applications in turn depend on the plasmon resonance that plays a key role in all the state-of-art devices. But as dimensions of the metallic nanostructures involved in the plasmonic devices decrease below 10 nm, the plasmon resonance becomes more sensitive to the quantum nature of the conduction electrons. These quantum-size effects arising due to nanoscale geometry or sub-nanometer gaps are difficult to explain using conventional plasmonics due to weak optical scattering and require exhaustive research.

In the present work, we study the field enhancement in plasmonic composite of indium arsenide (InAs) quantum dots (QD) of diameter d = 10 nm, arranged in hexagonal lattice on a silver film. The intensity is traced by scanning the absorption spectra for the system, resulting in highly sensitive composite. We found that the behaviour of the plasmonic composite changes by varying the thickness of metal film. It is observed that the sensitivity of the composite increases with decreasing the thickness of metallic film and the quantum-size effects dominate at sub-nanometer gap.

The interaction of quantum dot exciton with the plasmons of the silver metal causes transverse plexitonic coupling between the QD and silver, resulting in ultra high local field enhancement at the interface whereas the energy propagates longitudinally due to resonating quantum plasmonic tunnelling. The proposed system shows promising applications in lasing, sensing and spectroscopy.

9163-34, Session 8

Ultrafast silicon nanoplasmonic barristor

Shawn R. Greig, Abdulhakem Y. Elezzabi, Univ. of Alberta (Canada)

We present a detailed investigation of a silicon based CMOS compatible nanoplasmonic barrier transistor. A Si waveguide core is located between upper and lower Cu electrodes with a W grid buried in the Si core. The structure is excited with an 84 fs pulse centred around 1.55 µm, that becomes highly confined to a surface plasmon mode at the upper Cu-Si interface which decays away towards the W grid. Electrons are generated in the Si through two-photon absorption (TPA) of the nanoplasmonic field near the upper Cu electrode. Due to a high spatial gradient in the nanoplasmonic field the electrons experience unequal acceleration/deceleration from a ponderomotive potential, which allows them to achieve a distribution of energies as they approach the W grid. An effective energy barrier is created by applying a negative potential to the grid, thus controlling the number of electrons passing through it. Electrons that do pass through the grid reach the bottom Cu electrode where they are collected, creating a net current between the Cu electrodes. By varying the nanoplasmonic field and sweeping the grid voltage, the device exhibits a triode like behaviour. Increasing the nanoplasmonic field increases the number of TPA generated electrons and thus increases output current. Alternately, applying a more negative grid voltage creates a higher energy barrier which lowers the output current. The device is able to produce a pulsed output current of 11.7 mA/µm within 150 fs in a compact footprint.

9163-138, Session 8

Hybrid plasmonic platform for integrated nonlinear optical applications

Stefano Palomba, Fernando J. Diaz, The Univ. of Sydney (Australia); T. Hatakeyama, Junsuk Rho, Alessandro Salandrino, Kevin O'Brien, Univ. of California, Berkeley (United States); Xiang Zhang, Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

Fast transfer and processing of information are crucial to our modern society. They are mostly carried out by a combination of electronics, for processing the information and converting the outcome into light signals, and photonics, for transmitting those light signals over long distances via optical fibres. However, these traditional roles are not enough to fulfil the increasing demands for more and more information. Electronics equipment has become increasingly the bottleneck because of its bulkiness, its high power dissipation and consumption, its slow processing capabilities, and its vulnerability to electromagnetic interference. Being able to take over some tasks from electronics requires light to interact with itself, which does not happen at low light intensities. Two approaches have been explored to exploit substantial nonlinear phenomena: (i) transparent materials like glasses or semiconductors (photonics), which cannot compress light more than half a wavelength and thus require long propagation distances, leading to large linear dimensions; (ii) opaque, absorbing materials like metals (plasmonics), which can enormously compress light, giving rise to huge light intensities, so long propagation lengths are not required, leading to compact structures. However, the high losses tend to prevent this approach from reaching its full potential.

We present an alternative approach which combines the best characteristics of metals and dielectrics into a hybrid structure, which exhibits high light intensities, moderate losses and on-chip compatibility. The basic structure of every on-chip photonic device is a waveguide, which in this case is constituted by a nonlinear dielectric material (core), sandwiched between a metallic layer (plasmonic structure) and another dielectric material.

Such a hybrid plasmonic waveguide (HPWG) shows an increasing interpulse four-wave mixing (4wm) generation as a function of a decreasing in core thickness. Hybrid plasmonic architectures promise to be the keystone for future on-chip photonic signal processing and nonlinear optical devices.

9163-35, Session 9

Plasmon-exciton coupling between silver nanowire and two quantum dots *(Invited Paper)*

Qiang Li, Hong Wei, Hongxing Xu, Institute of Physics (China)

Controlling the interaction between single surface plasmons and individual quantum emitters is an outstanding problem in quantum science and engineering. Here we manage the coupling strength between a silver nanowire and individual quantum dots (QDs) by controlling the QD-nanowire separation distance. By using an atomic force microscope to manipulate a silver nanoparticle to create a nanogap between a silver nanowire and a Ag nanoparticle, the efficient coupling of the quantum dot in the nanogap with the silver nanowire is demonstrated by the enhanced emission intensity and the reduced fluorescence lifetime. We also experimentally realize resolving single plasmons generated by a pair of QDs on a silver nanowire. The separation between the two QDs is ranging from micrometers to 200 nm within the diffraction limit. The accurate position of each QD and the conversion efficiency of the exciton-plasmon coupling are obtained.

Nanoplasmonic devices are promising for next generation information and communication technologies because of their capability to confine light at subwavelength scale and transport signals with ultrahigh speeds. However, ohmic losses are inherent to all plasmonic devices so that further development of integrated plasmonics requires efficient in situ loss compensation of signals with a wavelength and polarization of choice. Here we show that CdSe nanobelt/Al_2O_3/Ag hybrid plasmonic waveguides allow for efficient broadband loss compensation of plasmonic signals of different polarizations at room temperature using an optical pump and probe technique.

9163-36, Session 9

Nanoplasmonic hydrogen sensing *(Invited Paper)*

Carl Wadell, Svetlana Syrenova, Christoph Langhammer, Chalmers Univ. of Technology (Sweden)

We will discuss how localized surface plasmon resonance (LSPR) based hydrogen sensing and spectroscopy has evolved. The field started with so-called direct hydrogen sensing schemes, which track the LSPR in palladium nanoparticles as hydrogen is absorbed. This concept was then followed by so-called indirect sensing techniques where inert plasmonic nanoantennas (e.g. Au or Ag) are used to probe the hydride formation process in adjacent nanoparticles. Using examples from our recent efforts, we will discuss how such plasmonic hydrogen sensors are of interest both from the point of reaching a fundamental understanding of hydrogen metal interactions at the nanoscale, and how they can be utilized as all optical gas sensors in a future hydrogen economy. Further developing the indirect sensing scheme, we will also illustrate how it becomes feasible to study hydrogen metal nanoparticle interactions at the individual particle level by designing appropriate nanoantenna arrangements. We will illustrate the strength of single particle studies compared to ensemble ones by highlighting the unique possibility to characterize the studied particle in detail by means of complementary techniques such as electron microscopy, and correlate the influence of particle size and shape on the metal hydrogen interaction at the nanoscale. This is important because such effects are hard to track in ensemble measurements as they are usually hidden due to size and shape distributions of the sample particles.

9163-37, Session 9

Observing charge transfer plasmons in nanocuboid dimers with large gaps

Ping Bai, A*STAR Institute of High Performance Computing (Singapore); Shu Fen Tan, National Univ. of Singapore (Singapore); Lin Wu, A*STAR Institute of High Performance Computing (Singapore); Michel Bosman, A*STAR Institute of Materials Research and Engineering (Singapore); Christian A. Nijhuis, National Univ. of Singapore (Singapore)

Charge transfer plasmon (CTP) is important in various applications including nano-electronics, chemical catalysis, nonlinear optics, and single molecule sensing. However, the CTP mode has only been predicted theoretically to occur through direct tunneling when the gap is reduced to ~ 0.4 nm, which is beyond the reach of current state-of-the-art fabrication technology. In order to experimentally observe the CTP in a relative larger gap between two metallic nanoparticles, we consider: 1) Using nanocuboids to increase the area of the cross-section. Larger cross-section can provide larger conductance if conductivity is the constant. 2) Choosing plasmonic metal with low work function such as Ag (4.26 eV) instead of Au (5.1 eV) for the nanocuboids to reduce the intrinsic tunneling barrier height. 3) Filling the gap with molecule insulators, such as self-assembled monolayers (SAM), instead of leaving it as vacuum. In this case, the tunneling barrier height depends on the alignment of the metal's Fermi level with the energy gap of the molecule insulators between the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO). Our simulations predict that the Au-vacuum-Au system requires a gap field on the order of 1010 V/m but the Ag-SAM-Ag system only requires a gap field on the order of 108 V/m to excite the CTP, which is within the reach of electron energy loss spectroscopy (EELS). We chemically synthesized the Ag nanocuboids, coated them with the SAM (e.g. 1,2-ethanedithiolates), assembled Ag-SAM-Ag dimers on a Si3N4 membrane, and finally excited and measured CTPs with EELS. We first time observed the CTP through the Ag-SAM-Ag dimers with a gap around 0.6nm and the Ag-SAM/SAM-Ag dimers with a gap around 1.2nm. This finding shows that the CTP could be excited in a large-gap dimer with longer molecules to perhaps 4-5nm and makes one more step for applying the CTP.

9163-38, Session 10

Simultaneous detection of nanoscale electric and magnetic fields *(Invited Paper)*

Laurens K. Kuipers, FOM Institute for Atomic and Molecular Physics (Netherlands)

Control of light at the nanoscale lies at the heart of the field of plasmonics. Crucial to the advances in the field is an improved understanding of the nanoscale behaviour of light, enabled by direct observations of the local electric fields near photonic nanostructures. The advent of metamaterials that interact with the magnetic component of light, has led to schemes to measure the nanoscale magnetic field. However, these metamaterials interact not only with the magnetic field, but also with the electric field of light. We show the simultaneous detection of both electric and magnetic fields with subwavelength resolution [1]. The simultaneous detection originates in the electro-magnetic response of our metallo-dielectric aperture probe of our near-field microscope [2,3]. By explaining our measurements through reciprocal considerations, we create a route towards designing probes sensitive to specific desired combinations of electric and magnetic field components.

Imaging of rectified plasmonic fields on nanoantennas with single nanometer precision

Curtis J. Firby, Abdulhakem Y. Elezzabi, Univ. of Alberta (Canada)

Our experiments demonstrate high resolution direct imaging of plasmon localization with the use of a scanning tunneling microscope (STM). STMs have the ability to simultaneously record both the tunneling current and topography of a sample with sub-nanometer precision. The gap between the STM tip and a gold nanoplasmonic antenna's surface creates a nonlinear tunneling junction that can rectify plasmonic fields. Modulating an incident optical signal produces modulated evanescent fields that interact with the junction, creating an additional current component superimposed on top of the traditional tunneling signal. This signal was shown to be solely related to the field rectification in the junction. Thus, this component was isolated from the total tunneling current measured by the STM via lock-in detection, and was used to map out the plasmonic field intensity over the surface of the nanoantenna. Correlating the current signals with the topographical images of the excited plasmonic nanoantenna allowed us to map out the plasmonic field localization within nanoscale fissures between the grains of the gold surface with a remarkable resolution of 1nm, measured in comparison to the topographical features in which they reside. The resolution in these experiments was limited only by the device size, STM scan window, and scanning speed, so this technique can be applied to potentially create angstrom resolution images of plasmonic resonances on a variety of structures.

9163-40, Session 10

Laser-directed deposition of silver nanostructures

Anatoliy O. Pinchuk, Ke Jiang, Kathrin Spendier, Univ. of Colorado at Colorado Springs (United States)

We report here, a new method for the laser assisted deposition of silver nanoparticles on glass and plastic substrates that does not require any surface treatment or modification. Deposition of silver nanoparticles from an aqueous solution was observed under illumination of a substrate with a focused laser beam. The wavelength of the laser which drives the deposition is near the surface plasmon resonance (SPR) wavelength of the nanoparticles, highlighting the crucial role of an induced and SPR enhanced dipole moment in the nanoparticles. SPR enhancement of the induced dipole in the nanoparticles was confirmed through total internal reflection fluorescence microscopy and has not previously been reported. Longer wavelength lasers did not cause the deposition of these nanoparticles, which demonstrates the size dependence of their SPR wavelength and allows for the selective placement of different sized particles based on the deposition laser line selected. Complete surface coverage can occur in less than one minute and precise control of the deposition area is possible.

9163-41, Session 10

Plasmonic optoelectronics on Si *(Invited Paper)*

Pierre Berini, Anthony Olivieri, Univ. of Ottawa (Canada)

Metallic nano-gratings of rectangular cross-section operate as a coupling structure that couples broadside p-polarised incident light to surface plasmon polaritons (SPPs) propagating on an underlying thin metal film. When deposited on a Si substrate the structures become useful as infrared (1310, 1550 nm) intensity modulators or photodetectors, exploiting SPP-enhanced carrier refraction in Si, or SPP-enhanced internal photoemission, respectively. The electro-optical performance of such structures is assessed over a broad optical wavelength range as a function of geometrical parameters, including grating thickness, pitch, and duty cycle. Various materials are considered, including materials that are standard for CMOS electronics. Electrical bandwidths in the tens of GHz are predicted for modulators and detectors. Their area can be extremely small, but in practice is set to the area of a tightly focussed incident optical beam. The structures proposed are fabricated via metal evaporation and lift-off, with the nanogratings defined by electron beam patterning.

9163-42, Session 11

Plasmonic enhancement of charge carrier photogeneration in conjugated polymers *(Invited Paper)*

Zilong Wang, Nanyang Technological Univ. (Singapore); Jun Zhao, Bettina Frank, Univ. Stuttgart (Germany); Qiandong Ruan, Nanyang Technological Univ. (Singapore); Giorgio Adamo, Univ. of Southampton (Singapore); Harald W. Giessen, Univ. Stuttgart (Germany); Cesare Soci, Nanyang Technological Univ. (Singapore)

We demonstrate a new concept for enhancing charge carrier photogeneration in conjugated polymers by resonant particle-plasmons. Charge carrier density is evaluated by probing photoinduced absorption and Infra-Red Active Vibrational Modes (IRAV) of the polymer. This concept may be used to enhance power conversion efficiency of organic photovoltaic cells.

9163-43, Session 11

3D-FEM analysis of SPP excitation through nanoholes in asymmetric metal-insulator-metal structure at tip of circular truncated conical fiber

Yasushi Oshikane, Osaka Univ. (Japan); Kensuke Murai, National Institute of Advanced Industrial Science and Technology (Japan); Motohiro Nakano, Osaka Univ. (Japan)

3D-electromagnetic (EM) analysis of surface plasmon polaritons (SPPs) excited by a single-mode (SM) propagation of visible lightwave in an optical fiber has been studied with a 3D-FEM package based on a finite element method. End of the fiber is formed to be a circular cone by wet etching process, and is FIBed to make a circular truncated conical shape with a flat circular surface a few micrometers in diameter. The flat end is covered with three layers of asymmetric metal-insulator-metal structure, thin metallic layer (M1), thick insulator layer (I), and thick metallic layer (M2), respectively. The outermost M2 layer has FIBed nanoholes to convert light waves at the extremity of the fiber into SPPs efficiently, and a bright tiny point light source will be generated on the surface of the M2 layer. In this study, the 3D-FEM models consists of both the MIM structure and the shrinking optical fiber tip coated with a metallic thin film has been designed and analyzed numerically. By applying perfect electric conductor and perfect magnetic conductor to planes containing the axis of rotation, the FEM model has a quarter of the circular truncated conical shape. The FEM analysis is formed in two steps. At the first step, a FEM mode analysis is performed to obtain a solution corresponding to the SM propagation in the fiber. The second level of action is the FEM analysis of EM field in the whole of model to find a stationary solution with the solution of mode analysis. Characteristic of wavelength-dependent excitation, propagation, and focusing of the SPPs will be presented with several experimental results of trial products of the fiber tip.

9163-44, Session 11

Surface plasmon decay in nanostructured systems *(Invited Paper)*

Prineha Narang, Ravishankar Sundararaman, Adam S. Jermyn, William A. Goddard III, Harry A. Atwater Jr., California Institute of Technology (United States)

Typical theoretical descriptions of the optical response of plasmonic systems have successfully used classical electromagnetic models to account for absorption, though quantum calculations have been applied to certain plasmonic phenomena such as coupling between nanoparticle dimers. Recently we analyzed the quantum decay of surface plasmon polaritons[1] and found that the prompt distribution of generated carriers is extremely sensitive to the energy band structure of the plasmonic material. In this context we present theory and calculations that elucidate the decay dynamics of plasmons to excited hot carriers in nanostructured plasmonic systems, based on the quantization of plasmon fields in conjunction with detailed electronic structure. We have developed a general theoretical and computational framework using a multi-scale model that combines long-range electromagentic solvers for the plasmons with density functional theory in a maximally-localized Wannier basis for the electrons. With a diagrammatic approach to processes involving plasmons, electrons and phonons built upon this model, we present realistic fi rst principles calculations for nanostructured plasmonic systems.

9163-45, Session 11

Tunable plasmons in atomically thin gold nanodisks

Alejandro Manjavacas, Rice Univ. (United States); Francisco Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

The ability to modulate light at high speeds is of paramount importance for telecommunications, information processing, and medical imaging technologies. This has stimulated intense efforts to master optoelectronic switching at visible and near-infrared (vis-NIR) frequencies, although coping with current computer speeds in integrated architectures still remains a major challenge. As a partial success, midinfrared light modulation has been recently achieved through gating patterned graphene [1].

Here [2] we show that atomically thin noble metal nanoislands can extend optical modulation to the vis-NIR spectral range. We find plasmons in thin metal nanodisks to produce similar absorption cross-sections as spherical particles of the same diameter. Using realistic levels of electrical doping, plasmons are shifted by about half their width, thus leading to a factor-of-two change in light absorption. These results are supported by a microscopic quantum-mechanical calculations based on the random-phase approximation (RPA), which we compare with classical simulations obtained solving Maxwell's equations using tabulated dielectric functions. Both approaches result in an excellent agreement for nanodisks with diameters above 13 nm, although quantum confinement and nonlocal effects play an important role for smaller sizes.

We analyze, as well, the optical response of periodic structures created from these thin nanostructures, for which we predict absorbances of

25% for metal layer filling fractions of 40%. These results hold great potential for the development of electrical vis-NIR light modulation in nanoscale devices.

9163-46, Session 11

Optical nanogap matrices for plasmonic enhancement applications

Stephen J. Bauman, Desalegn T. Debu, Avery M. Hill, Eric Novak, Univ. of Arkansas (United States); Douglas Natelson, Rice Univ. (United States); Joseph B. Herzog, Univ. of Arkansas (United States)

Plasmonics, a field studying the interaction between light and charges on metal surfaces, continues to grow as an interdisciplinary field spanning physics, engineering, and nanoscience research with applications that include enhance photovoltaic cells, plasmonically enhanced spectroscopy, and other optoelectronic devices. Plasmons have been shown to enhance or otherwise manipulate the electromagnetic field of light waves incident on a metal surface. Nanoscale structures and features have proven critical in controlling the plasmons for specific applications. The use of a nanoscale region or gap between other larger nanoscale structures allows for focusing of light at the nanoscale, leading to significant increases in the local electric field magnitude and optical gain in the gap. This optical enhancement is inversely proportional to the gap size, therefore it is of interest to fabricating gaps smaller than the typical electron beam lithography fabrication procedures. Thus, we make use of a previously developed self-aligned technique that can produce nanogaps with widths that can be controlled to be only a few nanometers wide (<5 nm). This work further develops the self-aligned technique by working towards making plasmonic nanostructures with nanoscale gaps in two dimensions. This technique enables the fabrication of a large-area matrix of such structures which will expand the current limits of plasmonic nanogap fabrication capability and prove useful for enhanced photovoltaics. Furthermore, this unique nanofabrication technique could also allow for other structures that could prove beneficial in various nanoscience studies and applications, in addition to the study of the physics of plasmons and nano-optical behavior.

9163-47, Session 11

Plasmon-enhanced photothermal response in heterogeneous metallic trimers

Seyfollah Toroghi, Pieter G. Kik, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

The ability of metallic nanoparticles to generate heat under optical illumination is of significant interest due the strong, rapid, and fast thermal response that can be achieved. This enables thermally assisted applications including photothermal and optoacoustic imaging and thermal nonlinear switching. For isolated metal nanospheres, the temperature change that can be induced by short pulsed illumination at a fixed fluence is known to become size independent in the quasi-electrostatic limit. Here, we demonstrate that the achievable temperature change can be increased by orders of magnitude by engineering the local environment of the particle. In particular, we investigate the optical and thermal response of a gold nanoparticle placed between two larger silver nanoparticles. Through numerical simulations we predict a temperature change of 100 K in a Ag-Au-Ag nanoparticle trimer consisting of two 80 nm diameter silver nanoparticles and a 10 nm diameter central gold nanoparticle in water shortly after a 20 nJ/mm2 pulse at 530 nm, compared to only 0.65 K for the isolated gold nanoparticle. It is shown through analytical calculations that this effect can be understood in terms of the hybridization of the silver dimer plasmon resonance and the gold nanoparticle resonance. The spherical shape of the elements of the trimer is expected to withstand relatively high temperatures without significant structural degradation. Notably the predicted effects can be achieved using experimentally accessible particle sizes, and occur largely outside the range of quantum plasmonics and nonlocal effects. The proposed trimer appears amenable to large-scale fabrication through chemical synthesis.

9163-48, Session 12

Nanomechanical transduction in plasmonic systems *(Invited Paper)*

Ewold Verhagen, FOM Institute for Atomic and Molecular Physics (Netherlands)

I will present our experiments on the aforementioned systems that integrate Si3N4 nanomechanical oscillators with plasmonic resonances in nanoslits as well as single antennas. We investigate both sensitive nanomechanical transduction as well as pronounced optical forces. We demonstrate parralel readout of many plasmonic optomechanical systems, facilitated by their efficient free-space coupling and nanoscale footprint. Finally, we study optical interactions in hybrid plasmonic-dielectric systems, consisting of nanoantennas evanescently coupled to whispering gallery mode cavities. Scattering experiments reveal how the nanoantenna polarizability is affected in proximity to the microcavity. Simultaneously, the antenna-cavity coupling causes the cavity mode spectrum to be strongly altered by the presence of the nanoantennas. Interestingly, both antenna-induced blue and red shofts are observed, as well as both decreased and increased cavity quality factors, depending on the nanoantenna properties. By placing the nanoantennas on nanomechanical oscillators, we aim to directly observe nanophotonic forces and realize a new class of nanomechanical transducers and actuators.

9163-49, Session 12

Nano-scale patterns of molybdenum on glass substrate for use in super-resolution imaging with metamaterials

Han Li, Andrew M. Sarangan, Partha P. Banerjee, Univ. of Dayton (United States)

Photolithography is widely used to transfer a geometric pattern from a mask to a photoresist film, but the minimum feature sizes are limited by diffraction through the mask. Focused ion beam (FIB) and electron beam lithography (EBL) can be used when higher resolution is desired, but the write times are long and costly. Here, deep ultraviolet (DUV) interference lithography, which is a maskless technique is used as an alternative to produce high resolution patterns with linewidths as small as 100nm. Since metamaterials may have the property to overcome Abbe's diffraction-limit for super-resolving and imaging sub-wavelength objects, there is a need for fabricating objects with sub-wavelength feature sizes to characterize the performance of these metamaterials. The DUV interference lithography and reactive ion etching process can be used to fabricate the sub-wavelength patterns on metal. In this talk, we present our results of fabrication and characterization of sub-wavelength objects for visible wavelengths using molybdenum (Mo) of typical thickness 50 nm initially sputtered on a glass substrate. A DUV source at 266 nm is used. An anti-reflection layer followed by a high resolution negative tone photoresist is coated on the top of Mo film. The cross-linked photoresist created after the development and bake processes is used as a mask for etching. Fabrication of the sub-wavelength object is completed by reactive ion etching in a fluorinated plasma. Finally the quality of the sub-wavelength object is characterized using TE and TM polarized illumination.

9163-50, Session 12

Dirac-like surface plasmons in metallic honeycomb lattices with directional edge states *(Invited Paper)*

Siying Peng, Sondra L. Hellstrom, Harry A. Atwater Jr., California Institute of Technology (United States)

We have observed Dirac-like band structures of surface plasmons in metallic honeycomb lattices, similar to electronic band structures of graphene [1, 2]. Full wave simulations (FDTD) on an infinite honeycomb lattice of silver nano-pillars revealed hybridization of localized plasmonic modes between two neighboring pillars and the consequent formation of bonding and anti-bonding modes that are energetically degenerate at Dirac points with a relative phase of Pi. This phase difference is a manifestation of the Berry phase similar to that in graphene. We broke the inversion symmetry of the infinite honeycomb lattice by shifting the relative position of the two triangular sub-lattices. This inversion symmetry-breaking perturbation opened a band gap at the Dirac point. Simulations on finite ribbon of the perturbed lattice showed two edge states within the gap with opposite propagation directions.

We fabricated the silver nano-pillars honeycomb lattice structure on silicon nitride membranes with e-beam lithography and a lift-off process. The band structures are experimentally characterized via cathodoluminescent spectroscopy. In the CL measurement, electron beams are incident on the sample to excite the plasmonic modes. The scattered light due to the decay of the surface plasmon excitations is collected by a parabolic mirror and mapped to the momentum space, yielding a direct construction of the band structures in the Brillouin zone. Our results provide a new way to control propagation direction of surface plasmon edge states without backscattering by selective excitation.

Theory of the resonance shift of plasmonic nanoresonators for dielectric sensing *(Invited Paper)*

Weihua Zhang, Nanjing Univ. (China)

Plasmonic nanoresonators which exhibit resonance shifts upon the change of their local environment promise all the properties and capabilities required for the next generation ultrasensitive biochemical nanosensors. [1] To date, a large number of plasmonic nanosensors have been demonstrated with various designs and materials. However, the reported sensitivities have large variations without showing any general rules.

In this work, we therefore study the spectral sensitivity of plasmonic nanoresonators using an analytical method. We first derive the analytical expressions for the resonance frequency shifts of a dispersive plasmonic nanoresonator upon the adsorption of nanoparticles, covering by a thin layer of molecules, and changes of the bulk refractive index of the surrounding liquid using the perturbation theory.[2] We emphasize the role of material dispersion, one of the fundamental differences between plasmonic nanoresonators and nondispersive dielectric microresonators. Furthermore, we discuss the relation of resonance shifts to the local electric field enhancement and Q-factor. Our results show that the resonance shifts are only related to the geometry-induced electric field enhancement, and independent with the Q-factor. Finally, statistic analysis is performed to determine the limit of detection of the system in experiments.

This work establish a comprehensive theory for dispersive plasmonic nanoresonator sensor, and provides practical guidelines for designing plasmonic sensing, as well as active plasmonic devices.

Plasmonic nanostructuring through direct laser interference patterning

Yuanhai Lin, Tianrui Zhai, Xinping Zhang, Beijing Univ. of Technology (China)

Direct writing of plasmonic nanostructures is demonstrated by nanoscale-tensile-stress-induced patterning through interference crosslinking in a polymer film and by single-pulse interference ablation of a continuous gold film. Through direct exposing to the interference pattern between UV laser beams at 325nm, the polymer molecules get cross-linked, resulting in the reduction in both the thickness and the refractive index of the polymer film. This process has been used to fabricate polymeric nanostructures. However, nanoscale-tensile-stress was produced during the interference crosslinking process. Thus, the continuous gold film evaporated on the top of the polymer film was stretched into gold nanolines, which are actually the transfer of the polymeric pattern. Consequently, one-dimensional plasmonic nanolines or two-dimensional nanodots with strong plasmonic response were achieved.

Furthermore, gold nanostructures can be directly written into gold films by interference ablation using a single UV laser pulse, which operates at 355nm with a duration time of about 5 ns. The continuous gold film, which was evaporated onto an ITO-coated silica substrate with a thickness of about 18 nm, can be directly removed within the bright interference fringes with high laser intensity. The remaining gold within the dark interference fringes forms the plasmonic photonic nanostructures with the period tuned from 350 to 1000 nm. Due to the high thermal conductivity of the gold, strong heat transfer dominates the process of interference ablation for the fabrication of the ultimate metallic photonic structures. The experimental results enable better understanding of the thermal processes that are possibly involved in laser ablation, which is important for controlling and optimizing the spatial resolution of the directly written plasmonic photonic crystal devices.

9163-53, Session 13

Plasmonic enhancement of optical absorption, electroluminescence, florescence, and Raman scattering by metal nanoparticles: limits and comparison *(Invited Paper)*

Greg Sun, Univ. of Massachusetts Boston (United States)

Nanometer-scale metallic structures have been extensively studied as a way to dramatically modify optical properties of various optically active objects of similar dimensions such as atoms, molecules, or quantum dots that are placed in close proximity of these metallic structures. We present an analytical model that elucidates and establishes the enhancement limits of various optical processes including optical emission, absorption, photoluminescence (PL) and Raman scattering by single, as well as coupled metal nanoparticles. This model is capable of explaining the origin for the much greater Raman enhancement that has been observed in experiments while that for the seemingly similar PL process is far more modest.

9163-54, Session 13

Effect of nanoscale surface roughness on surface-tuned nanoparticle plasmon resonances *(Invited Paper)*

Chatdanai Lumdee, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Binfeng Yun, Southeast Univ. (China); Pieter G. Kik, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Plasmon resonant metal nanoparticles on substrates have been considered for use in several nanophotonic applications due to the combination of large field enhancement factors, broadband frequency control, ease of fabrication, and structural robustness that they provide. Despite the existence of a large body of work on the dependence of the nanoparticle plasmon resonance on composition and particle-substrate separation, little is known about the role of substrate roughness in these systems. This is in fact an important aspect, since particle-substrate gap sizes for which large resonance shifts are observed are of the same order of typical surface roughness of deposited films. In the present study, scattering spectra of 80 nm diameter gold nanoparticles on a gold film were acquired using dark-field single-particle spectroscopy. The measured data show a mean average resonance wavelength of 745 nm and a particle-to-particle spectral variation of 14 nm (one sigma). The measured results are compared with calculated scattering spectra of gold nanoparticles on corrugated gold substrates with a surface morphology based on measured atomic force microscopy data. By combining a statistical analysis of the measured surface features with electromagnetic simulations of likely local particle environments, it is demonstrated that the experimentally observed spectral variations can be explained by taking into account the film surface roughness. This study demonstrates that nanoscale surface roughness can become an important source of spectral variation for substrate tuned resonances that use small gap sizes. The implications of our findings on the design of reliable plasmonic biochemical sensing substrates will be discussed.

9163-55, Session 14

Eigenvector expansion of discrete-dipole approximation: application to the simulation of optical extinction and electron energy-loss spectroscopies of coupled metallic nanoparticles

Stéphane-Olivier Guillaume, Univ. of Namur (Belgium); Francisco Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain); Luc Henrard, Univ. of Namur (Belgium)

In this work, we are interested in the simulation of extinction and electron energy loss (EEL) spectra of isolated and coupled metallic particles. To achieve this, we have developed an efficient procedure based on the discrete-dipole approximation (DDA). Instead of directly solving the full system of dipoles, we calculate the eigenvalues and the associated eigenvectors of a geometric matrix describing each particle. These eigenvectors are then used as a truncatable basis in which an expansion of the DDA-quantities is made. By choosing carefully the eigenvectors, it is possible to truncate the basis to few terms compared to the complete set containing thousands of vectors. The response of the whole system is then obtained by adding interaction terms which account for multiple scattering between the particles. The advantage of this method is that it reduces significantly the size of the system of equations to be solved (and then the computational effort) when one considers multiparticle systems. Substrate effects can also be taken into account thanks to the dipole image method. Translated in the eigenvector expansion (EVE) formalism, these effects appears as interaction (i.e. multiple scattering) between the particles and their image. The proposed EVE procedure has been used to calculate EEL and extinction spectra of isolated and coupled metallic nanoparticles of various shapes and the results have been confronted to full DDA calculations to validate the approach.

9163-56, Session 14

Enhanced up-conversion in nanocrystals coupled to silver nanowires

Aneta Prymaczek, Kamil Ciszak, Institute of Physics, Nicolaus Copernicus University (Poland); Marcin Nyk, Wroclaw Univ. of Technology (Poland); Dawid Piatkowski, Sebastian Mackowski, Nicolaus Copernicus Univ. (Poland)

The up-conversion phenomenon is a sequential absorption of two or more IR photons and it leads to light emission at shorter wavelengths than the excitation wavelength. Typical ions used for up-converting are Er3+ and Tm3+, co-doped with Yb3+, as they exhibit the highest up-conversion efficiency, which is particularly important for anti-Stokes bioimaging. Recently, plasmon excitations have been applied for increasing the efficiency of up-conversion processes in nanocrystals doped with rare earth ions. In principle, under appropriately optimized physical conditions such as spectral matching and optimal distance, plasmon oscillations can lead to both enhanced absorption and emission rates of rare earth ions.

In this work we distinguished experimentally different processes that contribute the overall plasmon enhancement up-conversion. We studied hybrid nanostructures composed of NaYF4:Er3+/Yb3+ nanocrystals coupled to silver nanowires. Plasmon-enhanced absorption is demonstrated using linearly polarized laser light. Confocal anti-Stokes fluorescence microscopy images show very intense emission from nanocrystals coupled to nanowires oriented parallel to the polarization vector of incident light. This indicates that the nanowires efficiently collect IR radiation and transfer the excitation energy to nanocrystals leading to enhanced absorption. At the same time Fluorescence Lifetime Imaging Microscopy yields shortened fluorescence lifetimes of nanocrystals coupled to silver nanowires and illustrates plasmon enhanced emission rates due to the Purcell effect. Finally, by applying Back Focal Plane Microscopy, we proved that the fluorescence energy additionally excites propagating surface plasmon polaritons in the nanowires which distribute and reemit fluorescence as leakage radiation, contributing to the overall up-conversion enhancement. Overall, our observations demonstrate the complex interplay of energy transfer and dissipation in this plasmon-enhanced up-converting hybrid nanostructure.

9163-57, Session 14

Superradiance effect in multiple plasmonic resonators

Zongfu Yu, Univ. of Wisconsin-Madison (United States)

We developed a classical optics description of the superradiance for N resonators based on a multi-resonator multi-channel temporal coupled mode theory. Using the theory, we showed subtle absorption effects that are absent in the emission process, such as superradiance-induced transparency where the absorption is suppressed by up to N^2 times. To validate theoretical predications, we implemented the analogy of superradiance using graphene ribbons, optical resonators that offer deep subwavelength sizes as well as easy control of near-field interaction.

9163-58, Session 14

Generation and characterization of plasmonic nanostructures in glass surfaces by means of excimer and solid state laser irradiation

Manfred Dubiel, Maximilian Heinz, Martin Stiebing, Martin-Luther Univ. Halle-Wittenberg (Germany); Jörg Meinertz, Jürgen

Ihlemann, Laser-Lab. Göttingen e.V. (Germany); Thomas Rainer, boraident GmbH (Germany)

The localized formation of very small metal particles enables the generation of nanostructured materials, which are of interest for manifold applications as surface plasmon devices. This study investigates the space-selective precipitation of Ag and Ag/Au nanoparticles and the creation of appropriate arrays thereof in surface regions of dielectric matrices like glasses by means of ultraviolet laser irradiation (193 and 405 nm) below the ablation threshold. The Ag and Au ions were introduced into the soda-lime silicate glass using melting and ion exchange processes. After laser processing, the experimentally recorded spectra of optical spectroscopy demonstrated that the reduction of metal ions is caused by defect generation, for example the generation of electron hole centres, or by redox reactions with polyvalent ions. Finally, the agglomeration of neutral metal atoms and the growth of nanoscaled structures occur due to heating of the specimens as direct result of laser irradiation or by subsequent thermal treatments. The interesting surface plasmon resonances were registered in UV/Vis range as a function of sizes and origin of nanoparticles and of specific arrays like line or grating configurations. The simulation of absorption spectra by means of Mie theory and additional experiments of small angle X-ray scattering (SAXS) allowed to identify the resulting surface plasmon resonance in correlation with nanoscaled configurations of metal structures in the dielectric matrix.

9163-59, Session 14

Quantum nonlocal effects in individual and interacting graphene nanoribbons

Iván Silveiro, Juan Manuel Plaza Ortega, Francisco Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

We show that highly doped graphene ribbons can support surface plasmons at near-infrared frequencies when their width W is in the nanometer range. We rely on a quantum-mechanical approach to the optical response [1] that allows us to go beyond a classical local description in order to account for nonlocal and quantum finite-size effects. The latter are important for widths below W~10 nm, as revealed by comparison with classical theory [2]. The scaling law wp~(EF/W)^0.5 of the plasmon frequency wp with the Fermi energy EF and the ribbon width W is approximately maintained down to small sizes, despite some discrepancies originating in nonlocality. Specifically, the orientation of the edges relative to the graphene atomic lattice plays a crucial role, with zigzag edges contributing to damp the plasmons at energies above the Fermi level, due to the participation of electronic edge states. In contrast, armchair ribbons can support well defined plasmons at energies above EF. We also investigate the interaction between ribbons in close proximity. Strong hybridization between plasmons in periodic arrays is observed at small separations below a few nanometers. A substantial dependence on edge orientation and relative atomic alignment is observed. At larger separations, the dipolar interaction between ribbons becomes dominant. Analytical expressions are formulated that agree well with numerical results in the small and large separation limits. Besides the fundamental interest of this study, our work supports the use of narrow ribbons to achieve electro-optical modulation in the near infrared.

Large chemically synthesized silver crystals for low-loss and active plasmonics

Chun-Yuan Wang, Hung-Ying Chen, Yu-Jung Lu, Shangjr Gwo, National Tsing Hua Univ. (Taiwan); Liuyang Sun, Xiaoqin Li, The Univ. of Texas at Austin (United States)

Surface plasmon polaritons (SPPs) supported on the noble-metal surfaces possess larger wavevectors than that of light at the same frequency from complete visible to the infrared range. Therefore, noble-metal nanostructures can function as near-field transducers in order to compress light below the diffraction limit and to realize novel applications such as plasmonic nanoantennas, nanolasers, and nanocircuits. However, the real-world applications of SPPs are very sensitive to plasmonic losses, which include (i) ohmic losses, (ii) in-plane scattering (e.g., grain boundaries), and (iii) far-field radiative scattering. Recently, several groups have demonstrated that ultrasmooth1 and single-crystalline2-5 noble-metal films1,2,4,5 and nanocrystals3 have lower plasmonic losses than those of polycrystalline films. For example, we had demonstrated low-threshold and diffraction-unlimited plasmonic nanolaser based on the epitaxial silver film4. Here, we report on novel chemical synthesis and plasmonic applications of macroscopic-sized, single-crystalline silver plates. In combination with the focused ion beam milling technique, we demonstrate that high-quality plasmonic nanocavities, nanocircuits, and nanoantennas could be fabricated on these plates. Furthermore, we have incorporated III-nitride semiconductor nanostructures as local coherent SPP sources (spasers) into these plasmonic structures for the possible realization of active integrated plasmonic systems.

Enhanced transient absorption of organic dyes induced by surface plasmons of silver nanoparticles

Ausra Gustainyte, Ctr. for Physical Sciences and Technology (Lithuania); Domantas Peckus, Ctr. for Physical Sciences and Technology (Lithuania) and Kaunas Univ. of Technology (Lithuania); Marius Franckevicius, Vidmantas Gulbinas, Ctr. for Physical Sciences and Technology (Lithuania); Sigitas Tamulevicius, Kaunas Univ. of Technology (Lithuania)

Ability to control shape and size of silver nanoparticles enables us to produce nanoparticles with various useful optical properties, but for their application it is important to get high concentrations of nanoparticles. In this paper, we used reduced silver nitrate salt for forming of Ag clusters and chose hydrogen peroxide to control nanoparticles size. In this synthesis method we prepared high concentration (50 mM) nanoparticles.

After the characterization of the structure of silver nanoparticles using Transmission electron microscopy (TEM) and UV-VIS spectroscopy we observed that in our experimental samples nanoparticles formed on average of 50nm, 80 nm and 100 nm diameter and triangular shape, whose size was dependent from the hydrogen peroxide concentration. This result is also confirmed by high-intensity visible extinction band in the optical absorption spectra at 500-800 nm depending of NPs size resulting from localized surface plasmon resonance typical to silver nanoparticles. From these high concentration nanoparticles using spin coating method high densities of NPs in thin films can be obtained. In this work we presented how to get high concentration silver nanoparticles for application in organic solar cells.

High sensitivity refractive index sensing in gold nanoslit arrays

Qiang Kan, Jun Yuan, Zhaoxin Geng, Yiyang Xie, ChunXia Wang, Hongda Chen, Institute of Semiconductors (China)

Extraordinary optical transmission (EOT) spectra of nano-aperture array are widely investigated since it was demonstrated by Ebbesen in 1998. The resonances of surface plasmons and cavity mode in some periodic nanostructures, such as nanohole and nanoslit, cause EOT in certain wavelengths. Since the resonant wavelength is changed under different surface conditions, the metallic nanostructures are expected to be good sensing elements. We investigate experimentally and theoretically the sensing performance of gold nanoslit array. Three-dimensional FDTD simulations are performed to analyze their transmission spectra and steady-state field intensity distributions. The nanoslit array pattern are defined by electron beam lithography, and transferred to gold film by ion milling process. We fabricated and measured several gold nanoslit arrays with varied period and width. The sensing performance of the gold nanoslit arrays are characterized via extinction spectra in various refractive index fluid environments. Geometrical investigation results of gold nanoslit arrays show that sensitivity approaches saturation as width of nanoslit is smaller than 70nm and is almost linearly proportional to the array period when nanoslit width is fixed. The highest sensitivity of the gold nanoslit arrays is 726nm/RIU, and the nanoslit arrays are demonstrated to be a superior choice of biosensor.

Mode parity-controlled Fano and Lorentz resonances in plasmonic nanorods

Niels Verellen, Katholieke Univ. Leuven (Belgium) and IMEC (Belgium); Fernando López-Tejeira, Univ. de Zaragoza (Spain); Ramón Paniagua-Domínguez, Instituto de Estructura de la Materia (Spain); Dries Vercruysse, IMEC (Belgium) and Katholieke Univ. Leuven (Belgium); Denitza Denkova, Katholieke Univ. Leuven (Belgium); Liesbet Lagae, Pol Van Dorpe, IMEC (Belgium) and Katholieke Univ. Leuven (Belgium); Victor V. Moshchalkov, Katholieke Univ. Leuven (Belgium); José A. Sánchez-Gil, Instituto de Estructura de la Materia (Spain)

We present the experimental observation of spectral lines of distinctly different shapes in the optical extinction cross-section of metallic nanorod antennas. Surface plasmon resonances of odd mode parity display Fano interference in the scattering cross-section resulting in asymmetric spectral lines. Contrarily, modes with even parity appear as symmetric Lorentzian lines. Finite element simulations are used to verify the experimental results. The emergence of either constructive or destructive mode interference is explained with a semi-analytical 1D line current model. This simple model directly explains the mode-parity dependence of the Fano-like interference. Plasmonic nanorods are widely used as half-wave optical dipole antennas. Our findings offer a perspective and theoretical framework for operating these antennas at higher order modes.

Plasmon coupling in upright magnetic SRR metamolecules

Wei-Lun Hsu, Pin Chieh Wu, Wei Ting Chen, Yao-Wei Huang, Chun Yen Liao, National Taiwan Univ. (Taiwan); Ai Qun Liu, Nanyang Technological Univ. (Singapore); Greg Sun, Univ. of Massachusetts Boston (United States); Din Ping Tsai, Academia Sinica (Taiwan)

In the past few years, a number of interesting designs have been proposed to generate artificial magnetism at optical frequencies using plasmonic metamaterials [1,2], but owing to the planar configurations of typically fabricated metamolecules that make up the metamaterials, the response to the incident magnetic field is very weak. To date a large majority of the manipulations on the plasmonic metamaterials are based on pure electric effects where only the electric component of the incident wave plays an active role. Still the quest to explore the interaction of metamaterials with the other half of the electromagnetics by expanding into the realm of magnetism that has been rarely ventured into is very much alive. One enabling element for this investigation is the fabrication of three-dimensional (3D) split ring resonators (SRRs) which behave as magnetic metamolecules sensitive to both the incident electric and magnetic fields upon excitation. However, the principle question on how the incident electric and magnetic fields interact with the plasmon hybridization of such 3D metamolecules still remains open. In this work, we study the magnetic plasmon response for isolated planar and 3D SRRs. And then we conduct experimental and numerical to investigate the coupling effect between incident fields and 3D SRR dimers by using oblique incidence which is able to vary the effective incident electric (magnetic) field that interacts with the metamolecules while maintaining the magnetic (electric) field unchanged for analyzing and tailoring the plasmon excitation at each plasmonic response. This work offers an important pathway to the realization of active manipulation of plasmon properties of metamaterials via magnetic coupling at optical frequencies.

Optimizing the quantum dot-plasmon interaction in a nano gap waveguide

Chamanei S. Perera, Kristy C. Vernon, Queensland Univ. of Technology (Australia)

Spontaneous emission (SE) of a Quantum emitter depends mainly on the transmission strength between the upper and lower energy levels as well as the Local Density of States (LDOS)[1]. When a QD is placed near a plasmon waveguide, LDOS of the QD is increased due to addition of the non-radiative decay and a plasmonic decay channel to free space emission[2-4]. The slow velocity and dramatic concentration of the electric field of the plasmon can capture majority of the SE into guided plasmon mode ( ).

This paper focused on studying the effect of waveguide height on the efficiency of coupling QD decay into plasmon mode using a numerical model based on finite elemental method (FEM). Symmetric and asymmetric gap waveguides were considered in this paper. Both waveguides are single mode and the QD is modeled as a dipole emitter. 2D simulation models are done to find normalized and 3D models are used to find probability of SE decaying into plasmon mode ( ) including all three decay channels. We show that changing gap height can increase QD-plasmon coupling, by up to a factor of 5 and an optimally placed QD can increase the QD-plasmon coupling up to a factor of 8. To make the paper more realistic we briefly studied the effect of sharpness of the waveguide edge on SE into guided plasmon mode. Preliminary GPW fabrication and testing are underway. Authors expect to compare the theoretical results with experimental outcomes in the future.

Transient plasmon-like modes in multi-level quantum emitter systems

Martin J. Gentile, William L. Barnes, Univ. of Exeter (United Kingdom)

We model a nanoparticle of organic dye molecules as an ensemble of multi-level quantum systems in order to determine the conditions necessary to yield temporal optical field enhancement for different probe energies. By utilizing a time-dependent density-matrix approach and by examination of the role played by both radiative and non-radiative decay processes between energy levels, we explore how optical pump and probe fields may be used to control the permittivity of the nanoparticle as a function of time. When an appropriate value of the permittivity occurs, a plasmon-like mode will be produced. In this work, we investigate systems in which these plasmon-like modes can be generated at probe energies detuned from the atomic transitions and sustained for timescales dependent on the lifetime of a meta-stable level in our system. Our results suggest that these plasmon-like modes may generate temporal optical field enhancement and that such nanostructures open a new realm in nanophotonics in which transient behaviour can lead to phenomena that cannot be attained in the steady-state regime.

Tailoring plasmonic field within two-color laser using metallic nanostructure for the generation of high harmonics

Ying-Ying Yang, Institute of Semiconductors (China); Qian-Guang Li, Hubei Univ. of Engineering (China); Ling Zhang, Xue-Chun Lin, Institute of Semiconductors (China)

We have theoretically investigated high-harmonic generation (HHG) and extreme-ultraviolet (XUV) radiation via nanoplasmonic field enhancement in a two-color laser field. We have proposed and optimized an asymmetric metallic nanostructure based on the finite element method (FEM). This asymmetric nanostructure could effectively enhance the incidence with two different wavelengths simultaneously. In order to tailor the plasmonic near-field, the asymmetric factor is introduced for this nanostructure in our work, which would affect its enhancement ability for the different incident wavelength. The electromagnetic properties of this asymmetric nanostructure are fully analyzed and discussed in temporal domain and spatial domain. Comparing with the case of the one-color field, this asymmetric nanostructure enables a broader bandwidth and smoother harmonic spectra under the condition of the two-color incidence field, which benefits the generation of broadband-isolated attosecond pulses. The theoretical simulations of the generated harmonic in enhanced laser fields via nanoplasmonic resonance are performed by the numerical solutions of the time-dependent Schrodinger equation. We have adopted the single active electron approximation and a softcore potential was employed in order to computer the high-harmonic spectra. By varying the parameter of the asymmetric nanostructure, and changing the relative phase of the two-color laser field, the influence to the temporal and spatial characteristics of the generated attosecond pulses are studied and analyzed. We also demonstrated that the isolated attosecond pulses were attained in the two-color enhanced field via the asymmetric nanostructure, while the attosecond pulse train appeared in the case of the one-color field. This work would have potential application in the time-resolved studies with high resolution.

Optical spectra of noble metal nanoparticles supported on zeolites

Catalina B. Lopez, Elena Smolentseva, Roberto Machorro, Vitalii P. Petranovskii, Univ. Nacional Autónoma de México (Mexico)

The synthesis and study of nanoparticles embedded in mesoporous materials is an important topic in nanoscience and nanotechnology. Metal nanoparticles dispersed over supports have found use as heterogeneous catalysts in many industries including fine chemistry, energy-related applications and environmental remediation. There is profound technological interest in zeolite based catalysts due mainly to its morphological properties that yield very high surface to bulk ratios. Zeolites are crystalline aluminosilicate materials comprised of a series of strictly uniform channels and cavities of nanosized dimensions repeating along the tri-directional structure of a lattice. The compositional and structural complexity of such nanosized systems offers many degrees of freedom for tuning their catalytic properties. The size and species distribution of metallic inclusions within zeolite templates has been shown to affect the catalytic activity of the sample . In this work the optical response of noble metal nano-particles supported on different types of zeolites are studied theoretical and experimentally. The absorbance spectra of Cu, Ag and Au nanoparticles supported on mordenite, β-zeolite, Na/Y and H/Y zeolites are analyzed. Spectra for pre-exchanged Au-Cu/Na/Y, Au-Ni/Na/Y and Au-Fe/Na/Y are also studied.

A simple effective medium approach (Maxwell-Garnett) is used to obtain a theoretical complex effective dielectric function of the composite and to asses the sensibility of the plasmon resonance to the parameters of the system. The knowledge of these properties can hopefully be applied to the development of optical tools to monitor the synthetic path and aid in the development of controlled synthesis of catalytic materials with predetermined properties.

Controlling light with the near-field interference

Pavel Ginzburg, King's College London (United Kingdom); Polina V. Kapitanova, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Francisco J. Rodríguez-Fortuño, Univ. Politècnica de València (Spain); Daniel P. O'Connor, Giuseppe Marino, King's College London (United Kingdom); Dmitry S. Filonov, Pavel M. Voroshilov, Alexander Poddubny, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Gregory A. Wurtz, King's College London (United Kingdom); Pavel A. Belov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Yuri S. Kivshar, The Australian National Univ. (Australia); Anatoly V. Zayats, King's College London (United Kingdom)

Young's double slit experiment is the most frequently used tool for demonstration of the interference principle. Key components for interference pattern creation are both temporal coherence of an excitation source and phase accumulation, undertaken via different trajectories (two slits). However, these fundamental requirements could be relaxed, if the vectorial nature of both excitation source and detection object is introduced. Vectorial coupling via near-field interaction could remove the fundamental requirement on the coherent propagating phase lag. Recently, this concept was proposed and experimentally demonstrated in several experiments [1,2]. These results will be presented at this talk.

The effect of near-field interference was demonstrated with the help of a single source of radiation coupled to a transverse magnetic mode (having vectorial structure of electromagnetic field) of a plasmonic waveguide. It was shown that an elliptically polarized dipole produces destructive or constructive interference in opposite directions and, as a result, excites propagating modes with a controlled directionality of propagation.

Furthermore, we exploited the scalability of optical phenomena to radio waves in order to demonstrate the effect of the near field interference with locally excited emitters. In particular, we show that a circularly polarized emitter (classical antenna in this case) near an anisotropic hyperbolic metamaterial slab will unidirectionally excite extraordinary transverse-magnetic modes in the sample. The direction of the excitation is controlled by the circular dipole handedness. The effect has been demonstrated in the RF regime with a hyperbolic metamaterial based on lumped circuit elements.

Dynamic optical properties of amorphous diamond like carbon nanocomposite films doped with Cu and Ag nanoparticles

Tomas Tamulevicius, Kaunas Univ. of Technology (Lithuania); Domantas Peckus, Ctr. for Physical Sciences and Technology (Lithuania); Asta Tamuleviciene, Andrius Vasiliauskas, Arvydas Ciegis, Sarunas Meskinis, Sigitas Tamulevicius, Kaunas Univ. of Technology (Lithuania)

Optical response of different transparent host matrixes embedded with noble metal nanoparticles is dramatically enriched by surface plasmons (SP) that enhance electromagnetic field in the proximity of the metal-dielectric interface. As a result, the optical properties of nanocomposite can be tuned by varying size, shape and packing density of the particles and by changing the particle-matrix interface. The investigation of electron dynamics and energy relaxation processes in noble metal nanoparticles upon ultrafast excitations by femtosecond laser pulses enables to understand the origin and the enhancement mechanism of the nonlinear optical properties for metal-dielectric nanocomposites.

In the current work we present studies on optical properties of diamond like carbon (DLC) (amorphous nanocomposite consisting of the sp2 graphite-like bonded carbon nanoclusters embedded into the sp3 bonded carbon) matrix containing silver and copper nanoparticles. Thin DLC nanocomposite films were synthesized employing unbalanced magnetron sputtering of metal targets with argon ions in acetylene gas atmosphere. The nanoparticle size distribution was analyzed employing scanning electron and atomic force microscopy and image processing software. Chemical composition of the films was determined employing energy dispersive x-ray analysis. The steady-state optical response of such nanocomposites enriched by SPs due to different metal content was analyzed employing UV-VIS-NIR spectrometer. Transient absorption measurements were obtained employing Yb:KGW femtosecond laser spectroscopic system (HARPIA, Light Conversion Ltd.). Steady-state and kinetic spectroscopy measurements were related to the metal filler concentration, nanoparticles size distribution and surface enhancement of Raman signal.

Metal-all-around nitride semiconductor plasmonic nanolasers

Yu-Jung Lu, Shangjr Gwo, National Tsing Hua Univ. (Taiwan)

Plasmonic nanolasers based on subwavelength-sized metal-oxide-semiconductor (MOS) structures have received much interest due to their capability to break the optical diffraction limit. Recently, epitaxial Ag films have been successfully utilized to fabricate low-loss MOS plasmonic cavities for low-threshold, continuous-wave (CW) operation of plasmonic nanolasers< sup>1< /sup>. However, such lasers are limited by the extensive size of metal film and the maximum achievable output power. Here, we report on the demonstration of high CW output power metal-all-around plasmonic nanolasers based on an MOS core-shell nanorod structure. The achieved device feature sizes are comparable with that of state-of-the-art nanowire transistors developed for nanoelectronics.

In this work, we have demonstrated a low CW lasing threshold (~100 W/cm< sup>2< /sup>) for the gold-all-around blue (440 nm) nanolaser operated at cryogenic temperature. Especially, no emission efficiency droop was observed even at a pump power density as high as 100 kW/cm< sup>2< /sup> for a single nanorod laser. Because of the metal-all-around structure, the lasing peaks showed sharp spectral lines with the same full width at half maximum and linearly increased lasing intensity over a wide range of optical pumping intensity (about three orders of magnitude). The availability of high-power, ultrasmall plasmonic nanolasers can open the way for a wide range of on-chip plasmonic applications.

Tunable plasmonic metamaterials composed of colloidal gold(core)/silver(shell) nanoparticles

Meng-Hsien Lin, National Tsing Hua Univ. (Taiwan)

Owing to the technical difficulty of top-down nanofabrication, most of demonstrated metamaterials have been limited in spectral range and sample size. Here, we experimentally and theoretically demonstrate a new approach for fabricating wafer-scale plasmonic metamaterials using the tunable plasmonic response from self-assembled colloidal Au(core)/Ag(shell) nanoparticle arrays. We show that this bottom-up process can be used to accurately fabricate plasmonic metamaterials with tunable plasmonic resonant frequencies. In particular, by controlling the core-shell ratio of the Au(core)/Ag(shell) nanoparticles, we can create broadband tunable plasmonic metamaterial in that spectral regions that cannot be achieved alone with Au and Ag nanoparticles.

In this work, we utilized colloidal Au(core)/Ag(shell) nanoparticles with varying dimensions (particle diameter: 5.5, 6.5, 7.5, and 9.5 nm; core diameter: 3.5, 4.5, 5.5, and 7.5 nm) to form two-dimensional (2D), close-packed nanoparticle superlattices on quartz substrates for optical absorption measurements. A clear and tunable red shift was observed as we increased the core size from 3.5 to 7.5 nm. We also found that the dispersed Au(core)/Ag(shell) nanoparticles exhibit almost identical absorption spectra, which are independent of their sizes, indicating that the change of shell and core dimensions do not significantly affect the absorption properties of dispersed nanoparticles in this size range. However, for the cases of strongly coupled nanoparticle superlattices, minute changes in the core-shell ratio can greatly impact the collective surface plasmon resonance. By using an effective medium model, we can accurately simulate the plasmonic absorption properties for these 2D superlattices, enabling fabrication of designable plasmonic metamaterials in a wide spectrum.

Plasmonic influence on the up-conversion luminescence in $NaYF_4$:Er^{3+}/Yb^{3+} nanocrystals

Kamil Ciszak, Nicolaus Copernicus Univ. (Poland); Marcin Nyk, Wroclaw Univ. of Technology (Poland); Dawid Piatkowski, Sebastian Mackowski, Nicolaus Copernicus Univ. (Poland)

In this work we study the energy transfer from nanocrystals to conjugated polymer poly(3-hexylthiophene) (P3HT), which is one of the most commonly used building blocks in bulk heterojunction solar cell architectures. It plays a role in absorbing photons and transferring them efficiently to electron acceptors, where charge separation takes place. By coupling nanocrystals, whose optical properties can be tuned over broad spectral range, it should be possible to extend and/or enhance the absorption of such a hybrid nanostructure. On the other hand, shifting the absorption and emission of the nanocrystals by changing their size or chemical composition, can yield important observations regarding the mechanisms of the energy transfer itself.

The nanostructure, in which nanocrystals were mixed directly into the P3HT layer, was studied by means of high-resolution fluorescence microscopy, both in continuous-wave and time-resolved modes. The experimental setup allows to probe the optical properties at single nanocrystal level.

We find that the emission of P3HT increases significantly by approximately 10-fold when nanocrystals are placed in the layer. This increase is accompanied with increase of fluorescence life-time of P3HT emission. On the other hand, the lifetime of nanocrystals emission gets shorter. These results indicate efficient energy transfer from the nanocrystals to the P3HT layer. We estimate the efficiency of this process to be in the range of 50%.

We anticipate that introducing plasmonically active nanoparticles in such a structure should result in further improvement of the optical, absorption in particular, properties of this system.

Using remote excitation-surface enhanced Raman scattering (RE-SERS) to study the influence of nanoparticle properties on hot-spots and spectra

Bart M. Kenens, Hiroshi Uji-I, Katholieke Univ. Leuven (Belgium)

Surface Enhanced Raman Spectroscopy (SERS) is a promising technique for biochemical imaging and sensing. The SERS enhancement factor can go up to 10 to the 14. The highest enhancements are obtained at hot-spots in the nanogap between nanoparticles (NPs). A challenge of SERS is the generation and control of position of hot-spots. Further, the hot-spots with the sample is exposed to a diffraction limited focal spot of the excitation beam. This leads to larger background signals and decrease in contrast between unenhanced Raman and SERS. A nanowire/nanoparticle system is proposed as potential probe. By using the propagating Surface Plasmon Polaritons on a silver nanowire, spatial confinement and transport of the light can be obtained. Light focused at the end of a nanowire (30µm) can excite SERS hot-spots between the nanowire and nanoparticle micrometers away from the focus (RE-SERS) The spectra obtained at these hot-spots during remote excitation show very little background compared to direct excitation. However, due to the dispersion relation mismatch, the coupling efficiency of light to SPPs at the end of the wire is very low. Second, the laser focus is much larger than the nanowire, precise control of laser focus position is needed. By attaching a nanoparticle at the end, the in- and out-coupling light efficiency is enhanced compared to a free nanowire under the same conditions. In this research, we investigated the influence of shape, size and type of the metal of the attached particle in order to obtain a highly efficient in-coupling, and therefore higher quality RE-SERS spectra.

Emergence of same-sign super-chiral electromagnetic fields in chiral clusters of achiral plasmonic particles

Hossein Alizadeh, Björn M. Reinhard, Boston Univ. (United States)

We report emergence of same-sign super-chiral electromagnetic fields in certain chiral geometry of a cluster of achiral plasmonic nano-particles. Until recently it was believed that circularly polarized light possesses highest possible chirality. The pioneering work by Tang and Cohen introduced the concept of super-chiral fields, the chirality of which exceeds that of circularly polarized light by orders of magnitude. These so-called super-chiral fields can be created in the near field of resonant plasmonic nano-particles. The most prominent application of super-chiral fields is deemed to be in enhancing the signal in Circular Dichroism Spectroscopy. CD spectroscopy measures the difference in transmission of differently polarized circular light from chiral biomolecules. However there are obstacles in this implementation. If the plasmonic structure is achiral the enhanced chirality in its near-field will change sign alternatively such that the integrated chirality surrounding the plasmonic particle yields zero. One way to alleviate this problem is to fabricate geometrical chiral structures such as Gammadions and G shaped wheels. However due to fabrication resolutions the big size of these structures shifts the plasmonic resonance frequencies to far-red and near-infrared regions which are far from the desired range of UV-Vis where most of molecular electronic transitions occur. We have observed that certain chiral geometry of achiral silver nano-spheres creates localized super-chiral hot spots with uniform sign of chirality. Since the plasmonic resonance of the constituent silver nano-spheres occurs near molecular transition frequencies this can pave the way to obtain ultra-enhanced interactions between chiral biomolecules and the plasmonic structures.

Surface plasmon amplification in Ag/InGaAsP hybrid nano-structures

Seunghyun Kim, Tae-Young Jeong, Seungwon Seo, Chungnam National Univ. (Korea, Republic of); Kwang-Jun Ahn, Seoul National Univ. (Korea, Republic of); Ki-Ju Yee, Chungnam National Univ. (Korea, Republic of)

We report on experimental and theoretical study for surface plasmon (SP) amplification by stimulated emission in Ag-InGaAsP hybrid nano-structures. For demonstrating efficient SP amplification at telecommunication frequencies, the structure of our device is the asymmetric slab waveguide, which is composed of three layers, with metallic 1D nano grating at the top layer, 700 nm thick InGaAsP semiconductor core as the middle layer, and InP substrate as the bottom layer. The spectral position of SP resonance can be controlled by adjusting of the slit period and fill factor, and the metal slit array has a fill factor of 0.3 ~ 0.7 and period of 330 ~ 460 nm. The normal-incidence transmission spectrum was measured in the near-infrared region. For slit period of 420 nm, transmission dip is appeared at wavelength of 1,440 nm. By comparing experimental results with the computational simulation, it was revealed that spectral dip in transmission spectrum has appeared due to the resonant excitation of the SP mode.

By the optical pumping, enormous carriers are created in the semiconductor gain medium, and the propagating SPs in the interface between the Ag slits and InGaAsP semiconductor can be amplified by the stimulated emission process in the complete compensation of the SP propagating loss. The amount of SP amplification depends on the gain spectrum in the InGaAsP, which can be controlled by adjusting the pumping power and temperature. The observed SP amplification can be applied to elements of metamaterial with compensated propagating loss, ultra-miniaturized energy device and ultrafast nano amplifier.

Background-suppressed surface-enhanced molecular detection by metamaterial infrared absorber

Atsushi Ishikawa, Okayama Univ. (Japan) and RIKEN (Japan); Takuo Tanaka, RIKEN (Japan) and Hokkaido Univ. (Japan)

A background-suppressed surface-enhanced molecular detection technique is experimentally demonstrated by utilizing the resonant coupling of plasmonic modes of a metamaterial absorber and infrared (IR) vibrational modes of a self-assembled monolayer (SAM). IR absorption spectroscopy of molecular vibrations is of importance in material/medical science and security detection, since it provides essential information of the molecular structure, composition, and orientation. For direct (far-field) detection of extremely small amounts of molecules, surface enhanced IR absorption (SEIRA) has been extensively studied to dramatically improve the sensitivity by several orders of magnitude. Here, we demonstrate low-background resonant SEIRA by using the metamaterial IR absorber that offers significant background suppression as well as plasmonic enhancement. The fabricated metamaterial consisted of 1D array of Au micro-ribbons on a thick Au film separated by an MgF2 gap layer. The surface structures were designed to exhibit an anomalous IR absorption at ~ 3000 cm-1, which spectrally overlapped with C-H stretching vibrational modes. 16-Mercaptohexadecanoic acid (16-MHDA) was used as a test molecule, which formed a 2-nm thick SAM with their thiol head-group chemisorbed on the Au surface. In the FTIR measurements, the symmetric and asymmetric C-H stretching modes were clearly observed as reflection peaks within a broad plasmonic absorption of the metamaterial. The corresponding numerical simulation well reproduced the experimental results, revealing that a Fano-like anti-resonance arose from the resonant coupling between the plasmonic metamaterial and molecular vibrations. Our metamaterial approach may open up new avenues for further lowering the detection limit of direct IR vibrational spectroscopy.

Observation of optical domino modes in arrays of non-resonant plasmonic nanoantennas

Ivan S. Sinev, Anton K. Samusev, Pavel M. Voroshilov, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation); Ivan S. Mukhin, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation) and St. Petersburg Academic Univ. (Russian Federation); Andrey I. Denisyuk, Michael E. Guzhva, Pavel A. Belov, Constantin R. Simovski, National Research Univ. of Information Technologies, Mechanics and Optics (Russian Federation)

Domino modes are highly-confined collective modes that were first predicted for a periodic arrangement of metallic parallelepipeds in far-infrared region [1]. The main feature of domino modes is the advantageous distribution of the local electric field, which is concentrated between metallic elements (hot spots), while its penetration depth in metal is much smaller than the skin-depth. Therefore, arrays of non-resonant plasmonic nanoantennas exhibiting domino modes can be employed as broadband light trapping coatings for thin-film solar cells [2]. However, until now in the excitation of such modes was demonstrated only in numerical simulations.

Here, we for the first time demonstrate experimentally the excitation of optical domino modes in arrays of non-resonant plasmonic nanoantennas [2]. We characterize the nanoantenna arrays produced by means of electron beam lithography both experimentally using an aperture-type near-field scanning optical microscope and numerically. To associate the calculated field components with measured near-field signal we use the approach based on optical reciprocity theorem [3,4]. Good agreement between experimental and numerical near-field patterns allows us to interpret the observed near-field modes as domino modes.

The proof of domino modes concept for plasmonic arrays of nanoantennas in the visible spectral region opens new pathways for development of low-absorptive structures for effective focusing of light at the nanoscale.

The contribution of plasmon-enhanced photoluminescence to the SERS background

Loan Le Thi Ngoc, Justyna Wiedemair, Univ. Twente (Netherlands) and MESA+ Institute for Nanotechnology (Netherlands); Albert van den Berg, Univ. Twente (Netherlands); Edwin Carlen, Univ. of Tsukuba (Japan)

Although the surface-enhanced Raman scattering (SERS) effect was discovered almost 40 years ago, the broad continuum emission, called the SERS background, that accompanies the Raman bands remains poorly understood. Several models have been reported to explain the SERS background based on inelastic scattering, adsorbate luminescence, plasmon-enhanced fluorescence, and image-molecule mediated coupling in the metal. Photoluminescence (PL) from noble metals is also identified as an important component of the SERS background.

We present measurements of plasmon-enhanced PL, in combination with SERS measurements of benzenethiol self-assembled monolayers, from gold nanowire array (Au-NW) plasmonic surfaces. Measurements from flat as-deposited polycrystalline gold layers show two weak PL emissions at E1~1.9 eV and E2~2.2 eV using laser excitation wavelengths (energies) 632.8 nm (1.96 eV) and 532 nm (2.33 eV), respectively. Emission energies E1 and E2 are attributed to interband transitions near the X and L symmetry points of the Au lattice, respectively. Similar measurements of Au-NW surfaces show the same two emission energies, however, the PL efficiency is significantly increased ~100-200? by tuning the surface plasmon resonance energy close to PL emission energy. SERS measurements of benzenethiol on the Au-NW surfaces reveal that the background shape and peak emission energy are very similar to the measured plasmon-enhanced PL characteristics. Furthermore, the background and PL amplitudes both increase approximately linearly with increased laser excitation power. Our observations indicate that PL is the main contributor the SERS background on Au substrates.

Visible light responsive TiO2 photoanodes based on plasmonic meta-structures

Jeong Min Baik, Joonmo Park, Ulsan National Institute of Science and Technology (Korea, Republic of)

Ever since Fujishima and Honda have reported the photoelectrochemical water splitting by using a titanium oxide in 1972, many researchers has intensively studied the water splitting using semiconductor photoelectrodes such as Fe2O3, TiO2 etc. Although TiO2 shows good reliability with low cost, but the photocatalytic efficiency is still low because of the low light absorption in the visible range. Recently reported, surface plasmon resonance to boost visible light absorption of TiO2, and enhance the hydrogen production of photochemical cell. Here, we report the simple fabrication method of the meta-structured photoanodes for highly-efficient photoelectrochemical cell based on the TiO2 film and Au nanoparticles. The anode consists of Au layer (100 nm), TiO2 film (10 ~ 50 nm), and Au nanoparticles on TiO2 film. Compared with pure TiO2 film, the meta-structured film shows the enhanced visible-light absorption, resulting in the 6 times improvement in the photocurrent. It is ascribed to the the plasmon resonance energy of meta-structure transfer in the TiO2 photocatalyst. We also report the effect of the light absorption by the TiO2 thickness and the Au nanoparticles size on the photocatalytic efficiency.

Coherence changes of partially coherent beams in transmission through subwavelength metallic gratings

Hanna Lajunen, Toni Saastamoinen, Univ. of Eastern Finland (Finland)

Since the discovery of the extraordinary light transmission through a metallic film with subwavelength holes, the transmission resonances of electromagnetic fields incident on periodic slit and hole arrays have been widely studied. It has been shown that it is possible to tailor the spectral transmission properties of the metallic subwavelength structures by varying their geometrical parameters. While there are fewer studies considering the influence of similar structures on the coherence properties of electromagnetic fields, the effect of surface plasmons on field correlations between specific points has been considered in the case of finite slit and hole arrays in metallic films.

In this work we theoretically study the coherence changes induced in periodic subwavelength metallic gratings with narrow linear slits using rigorous numerical simulations based on the Fourier modal method and the coherent mode representation of partially coherent fields. The relation of the grating parameters to the effective degree of coherence of the transmitted field is studied by the numerical simulations and the changes in the coherence functions are illustrated for a Gaussian Schell-model (GSM) beam.

Our numerical results show that by choosing suitable parameters for the grating, the degree of coherence of the beam can be significantly

increased. The coherence properties directly affect, e.g., the propagation characteristics of electromagnetic fields and the novel possibilities to flexibly control them with nanophotonic components could thus be valuable for many types of applications.

Super long-range surface plasmons in a silver nano-slab waveguide

Mai Higuchi, Masashi Miyata, Junichi Takahara, Osaka Univ. (Japan)

A metal in plasmonic waveguides introduces high propagation losses, resulting in the limitation of application range. Recently, long-range SPPs (LRSPs) with extremely low losses have been studied as key elements for important applications. Regarding slab- shaped waveguide, we have already reported in theory that the smaller waveguide width made the propagation length longer. Here, we experimentally demonstrate the increase of LRSP propagation length in a slab-shaped silver waveguide as the width decreases. According to the calculation, it is found that the propagation losses can be significantly reduced when the waveguide width becomes shorter than the wavelength; we named this mode "super LRSPs". For the experimental demonstration of super LRSPs, we fabricated slab-shaped waveguides by FIB milling. The waveguide consists of a slab-shaped silver film embedded between SiO2 and index-matched polymer. Input and output couplers are defined on the edge of each waveguide to in- and out-couple SPPs. I measured the intensity from the output coupler as a function of the waveguide length. From a simple exponential fit to data, a SPP propagation length of 43.1 μm is extracted, while calculated one is 42.1μm. It means that we successfully demonstrated the propagation property of the fabricated waveguide. In addition, the increase of propagation length will be discussed for subwavelength width in the waveguide.

Optical and structural properties of graphene oxide-noble metal bilayers

Paola Zuppella, IFN-CNR Padova (Italy); Francesca Gerlin, CNR-IFN UOS Padova (Italy); Sara Zuccon, IFN-CNR Padova (Italy); Marco Nardello, Univ. degli Studi di Padova (Italy); Enrico Tessarolo, CNR-IFN UOS Padova (Italy); Alain J. Corso, IFN-CNR Padova (Italy); Simone Silvestrini, Michele Maggini, Univ. degli Studi di Padova (Italy); Maria G. Pelizzo, IFN-CNR Padova (Italy)

Graphene Oxide – metal bilayers are appealing nanostructures in many research fields: biosensors based on Graphene Oxide – gold stack have been recently used for Surface Plasmon Resonance equipment devoted to detection of chemical processes, similar and more complex coatings are also intriguing for development of optical elements in the EUV – UV spectral range. A good knowledge of the samples is required for the proper use because unexpected properties often occur when things arrange on a small scale. The samples have been prepared by tailoring the process according to the needs. We present their full characterization in terms of optical responses and surface and physical properties. The specimens have been observed by Optical Microscope and Atomic Force Microscope to identify flakes and island on the metal. Near Edge X – Ray Absorption Fine Structure spectroscopy has been used to characterize the electronic states, the orientation and the intramolecular bond lengths of the molecules on the surface.

Photothermal reshaping of single gold nanorods below melting point driven by surface diffusion

James W. M. Chon, Adam B. Taylor, Arif M. Siddiquee, Swinburne Univ. of Technology (Australia)

The use of gold nanorods has become pervasive in many recent technological advancements, with some of the most prominent applications including sensing, photovoltaics, biolabelling and cancer therapy [1, 2]. Gold nanorod stability is vital for preserving the LSPR and the success of these applications. However, instability of the shape during laser exposure has been reported by many and reshaping of nanorods was observed to occur at temperatures far below the bulk or surface melting points [3]. Here, we report a systematic study on photothermal reshaping behaviour of gold nanorods with varying aspect ratios, and show that the behaviour is largely dependent on aspect ratio and has less obvious relationship with bulk or surface melting points. From this result we infer that the curvature-driven surface diffusion plays more important role in photothermal reshaping process than previously thought and need to be considered together with other melting processes. Previously observed low temperature reshaping of gold nanorods at 100-200 degrees Celsius can be well explained with surface diffusion, without invoking the concept of low melting point.

Plasmonic response of different metals for specific applications

Sara Zuccon, Paola Zuppella, IFN-CNR LUXOR Lab. (Italy); Simone Silvestrini, Univ. degli Studi di Padova (Italy); Alain J. Corso, Francesca Gerlin, IFN-CNR LUXOR Lab. (Italy); Michele Maggini, Univ. degli Studi di Padova (Italy); Maria G. Pelizzo, IFN-CNR LUXOR Lab. (Italy)

Each metal presents different characteristics when used in a surface plasmon resonance (SPR) experiment. These include the shape of the SPR figure, the wavelength of better operation, the tendency to oxidize, the sensitivity to environmental changes, the range of refractive indices detectable and the capability of binding to specific targets or analytes.

When choosing the metal for our SPR experiment all of these characteristics have to be taken into account.

We investigate the behavior of different metals comparing their characteristics to gold. We deeply investigate both theoretically and experimentally the behavior of palladium. This metal leads to an inverted curve with a maximum of reflected intensity instead of a minimum. In fact, in this case we speak of Inverted Surface Plasmon Resonance (ISPR). Aluminum and copper have also been considered because of their potentiality in specific applications.

High resolution characterization of plasmon resonances in silver nanostructures

Edson P. Bellido, David Rossoud, Gianluigi A. Botton, McMaster Univ. (Canada)

In order to study surface plasmon resonances (SPR) at the nanoscale, a characterization technique providing high spatial and energy resolution

is required. Energy loss spectroscopy (EELS) in a scanning transmission electron microscope (STEM) is one of the best techniques for imaging SPR, because the STEM can reach the ultimate spatial resolution, thanks to advancements in electron sources and electron optics. However, EELS has been limited to frequencies in the visible range and higher; mainly because the high intensity of the zero loss peak (ZLP) tail compared with low loss signal intensity. In order to reduce the intensity of the ZLP tail we need to improve the energy resolution of the EELS system.

In this work, we use electron beam lithography to fabricate silver nanorods and nano-squares on silicon nitride membranes. We acquire energy-filtered maps of SPR modes using a state of the art STEM/TEM system, obtaining an energy resolution of 74±5meV. To further increase the energy resolution and reduce the contribution of the ZLP, we apply the iterative Richardson-Lucy (RL) deconvolution. With this method, we obtain a record effective energy resolution of 30 meV after 50 iterations, and an effective resolution of 10 meV after 500 iterations for spectral features below 1 eV energy loss. We extract high-resolution images and energy-filtered maps of SPR of a silver nanorod at energies down to 0.25 eV, corresponding to the mid-infrared region on the electromagnetic spectrum. We were also able to identify hydrid-SPR peaks separated by only 70meV from two silver nano-squares with a gap of 100nm between them.

Asymmetric gold nanoparticle reduction into polydimethylsiloxane thin films

Jeremy Dunklin, Gregory T. Forcherio, Donald K. Roper, Keith Berry Jr., Univ. of Arkansas (United States)

Polymer thin films embedded with plasmonic gold nanoparticles (AuNPs) are of significant interest in biomedicine, optics, photovoltaic, and nanoelectromechanical systems. Thin polydimethylsiloxane (PDMS) films containing 3-7 micron layers of AuNPs that were fabricated with a novel diffusive-reduction synthesis technique attenuated up to 85% of incoming laser light at the plasmon resonance. Rapid diffusive reduction of AuNPs into asymmetric PDMS thin films provided superior optothermal capabilities relative to thicker films in which AuNPs were reduced throughout. A photon-to-heat conversion of up to 3000°C/watt was demonstrated, which represents a 3-230-fold increase over previous AuNP-functionalized systems. Optical attenuation and thermal response increased in proportion to order of magnitude increases in tetrachloroaurate (TCA) solution concentration. Optical and thermoplasmonic responses were observed with and without an adjacent mesh support, which increased attenuation but decreased thermal response. Morphological, optical, and thermoplasmonic properties of asymmetric AuNP-PDMS films varied significantly with diffusive TCA concentration. Gold nanoparticles, networks, and conglomerates were formed via reduction as the amount of dissolved TCA increased across a log10-scale. Increasing TCA concentrations caused polymer surface cratering, leading to a larger effective surface area. This method, utilizing the diffusion of TCA into a single exposed partially cured PDMS interface, could be used to replace expensive lithographic or solution synthesis of plasmon-functionalized systems.

Increased upconversion quantum yield in plasmonic structures

Christopher Lantigua, William Hayenga, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Mathieu Lessard-Viger, Adah Almutairi, Univ. of California, San Diego (United States); Mercedeh Khajavikhan, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Upconversion processes by which two or more low-energy photons are converted into one higher-energy photon have found widespread applications in drug delivery, bio-imaging and silicon solar-cells. Currently, the main drawback of upconverting materials is their low quantum yield. Nano-patterning can improve the upconversion quantum efficiency through two processes: first, radiation can be absorbed more effectively by appropriately patterned structures that lead to higher local irradiances. Second, the rates of the radiative transitions between selected ionic states within the upconverting material can be altered by judiciously modifying the local density of states.

In this talk we present a theoretical model that analyzes the impact of a plasmonic shield structure on upconversion. We use this model to assess the efficiency of upconverting NaYF4: Tm3+ Yb3+/NaYF4 core-shell nanoparticles when embedded in a polymer matrix and covered by a metallic can-like structure. The simulation combines a rate equation approach for the upconversion processes with finite element models that describe the local absorption within the system and the modification of the local density of states due to plasmonic resonances. We find that as a result of this specific plasmonic structure the upconversion luminescence from near infrared to ultraviolet can be increased by a factor of 8 and the upconversion quantum yield can be improved on average by a factor of 20 compared to the unaided case. The high directivity of the radiation pattern emitted from this plasmonic configuration will be also discussed.

Geometric optics of gold nanoparticle-polydimethylsiloxane thin films

Jeremy Dunklin, Gregory T. Forcherio, Donald K. Roper, Univ. of Arkansas (United States)

Interest in the optical properties of plasmonic nanoparticles embedded in transparent polymers is expanding due to potential uses in sustainability, biomedicine, and manufacturing. Geometric optics of polydimethylsiloxane (PDMS) thin films containing uniformly or asymmetrically distributed polydisperse reduced gold nanoparticles (AuNPs) or uniformly distributed monodisperse solution synthesized AuNPs were recently evaluated using a compact linear algebraic sum. Algebraic calculation of geometric transmission, reflection, and attenuation for AuNP-PDMS films provides a simple, workable alternative to effective medium approximations, computationally expensive methods, and fitting of experimental data. Generally, transmission and reflection increased with AuNP isotropy and particle density, as displayed on a novel ternary diagram. Irregular AuNP morphology and size distribution caused optical attenuation from polydisperse films to increase in proportion to log10 increases in gold content, resulting in lower attenuation per gold mass when compared to monodisperse AuNPs. Uniform monodisperse AuNP-PDMS films attenuated light in proportion to gold content, with films attenuating 0.15 fractional units per 0.1 mass-percent AuNPs. Thin layers of concentrated AuNPs attenuated light more efficiently. A 25 micron thick layer of 1.2 mass-percent AuNPs attenuated 0.5 fractional units, the same number as a 130 micron thick 0.6 mass-percent film. Measured optical responses from asymmetric AuNP-PDMS films with an adjacent back-reflector and pairs of uniformly distributed films were predictable within 0.04 units of linear algebraic estimates based on geometric optics. This approach allows for the summative optical responses of a sequence of 2D elements comprising a 3D assembly to be analyzed.

Second-order coherence properties of nanoscale coaxial lasers

Nicholas Nye, Mercedeh Khajavikhan, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Metallic nanolasers belong to an emerging family of lasers that have ultra-small size, low threshold, and excellent thermal dissipation properties. This class of nanolasers can be potentially useful for applications such as

on-chip optical communication, near-field probing, ultra-dense sensing and imaging, as well as quantum information technologies.

Coherent laser emission is characterized by high spectral and spatial coherence. In most lasers, an abrupt linewidth narrowing at threshold is typically considered to be an indication of coherent emission. On the other hand, semiconductor-based nanolasers have lower cavity quality factors, operate at reduced pump levels, and have larger linewidth enhancement factors. These aspects lead to a more gradual transition around threshold, thus making it more difficult to unequivocally determine the onset of lasing.

In this work we present experimental measurements of the second order coherence (g(2)) for sub-wavelength nanolasers based on metallic coaxial cavities. As it is well known, the g(2) factor provides a clear and undisputed indication for coherent radiation. Here we use a Hanbury-Brown-Twiss setup in which the output of the device under study is divided equally by a directional coupler, followed by two single-photon detectors. The detectors' outputs are then collected by a 25 GHz oscilloscope that feeds the data to a computer in which the correlation is performed digitally. Results concerning the coherence properties of these nanolasers, above and below threshold, will be presented in this talk. Our experimental findings confirm that coherent emission can indeed be achieved in this newly emerging type of metallic coaxial nanolasers.

Optical conductivity of a two-dimensional electron gas with Rashba and Dresselhaus spin-orbit coupling

Jesus A. Maytorena, Catalina B. Lopez, Elmer M. Cruz, Univ. Nacional Autónoma de México (Mexico)

The tunability of the spin-orbit interaction (SOI) in systems with reduced symmetry through electrical gating has motivated the search for new ways of manipulating electron spins without employing magnetic materials and external magnetic fields.

Here we study the dielectric response of a two-dimensional electron gas with both Rashba and Dresselhaus SOI within the self-consistent field approach. We calculate the optical conductivity and dispersion relations of collective modes and single-particle excitations related to intra- and inter-spin-split subband transitions. The interplay of both types of SO couplings give rise to an anisotropic spin-splitting of the electronic subbands. We find that (i) the SO-induced modification of the intra-subband plasmon is too small for realistic values of the parameters, (ii) the inter-subband plasmon branch of the spectrum lies within the corresponding continuum of single-particle excitations, (iii) this continuum and the plasmon spectrum depends not only on the modulable Rashba parameter but also on the direction of propagation, and (iv) the optical conductivity shows the same anisotropic character as a function of the direction of the applied electric field. This anisotropic response can be explained in terms of the nonisotropic momentum space available for transitions due to the simultaneous presence of Rashba and Dresselhaus SO couplings.It suggests new possibilities of tunning of plasmon propagation and control of the optical response.

We acknowledge the support from DGAPA-UNAM under the Grants. Nos. IN112012 and IN111013, and CONACyT Mexico.

Nonlinear plasmonics for nanoscale light manipulation and imaging

Alexey V. Krasavin, Paulina Segovia Olvera, Pavel Ginzburg, Anatoly V. Zayats, King's College London (United Kingdom)

Plasmonic nanostructures gave a new boost to the development of nonlinear optics via extreme levels of local field enhancement. Furthermore, metal producing them can also serve as a strong nonlinear source itself, which can be rigorously demonstrated with the help of the hydrodynamic model for conduction band electrons. This leads to a number of both intriguing and practically promising phenomena, which will be reported in our presentation. First, it will be addressed the dynamics of nonlinearly coupled localized plasmon resonances in metal nanoparticles, revealing the role of symmetries in their interaction [1]. The distinctive result of the theory is that the second harmonic generation efficiency, predominately originating from surface nonlinearity, is proportional to the ratio between particle surface area and volume, which emphasizes the significant benefit of nanostructuring. In further development of the nonlinear plasmonic approach, a novel concept of cascaded surface plasmon polaritons, propagating at the interface between a linear dielectric and a metal, will be presented, showing that the beam propagation can be described by the effective nonlinear Schrodinger equation [2]. These theoretical predictions are supported by the comprehensive numerical model, demonstrating soliton formation in an explicit way in the regime of realistic propagation losses.

Plasmon-mediated photo-reactions on gold and silver nanostructures

Hans D. Robinson, Brenden A. Magill, Erich M. See, Xi Guo, Roberto L. Reyes, Richey M. Davis, Webster L. Santos, Virginia Polytechnic Institute and State Univ. (United States)

We report on our work to use plasmonic enhancement to selectively induce photochemical reactions at the hotspots in plasmonic nanostructures. This can be used to modify the properties of the surface at the hotspot, with the goal of inducing self-assembly of well-defined nanostructures. For example, metal spheres can be illuminated by polarized light, causing preferential photocleavage of ligands bound to opposite poles, onto which other particles can then be assembled, forming dumbbells aligned with the polarization.

We demonstrate than in the case of silver, the interaction with the plasmon mode has a catalytic effect on o-nitrobenzyl-based photocleavable ligands bound to the metal. This group normally requires energetic UV photons to undergo a photoreaction, but the silver sensitizes them to visible light of wavelengths near 550 nm, a wavelength to which plasmon resonances in silver nanostructures can be readily tuned.

In gold, no such sensitization takes place. Combined with the lower plasmon frequency in gold, this means that selectively induced photoreactions at the hot-spots of gold nanostructures must make use of two-photon absorption. We have therefore investigated the effect of ultra-short visible light pulses on our ligands when bound to gold surfaces. The reaction is activated through a combination of thermal activation and two-photon absorption, while at higher power densities, ligands can be ablated from the surface through breaking of the gold-thiol bond. We will present data on the interplay of these effects as a function of laser power and exposure time, and demonstrate assembly of nanoparticles onto optically patterned surfaces.

Field effect frequency-tunable epsilon-near-zero metamaterial in the visible

Georgia T. Papadakis, Howard Lee, Luke Sweatlock, Harry A. Atwater Jr., California Institute of Technology (United States)

The epsilon-near-zero (ENZ) response of matter enables unique optical functions such as tunneling of electromagnetic waves and directive emission. Metamaterials composed of multilayer stacks of metals and dielectrics can constitute effective media with ENZ for a small range of wavelengths that depends on the geometry and materials [1]. However, in previous reports, the ENZ wavelength is fixed at the time of metamaterial fabrication. We demonstrate the design of a tunable ENZ metamaterial based on metal and transparent conductive oxide (TCO) multilayers, using the field effect to tune the permittivity of the TCO across thin gate dielectric layers [2]. Our design consists of a multilayer geometry of two layers of Au, separated by an active layer of indium tin oxide (ITO). The two materials are isolated from each other with Al2O3. Under applied bias between the Au and the ITO, an accumulation layer is formed at the Al2O3-ITO interface. The structure is excited with a TE-polarized plane wave. By obtaining the complex reflection and transmission coefficients of the stack using an analytical transfer matrix model, we retrieve the effective permittivity of the metamaterial, by directly relating the metamaterial response to analytical expressions for the transmission and reflection coefficients of the single-homogeneous layer problem [3]. Our calculations show that tunability of the ENZ wavelength as much as 80 nm is possible in the 400-700 nm wavelength regime for carrier concentration changes up to one order of magnitude, comparable to those obtained experimentally [2].

Localized and non-localized plasmon resonance modes and enhanced optical absorption in patterned metal-insulator-metal nanostructures

Wonkyu Kim, The Univ. of Alabama in Huntsville (United States); Blake S. Simpkins, James P. Long, U.S. Naval Research Lab. (United States); Boyang Zhang, Junpeng Guo, The Univ. of Alabama in Huntsville (United States)

Patterned metal-insulator metal structures have been extensively investigated for enhancing optical absorption in the past several years. The advantage of this type of structures is that the absorption wavelength can be tuned by varying the geometry and size of the plasmonic resonators in the structure. Although it is understood that the localized magnetic plasmon resonance is responsible for the strong optical absorption, non-localized plasmon resonance modes also cause strong optical absorptions in the visible and near infra-red wavelength range. In this work, we fabricated this type of nanostructures with varying size and period of gold nano-disks and systematically investigated localized and non-localized plasmon resonance modes and associated light absorptions. The fabricated device structure consists of a patterned gold nano-disk array on a thin aluminum nitride film deposited on a thick gold film. It is found that strengths of both localized magnetic resonance and non-localized plasmon resonance strongly depend on the size and period of gold nano-disks in the structure. The findings in this work can help design efficient light absorbers in the visible and near infra-red regime for energy harvesting and sensor applications.

Roughness induced leakage and visualization of surface plasmon-polaritons

Elena Tchaikina, Eduardo Pisano, Ivan Avilés, Eugenio R. Méndez, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Plasmonics is a subfield of nanophotonics that is primarily concerned with the manipulation of light at the nanoscale using the properties of propagating and localized surface plasmons. Crucial to the development of practical devices based on Surface Plasmon-Polaritons (SPPs) are the excitation, visualization and detection of these surface-traveling waves. It is well known that the propagation of SPPs is very sensitive to surface features; isolated defects, as well as periodic or random structures can be used for both, launching SPPs, and converting them into volume waves. This latter mechanism can be used for their detection or observation.

In this work we study the propagation of SPPs through a surface with random roughness and search for appropriate parameters to promote their controlled leakage and subsequent observation. A balance must be found between the leakage into volume waves and the propagation length. The roughness also determines the directions of leakage. The visualization of the path followed by the SPPs is then possible by collecting the light scattered by this interaction.

Rough surface samples were fabricated by exposing photoresist covered glass substrates to speckle patterns produced with the blue light of a He-Cd laser (λ=442 nm). The properties of the fabricated surface are determined by the exposure and the statistical properties of the speckle patterns. A thick metallic film of gold or silver was deposited on top of the fabricated photoresist film. Visualization experiments illustrating the scattering of SPPs by surface defects have been carried at two popular wavelengths (633 and 980nm).

9163-121, Session PWed

Localized surface plasmon resonances in transformed spaces

Veronica Perez-Chavez, Eugenio R. Méndez, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

The quasistatic approximation is useful tool for determining the plasmonic resonances of metallic particles that are much smaller than the wavelength of light. In this limit, the interaction is governed by electrostatics rather than electrodynamics and the field can be determined by solving Laplace's equation with appropriate boundary conditions.

Transformation optics (TO), on the other hand, is an emerging area of optics that provides a methodology for manipulating light in unusual ways. It is based on the fact that Maxwell's equations are form invariant under coordinate transformations. Coordinate transformations in which local angles are preserved, are called conformal mappings. They are particularly attractive because they lead to relatively simple modifications of the governing equations. Laplace's equation, for instance, is invariant under a conformal transformation. Not surprisingly, these techniques have been used to study electromagnetic problems in complex geometries. The usual strategy is to start with a well-understood system and, by applying a conformal mapping, find the solution of a more complex system.

We study the localized surface plasmon resonances of metallic nanoparticles in two geometries connected by a conformal coordinate transformation. The conditions are such that the quasistatic approximation should be valid in the initial space. The electromagnetically equivalent problems are solved in the two spaces with rigorous techniques. For comparison, we also consider the problem under the quasistatic approximation and map the solution to the transformed space. The results show that care should be exercised when applying TO techniques under the quasistatic approximation.

Wafer-scale aluminum nano-plasmonics

Matthew C. George, Rumyana Petrova, James Frasier, Eric W. Gardner, MOXTEK, Inc. (United States)

Periodic micro- and nano-structures are gaining traction in diverse areas such as bio-sensing, surface enhanced Raman spectroscopy (SERS), solar cell concentration and antireflection strategies, solid state lighting, as well as in optical filters, metamaterials, integrated micro-optics, and even electrochemical devices. Unfortunately, obtaining a reliable, cost effective, yet flexible manufacturing source for such structures has often been a challenge. Many research groups and companies perform their own lithography and etching or use a foundry to generate such structures, but this typically limits the substrate size to a few square inches and can have large up-front costs for masks and other tooling. In addition, the periodicities of structures readily available from commercial sources are typically limited to several hundred nanometers and larger. Moxtek has addressed some of these challenges by leveraging existing capabilities in wafer-scale patterning of sub-wavelength wire grid polarizers into the fabrication of one- and two-dimensionally periodic plasmonic structures.

This presentation will discuss fabrication, characterization, and optical modeling results for aluminum nano-hole arrays with potential applications in surface plasmon resonance sensing, SERS, and surface-enhanced fluorescence spectroscopy (SEFS). Potential markets include micro-arrays for bio-related assays and trace level chemical detection. In addition, the presentation will review recently-commercialized work on narrow-band, cloaked wire grid polarizers composed of nano-stacked metal and dielectric layers patterned over 200 mm diameter wafers for projection display applications. The stacked sub-wavelength nanowire grid results in a narrow-band reduction in reflectance by a factor of about 20, which can be tuned throughout the visible spectrum for stray light control.

The field enhancement and optical sensing in array of almost adjoining metal and dielectric nanorods *(Invited Paper)*

Andrey Ivanov, R&D Co. VICHEL (High- Frequency Systems) (Russian Federation); Alexander N. Shalygin, R&D Co. VICHEL (High-Frequency Systems) (Russian Federation); Andrey N. Lagarkov, Institute for Theoretical and Applied Electromagnetics (Russian Federation); Alexander Vaskin, Moscow Institute of Physics and Technology (Russian Federation); Andrey K. Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation)

The surface plasmon (SP) excitations in the ordered array of nanorods have attracted significant attention in recent years due to numerous potential applications in nanoplasmonics including transmitting and processing optical signals on a scale much smaller than the wavelength.

In our work the plasmonic system consisting of two-dimensional periodic array of nanorods is considered. We use computer simulating as well as exact analytical solution to find reflectance and transmittance from plane composed of nanorods, which have various diameters and inter-particle spacing. As the nanorods approach each other, a series of surface plasmon resonances are excited, which are strongly localized between nanorods due to collective resonances. It is shown that the local electric field is much enhanced in the interparticle gap at the resonance. The reflectance and transmittance have sharp minima and maxima corresponding to the excitation of various SP resonances. The local electric field concentrates at the scale much smaller than the diameter of the rod. The computer simulations are in a good agreement with our analytical theory. The resonance frequencies and field enhancement can be tuned by variation of the shape and arrangement of the nanorods. The system of nanorods that almost touch each other by their generatrices can be used in creating the surface of plasmonic sensors. It is possible to tune resonance frequencies in our system so they correspond to Stokes shifts in an analyte. Therefore we propose very effective SERS sensors to generatrices various substances.

Investigation of optical limiting properties of aluminium nanoparticles prepared by laser ablation in different carrier media

K. Mayank S. Sharma, Pranam Prakash, Cochin Univ. of Science & Technology (India) and Univ. of Hyderabad (India)

In this communication, we carried out the systematic investigation of nonlinear absorption and scattering properties of Aluminum nanoparticles (Al NPs) in various polar and non-polar solvents.Al NPs were synthesized with pulsed Nd:YAG laser operated at 1064 nm by ablating Al target in polar and non-polar liquid environment like chloroform, chlorobenzene, toluene, benzene, and carbontetrachloride. Synthesized Al NPs colloids of various solvents differ in appearance and UV-Vis extinction spectra exhibit absorption in the UV region. The characterization of Al NPs performed by Transmission electron microscopy (TEM) studies reveal that NPs are made up of a well crystallized Al inner part (bright zone) embedded with an amorphous metal Al shell (dark region). Growth, aggregation, and precipitation mechanisms which influence the optical properties and stability of NPs are found to be related to the dipole moment of the surrounding liquid environment. The nonlinear absorption and scattering studies are performed by open aperture Z-scan technique with 532 nm under nanosecond pulse excitation. The Z-scan measurements are fitted theoretically to estimate both two-photon absorption (TPA) and nonlinear scattering (NLS) coefficients. In polar solvents like chlorobenzene, chloroform synthesized Al NPs exhibited higher TPA, NLS coefficient values, and lower optical limiting threshold values in comparison with partially polar solvent like toluene and non-polar solvents like benzene and carbontetrachloride. These results indicate the potential use of Al NPs as a versatile optical limiting material.

Exciton-plasmon interaction in core/shell spherical nanoparticles

Anton V. Zasedatelev, National Research Nuclear Univ. MEPhI (Russian Federation); Alexey B. Karpo, A. M. Prokhorov General Physics Institute (Russian Federation); Vitaly I. Krasovskii, A. M. Prokhorov General Physics Institute (Russian Federation) and National Research Nuclear Univ. MEPhI (Russian Federation); Ivan N. Feofanov, P.N. Lebedev Physical Institute (Russian Federation); Alexander A. Chistyakov, National Research Nuclear Univ. MEPhI (Russian Federation)

Optical excitation in Fluorophore-Metall core/shell nanostructures can lead to energy transfer or to charge transfer between layers, these processes can proceed from fluorophore to metall particle and vice versa. Depending on the spatial arrangement of the layers in the structure and photophysical properties of core/shell components, linear and nonlinear properties can change dramatically. One of the most important reasons for mentioned above changes is to excite oscillations of an electron density in metallic structures, such as gold nanoparticles. So localized plasmons are excited in laser field. The superposition of plasmonic modes defines a near-field distribution of intensity. Fluorophores placed near the gold nanoparticle are excited by plasmon-generating near-field. It is shown that the intensity of the field near the gold nanoparticle is more one order of magnitude higher than the incident field intensity. High intensity in the near field leads to increase the probabilities of fluorophore electronic excited state transition.

However, the excited states relaxation rate of fluorophores placed near gold nanoparticles is also undergoing significant changes. The phenomenon of change in the decay rate of fluorophores in a heterogeneous environment is known as Purcell effect. Changes in the excited states decay rate by Purcell effect give changes in the quantum yield of fluorophore luminescence. Thus, in the proposed model a treatment of the processes of absorption, scattering and luminescence in multilayered spherical nanostructures is reduced to solve the problem of electromagnetic waves scattering on a multilayered sphere, finding the field distribution in the layer of fluorophore, followed by presentation of fluorophores in the form of a 2-level quantum system and determining the rate of spontaneous decay of these systems in the relevant field near the gold core.

Study of plasmonic coupling between InAs quantum dots and ErAs nanoparticles in an epitaxial matrix

Luke J. Bissell, Kurt G. Eyink, Elizabeth H. Steenbergen, Joshua R. Hendrickson, Frank Szmulowicz, Krishnamurthy Mahalingam, Lawrence Grazulis, Daniel Esposito, Andrew Aronow, Jeremy A. Massengale, Madelyn Hill, Air Force Research Lab. (United States)

We have studied the optical emission and absorption characteristics of ErAs semimetal nanoparticles (sMNPs) and InAs quantum dots (QDs). Vertical stacks of ErAs sMNPs and InAs QDs were created by strain-driven self-assembly using solid-source molecular beam epitaxy. The composite structures consisted of 8 periods of a layer of InAs QDs followed by a layer of ErAs sMNPs, each in a GaAs matrix. The spacing between ErAs and InAs layers was varied: 8, 10, 12, and 40 nm. The nominal period was 80 nm; the periods measured by XRD were 83 nm – 89 nm. We correlated changes in the photoluminescence (PL) intensity of these layers with changes in the spacing between ErAs and InAs layers. For samples with 10, 12, and 40 nm spacing, the PL integrated intensity increased with increasing InAs – ErAs layer separation. This could be evidence of plasmonic coupling between the sMNPs and QDs. Using time-resolved PL, we measured the sum kPL = kr + knr of the radiative, kr, and non-radiative, knr, decay rates of the InAs QDs. Our measurements showed that kPL decreased with increasing layer separation. It is likely that both plasmonic enhancement of QD emission, and non-radiative quenching, occurred simultaneously. Preliminary results from our analytical model of the plasmonic coupling in this system show that enhancement of QD absorption by a factor of more than 500 is possible.

Tunable sensitivity and wide dynamic range phase detection of multichannel grating-coupled SPR sensor

Wen-Kai Kuo, National Formosa Univ. (Taiwan)

We report a multichannel grating-coupled surface plamson resonance (GCSPR) sensor by utilizing a proposed phase-shift interferometer (PSI) for tuning sensitivity and wide dynamic phase detection. The grating structure of the sensor device was fabricated by nano-imprinting technique and a thin meal film was thermally evaporated onto the grating surface. In our system, a cylindrical lens with focal length of 60 mm to form a V-shaped convergent beam with incident angles ranging from 12 degree to 16 degree. Two liquid-crystal modulators (LCM) able to produce over one wavelength retardation were used to produce five-step phase shift in the PSI system. A low-cost web-camera with 130 Mega pixels was used to capture these phase shift images of the multichannel GCSPR sensor and then the five-step phase-shift reconstruction algorithm can obtain spatial phase-shift information. The phase detection sensitivity can be tuned by rotating a polarizer in front of the web-camera. Experimental result shows that detection range larger than 0.01 RIU and detection sensitivity tuning approximately from 10E-5 to 10E-7 RIU can be obtained in our system. In conclusion, this tunable sensitivity and wide range phase detection functions can provide a more flexible SPR sensor detection method. Moreover, the grating coupled and multichannel scheme can provide low-cost and high throughput detection.

Optical properties of magnetic-plasmonic nanoparticle multilayers

Ward Brullot, Thierry Verbiest, Katholieke Univ. Leuven (Belgium)

Magnetic-plasmonic materials are an interesting class of materials for fundamental research into magnetoplasmonics, active plasmonics and plasmon-enhanced nonlinear and magneto-optics and for applications in sensing, optical switching and optical components fabrication. For all these research paths, a thorough knowledge of the optical properties and their origin in the materials is a prerequisite.

Using a recently developed layer-by-layer synthesis method, we fabricated magnetic-plasmonic gold/magnetite, silver/magnetite and gold/magnetite/silver nanoparticle multilayers on glass substrates with bifunctional molecular linkers and measured their optical properties.

Discrete dipole approximation calculations to model the optical properties of such materials starting from single nanoparticles up to multilayers allow us to understand the observed optical features. Distances between nanoparticles, the dielectric environment, the number of adjacent particles, the angle compared to the normal, the multipolar order of excitation and the polarization of the incoming light beam are all relevant parameters. In this contribution, we first analyze the obtained theoretical results and then compare them to the experimental observations.

This comparison provides us with a detailed insight in the build-up of the nanoparticle multilayers a.f.o the number of layers. While scanning force microscopy measurements on samples with a certain number of layers confirm a linear increase of thickness as a function of added layers, the calculated and experimental optical properties show a more nuanced trend. Instead of depositing full consecutive nanoparticles layers, the data indicates that nanoparticles of the added layers fill the holes in previous layers and improve the general quality of the sample.

Ultra-broadband polarization manipulation and spin-orbit angular momentum conversion based on dispersion engineered metamaterials

Mingbo Pu, Xiangang Luo, Institute of Optics and Electronics (China)

Geometric phase stemming from spin-orbit angular momentum conversion in the adiabatic change of polarization statesis of great importance in applications such as beam shaping and focusing of light. However, the bandwidth of operation is typically limited in the polarization transformation due to the resonant characteristics of metal-dielectric nanostructures. Here we report the demonstration of ultra-broadband polarization transformation based on the complex dispersion properties of anisotropic metallic nanostructures. A typical bandwidth exceeds one octave is obtained in the optical frequencies. The applicability in broadband beam deflection is also discussed. Also, it is shown that broadband optical vortex can be easily realized. The results show that the proposed method is of great advantage over traditional approaches and may lead to a new degree of light beam manipulation.

9163-131, Session PWed

An ultra-broadband nano-plasmonic reflector with an asymmetric nano-ring resonator

Yuhsin Chang, Chyong-Hua Chen, National Chiao Tung Univ. (Taiwan)

An ultra-broadband plasmonic reflector with an asymmetric nano-ring resonator structure based on metal-insulator-metal (MIM) waveguides is numerically proposed. The input and output waveguides are directly connected to this ring resonator, resulting in the excitation of both clockwise and counter-clockwise traveling modes propagating inside the resonator. As a consequence, two interference phenomena are occurred in this structure: ring resonance and Mach Zehnder interference (MZI). We develop analytical formulations to describe these interference behaviors by using the equivalent circuit model based on the transmission line theory. Subsequently, we adjust the lengths of the ring structure to manipulate the resonant wavelengths of the ring resonance, and then the bandwidth roughly equals to the difference of the first and second resonant wavelengths. In addition, the lengths are chosen such that the wavelength for the transmission minimum of the cosine-like MZI envelope is located between these two resonant wavelengths in order to obtain a flat band. The widths of the structure are modified to diminish the low-transmission ripples by minimizing the load voltage on the output waveguide. An example of the plasmonic reflector with the dimension of 200x522 nm^2 and the bandwidth of 1000 nm is numerically accomplished, and the calculated performance is validated with the simulated results obtained by the two-dimensional finite-difference time domain method. Furthermore, the relation between the bandwidth and the dimension of this structure is investigated, showing that the bandwidth is approximately inversely proportional to the device's size.

Design of an active terahertz polarizer based on chiral metamaterial

Xiaoliang Ma, Mingbo Pu, Xiangang Luo, Institute of Optics and Electronics (China)

Metamaterials have got intensive interest in tuning the electromagnetic waves, and present various applications in optical and microwave range. In this paper, we demonstrate an active polarizer operating in Terahertz band based on the concept of chiral metamaterial. Period twisted planar metallic spiral structures are constructed on the tunable substrate, whose dielectric permittivity of the substrate can be tuned with outside stimuli. The unit structure of the metamaterial presents chirality due to the broken symmetric, and has the ability of manipulating the polarization states of the incident wave due to its circular dichroism and optical rotation character. When the dielectric permittivity of the substrate is tuned in the range from 3.25 to 3.85, the metamaterial correspondingly converts the incident linearly polarized wave into left-handed circularly polarized, right-handed circularly polarized wave or its cross polarized wave at the resonance of 40 THz. The active metamaterial can be scaled to higher frequency or to microwave range, and it may have potential applications in polarization detective and sensors.

9163-133, Session PWed

Focusing of surface plasmons with a plasmonic lens

Thanh Phong Vo, James E. Downes, David W. Coutts, Judith M. Dawes, Macquarie Univ. (Australia); Alireza Maleki, Macquarie University (Australia)

We report surface plasmonic focusing properties of plasmonic lenses consisting of sectors of concentric circular gratings with period of 776nm and gap width of 310nm perforated on 30nm-thickness gold film on glass. Those structures were studied experimentally and via numerical simulations (COMSOL Multiphysics) as a function of sector angle and number of concentric rings at wavelength of 700nm. With proper arrangement of each single grating so that the grating period matches the wavelength of the plasmonic modes, the surface plasmons excited by scattering incident light at adjacent gratings are constructively interfered when propagating along the air-gold interface, creating an intense focal spot at the focal plane of the circular gratings. Experiment setup was designed for a backside illumination to maximum reduction of background noise and near-field scanning microscopy (NSOM) was used to measure the near-field intensity of surface plasmon modes at 10nm distance from the air-gold interface to experimentally demonstrate the focusing properties of such structures.

We found that the plasmonic field enhancement can be improved abruptly (orders of magnitude) by adding more concentric rings while maintaining the spot size. In turn, the focal spot size at the focal plane of the plasmonic lens is decreased with increased sector angle: at 20o, the focal spot size is 2.4μm, while >90o sectors focus below the diffraction limit. The focusing properties of these plasmonic lenses were confirmed by exciting the plasmonic lens at different locations, i.e edges of circular grating, and in any case, focal spots always present at focal plane.

Dark and bright modes manipulation for plasmon-triggered optical switching

Simone Panaro, Andrea Toma, Adnan Nazir, Carlo Liberale, Hai Wang, Francesco De Angelis, Remo Proietti Zaccaria, Istituto Italiano di Tecnologia (Italy); Enzo Di Fabrizio, King Abdullah Univ. of Science and Technology (Saudi Arabia) and Univ. degli studi Magna Græcia di Catanzaro (Italy)

In the last decade, several efforts have been spent in the study of plasmonic coupled systems, in order to induce hybridization of single plasmonic structure modes [1]. Within this context, particular attention has been recently paid on the possibility to couple conventional bright modes to dark plasmonic oscillations triggered by near-field interaction [2]. As a result of such phenomenon, a Fano resonance appears as a characteristic sharp dip in the scattering spectra [3]. A possible way for hybridizing a plasmonic dark mode relies on the excitation of multipolar modes in complex nano-systems [4]. Instead, a more direct approach exploits the combination of dipolar modes properly arranged, requiring a deeper study of elemental LSP modes [5].

Here we present how a symmetry breaking process applied on a nanoantenna dimer can induce the excitation in far-field of the low-energy eigenmodes supported by the system [6]. Such two plasmonic modes can be considered as a minimum set of elemental modes that can be employed for the generation of dark modes in more complex nano-systems. Finally, a T-shape nanoantenna trimer is presented as a strongly polarization-sensitive device supporting plasmonic Fano resonance. In fact, according to incoming light polarization it is possible to "switch" from a conventional plasmonic resonance (high extinction) to a plasmon-triggered Fano resonance.

A direct consequence of Fano hybridization is the definition of a narrow spectral window in which the transmittance of a system can be abruptly increased. Combining such unique property to ultra-fast plasmonic processes, interesting perspectives can be opened towards all-optical switching for tomorrows photonic devices.

Nonlocal quantum effect on optical scattering form small metallic nanoparticles on multilayer films

Huai-Yi Xie, P. Ching-Hang Chien, Yia-Chung Chang, Academia Sinica (Taiwan)

We have studied optical scattering from nanoparticles on the multilayer films and then demonstrate clustering effect of nanoparticles plays an important role between closely-spaced aggregations. However, if the size of a particle is smaller than 10nm, nonlocal correction of nanoparticles must be included. In this work, we present theoretical formulation to investigate optical scattering from small metallic nanoparticles which has correct nonlocal dielectric function. We use a jellium model to calculate the nonlocal dielectric function quantum mechanically within the random phase approximation (RPA) instead of using a translational invariant function as considered in the hydrodynamics model. Within the frame of quantum-mechanical nonlocal dielectric model, our result reduce to both Drude model and local random phase approximation (LRPA) as derived by Lindhard when the size of the particle is larger then 10nm. Based on this quantum-mechanical nonlocal dielectric function of nanoparticles, we include the substrate effect by using the nonlocal scattering integral equations with the multilayer Green's function. The basis functions inside nanoparticles are taken to be linear combinations of scalar harmonic functions and then use Quasi-Minimal Residual (QMR) iteration to solve the unknown coefficients in the nonlocal scattering equation. We calculate optical fields both inside and outside the nanoparticles. For far-field calculation, we evaluate the principle-order reflection coefficient and obtain the ellisometric parameters, Ψ and Δ, which can be used to compare with spectral ellipsometry experiments. Our numerical results illustrate the importance of nonlocal effect for nanoparticles with diameter less than 10nm and provide a more physical prediction than Kubo's model.

9163-136, Session PWed

Polarizability extraction for rapid computation of Fano resonance in nanoring lattices

Gregory T. Forcherio, Drew DeJarnette, Phillip Blake, Donald K. Roper, Univ. of Arkansas (United States)

Rapid modeling of far-field Fano resonance supported by lattices of complex nanostructures is possible with the coupled dipole approximation (CDA) using point, dipole polarizability extrapolated from a higher order discrete dipole approximation (DDA). Fano resonance in nanostructured metamaterials has been evaluated with CDA for spheroids, for which an analytical form of particle polarizability exists. For complex structures with non-analytic polarizability, such as rings, higher order electrodynamic solutions must be employed at the cost of computation time. Point polarizability is determined from the DDA by summing individual polarizable volume elements from the modeled structure. Extraction of single nanoring polarizability from DDA permitted CDA analysis of nanoring lattices with a 40,000-fold reduction in computational time over 1000 wavelengths. Maxima and minima of predicted Fano resonance energies were within 1% of full volume elements using the DDA. This modeling technique is amenable to other complex nanostructures which exhibit primarily dipolar and/or quadrupolar resonance behavior. Rapid analysis of coupling between plasmons and photon diffraction modes in lattices of nanostructures supports design of plasmonic enhancements in sustainable energy and biomedical devices.

Broadband, tunable, lattice plasmon resonances with high quality factors

Yi Hua, Claire Deeb, Northwestern Univ. (United States); Gary P. Wiederrecht, Argonne National Lab. (United States); Teri W. Odom, Northwestern Univ. (United States)

Plasmonic metal nanostructures are important for many applications including optical sensors, subwavelength lasers and nonlinear optics. The short lifetime of optical modes in plasmonic structures, however, limits the optical enhancement that can be achieved. Recently, 2D nanoparticle arrays have been demonstrated to support out-of-plane lattice plasmons with extremely high quality factors. In these structures the resonance can be tuned by controlling the height of the nanoparticles as well as the incident angle of the light. Here we report the observation of the out-of-plane dipolar interaction in an easily fabricated nanostructure – nanogratings. In this new structure, we were able to tune the resonance over an even broader wavelength range by controlling the azimuthal angle of the incident light. By adjusting the orientation of the sample relative to the light, the out-of-plane lattice plasmon mode displays a different quality factor that is associated with the change of the spatial confinement of the optical fields around the grating. By controlling orientation of the grating, we investigated the spatial and spectral coupling between J-aggregated meso-tetra(4-sulfonatophenyl)porphyrin (TSPP) with this subradiant plasmon mode.

Computational electromagnetic study of plasmonic effects in interdigital arrays

Avery M. Hill, Ahmad I. Nusir, Paul Nguyen, M. Omar Manasreh, Joseph B Herzog, Univ. of Arkansas (United States)

Plasmonic nanostructures have been shown to act as optical antennas that enhances optical devices. This study focuses on computational electromagnetic (CEM) analysis of GaAs photodetectors with gold interdigital electrodes. Experiments have shown that the photoresponse of the devices depend greatly on the electrode spacing and the polarization of the incident light. Smaller electrode spacing and transverse polarization give rise to a larger photoresponse. This computational study will simulate the optical properties of these devices to determine what plasmonic properties and optical enhancement these devices may have.

Our model will be solving Maxwell's equations with a finite element method (FEM) algorithm provided by software COMSOL MultiPhysics. The preliminary results gathered from the simulations follow the same trends that were seen in the experimental data collected, that the spectral response increases when the the electrode spacing decreases. Also the simulations show that incident light with the electric field polarized transversely across the electrodes produced a larger photocurrent as compared with longitudinal polarization. This dependency is similar to other plasmonic devices. The simulation results compare well with the experimental data. This work will also model enhancement effects in nanostructure devices with dimensions that are smaller than the current samples to lead the way for future nanoscale devices. By seeing the potential effects that the decreased spacing could have, it opens the door to a new set of devices on a smaller scale, potentially ones with a higher level of enhancement for these devices.

In addition, the precise modeling and understanding of the effects of the parameters provides avenues to optimize the enhancement of these structures making more efficient photodetectors. Similar structures could also potentially be used for enhanced photovoltaics as well.

Kerr effect from single gold nanoparticles

Emeric Bergmann, Anthony Maurice, Emmanuel Benichou, Christian Jonin, Pierre-François Brevet, Univ. Claude Bernard Lyon 1 (France)

The optical modulation (or Kerr effect) from a gold metallic nanoparticle has been obtained by the P-Scan method. Commercial colloidal solutions of gold nanoparticles were diluted and dispersed onto a thin glass substrate by spin coating. These nanoparticles were then studied with a tightly focused femtosecond laser beam at the fundamental wavelength of 840 nm and for different incident intensities. The retro-reflected intensity was recorded in far field. Clear deviations from the linear regime was observed and attributed to both nonlinear refraction and nonlinear absorption.

9163-61, Session 15

Transmission characterization and control of metallic nanohole arrays by sub 5 fsec laser light pulses

Kellie Pearce, Ludwig-Maximilians-Univ. München (Germany) and Max-Planck-Institut für Quantenoptik (Germany); Jürgen Schmidt, Christian Späth, Ludwig-Maximilians-Univ. München (Germany); Huaihai Pan, Max-Planck-Institut für Quantenoptik (Germany) and Ludwig-Maximilians-Univ. München (Germany); Hassan M. Ouacha, Abdallah M. A. Azzeer, King Saud Univ. (Saudi Arabia); Ulf Kleineberg, Ludwig-Maximilians-Univ. München (Germany) and Max-Planck-Institut für Quantenoptik (Germany)

The phenomenon of extraordinary optical transmission (EOT) has generated much theoretical and experimental interest since its discovery 16 years ago . Arrays of subwavelength apertures in ordinarily opaque metal films have demonstrated remarkably high transmission efficiencies, in some cases even exceeding unity when normalised to the holes' areas. This ability has been attributed to the excitation of surface plasmons at the interfaces of the film. Potential applications of such arrays include biological sensing, and integration into novel photonic devices.

Two important factors contributing to EOT are the interactions between individual holes, and the coupling between the two interfaces of the film, which transpire on femtosecond time scales. Additionally, the possibly short lifetimes of the plasmon resonances may limit the use of hole arrays in devices, so understanding the temporal dynamics of EOT is important from both a fundamental and practical standpoint. We perform time-resolved measurements of the transmission through subwavelength hole arrays using sub-5fs laser pulses. An initial pump pulse excites the surface plasmon modes followed by a second, weaker probe pulse. The change in the transmission with varying time delay between the pump and probe pulses is measured. Hole arrays with differing hole spacings, shapes and thicknesses are investigated.

As an outlook, we wish to observe the influence of the carrier envelope phase (CEP) of an ultrashort pulse on EOT, thereby determining the extent to which the transmission can be controlled by the incident electric field.

9163-62, Session 15

Engineering plasmonic interactions in three dimensional nano-structured systems

Haobijam J. Singh, Ambarish Ghosh, Indian Institute of Science (India)

Engineering plasmonic interactions in a system of metal nanoparticles can lead to new optical effects of immense technological importance. In particular, the role of geometrical arrangement of the metal nanoparticles (MNPs) can have strong influence on their collective optical response. While the effects of these interactions in one (1D) and two (2D) dimensional systems are reasonably well understood, the realm of 3D systems is much less explored.

When it comes to arranging MNPs in three dimensions, one way is to position them one on top of the other, in a stacking fashion. We used a wafer scale technique, known as Glancing Angle Deposition (GLAD), where we evaporate metallic and dielectric materials alternately at a glancing angle to the underlying substrate. The resultant porous structure consisted of MNPs arranged in a stacking fashion separated by the dielectric material. A trivial extension of this method is to arrange the MNPs in a helical (chiral) fashion, which has been achieved in our experimental system. The chiral arrangement of the MNPs obtained in our experiments shows very large circular dichroism, i.e. it absorbs left and right circularly polarised light by different amounts. In the present paper, we describe the method of fabrication, and how the plasmonic interactions can be engineered to obtain a very large and spectrally wide chiro-optical response across the visible regime. These functionalities may be useful in developing new sensors for chiral molecules such as various proteins, as well as in realising broadband circular polarisers in the visible.

9163-64, Session 15

Charge transfer and quantum coherence in solar cells and artificial light harvesting system *(Invited Paper)*

Christoph Lienau, Carl von Ossietzky Univ. Oldenburg (Germany)

In artificial light harvesting systems the conversion of light into electrical or chemical energy happens on the femtosecond time scale, and is thought to involve the incoherent jump of an electron from the optical absorber to an electron acceptor. Here we investigate the primary dynamics of the photoinduced electronic charge transfer process in two prototypical structures: (i) a carotene-porphyrin-fullerene triad, a prototypical elementary component for an artificial light harvesting system and (ii) a polymer:fullerene blend as a model system for an organic solar cell. Our approach [1] combines coherent femtosecond spectroscopy and first-principles quantum dynamics simulations.

Our experimental and theoretical results provide strong evidence that the driving mechanism of the primary step within the current generation cycle is a quantum-correlated wavelike motion of electrons and nuclei on a timescale of few tens of femtoseconds. We furthermore highlight the fundamental role played by the flexible interface between the light-absorbing chromophore and the charge acceptor in triggering the coherent wavelike electron-hole splitting.

Mechanism of plasmon enhanced upconversion processes in $NaYF_4$:Yb^{3+},Er^{3+} nanoparticles

Dawei Lu, Suehyun K. Cho, Sungmo Ahn, Univ. of Colorado at Boulder (United States); Loic Brun, Christopher J. Summers, Georgia Institute of Technology (United States); Wounjhang Park, Univ. of Colorado at Boulder (United States)

Rare-earth activated upconversion material is receiving renewed attention for their potential applications in bioimaging and solar energy conversion. To enhance the upconversion efficiency, surface plasmon has been employed but widely varying enhancements from 3-fold to 310-fold have been reported, as the enhancement mechanism awaits clear elucidation.

In this study, we synthesized upconversion nanoparticles (UCNPs) coated with amphiphilic polymer which makes UCNPs water-soluble and negatively charged. Three-layer UCNPs were deposited by polyelectrolyte-mediated layer-by-layer deposition on silver nanograting fabricated by laser interference lithography. The final structures exhibited surface plasmon resonance at 980 nm, the UCNP absorption wavelength.

The green and red photoluminescence intensity of UCNPs on grating was up to 16 and 39 times higher than the UCNPs on flat silver film, respectively. However, under strong excitation, the enhancement factor decreased to 3.1. A thorough analysis of rate equations showed that the enhancement was due entirely to absorption enhancement in the strong excitation regime while it equals (FA*FC)^2 under weak excitation, where FA and FC are enhancement of absorption and Förster energy transfer, respectively. Purcell factor was small and unimportant because the non-radiative decay dominates the relaxation processes. From the experimentally observed enhancements, we concluded enhancement factors of 3.1 and 1.3 for absorption and energy transfer, respectively.

This study clearly elucidates the plasmon enhancement mechanism, allowing the fair comparison between various plasmonic UCNP systems and also the rational design of optimal plasmonic structures.

9163-66, Session 15

Experimental demonstration of plasmonic resonant guided wave network

Howard Lee, Stanley P. Burgos, California Institute of Technology (United States); Arian Kriesch, Max-Planck-Institut für die Physik des Lichts (Germany); Eyal Feigenbaum, Ryan M. Briggs, California Institute of Technology (United States); Ulf Peschel, Harry A. Atwater Jr., Max-Planck-Institut für die Physik des Lichts (Germany)

Resonant guided wave networks (RGWNs) have been theoretically proposed to function as topological optical networks that can be engineered to have optical functionality such as serving as resonators and color routers [1]. The RGWN concept is quite general, consisting of optically isolated waveguides in a network layout, whereby the isolated waveguides serve to transport energy and information within the network and the waveguide crossings serve to redistribute that information within the network [2]. In this work, we experimentally demonstrate a plasmonic implementation of the RGWN concept by demonstrating that a properly excited 90-degree waveguide crossing of two v-groove channel plasmon polariton (CPP) waveguides operates as an ultra-compact power-splitting element, the key component for the realization of the RGWN concept. By combining these plasmonic power splitters together with the CPP waveguides that comprise them in a network layout, we demonstrate a prototype plasmonic nanocircuit composed of four v-groove waveguides in an evenly spaced 2 x 2 configuration, which functions as a compact optical logic device at telecommunication wavelengths, routing different wavelengths via different on/off combinations to separate transmission ports. The reported logic device exhibits expanded 8-port functionality compared to other photonic crystal/plasmonic add/drop filters, in which only two on/off states are accessible. We also investigate the RGWN using antenna-coupled slot waveguides [3] and examine the coherent resonant effect by reducing the size of resonator to sub-micron range. This work illustrates how ultra-compact plasmonic components can form the platform for next-generation integrated plasmonic circuits, and paves the way for the integration of Si-photonics with sub-wavelength mode volume plasmonic waveguides.

9163-67, Session 15

Near-field vector analysis of plasmonic structures enhancement on infrared photodetectors

Guiru Gu, Xuejun Lu, Univ. of Massachusetts Lowell (United States)

In this work, we fabricated and compared two complimentary plasmonic structures: the metallic circular disc array and the 2 dimensional subwavelength hole array (2DSHA). The near field electric-field (E-field) vector distributions of the two different plasmonic structures are analyzed. We also investigated the different plasmonic structure enhancements on quantum dots infrared photodetectors (QDIP). To fully ascertain the plasmonic enhancements in QDIPs, it is crucial to understand the E-field vector distributions in the plasmonic enhanced QDIP and identify their contributions. The E-field vertical extension of different plasmonic structures and their overlap with the quantum dot (QD) active regions are also simulated. Our studies indicate that the overlapping of the E-field vectors with the QD active region is critical to improve the QDIP performance. Detailed results and analysis will be discussed in the paper. We believe that the vector field analysis not only advances the knowledge of E-field components in plasmonic structures and their interaction with the QDs, but also provides the design guidance for high performance plasmonic enhanced optoelectronic devices.

9163-68, Session 16

Chirality enables unusual optical force *(Invited Paper)*

Shubo Wang, Che Ting Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Light can exert radiation pressure on any object it encounters and that resulting optical force can be used to manipulate particles. It is natural to expect that light should push a particle forward. However, our results indicate that an anomalous lateral force can be induced in a direction perpendicular to that of the incident photon momentum if a chiral particle is placed above a substrate that does not break any left-right symmetry. We demonstrate the existence of the lateral force by calculating the optical forces acting on helical gold particles induced by a linearly polarized plane wave. Analytical theory shows that the lateral force emerges from the coupling between structural chirality and the light reflected from the substrate surface. Such coupling induces a sideway force that pushes chiral particles with opposite handedness in opposite directions.

9163-69, Session 16

Polarimetric analysis of the extraordinary optical transmission through subwavelength hole arrays

Oriol Arteaga, Univ. de Barcelona (Spain); Shane Nichols, New York Univ. (United States); Ben Maoz, Gil Markovich, Tel Aviv Univ. (Israel); Bart Kahr, New York Univ. (United States)

This work examines the complete polarimetric response of oblique- and square- lattices of metal subwavelength hole arrays that display extraordinary optical transmission at certain frequencies mediated by the excitation of surface plasmons. The study is based on the analysis of the Mueller scattering matrix measured at normal and oblique incidence for plane wave illumination. At normal incidence the square lattice of nanoholes shows a fully isotropic optical response in which the intensity of transmitted light is insensitive to the incoming polarization. However, the oblique lattice has a marked anisotropic character, which permits some types of polarization to be transmitted more efficiently than others.

Moreover, from the spectroscopic Mueller matrix measurements, it is deduced that the oblique array has a rather strong natural optical activity that is combined with asymmetric (non-reciprocal) transmission of circularly polarized light. A repeated measurement with the sample turned over confirms this effect, which is most likely due to the coupling of the linear optical anisotropies induced by misaligned surface plasmons in the film. At oblique incidence the square lattice also shows asymmetric transmission at non-normal incidence, whenever the plane of incidence does not coincide with a mirror line.

9163-70, Session 16

ZnO as a tuneable metal: new types of surface plasmon polaritons at infrared wavelengths

Sascha Kalusniak, Sergey Sadofev, Fritz Henneberger, Humboldt-Univ. zu Berlin (Germany)

The interaction of metals with electromagnetic radiation gives rise to collective charge excitations called surface plasmon polaritons (SPPs). Though discovered a long time ago, strongly reinforced scientific and practical interest in these coupled light-matter states aroused in recent years building the interdisciplinary field of plasmonics. Fascinating examples involving SPPs are the sub-wavelength control of light, below-diffraction-limit microscopy, radiation hot spots, or biosensing, to name only a few. However, currently available plasmonic functions are still constrained by the limited ability to tailor the SPP's frequency-versus-wavevector dispersion, even when utilizing modern nanofabrication techniques. Here we show that use of the free-electron gas in a heavily doped semiconductor (ZnO:Ga) enables the realisation of almost arbitrarily shaped SPP dispersion curves, not only by tuning of the dielectric function but also by coupling of SPPs in planar multi-layered structures. In particular, by preparing metal/metal-type interfaces, we demonstrate SPPs exhibiting finite frequencies in the long-wavelength limit, in marked contrast to the conventional dielectric/metal SPPs. Moreover, the controlled formation of frequency gaps or, alternatively, opening of otherwise forbidden regions are made possible by an appropriate layer design. The operational spectral range covered by our approach extends from the mid infrared to telecommunication wavelengths (where traditional metals suffer from strong dissipation losses) manifesting thus an enormous technological potential: The existence of finite-frequency long-wavelength SPPs allows for targeting new concepts for nanophotonic lasing. By engineering of the dispersion relations, phase matching can be achieved enabling nonlinear plasmonic processes, like second-harmonic generation, or control of the SPP propagation by adjusting their group velocity. Given the advanced possibilities to structure semiconductors down to the nanometer-length scale, we anticipate novel plasmonic functional elements and devices even beyond the planar setting of our study.

9163-71, Session 16

Enhancement in conversion efficiency of organic photovoltaic devices by plasmonic nanostructure

Wakana Kubo, RIKEN (Japan) and Japan Science and Technology Agency (Japan); Takuo Tanaka, RIKEN (Japan) and Hokkaido Univ. (Japan)

Au nanodot arrays were embedded in an organic photovoltaic device for the purpose of light trapping. Consequently, the photovoltaic device with Au nanodots showed an improvement in conversion efficiency. For discussing its enhancement mechanisms, we examined an induced photon to conversion efficiency of the device with Au nanodots and optical characteristics of Au nanodots. Finally, we found a correlation between plasmon resonance of Au nanodots and an induced photon to conversion efficiency spectrum of the device with Au nanodots.

9163-72, Session 16

Far-field and near-field analysis of gold nanoantennas in Kretschmann configuration

Kuo-Ping Chen, Yi-Hsun Chen, National Chiao Tung Univ. (Taiwan)

Gold nanoantenna arrays with Kretschmann prism coupling configuration are designed as high sensitivity bio-sensor. Comparing to normal incidence of gold nanoantennas, total internal reflection does not only achieve higher near-field enhancement, but also transfer input energy into localized surface plasmon resonance with less impedance mismatch.

In this work, gold nanoantennas are fabricated by E-beam lithography. The transmittance and reflectance spectra are measured in normal incidence and also in Kretschmann prism coupling configuration, which is with BK7 prism and water as surrounding medium. By analyzing the far-field reflectance spectra, in TM polarization, the resonance wavelength is at 780nm in normal incidence but at 690nm when the incidence angle is larger than the critical angle. Not only the resonance wavelength is with 90 nm blue-shift, but also the FWHM is reduced from 165nm to 58nm, which provides the better Q-factor. More interestingly, by analyzing near-field EM wave distributions, the phase of each particle in paired nanoantennas is analyzed in resonance condition. In normal incidence, the resonance of two particles are in phase , but with 180 degree phase difference when the incidence angle is larger than critical angel, which could be indicated to bright mode and dark mode resonances. By applying to bio-sensor application, the figure of merit of gold nanoantennas shows 4.15 times higher by using Kretschmann configuration than the case in normal incidence.

9163-73, Session 17

Near-field, back-action cooling and amplification

Iman Hassani Nia, Hooman Mohseni, Northwestern Univ. (United States)

Plasmonic structures produce well-known enhancement of the near-field optical intensity due to sub-wavelength optical confinement. These properties can produce a significant change of reflection upon small mechanical change of the antenna configuration. We have developed a method based on this enhanced sensitivity for cooling and amplification of a moving mirror. Using finite difference time domain method and standard optomechanical coupled-equation, different regimes of operation such as laser detuning and cavity length were studied to compare the effect of the near-field enhancement with the conventional radiation pressure. Using practical microcavity parameters, we demonstrate significantly higher cooling - or amplification- efficiency for the near-field plasmonic effect compared with that of the radiation pressure. Moreover, the volume of the system is very small. We believe that the significant efficiency improvement and reduced volume due to the proposed near-field effect can make this approach practical for many applications ranging from gravitational wave detection to photonic clocks, high precision accelerometers, atomic force microscopy, laser cooling and parametric amplification. While all existing optomechanical structures rely on the momentum exchange of propagating photons to produce the back-action, we show that utilization of near-field photons might in fact be a much better choice.

9163-74, Session 17

Polarization manipulation with subwavelength nano apertures

Jasper J. Cadusch, Timothy James, The Univ. of Melbourne (Australia); Timothy J. Davis, Commonwealth Scientific and Industrial Research Organisation (Australia); Ann Roberts, Amir H. Djalalian-Assl, The Univ. of Melbourne (Australia)

Manipulation and determination of circularly polarization states of light with nanoscale optics form a building block for future telecommunication and biosensing technologies. One potential method is to exploit localized surface plasmon resonances in patterned thin metallic films. Here we demonstrate a compact plasmonic quarter wave plate (PQWP) based upon detuned orthogonal nanoapertures. We also demonstrate a thin circular polarization filter based upon a far field interference of light transmitted through a pair of nanoapertures comprising a planar chiral unit cell.

Our PQWP design consists of an array of asymmetric cross apertures in a 50 nm silver film. The asymmetry in cross arm lengths is tailored to impart a 90° phase difference between orthogonal components of the transmitted field. Full polarization tomography reveals the fabricated array does indeed act as a quarter wave plate.

Our 2D chiral metamaterial based circular polarization filter uses an array of chiral pairs of apertures in a 50 nm Ag film. The apertures are designed si that when illuminated with LHCP light, the transmitted field interferes constructively, whereas RHCP light interferes destructively, leading to an asymmetric transmission of 10%.

9163-75, Session 17

Observation of quantum interference in the plasmonic Hong-Ou-Mandel effect

Yannick Sonnefraud, Ctr. National de la Recherche Scientifique (France); Giuliana Di Martino, Imperial College London (United Kingdom); Mark S. Tame, Univ. of KwaZulu-Natal (South Africa); Stéphane Kéna-Cohen, Frederik Dieleman, Imperial College London (United Kingdom); Sahin K. Ozdemir, Washington Univ. in St. Louis (United States); Myungshik Kim, Stefan A. Maier, Imperial College London (United Kingdom)

Optical signals are increasingly used to transfer and process information, because of their high speed, bandwidth, and propagation distances in transparent optical networks. However, the miniaturization of photonic devices faces a hard block: the diffraction limit. One proposed means to go beyond this limit is to use surface plasmons polaritons (SPPs), charge density waves at the interface between a metal and a dielectric, which can be excited with light, as the carrier of the information. So far, the study of plasmons has been confined to the classical regime, but recently more attention is given to the quantum regime: several interesting devices taking advantage of the large field confinement provided by SPPs have been proposed, such as single photon switches. However, at this stage, little is known about the behavior of SPPs in the quantum regime. In this presentation, we report direct evidence of the bosonic nature of SPPs in a scattering-based beamsplitter, in one of the most simple experiments of quantum optics - done using SPPs instead of photons propagating in air. A parametric down-conversion source is used to produce two indistinguishable photons, each of which is converted into a SPP on a metal-stripe waveguide and then made to interact through a semi-transparent Bragg mirror. In this plasmonic analog of the Hong-Ou-Mandel experiment, we measure a coincidence dip with a visibility of 72%, a key signature that SPPs are bosons and that quantum interference is clearly involved.

9163-76, Session 17

Plasmon hybridization in ITO/Ag core shell nanoarrays

Akram A. Amooali, Palash Gangopadhyay, Robert A. Norwood, The Univ. of Arizona (United States)

Metal and metal oxide electrodes play a significant role in many cutting edge applications including photonics, membranes, biological supports, sensing, electrochromics, and in various green technologies, such as, photocatalytics, Li-ion batteries and photovoltaics. There is strong interest in the ability to create one-dimensional nanoscale metal and metal oxide electrode structures that provide high surface area, tunability of the electrode – organic interfaces, and low tortuosity for improved electron / hole transport characteristics. Interest in patterning polymer based nanodevices and creating sub-100 nm metal and transparent conducting oxide (TCO) based nanostructured electrodes (NSEs) has led us to modify the traditional imprint lithography technique to enable synthesis of an array of sub-30 nm diameter polymer nanostructures. In this approach, a hard e-beam lithographed Si or SiC master is used to directly imprint a large area nanopattern onto polyacrylonitrile (PAN) film. The PAN film is then cured at ~ 200 °C to synthesize nanostructures. Large area nanostructured hybrid silver and indium tin oxide (ITO) arrays with feature sizes below 100 nm have been fabricated. The optical and electrical properties of these core shell electrodes including the surface plasmon frequency can be tuned by suitably changing the dielectrics and their dimensions. The surface plasmon wavelength of the nanopillar Ag changes from 650nm to 690nm depending on the dimensions of the pillars. Adding layers of ITO to the structure shifts the resonance wavelength toward the infrared region by an amount depending on the sequence and thickness of the layers in the structure.

9163-77, Session 17

Plasmonic black metals in resonant nanocavities

Mihail Bora, Elaine M. Behymer, Jerald A. Britten, Cindy C. Larson, Allan Chang, Hoang T. Nguyen, Tiziana Conese Bond, Lawrence Livermore National Lab. (United States)

We investigate a plasmonic resonant structure tunable from ultra-violet to near infrared wavelengths with maximum absorbance strength over 95% due to a highly efficient coupling with incident light. Additional harmonics are excited at higher frequencies extending the absorbance range to multiple wavelengths. We propose the concept of a ‘black’ plasmon resonator that exhibits broadband absorbance characteristics by spacing the modes closer through increasing the resonator length and by employing adiabatic plasmonic nano-focusing on the tapered end of the cavity.

Plasmons have a wide range of uses for refractive index based bio-sensing, molecular specific surface enhanced Raman spectroscopy (SERS), improvement of photovoltaic efficiency, and plasmonic laser devices. These applications require high extinction strength of the plasmonic resonances such that near field effects dominate the physical behavior, hence design considerations for optimal structures aim at controlling both the resonant wavelength and the coupling with the incident light. Solar cell efficiency increases through conversion of evanescent plasmon field into excitons have been demonstrated, but these approaches have limited practicality because either they are effective only for narrow spectral and incidence angle ranges or rely on attenuated total internal reflection coupling geometry which is often impractical . Nevertheless, recent studies that incorporate metallic nanostructures with strong coupling of incident light and broad spectral and angular coverage can provide a path for more efficient photovoltaics by means of plasmon-exciton conversion. Herein we present a structure that addresses the broadband absorbance requirement for plasmonic photovoltaics.

9163-78, Session 18

Quantum-coherence-enhanced plasmonic nanostructures for near-field spectroscopy and control

Dmitri V. Voronine, Texas A&M Univ. (United States)

Quantum coherence [1] has previously been used to enhance nonlinear optical signals, for example, in coherent Raman scattering. Near field enhancement from plasmonic nanostructures can also dramatically improve Raman signals. We investigate quantum coherence effects in plasmonic nanostructures coupled to gain media to enhance

the efficiency of surface plasmon generation [2]. We simulate the dependence of surface-enhanced coherent anti-Stokes Raman scattering (SECARS) spectra on the position and line width of the surface plasmon resonance, and attribute small (and even negative) enhancement factors to local destructive interference. We report measurements of nanoscale phase effects in SECARS of pyridazine on gold nanoparticle aggregates, and propose strategies to increase enhancement factors towards theoretical predictions. The new quantum-coherence-enhanced nanostructures can be used for a variety of spectroscopic applications.

RF-based optical patch antenna design and analysis

G. Seda Unal, M. I. Aksun, Koç Univ. (Turkey)

Optical antennas help surpass the diffraction limit, hence enable visualization, manipulation and control of light-matter interaction at subwavelength scale. These nano-scale antennas promise a breakthrough in the areas of energy harvesting, information technology, sensing, imaging, biophotonics and nanophotonics.

Optical antennas yield efficient coupling between the propagating field and the local electric field hence, show a strong analogy to their RF counterparts which collect radiated electromagnetic energy efficiently into a small volume on the receiver side, and provide more directive and efficient radiation of electromagnetic energy into a target volume on the transmitter side. Many well known RF antenna structures have been mapped to optics in this regard, yet, not so much attention has been paid to their design methods. The aim of this work is to implement the cavity model, an analytical and highly intuitive design and analysis method, for optical patch antennas.

Cavity model treats the RF patch antenna as a dielectric loaded cavity with electric conductors above and below and magnetic walls along the perimeter of the patch. The radiated field from a patch antenna is produced by the surface electric currents on the conducting patch. Equivalence principle shows that fields produced below the conducting patch, which closely resemble the resonant fields in the cavity, are equivalent to electric currents on the patch. Therefore, cavity model provides an analytical approach for patch antenna design and analysis. Optical patch antennas can also be analyzed via cavity model considering the differences due to lossy metal behavior in optics provided that similar surface currents are excited as of their RF counterparts’. Cavity model predicted antenna modes and corresponding radiation patterns are observed for optical patch antennas. Moreover, tools on circular polarization and frequency tuning are recorded for optical patches. This work indicates that cavity model, an analytical RF antenna design tool, can be mapped to optics as a complete package.

9163-80, Session 18

Plasmon-induced hot carriers in metallic nanoparticles

Alejandro Manjavacas, Jun Liu, Vikram V. Kulkarni, Peter Nordlander, Rice Univ. (United States)

Plasmon-induced hot carriers are attracting an increasing research interest due to its enormous potential applications to catalysis, photodetection and solar energy harvesting [1]. These excitations provide a very efficient mechanism for direct conversion of light energy into electronic energy that can be used to induce energetically unfavorable chemical reactions or to produce electrical currents. However, despite the enormous experimental effort, a complete theoretical understanding of the physical mechanisms behind the generation of plasmon-induced hot carriers is still missing [2].

In this work [3] we analyze the plasmon-induced hot carrier generation in metallic nanoparticles and nanoshells using a simple theoretical model in which the electrons are described as free particles in a finite spherical potential well, and the plasmon-induced dynamics is obtained through Fermi’s “golden rule”. Using the developed model we confirm that the number hot carriers generated follows the plasmonic spectral profile. Interestingly, we find that both the efficiency of the hot carrier generation and the energy of the hot carriers depend crucially on the size of the nanoparticle and on the electron lifetime. Furthermore, we analyze the importance of many-body effects by replacing the free electron wavefunctions with those obtained using density functional theory, finding an excellent agreement between both approaches, which supports the accuracy of our free electron model.

Optical properties gold-silver alloy nanoparticles and their biomedical applications

David Rioux, Mikaël Simard, Eric Bergeron, Sergiy V. Patskovsky, Michel Meunier, Ecole Polytechnique de Montréal (Canada)

Gold silver alloy nanoparticles (NPs) are promising for chromatic labeling of biological material because of their composition-dependent plasmon resonance. For example, alloy NPs with various compositions can be used to target specific cells. Hyperspectral imaging of these cells can be used to spatially localize NPs on cells and extract the scattering spectrum of each NPs to identify their composition. Furthermore, because of the field enhancement at their surface, such NPs are also good candidates as SERS probes for cell labelling. In this case, NPs can be coated with a Raman reporter and functionalized to target specific cell receptors. Both chromatic and SERS labelling can be combined to provide highly-multiplexed detection of cells. It is important to understand and predict beforehand the optical properties of such alloy NPs in order to optimize them for SERS and chromatic labelling. We present an analytic model for the dielectric function of gold silver alloys. This model is based on the Drude model for the intraband contribution and on the analysis of the band structures of gold and silver for the interband contribution to the dielectric function. We use this model with Mie theory to predict the optical properties of alloy NPs. We namely study the influence of NPs size and composition on their extinction and scattering spectra as well as the electric field distribution around the nanostructures. These theoretical results are compared with the experimental scattering and Raman properties of alloy nanoparticles produced by femtosecond laser ablation.

9163-83, Session 18

Self-assembled nano-antennas by placing metallic nanoparticles on DNA-origami for enhancing the fluorescence intensity and photostability

Guillermo P. Acuna, Friederike M. Möller, Phil Holzmeister, Anastasiya Puchkova, Technische Univ. Braunschweig (Germany); Jesica Pellegrotti, Ctr. de Investigaciones in Bionanociencias “Elizabeth Jares-Erijman” (Argentina); Birka

Lalkens, Technische Univ. Braunschweig (Germany); Fernando D. Stefani, Ctr. de Investigaciones in Bionanociencias “Elizabeth Jares-Erijman” (Argentina); Philip Tinnefeld, Technische Univ. Braunschweig (Germany)

In this contribution, we introduce self-assembled DNA origami structures [1] as a platform where metallic nanoparticles as well as single organic fluorophores can be placed with nanometer precision. These hybrid structures were used to study the distance dependence quenching of fluorophores by gold nanoparticles [2] and to determine the fluorescence intensity angular dependence close to metallic nanoparticles [3]. Additionally, these structures were employed to built nano-antennas based on 100 nm gold dimers to focus light at the nano-scale leading to a fluorescence enhancement of more than two orders of magnitude [4] ready for single molecule measurements at concentrations as high as 500 nM [5]. Furthermore, we will report on the reduced photobleaching of organic dyes in the vicinity of gold nanoparticles with an increment of the number of total emitted photons. Finally we will introduce a method for experimentally determining the three relevant photophyscial rates (excitation, radiative and non radiative) that fully characterize the interaction between metallic structures and organic dyes based on the blinking kinetics.

9164-1, Session 1

Optical tweezing in a slow light medium

Ebrahim Karimi, Univ. degli Studi di Napoli Federico II (Italy); Israel De Leon, Univ. of Ottawa (Canada); Mahammad Zahirul Alam, Univ. of Ottawa (Canada); Robert W. Boyd, Univ. of Ottawa (Canada)

Following by the Abraham-Minkowski controversy, which deals with correct expression of light linear momentum inside a medium, theoretical arguments suggest that the magnitude of the force exerted by a light beam on a dielectric object may depend on the group index of the object and on the group index of the surrounded medium. This, indeed, suggests a significant control on the optical forces, since the group index of a medium can vary over a significant range. In this work, we describe the status of our experimental effort aimed at determining the dependence of optical forces on group and refractive indices by means of optical tweezing. In particular, we study the case of dielectric particles embedded in an atomic gas and examine the optical forces acting on the particles when the light beam's frequency is close to the atomic resonance.

9164-2, Session 1

Cavity cooling a trapped nanosphere

Peter F. Barker, Piergiacomo Z. G. Fonseca, James Millen, Tania S. Monteiro, Univ. College London (United Kingdom)

We demonstrate the cooling of the center-of-mass motion of a dielectric nanoscale particle trapped in a Paul trap and in the optical field of a Fabry-Perot cavity in a vacuum [1,2]. This goal has recently been achieved for optically levitated nanoparticles at low vacuum[3], and for free nanoparticles passing through a cavity in high vacuum [4]. In our experiment, particles are confined within a Paul trap at the center of the cavity, allowing us to keep spheres trapped in high vacuum. The fundamental optical mode of the cavity is kept on resonance with a low-power laser beam by using the Pound-Drever-Hall technique, while a second higher power beam is red detuned from the cavity resonance to achieve cooling by dynamical back action. By analyzing the time dependence of the light scattered from the trapped particle in the cavity field, and by the the light transmitted through the cavity, we observe cooling of the motion of the particle using a modest cavity finesse of 14000. In this talk we will describe these experiments as well as newer experiments with a higher finesse cavity in the 10^5 range where we aim to achieve sideband cooling to the ground state.

9164-3, Session 1

Doppler cooling microspheres

Peter F. Barker, Li Ying, Univ. College London (United Kingdom)

We describe experiments that are working towards cooling the center-of-mass motion of levitated silica microspheres via the velocity dependent scattering force from excitation of whispering gallery mode (WGM) resonances [1]. The technique is comparable to Doppler cooling as the motion is damped using light red detuned from the WGM resonance. This differs from conventional microparticle cavity cooling [2,3] as the microsphere acts as it's own high-Q (up to 109) cavity. Initial experiments have excited WGM resonances in a silica microsphere cantilever achieved by evanescent field coupling from a tapered optical fiber. We frequency lock the excitation laser to the WGM using the Pound-Drever-Hall locking scheme and damp the center-of-mass motion of the microsphere cantilever system. Further experiments will move to coolng free spheres that are optically trapped within an optical tweezer coupled to the evanescent light field, but uncoupled to the environment.

9164-4, Session 1

Parametric stabilization and cooling of microparticles in a quadrupole ion trap

Pavel Nagornykh, Bruce E. Kane, Univ. of Maryland, College Park (United States)

Discovery of graphene, 2D material with unique properties, led to intense search for a way to fully unlock its potential. It was found early that graphene strongly interacts with the substrate it is placed on, following the substrate topographically and is affected by its charge distribution. One of the ways to avoid this kind of interaction and access intrinsic physics of graphene is by levitating it so that only trapping fields are having any significant effect on the graphene. In our system we achieve the levitation by trapping charged flakes in home-built quadrupole trap in the UHV chamber. Particles are stabilized and cooled down after being trapped and transferred into the UHV chamber. In this talk we discuss the process used for particles' cooling and calibration of temperature, charge and mass of those particles by tracking amplitude and frequency of their motion. Current progress on controlling charge of graphene flakes in situ by using an electron gun is also discussed.

9164-5, Session 1

Dynamics of optically trapped microparticles in vacuum

Yoshihiko Arita, Michael Mazilu, Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Quantum state preparation of mesoscopic objects is a powerful playground for the elucidation of many physical principles. These quantum regimes can only be achieved through laser cooling and by minimizing the state decoherence. An optically trapped nano- or micro-particle in vacuum is an ideal system for investigating quantum effects as the particle is well isolated from the thermal environment. Recently, we have demonstrated an optically trapped microgyroscope in vacuum, which leads to the positional stabilization in effect cooling the particle to 40K in all three translational directions without any feedback laser. This presents a novel and unique form of optomechanical system including the rotational degrees of freedom and is a major step towards measuring rotational quantum frictional forces in vacuum. We have extended the current system for multiparticle studies, which are essential for a number of key studies such as optical binding, multiparticle entanglement and quantum friction. We show the dynamics of multiple particles trapped and rotating in vacuum at different surface-to-surface distance (two to ten microns) between the particles. Further, we demonstrate for the first time microparticles trapped in more exotic optical landscapes, namely a Laguerre-Gaussian mode, wherein this case, particles orbit around the annular beam profile as well as spinning about their own axis when using a circularly polarized light field.

9164-6, Session 1

On-chip optical trapping for atomic applications

Maximillian A. Perez, Evan Salim, Dan Farkas, Janet Duggan, ColdQuanta, Inc. (United States); Megan Ivory, ColdQuanta Inc (United States); Dana Z. Anderson, ColdQuanta, Inc. (United States)

To simplify applications that rely on optical trapping of cold and ultracold atoms, ColdQuanta is developing techniques to incorporate miniature optical components onto in-vacuum atom chips. The result is a hybrid atom chip that combines an in-vacuum micro-optical bench for optical control with an atom chip for magnetic control. Placing optical components on a chip inside of the vacuum system produces a compact system that can be targeted to specific experiments, in this case the generation of optical lattices. Applications that can benefit from this technology include timekeeping, inertial sensing, gravimetry, quantum information, and emulation of quantum many-body systems.

ColdQuanta's GlasSi atom chip technology incorporates glass windows in the plane of a silicon atom chip. In conjunction with the in-vacuum micro-optical bench, optical lattices can be generated within a few hundred microns of an atom chip window through which single atoms can be imaged with sub-micron spatial resolution. The result is a quantum gas microscope that allows optical lattices to be studied at the level of single lattice sites.

Similar to what ColdQuanta has achieved with magneto-optical traps (MOTs) in its miniMOT system and with Bose-Einstein condensates (BECs) in its RuBECi® system, ColdQuanta seeks to apply the on-chip optical bench technology to studies of optical lattices in a commercially available, turnkey system. These techniques are currently being considered for lattice experiments in NASA's Cold Atom Laboratory (CAL) slated for flight on the International Space Station.

9164-7, Session 2

Quantum mechanics compatible Maxwell's stress tensor

Michael Mazilu, Univ. of St. Andrews (United Kingdom)

There are many ways to calculate the optical forces acting on scattering particles such as Maxwell's stress tensor, Lorentz forces, gradient and scattering forces, Lorenz-Mie formalism, T-matrix, etc…. All these approaches use the electromagnetic field and define the amount of linear momentum transferred to the scattering particles. By definition, the resulting momentum transferred is proportional to the intensity of the incident fields, however, the single photon momentum (hbar k) does not naturally appear in these classical expressions. In this paper, we discuss an alternative Maxwell's stress tensor based formalism that renders the classical electromagnetic field momentum compatible to the quantum mechanical one (hbar k). This same approach can be used for angular momentum and energy.

9164-8, Session 2

Calculating the optical gradient and scattering force and the creation of conservative optical force field

Jack Ng, Junjie Du, Isaac Yuen, Hong Kong Baptist Univ. (Hong Kong, China); Zhifang Lin, Fudan Univ. (China); Che Ting Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

It is customary and useful to separate the optical force into two physically and mathematically distinct parts. The first is the conservative curl-less gradient force, which is responsible for optical trapping, producing optical potential landscape etc. The scattering force is responsible for Brownian motor, optical rotation, particle transportation etc.

Despite the importance of the concepts of gradient and scattering force, they have been calculated only for particle small or large compared to a wavelength. Nevertheless, these size regimes are not readily accessible in experiments, because small particle suffers from Brownian fluctuation while large particle suffers from strong gravity. The gradient and scattering force for the intermediate, experimentally accessible sizes have never been calculated before.

Here we report an analytical and a numerical approach to calculate the gradient and scattering force in the Mie regime. The analytical formulation provides insight and the independent numerical approach allows efficient calculation. The gradient and scattering force for various types of beams, including the widely employ fundamental Gaussian beam, will be presented.

Owing to the scattering force, a collection of particles illuminated by light do not come to equilibrium, instead it reaches a steady state. In many situations, a conservative force is preferable and it will be beneficial to eliminate the scattering force. We will present a recipe that allows us to eliminate the scattering force for spherical particles.

9164-9, Session 2

Momentum measurements with holographic optical tweezers for exploring force detection capabilities on irregular samples

Frederic Català , Univ. de Barcelona (Spain); Ferran Marsà Samper, Arnau Farré Flaquer, Mario Montes-Usategui, Impetux Optics, S.L. (Spain) and Univ. de Barcelona (Spain); Estela Martin-Badosa, Univ. de Barcelona (Spain)

Different methods allow measuring forces with optical tweezers. An attractive option relies on the detection of the momentum change of the trapping beam. This barely used alternative resorts to general principles and therefore provides a shorter route to the force, with clear advantages compared to other methods. As the magnitude is not derived from the sample displacement, no in situ calibration is required to obtain the force, and measurements are not restricted to specific conditions (spherical particle, Gaussian beam, homogeneous medium, etc.). Nevertheless, its combination with optical tweezers was not shown until recently, so its use has been restricted to the more complex counter-propagating beam geometry. With the use of gradient traps one gains more flexibility to, for example, combine force measurements with other technologies, such as spatial light modulators or acousto-optic deflectors that generate multiple traps. We show here how the measurement of the light momentum can be specifically used with holographic optical tweezers to leverage the potential of this force detection method. In particular, we show that forces can be measured with irregular particles and beams by simultaneously applying a force in the same direction by means of a constant flow to different holographically-trapped particles. This is, an important advantage compared to the traditional calibration approach.

9164-10, Session 2

Electromagnetic force and torque in Lorentz and Einstein-Laub formulations

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

The classical theory of electrodynamics is built upon Maxwell's equations and the concepts of electromagnetic field, force, energy, and momentum, which are intimately tied together by Poynting's theorem and the Lorentz force law. Whereas Maxwell's macroscopic equations relate the electric and magnetic fields to their material sources (i.e., charge, current, polarization and magnetization), Poynting's theorem governs the flow of electromagnetic energy and its exchange between fields and material media, while the Lorentz law regulates the back-and-forth transfer of momentum between the media and the fields. As it turns out, an alternative force law, first proposed in 1908 by Einstein and Laub, exists that is consistent with Maxwell's macroscopic equations and complies with the conservation laws as well as with the requirements of special relativity. While the Lorentz law requires the introduction of hidden energy and hidden momentum in situations where an electric field acts on a magnetic material, the Einstein-Laub formulation of electromagnetic force and torque does not invoke hidden entities under such circumstances. Moreover, the total force and the total torque exerted by electromagnetic fields on any given object turn out to be independent of whether force and torque densities are evaluated using the Lorentz law or in accordance with the Einstein-Laub formulas. Hidden entities aside, the two formulations differ only in their predicted force and torque distributions throughout material media. Such differences in distribution are occasionally measurable, and could serve as a guide in deciding which formulation, if either, corresponds to physical reality.

9164-11, Session 3

Optical vault: a reconfigurable bottle beam based on conical refraction of light

Wieslaw Z. Krolikowski, The Australian National Univ. (Australia) and Texas A&M Univ. at Qatar (Qatar); Alejandro Turpin, Univ. Autònoma de Barcelona (Spain); Vladlen G. Shvedov, Cyril Hnatovsky, The Australian National Univ. (Australia); Yurii V. Loika, Univ. of Dundee (United Kingdom); Jordi Mompart, Univ. Autònoma de Barcelona (Spain)

We study trapping of absorbing particles by using an optical bottle formed via conical diffraction of circularly polarized light beam in biaxial KTP crystal. When the circularly polarized beam propagates along one of the optical axes of biaxial crystal the beam outside the crystal forms an optical bottle, i.e. it acquires a form of dark circularly symmetric area surrounded by high light intensity. When the incident light is of linear polarization the emerging pattern loses its circular symmetry. Instead of the rings, the transverse light intensity distribution now takes the form of crescents, which are produced within a certain interval along propagation direction. In 3-D, this implies the formation of a gap in the side wall of the otherwise perfect optical bottle. In our experiments we employed 11.3 mm long KTP crystal. illuminated by 100mW laser beam at 532nm wavelength to create the bottle which was subsequently used to trap glass shells covered with a thin layer of carbon (~200 nm) in order to make them light-absorbing. To prevent accidental air flows from affecting the trapping process, the optical bottle was formed inside a transparent cylindrical glass cell placed immediately behind the biaxial crystal. We found that while a particle could be trapped using either a fully closed (i.e., circular input polarization) or opened (i.e., linear input polarization) bottle, the loading much faster in the latter case. The trapping was generally very robust, with the particles stably resting at the lower light wall due to gravity. The ability to open or close the bottle at will by varying the input beam polarization gives a unique opportunity not only to easily trap micro-objects but also to release them.

9164-12, Session 3

Shaping self imaging optical bottles with modified quasi-Bessel beams

Woei-Ming Lee, The Australian National Univ. (Australia); Li Li, Xiangsheng Xie, Sun Yat-Sen Univ. (China); Wieslaw Z. Krolikowski, Andrei V. Rode, The Australian National Univ. (Australia); Jianying Zhou, Sun Yat-Sen Univ. (China)

Coherent generated of self-imaging bottle beams, typically formed by interfering two coherent Quasi-Bessel beams, possess a periodic array of intensity maxima and minima along their axial direction. In practice, the overall quality of the self-repeating intensity patterns possesses large intensity variations that have yet to be unresolved. In this paper, we increase consistency of intensity of self-imaging bottle beams through a spatial frequency optimization routine. By doing so, we increased the effective length of self-imaging bottle beams by 74%. Further, we show that this approach is applicable to higher-order self-imaging beams which display complex intensity structures. The enhancement in these modified self-imaging beams could play a significant role in optical trapping, imaging and lithography.

9164-13, Session 3

Focusing and imaging with increased numerical apertures through multimode fibers with micro-fabricated optics

Silvio Bianchi, Univ. degli Studi di Roma La Sapienza (Italy); Vijayakumar Rajamanickam, Carlo Liberale, Lorenzo Ferrara, Istituto Italiano di Tecnologia (Italy); Enzo Di Fabrizio, King Abdullah Univ. of Science and Technology (Saudi Arabia); Roberto Di Leonardo, Consiglio Nazionale Ricerche (Italy)

The use of individual multimode optical fibers in endoscopy applications has the potential to provide highly miniaturized and noninvasive probes for microscopy and optical micromanipulation. A few different strategies have been proposed recently, but they all suffer from intrinsically low resolution related to the low numerical aperture of multimode fibers. Here, we show that two-photon polymerization allows for direct fabrication of micro-optics components on the fiber end, resulting in an increase of the numerical aperture to a value that is close to 1. Coupling light into the fiber through a spatial light modulator, we were able to optically scan a submicrometer spot (300 nm FWHM) over an extended region, facing the opposite fiber end. Fluorescence imaging with improved resolution is also demonstrated.

9164-15, Session 3

Engineering particle trajectories in microfluidic flows using speckle light fields

Giorgio Volpe, Institut Langevin (France); Sylvain Gigan, Institut Langevin (France); Giovanni S. Volpe, Bilkent Univ. (Turkey)

Current optical trapping techniques rely on carefully engineered setups to manipulate nanoscopic and microscopic objects at the focus of a laser beam. Since the quality of the trapping is strongly dependent on the focus quality, these systems have to be very carefully aligned and optimized, thus limiting their practical applicability in complex environments. One major challenge for current optical manipulation techniques is the light scattering occurring in optically complex media, such as biological tissues, turbid liquids and rough surfaces, which give rise to apparently random light fields known as speckles. Here, we present a novel experimental technique for optical manipulation based on speckles. We experimentally show how to take advantage of the statistical properties of speckle patterns in order to perform basic optical manipulation tasks such as trapping, guiding and sorting. In particular, we demonstrate sieving and sorting of Brownian particles of different size (2 and 5 μm) and refractive index ($n = 1.42$ and $n = 1.68$) in a microfluidic chamber. The speckle pattern to perform such tasks, is generated by mode mixing in a multimode optical fiber so that an incident laser power as little as a few tens of microWatt per square micrometer (maximum power = 30 μW/μm2) is needed. Moreover, apart from the excitation laser, all the components needed to generate the speckle pattern can be integrated in the walls of the microfluidic chamber. The simplicity of this technique will foster its application in biological and biomedical applications where automated and turn-key techniques are especially appreciated.

9164-92, Session 3

Spontaneous revolution of micro-swimmers in a spherically aberrated optical trap

Basudev Roy, Argha Mondal, Soumyajit Roy, Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

Artificial micro-swimmers are fast emerging as models to mimic and thereby understand the movement patterns of microorganisms and biological cells which self-propel themselves by generating fields or gradients that cause fluid flow around their surface by phoretic surface effects, such as thermophoresis [1] or electrophoresis [2]. In this paper, we demonstrate that radiation pressure can lead to spontaneous revolution of a micron-sized asymmetric particle inside an annular potential formed due to geometrical aberrations of a Gaussian beam focused into a stratified medium using a high numerical aperture microscopic objective [3]. The rate of revolution can be controlled from a few Hz to tens of Hz by changing the intensity of the trapping light which can be achieved either by modifying the laser power or the annular trap diameter. Theoretical simulations performed using Finite-difference time-domain method in Lumerical verify the experimental observations. The electric field distribution confirms that the particle revolution is the effect of asymmetrical scattering by the particle in the annular potential that gives rise to a tangential force. A proper Maxwell stress-tensor analysis of the problem demonstrates this uniform tangential force acting on the particle inside the ring. The model also shows that particles could be custom designed in order to spontaneously revolve in such annular trapping potentials. Thus, such systems could be used in place of LG beams to apply torque on DNA strands in order to study protein-DNA interaction [4], or to study the hydrodynamic synchronization [5] among multiple rotating objects.Reference:

9164-16, Session 4

Observation of the rotational Doppler effect from an optically trapped micro-particle

David B. Phillips, Michael P. Lee, Stephen M. Barnett, Univ. of Glasgow (United Kingdom); Stephen H. Simpson, Univ. of Bristol (United Kingdom); Martin P. Lavery, Fiona C. Speirits, Miles J. Padgett, Graham M. Gibson, Univ. of Glasgow (United Kingdom)

The linear Doppler shift forms the basis of various sensor types for the measurement of linear velocity, ranging from speeding cars to fluid flow. Recently, it has been shown that similar effects can be observed for rotating objects even when the linear Doppler shift is zero. If measurement of the light scattered from a rotating object is restricted to a mode corresponding to a defined state of Orbital Angular Momentum (OAM), then a frequency shift is observed given as the product of the rotation rate of the object, and the OAM of the scattered photon. Illuminating the spinning surface with two beams of opposite handedness OAM, hence giving rise to opposite frequency shifts, results in interference and an intensity modulation from which the rotation speed can be deduced.

Here, we measure the rotational Doppler shift from micron sized calcite particles spinning within an optical tweezers in water at 10s of Hz. In this case the signal is complicated by the geometry of the particle, and its Brownian motion. We describe how the rotational Doppler shift signal can still be used to measure the particle's rotation rate.

9164-17, Session 4

Optical trapping with a perfect vortex beam

Mingzhou Chen, Michael Mazilu, Yoshihiko Arita, Univ. of St. Andrews (United Kingdom); Ewan M. Wright, College of Optical Sciences, The Univ. of Arizona (United States); Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Vortex beams with different topological charge usually have different profiles and radii of peak intensity. This introduces a degree of complexity the fair study of the nature of optical OAM (orbital angular momentum). To avoid this, we introduced a new approach by creating a perfect vortex beam using an annular illuminating beam with a fixed intensity profile on an SLM that imposes a chosen topological charge. The radial intensity profile of such an experimentally created perfect vortex beam is independent to any given integer value of its topological charge. The well-defined OAM density in such a perfect vortex beam is probed by trapping microscope particles. The rotation rate of a trapped necklace of particles is measured for both integer and non-integer topological charge. Experimental results agree with the theoretical prediction. With the flexibility of our approach, local OAM density can be corrected in situ to overcome the problem of trapping the particle in the intensity hotspots. The correction of local OAM density in the perfect vortex beam therefore enables a single trapped particle to move along the vortex ring at a constant angular velocity that is independent of the azimuthal position. With such a vortex field in hand, we further investigate the quantisation of OAM. Due to its particular nature, the perfect vortex beam may be applied to other studies in optical trapping of particles, atoms or quantum gases.

9164-18, Session 4

Behavior of oblate spheroidal microparticles in a tightly focused optical vortex beam

Alejandro V. Arzola, Univ. Nacional Autónoma de Mexico (Mexico); Petr Jákl, Lukáš Chvátal, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Mojmíršerý, Institute of Scientific Instruments of the ASCR (Czech Republic); Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

Behaviour of dielectric microparticles optically confined in a focused optical vortex beam will be investigated. Comparison of our own precise experimental measurements with theoretical model will be presented and discussed for various topological charges and beam polarizations.

9164-19, Session 4

Interesting manifestations of spin orbit interaction and spin Hall shift of light in an optical trap

Basudev Roy, Nirmalya Ghosh, Indian Institute of Science Education and Research Kolkata (India); S. Dutta Gupta, Univ. of Hyderabad (India); Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

The spin orbit interaction (SOI) of light leading to the evolution of trajectory dependent geometric phase and associated spin Hall

shift (SHS) in circularly polarized light has led to several fascinating manifestations in scattering, tight focusing, and imaging processes. However, most of these observations are at the sub-wavelength level, with somewhat limited applications of a general nature. We investigate the SOI in an optical trap for a linearly polarized trapping beam where the both the trajectory dependent geometric phase as well as the SHS are magnified significantly due to a stratified medium. The stratified medium is created using an index mismatched cover slip that modifies the radial intensity distribution near the focal plane of the trap due to diffraction effects. The modified intensity distribution causes trapping of polystyrene beads in ring-like patterns, while the tight focusing in the stratified medium also leads to a large spin redirectional geometric phase that creates intensity side lobes in the azimuthal direction near the focal plane. Single trapped asymmetric particles can be trapped in the side lobes and translated along the ring by changing the polarization angle of the input beam. A 3D analysis of polarization reveals the generation of polarization vortices as well as spatially separated regions of opposite circular polarizations near the focal plane leading to controlled rotation of trapped particles, again by a linearly polarized input beam. The study can have several interesting consequences in the manipulation of mesoscopic particles in an optical trap.

9164-20, Session 4

Helicity-dependent optomechanics of chiral microparticles *(Invited Paper)*

Etienne Brasselet, Georgiy V. Tkachenko, Univ. Bordeaux 1 (France)

To exploit the angular momentum degree of freedom of the light to control the mechanical effects that results from its linear momentum is an intriguing challenge that may open several new routes towards enhanced optical trapping, manipulation and sorting of microscopic entities. This issue can be addressed by exploiting the interplay between the chirality of matter and the chirality of optical fields. Here we will report on our recent progresses on helicity-dependent optomechanics of chiral microparticles.

9164-21, Session 5

Measurement of interparticle force between nematic colloids by optical tweezers

Yasuyuki Kimura, Kuniyoshi Izaki, Kyushu Univ. (Japan)

When the micrometer-sized colloidal particles are dispersed in nematic liquid crystal which have orientational order, the particles (nematic colloids) themselves become topological defects and spontaneously induce another defects to relax the deformation around the particles. They also interact with each other via characteristic anisotropic interaction to reduce the orientaitonal elastic energy of liquid crystal. There are various kinds of nematic colloids with different detects and their interaction is different each other. In this study, we directly measured the interparticle force between the same and the different types of nematic colloids by various methods utilizing optical tweezers. The measured interaction can be both attractive and repulsive depending on the relative arrangement of the particles. The obtained force is quantitatively well described by the elastic theory of liquid crystal.

We also construct various exotic microstructures those cannot be realized in isotropic liquids by optical tweezers. For example, although the particles with attractive interaction will take compact structures in isotropic liquid, the anisotropic attractive and repulsive interaction in nematic colloids enables us to construct stable open structures such as dendric or snowflake-like structures.

9164-22, Session 5

Optical tweezers rotational microrheology: achieving viscoelastic measurements in confined geometries

Lachlan Gibson, Daryl C. Preece, Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Many biological fluids, including the cytoplasm inside cells, synovial fluid between bone joints and tear film, manifest both viscous and elastic properties. Measuring the viscoelasticity of these fluids is difficult because they can be highly inhomogeneous or only available in ultra-small volumes. Conventional rheological techniques are precluded from measuring the properties of these fluids because they require large samples (mL). As a result, it has been necessary to develop an optical tweezers microrheometer which functions in ultra-low volumes (pL) or inside confined spaces. Our novel optical tweezers microrhemeter achieves superb temporal (~mHz-kHz) and spatial resolution by observing both passive and active rotational dynamics of a single optically trapped particle. The probe particles are birefringent vaterite microspheres allowing the particle's azimuthal angle to be accurately controlled and monitored with a high sampling rate. High frequency viscoelastic data is measured by observing rotational Brownian motion while lower frequencies can be evaluated by actively rotating the particle between two coaxial angularly offset traps. Analysis of the active measurements in ethanol confirms the existence of a non-linear angle dependent optical torque exerted by the trap. Microrheological measurements in water, ethanol and dilutions of Celluvisc eye drops agree with macrorheological data. These results demonstrate the accuracy and high temporal resolution of this method. Further measurements inside artificial liposome spheres could confirm the expected spatial resolution which would motivate investigations into the precise properties of highly inhomogeneous fluids or to take rheological measurements in confined geometries such as a cell.

9164-23, Session 5

Anti-reflection coated particles for biophysical measurements

Derek Craig, Igor Andreyev, Yoshihiko Arita, Michael Mazilu, David C. Hamilton, Peter Pogorzelec, Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Improvements in optical tweezing have largely focused on modifications of instrumentation and the shaping of the trapping beam. Recent advances in this area have exploited the more pertinent component of optical tweezing, the physical and material properties of the trapped particle. The production of anti-reflection coated, high-refractive index core-shell microparticles (AR particles) has broadened the capacity for optical trapping investigations with optical forces greater than a nanonewton having been reported. Here, we demonstrate the reproducible synthesis of such particles with comparable trap stiffnesses to those previously reported.

Building on this concept we have performed the first set of biophysical measurements using these particles, including the exploration of cell microrheology, to manipulate the stretching of red blood cells (RBC) and their use in flow viscosity measurements. The advantages of these particles opens up new directions for optical trapping studies

9164-24, Session 5

Quantifying change in stiffness heterogeneity in 3D around cells embedded in natural ECMs over time

Abhishek Kurup, Mark Keating, Univ. of California, Irvine (United States); Martha B. Alvarez-Elizondo, Technion-Israel Institute of Technology (Israel); Elliot L. Botvinick, Univ. of California, Irvine (United States)

Cells within their microenvironment engage in a ‘push-pull’ relationship with their surrounding extracellular matrix (ECM). The ECM mesh is readily deformed by cell-generated forces and ECM stiffness increases with local mesh deformation. Thus, we cannot infer forces acting on or generated by cells if we measure local deformation alone. The changing stiffness must be measured as well. To investigate roles for forces and ECM stiffness we culture cells within 3D ECM hydrogels containing microbeads. We implement automated optical tweezers active microrheology (aAMR) to map ECM stiffness surrounding cells. Hundreds of beads are probed in one hour to map the mechanical landscape and to seek correlations between local stiffness and cell properties such as contractility, signaling and differentiation. To estimate forces acting on each bead we first map stiffness around the same cell over time, carefully probing the same beads at each time point. Forces are estimated as the product of bead displacement and stiffness.

We cultured primary human aortic smooth muscle cells (AoSMCs) within collagen hydrogels and observed local stiffness ranging by an order of magnitude. Cells were treated with inhibitors of contractility after which microbeads displaced towards cells while local ECMs softened significantly. Time-lapse aAMR shows ECM stiffening at the leading front of migrating cells and a loose correlation between bead displacement and force, reinforcing our assertion that traction forces cannot be measured without consideration of the heterogeneous scaffold of the local ECM.

9164-26, Session 5

Temporal response of biological cells to high-frequency optical jumping and vibrating tweezers

Lingyao Yu, Yunlong Sheng, Univ. Laval (Canada)

Vibrating and jumping laser beams are recently used for tugging, wiggling and stretching biological cells and macromolecules with Pico-Newton forces. A laser beam can jump to several locations in the cell to implement multiple traps in time-sharing regime. Laser beam trapped the proximity of the cell and vibrated in position for an active rheology assay. Dynamic viscoelasticity of the cell was measured in high-throughput flow cytometer, where the cell flows into a channel formed by one-dimensionally focused linear diode laser bars with vibrating intensity. In many cases however the analysis was only a too simplified. The time-sharing optical tweezers was based on an intuitive concept that a viscoelastic object does not “sense” blinking of the optical beam, so that a jumping beam is equivalent to a static multi-trap. In many cases the biological object was modeled as a 1D circuit of springs and dashpots, or as material of inelastic 1D power law without considering the real 3D shape and internal structure of the cell. We used the finite element method to model full 3D structure, viscoelastic continuum materials of the cell and its temporal response to high-frequency jumping and vibrating of the external load. New phenomena were studied and might be further investigated with more accurate experiments, such as the jumping of local stress and local strain independently on the material recovery time and the jumping frequency; the energy dissipation in the hysteresis cycles etc. Moreover, the cytoplasm fluid field and its interaction with the cell membrane are investigated

9164-27, Session 6

Local probing and stimulation of neuronal cells by optical manipulation *(Invited Paper)*

Danut-Adrian Cojoc, CNR-IOM (Italy)

During development and in the adult brain, neurons continuously explore the environment searching for guidance cues, leading to the appropriate connections. Elucidating these mechanisms represents a gold goal in neurobiology. Here, I discuss our recent achievements developing new approaches to locally probe the growth cones (GC) and stimulate neuronal compartments with high spatial and temporal resolution.

Optical tweezers force spectroscopy applied in conjunction with metabolic inhibitors reveal new properties of the filopodia and lamellipodia dynamics of GC [1].

On the other hand, using optically manipulated (OM) microvectors as functionalized beads or filled liposomes, we demonstrate focal stimulation of neurons by small number of signaling molecules. For example, beads coated with Brain Derived Neurotrophic Factor and OM to specific sites on the dendrites, are shown to trigger TrkB receptor pathway [2]. Since beads can be easily functionalized with any type of protein, the technique can be generalized for many other schemes of stimulation. However, since the molecules cannot leave the bead surface this approach cannot be applied for experiments requiring freely diffusing molecules. Therefore we have considered another type of vector: filled liposomes, where molecules are released by liposome membrane photolysis. This approach allows to scale down to very small numbers of molecules as we demonstrate for guidance molecules Netrin-1 and Semaphorin3A [3,4,].

MicroTsunamis: a method for high-throughput screening of cellular mechanotransduction using laser microbeam generated cavitation bubbles

Jonathan Compton, Justin Luo, Huan Ma, Vasan Venugopalan, Elliot L. Botvinick, Univ. of California, Irvine (United States)

We introduce an all optical platform for rapid, high-throughput screening of exogenous molecules affecting cellular mechanotransduction without reliance on flow chambers or microfluidics. Our method initiates mechanotransduction in adherent cells using single laser-microbeam generated micro-cavitation bubbles (µCBs). These µCBs expose adherent cells to a microTsunami: a transient microscale burst of hydrodynamic shear stress that stimulates cells over areas approaching 1mm2. We demonstrate microTsunami-initiated mechanosignaling in primary human endothelial cells. This observed signaling is consistent with G-protein-coupled receptor stimulation, a hallmark of mechanotransduction, resulting in Ca2+ release by the endoplasmic reticulum. Moreover, we show dose-dependent modulation of Ca2+ signaling through exogenous administration of a known inhibitor to this pathway. We utilize this capability to screen the effects of a set of small molecules on cellular mechanotransduction in 96-well plates using standard imaging cytometry.

9164-29, Session 6

Force measurements with optical tweezers inside living cells

Josep Mas, Univ. de Barcelona (Spain) and Univ. of Saint

Andrews (United Kingdom); Arnau Farré Flaquer, Impetux Optics, S.L. (Spain) and Univ. de Barcelona (Spain); Jordi Sancho-Parramon, Institut Ruder Boškovic (Croatia); Estela Martín-Badosa, Univ. de Barcelona (Spain); Mario Montes-Usategui, Univ. de Barcelona (Spain) and Impetux Optics S.L. (Spain)

The study of intracellular transport with optical traps has made a remarkable step ahead in recent years translating the debate about the mechanochemical properties of motor proteins to their natural environment: the cell. Different works have shown the possibility to obtain reliable information of molecular motors inside cells at the single-molecule level. The opportunity to carry experiments in vivo opens the field to new questions which were not addressable until now. This change has been driven by the advent of new calibration methods for measuring forces in cells. Here, we present an alternative method for optical tweezers, based on the detection of the light momentum changes of the trapping beam. The force measurements follow this more general principle and are therefore less vulnerable to particular conditions of the experiment as no approximations relative to the interaction between the sample and the beam are required. The instrument is calibrated by measuring some parameters exclusively related to its optical design so that it is possible to obtain a conversion factor from volts to piconewtons that is independent of the physical properties of the sample and the beam. We compared this value with calibrations performed in vivo on different lipid droplets through the active-passive method proposed by Berg-Sørensen et al., and found a remarkable agreement between both. The results show that the measurement of forces on arbitrary-shaped biological objects inside cells without an in situ calibration is feasible. We found that our measurements were barely affected by the presence of other structures, such as neighbouring vesicles or the cell membrane. We finally used the instrument to measure the stall forces of kinesin and dynein inside A549 cells.

9164-30, Session 6

Measuring local viscosities near membranes of living cells with photonic force microscopy

Felix Jünger, Alexander Rohrbach, Albert-Ludwigs-Univ. Freiburg (Germany)

The diffusive motion of a particle in the vicinity of a boundary surface is relevant from a biological point of view, since the viscous drag γ changes significantly with the distance to the interface such as a cell membrane. In this study we use photonic force microscopy (PFM) to investigate how γ changes when an optically trapped 1µm polystyrene bead approaches the plasma membrane of different biological cells. The bead's temporal fluctuations are tracked interferometrically in three dimensions with nanometer precision and on a microsecond time scale. The autocorrelation of the bead's motion reveals the friction coefficient γ(d) as a function of bead-membrane distance d.

We investigated the hydrodynamic decay length γ(d) for different cell types (J774, HT29, MDCK) and a giant unilamellar vesicle (GUV). Consisting only of a lipid bilayer and lacking cytoskeleton and molecular motors, the GUVs serve as a model for biological cells with greatly reduced complexity. Interestingly, we find that all decay lengths γ(d) measured at biological membranes are significantly longer than those of a rigid glass coverslip, giving rise to the conclusion that the deformable shape of the membrane influences the hydrodynamic interaction. The precise knowledge of γ(d) enables us to determine another biologically relevant quantity, the mean first passage time (MFPT). All cell types investigated show significantly enlarged and furthermore anisotropic MFPTs for diffusion close to the membrane.

9164-31, Session 6

Structuring bacterial biofilms on the single-cell level using optical trapping

Vernita Gordon, Jaime Hutchison, Christopher Rodesney, Karishma Kaushik, Henry Le, Daniel Hurwitz, Yasuhiko Irie, The Univ. of Texas at Austin (United States)

In biofilm infections, changes in bacterial phenotype result from spatial structure and can impact the clinical tractability and outcome. Understanding the role of spatial structure requires methods to control the spatial structure of biofilms. We control the initial positions of bacteria at the begining of biofilm formation by using laser trapping to place single cells on the glass coverslip of a flow cell. The challenge was developing a protocol such that laser trapping does not impinge bacterial viability. We do so by working at minimal oxygen levels and by keeping the time a cell stays in the optical trap to less than three minutes. We demonstrate that trapping has not permanently-altered cell behavior by comparing the doubling times of trapped cells and their descendants to the doubling times of never- trapped cells, for P. aeruginosa and S. aureus, two important human pathogens that form biofilm infections.

Our technique can reveal effects of spatial structure in early biofilm formation that could not be studied using conventional techniques for biofilm culture. We show this for two cases: (1) In an appropriate culture environment, P. aeruginosa in small clusters grow 15% faster than non-clustered P. aeruginosa (p-value <0.0001). (2) A few P. aeruginosa cells increase the doubling time of S. aureus by 10% (p-value 0.06).

Because the laser trap we use is very basic and the other equipment required is inexpensive and standard, we believe that our technique will be a widely-usable tool for biological and physical collaborators at many types of institutions.

9164-32, Session 6

Tailored manipulation of rod-shaped bacteria and adhesive cellular clusters with tug-of-war optical tweezers

Anna S. Bezryadina, San Francisco State Univ. (United States); Daryl C. Preece, The Univ. of Queensland (Australia); Zhigang Chen, Joseph C. Chen, San Francisco State Univ. (United States)

In this work we demonstrate a new approach to achieve stable in-plane optical trapping and full control of rod-shaped bacteria. This approach is based on specially designed "tug-of-war" optical tweezers which better match bacteria morphology and thus require less trapping power. Such "tug-of-war" tweezers avoid the problem of flipping or self-aligning of rod-shaped objects inevitable in conventional dual trap tweezers. More importantly, these optical tweezers can be used simultaneously as an optical stretcher, applying a tunable lateral pulling force to a cell or a cell cluster with better stability and larger lateral forces. Both scattering and gradient forces work in pulling bacteria apart. In particular, we demonstrate that the pulling force is strong enough to break up strongly adhesive cellular clusters of bacteria in aqueous media. For example, S. meliloti cells nominally are about 2 ?m long in rod shape, but different chemicals and structures are generated during specific growth periods which allow the bacteria to adhere to each other and form long clusters of cells. With the "tug-of-war" tweezers, we can identify the strong and weak clustering of S. meliloti cells as a function of the growth media and/or different pH levels. Our approach may help to reveal new perspectives on bacterial cellular clustering and aggregation, and the "tug-of-war" optical tweezers may find a variety of applications in studying cellular viscoelasticity, cell motility, and intercellular interactions.

9164-33, Session 6

The Pocketscope: a spatial light modulator based epi-fluorescence microscope for optogenetics

Anna Linnenberger, Univ. of Colorado (United States); Rafael Yuste M.D., Darcy Peterka, Columbia Univ. (United States); Sean Quirin, Columbia University (United States)

Microscopy with spatial light modulators (SLMs) enables use of optical techniques to study neuronal circuit activity, allowing the ability to both monitor and manipulate the activity of neuronal ensembles, in vitro and in vivo. In this paper we present a portable (22 cm x 42.5 cm x 30 cm), SLM-based epi-fluorescence upright microscope ("Pocketscope"). The core of this technology takes advantage of algorithms and techniques developed for holographic optical tweezers. However, the tool is no longer used to manipulate the position of objects within a 3D volume. Instead the volume of focal points are used as an enabling tool to probe and manipulate neural circuits in the brain. Here we describe the implementation of the instrument, and demonstrate 3D calcium imaging of neurons in brain slices.

9164-34, Session 6

Optical heating of Gold Nanoparticles as a Tool for investigating Membrane Phase Behavior

Thomas Andersen, Univ. of Copenhagen (Denmark); Azra Bahadori, Dino Ott, Univ of Copenhagen (Denmark); Anders Kyrsting, Univ. of Copenhagen (Denmark); Nader S Reihani, Univ of Copenhagen (Denmark) and Department of Physics, Sharif University of Technology, Teheran 11365- 9161, Iran (Iran, Islamic Republic of); Poul M. Bendix, Univ. of Copenhagen (Denmark)

Cell membranes show great heterogeneity with laterally organized ordered and disordered nanoscale domains. The functional importance for cells to dynamically organize the membrane into domains of different order could be to transiently cluster signaling proteins in a nanoscale environment to facilitate chemical reaction between membrane proteins by proximity. The transient nature of so called ordered raft domains makes it difficult to study dynamic phase behavior of cell membranes. We have developed a new assay to create local phase changes in Giant Unilamellar lipid Vesicles (GUVs) by using an optically trapped gold nanoparticle to locally heat the lipid membrane and induce a phase transition. Membrane phase transitions can be rapidly turned on and off by controlling the laser power or the distance between the heated nanoparticle and the membrane. By using phase sensitive fluorophores we can clearly detect the size of the region that has undergone a phase transition. By using a self-quenched dye encapsulated within the GUV we are able to detect single permeation events, associated with the locally melting membrane, when the encapsulated dye de-quenches into the extravesicular solution. Importantly, our results reveal that a phase transition in a lipid bilayer is associated with transient and localized permeation having similar lifetimes as ion channel conductance measured in patch clamp experiments on cell membranes.

9164-35, Session 7

Quad stereomicroscopy

Rebecca F. Hay, Graham M. Gibson, Michael P. Lee, Miles J. Padgett, David B. Phillips, Univ. of Glasgow (United Kingdom)

Stereomicroscopy enables a sample to be imaged from directions directions simultaneously by using two illumination sources, which allows the tracking of microscopic objects in three dimensions.

In stereomicroscopy, each illumination direction produces an individual image, which would normally be combined into one single image that is viewed in the imaging plane. By placing a spatial light modulator (SLM) in the Fourier plane of the stereomicroscope, it is possible to separate these multiple images. By performing 2-dimensional image tracking analysis on each image, the 3-dimensional coordinates of an object can be recovered using parallax. This is powerful technique when combined with Holographic Optical Tweezers, as multiple trapped objects can be tracked in three dimensions without the need for calibration images.

We now plan to extend this to four different illumination directions, quad stereomicroscopy. This gives a direct measurement of the error in particle tracking. We use the SLM again to separate the four images. There is also a fifth on axis illuminator, for observing the undistorted 2D image, while the quad illumination is simultaneously used to obtain the 3D information.

We investigate how changing the angle between the illumination and sample affects 3D tracking in the system, and determine the optimum angle for stereomicroscopic tracking.

9164-36, Session 7

Enabling accurate photodiode detection of multiple optical traps by spatial filtering

Dino Ott, Niels Bohr Institute (Denmark); S. Nader S. Reihani, Sharif Univ. of Technology (Iran, Islamic Republic of) and Niels Bohr Institute (Denmark); Lene B. Oddershede, Niels Bohr Institute (Denmark)

Dual and multiple beam optical tweezers allow for advanced trapping geometries beyond single traps, however, these increased manipulation capabilities typically come at the price of more challenging position and force detection. The accuracy of position and force measurements is often compromised by crosstalk between the detected signals, this crosstalk leading to a systematic error on the measured forces and distances. This is true both for dual-beams optical traps and multiple beam optical traps. In a dual-beam optical trapping facility, the two traps are often orthogonally polarized and cross-talk can be minimized by inserting polarization optics in front of the detector, however, this method is not perfect because of the de-polarization of the trapping beam introduced by the required high numerical aperture optics. Here we present an easy-to-implement simple method to efficiently eliminate cross-talk both in dual beam and multiple beam setups. The method is based on spatial filtering and is highly compatible with standard back-focal plane photodiode based detection of position and force. In a dual-beam setup, our spatial filtering method reduces cross-talk up to 500 percent better than polarization filtering alone. The methodology here proposed enables fast, easy, and convenient photodiode detection of forces and distances in multiple trapping platforms and significantly improves the accuracy of force-distance measurements, e.g., of single molecules, hence providing much more scientific value for the experimental efforts.

9164-37, Session 7

A force measurement instrument for optical tweezers based on the detection of light momentum changes

Arnau Farré Flaquer, Ferran Marsà Samper, Mario Montes Usategui, Impetux Optics, S.L. (Spain) and Univ. de Barcelona (Spain)

In optical tweezers, forces are typically determined by virtue of the linear relation between force and sample displacement, which requires the calibration of the system to obtain the conversion factor between both magnitudes. Unfortunately, the calibration depends in a strong manner on the physical properties of the sample and needs hence to be determined prior to performing an experiment. An alternative solution is based on the detection of the momentum change of the trapping beam, a much less used approach because of the practical difficulties in its implementation. The force is a magnitude that cannot typically be obtained through a direct measurement but it is more often derived from an additional quantity, such as the position. Following the direct route, by contrast, has multiple advantages as force is determined from first principles and provides therefore a direct access to this information. For example, once the instrument is calibrated, forces are measured regardless of the nature of the sample, or without requiring an in situ calibration. Here, we present a force sensor instrument based on this method, which, although originally devised for counter-propagating beams, can be

adapted to operate with optical tweezers. The developed instrument incorporates technical solutions that overcome the practical difficulties when the momentum method is implemented. We specifically show the requirements that an instrument based upon this method must fulfill in order to operate with single-beam gradient traps, as well as the optical and electronic improvements needed to obtain a high-precision force calibration, which is constant and permanent.

9164-38, Session 7

Optical tweezers escape forces

Ann A. M. Bui, Alexander B. Stilgoe, The Univ. of Queensland (Australia); Nima Khatibzadeh, Beckman Laser Institute and Medical Clinic (United States); Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia); Michael W. Berns, Univ. of California, Irvine (United States)

Optical tweezers can be used to measure forces within microscopic environments.To do this, the optical trap needs to be calibrated. Two quantities are of most interest: the spring constant, and the maximum force exerted by the trap. The latter is the force required to escape from the trap. One method to determine this is to use viscous drag to remove a particle from the trap, typically by moving the stage. The stage velocity required to remove the particle then gives the escape force. However, the escape force can vary by up to 30%, depending on the particle trajectory. This is seen in experiments in different laboratories, and further confirmed by simulation. This can have significant quantitative impact on measurements. We describe the variation of escape force and escape trajectory, using both experimental measurements and simulations, and discuss implications for experimental measurement of forces.

9164-39, Session 7

A new technique for high sensitive detection of rotational motion in optical tweezers by a differential measurement of backscattered intensity

Basudev Roy, Sudipta K. Bera, Argha Mondal, Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

Asymmetric particles, such as biological cells, often experience torque under optical tweezers due to birefringence or unbalanced scattering forces, which makes precise determination of the torque crucial for calibration and control of the particles. The estimate of torque relies on the accurate measurement of rotational motion, which has been achieved by various techniques such as measuring the intensity fluctuations of the forward scattered light [1], or the polarization component orthogonal to the trapping light polarization in plasmonic nanoparticles [2] and vaterite crystals [3]. Here we present a simple yet high sensitive technique to measure rotation of such an asymmetric trapped particle where the scattered light is elongated in shape by detecting the light backscattered onto a quadrant photodiode, and subtracting the signals along the two diagonals of the quadrants. This automatically suppresses the common mode translational signal obtained by taking the difference signal of the adjacent quadrants, while amplifying the rotational signal. Using this technique, we obtain a S/N of 200 for angular displacement of a trapped micro-rod by 5 degrees, which implies a sensitivity of 50 mdeg with S/N of 2. We also detect the rotational Brownian motion of red blood cells which acquire a small form birefringence and asymmetric shape when placed in a hypotonic NaCl solution, leading to the rotational component that may be too weak to detect by polarization dependent detection techniques. The technique is thus independent of birefringence and polarization properties of the asymmetric particle and depends only on the scattering cross-section.

Optical tweezers calibration with Bayesian inference *(Invited Paper)*

Maximilian U. Richly, Silvan C. Türkcan, Ecole Polytechnique (France); Antoine LeGall, Nicolas Fiszman, Lab. Charles Fabry (France); Jean-Baptiste Masson, Institut Pasteur (France); Nathalie Westbrook, Karen Perronet, Lab. Charles Fabry (France); Antigoni Alexandrou, Ecole Polytechnique (France)

We present a new method for calibrating an optical-tweezer setup that is based on Bayesian inference [Richly et al., Opt. Express 2013]. This method employs an algorithm previously used to analyze the confined trajectories of receptors within lipid rafts [Türkcan et al., Biophys. J. 2012]. The main advantages of this method are that it does not require input parameters and is insensitive to systematic errors like the drift of the setup. Additionally, it exploits a much larger amount of the information stored in the recorded bead trajectory than standard calibration approaches. The additional information can be used to detect deviations from the perfect harmonic potential or detect environmental influences on the bead. The algorithm infers the diffusion coefficient and the potential felt by a trapped bead, and only requires the bead trajectory as input. We demonstrate that this method outperforms the equipartition method and the power-spectrum method in input information required (bead radius and trajectory length) and in output accuracy. Furthermore, by inferring a higher order potential our method can reveal deviations from the assumed second-order potential. More generally, this method can also be used for magnetic-tweezer calibration.

9164-41, Session 8

STED nanoscopy combined with optical tweezers reveals protein dynamics on densely covered DNA

Iddo Heller, Gerrit Sitters, Onno D. Broekmans, Géraldine Farge, Vrije Univ. Amsterdam (Netherlands); Carolin Menges, Wolfgang Wende, Justus-Liebig-Univ. Giessen (Germany); Stefan W. Hell, Max-Planck-Institut für Biophysikalische Chemie (Germany); Erwin J. G. Peterman, Gijs J. Wuite, Vrije Univ. Amsterdam (Netherlands)

Dense coverage of DNA by proteins is a ubiquitous feature of cellular processes such as DNA organization, replication and repair. We present a single-molecule approach capable of visualizing individual DNA-binding proteins on densely covered DNA and in the presence of high protein concentrations. Our approach combines optical tweezers with multicolor confocal and stimulated emission depletion (STED) fluorescence microscopy. Proteins on DNA are visualized at a resolution of 50 nm, a sixfold resolution improvement over that of confocal microscopy. High temporal resolution (<50 ms) is ensured by fast one-dimensional beam scanning. Individual trajectories of proteins translocating on DNA can thus be distinguished and tracked with high precision. We demonstrate our multimodal approach by visualizing the assembly of dense nucleoprotein filaments with unprecedented spatial resolution in real time. Experimental access to the force-dependent kinetics and motility of DNA-associating proteins at biologically relevant protein densities is essential for linking idealized in vitro experiments with the in vivo situation.

9164-42, Session 8

DNA origami based assembly of gold nanoparticle dimers for surface-enhanced Raman scattering

Vivek Thacker, Lars O. Herrmann, Daniel O. Sigle, Univ. of Cambridge (United Kingdom); Tao Zhang, Tim Liedl, Ludwig-Maximilians-Univ. München (Germany); Jeremy J. Baumberg, Ulrich F. Keyser, Univ. of Cambridge (United Kingdom)

Plasmonic sensors are extremely promising candidates for label-free single molecule analysis but require exquisite control over the physical arrangement of metallic nanostructures. We employ self-assembly based on the DNA origami technique[1] for accurate positioning of individual gold nanoparticles. Our innovative design leads to strong plasmonic coupling between two 40 nm gold nanoparticles reproducibly held with gaps of 3.3 ± 1 nm. This is confirmed through far field scattering measurements on individual dimers which reveal a significant red shift in the plasmonic resonance peaks, consistent with the high dielectric environment due to the surrounding DNA. We use surface enhanced Raman scattering (SERS)[2] to demonstrate local field enhancements of several orders of magnitude through detection of a small number of dye molecules as well as short single-stranded DNA oligonucleotides. This demonstrates that DNA origami is a powerful tool for the high-yield creation of SERS-active nanoparticle assemblies with reliable sub-5 nm gap sizes.

9164-43, Session 8

Optical tweezers for free-solution label-free single bio-molecule studies

Abhay Kotnala, Ahmed Al-Balushi, Reuven Gordon, Univ. of Victoria (Canada)

Nanoaperture based trapping has developed as a significant tool among the various optical tweezer systems for trapping of very small particles down to the single nanometer range. The double nanohole aperture based trap provides a method for efficient, highly sensitive, label free, low cost, free solution single molecule trapping and detection. We use the DNH tweezer to understand biomolecular phenomena like protein unfolding, binding, structural conformation of DNA, protein-DNA interactions, and protein small molecule interactions. Statistical analysis of the trapping data is used for sensing the concentration and sizes of particles in a heterogeneous solution. The transient and Brownian fluctuation of the trapped particle is used to evaluate the efficiency of the trap and also further used to study the protein-binding interactions. The DNA binding interaction with a proteins is studied and quantitative evaluation of binding energies is shown. Extending this work to protein-interactions is of great interest for basic understanding of life function and for drug discovery applications

9164-44, Session 9

The electrostatic fluidic trap: a new approach to the spatial control and manipulation of matter at the nanometer scale

Madhavi Krishnan, ETH Zürich (Switzerland)

We have demonstrated that single nanoscale objects in solution can be trapped in three dimensions in a fluidic nanoslit, without the application of external forces. Tailoring the geometry of the walls of the slit gives rise to an electrostatic free energy landscape, where local potential wells passively and stably confine single charged entities for long periods. As the method relies solely on net charge, objects that offer little dielectric contrast in a given medium, e.g. aqueous lipid vesicles in water, may easily be trapped by this method.

Relating the statistical properties of a trapped object's motion to a free energy calculation permits a direct measurement of its charge. Thus we predict the ability to measure single charge fluctuations on a particle carrying upto around 50 charges with millisecond time resolution by this method. Furthermore, in addition to spatial trapping, we have demonstrated that the geometry of the potential well can be used to control the orientiation of individual anisometric objects such as nanorods.

We further demonstrate the experimental realization of a levitation based nanophotonic switch that can be operated in both volatile and non-volatile modes. A plasmonic nanorod trapped in a bistable angular potential well and illuminated with light polarized along its long-axis fluctuates between two states – bright and dark. Application of an external electrical or optical field rapidly switches a single nanorod between the ON and OFF states, thus opening doors to soft-matter based digital photonic devices.

Metal/dielectrique structures fabrication using the photomechanical properties of azobenzene molecule

Nicolas Desboeufs, Anh-Duc Vu, Thierry Gacoin, Jacques Peretti, Yves Lassailly, Khalid Lahlil, Ecole Polytechnique (France)

Photochromic materials containing azobenzene derivatives exhibit spectacular photomechanical properties which allow controlling the formation of surface structures upon illumination in the chromophore visible absorption band. An impressive example is the significant light induced surface mass transport that can be observed on nano to micrometer scales.

Size and shape of the photo-induced surface pattern can be easily tailored over a large scale ranging from a few tens of nanometers up to several microns by controlling the projected optical pattern. These systems can be used in various technological applications, including holographic recording, photo-mechanics, diffraction optics, and micro- or nano-patterning.

Here, we use azobenzene containing films as photoactive layer for a one-step, non-contact and non-destructive lithography process. Using this technique we will show that, metal/dielectric hybrid 1D or 2D structures can be elaborated whose optical and mechanical properties can be controlled by light. Azobenzene molecules are inserted in PMMA or sol-gel matrices and deposited on glass substrate by spin-coating. Combining holographic patterning of the photochromic film with metal deposition under grazing incidence,, various surface patterns can be elaborated over large area. Considering that large absorption from the azo chromophore is a strong limitation for optical investigations, an original technique has been developed to remove completely the azobenzene chromophore while preserving the lithographic structuration of the films

Such hybrid system exhibits specific and intriguing optical and plasmonic properties. Both far field and near-field measurements are subsequently performed using angular resolved reflection spectroscopy and Scanning near-field microscopy (SNOM). Surface plasmon coupling and propagation can be tuned by adjusting the parameters of the structures at subwavelength scale. The experimental results are supported by electromagnetic modeling. Our results demonstrated a promising technique to reversibly elaborate nanostructured surface with tunable plasmonic properties.

9164-46, Session 9

Micron-scale motions from molecular-scale photochemistry

Christopher J. Bardeen, Univ. of California, Riverside (United States); Rabih Al-Kaysi, King Abdulaziz City for Science and Technology (Saudi Arabia) and King Abdullah International Medical Research Ctr. (Saudi Arabia); Lingyan Zhu, Taehyung Kim, Univ. of California, Riverside (United States)

Optical trapping and radiation forces allow light to directly exert forces on microscopic objects. An alternative approach is to transform light into chemical energy and use molecular motions to generate mechanical work. By assembling molecules into ordered crystals, sub-nanometer motions generated by photochemical reactions can be synchronized to produce displacements on the micron scale. By manipulating crystallization conditions, it is possible control the size and shape of crystals composed of photochemically reactive molecules. When these crystals are exposed to light, the aligned molecules undergo photochemical reactions that can drive dynamic shape changes of the crystal. If the photochemical reaction is reversible, the overall shape changes can also be reversible. Using a variety of methods, we prepare different classes of single crystal shapes, including nanowires, micro-ribbons, and micro-needles. Depending on the nature of the photochemical reaction, the shape of the crystal, and the orientation of the molecules within the shaped crystal, different types of motions can be induced by photoexcitation, including expansion, bending, twisting, and curling.[1] Micron and nanometer-scale structures that undergo well-defined shape changes when exposed to light could have applications as actuators or as components of nanoscale machines.

9164-47, Session 10

On-chip photonic tweezers: integrated tools for optical trapping, self-assembly and micromanipulation

Christophe Pin, Claude Renaut, CEA Grenoble (France) and Univ. de Bourgogne (France); Emmanuel Picard, CEA Grenoble (France); David Peyrade, Ctr. National de la Recherche Scientifique (France); Emmanuel Hadji, CEA Grenoble (France); Frédérique de Fornel, Ctr. National de la Recherche Scientifique (France) and Univ. de Bourgogne (France); Benoit Cluzel, Univ. de Bourgogne (France)

In order to design future lab-on-a-chip, integrated optofluidic tools for trapping and manipulation of micro- and nano-objects are needed [1-4]. Following the example of free-space optical tweezers, this work aims at developing on-chip optical tweezers based on resonant photonic nanostructures. Optofluidic chips with integrated photonic tweezers are fabricated by adding a polydimethylsiloxane (PDMS) microfluidic channel on top of silicon-on-insulator (SOI) photonic "nanobeam" cavities [5]. The light resonance inside such photonic crystal cavities leads to a high spectral and spatial confinement of the electromagnetic field. This light confinement generates strong and localized near-field gradient forces that enables optical trapping and self-assembly of microparticles [6]. By coupling several cavities, spectral and spatial characteristics of resonant modes can be tailored in order to translate or rotate microparticles [7].

Particle tracking is used to study the trapping efficiency of the fabricated photonic tweezers. In the case of polystyrene microspheres 1µm in diameter, a lateral stiffness of 5 pN.µm-1 is measured, whereas it is found to decrease to 0.5 ± 0.1 pN.µm-1 along the waveguide axis. In addition, the trap is proved to resist to a lateral fluidic force of typically 10-1pN.

We also propose a new characterisation method based on the influence of a trapped particle on the cavity resonance. The guided signal transmitted by the cavity shows a different correlation time depending on the particle motion. This property is used to distinguish particles of different size and is investigated as a valuable integrated method to characterise the trapping efficiency of photonic tweezers.

Investigations of the dynamics of resonantly trapped nanospheres in a hollow photonic crystal cavity

Mario Tonin, Nicolas Descharmes, Ulagalandha Dharanipathy, Romuald Houdré, Flavio M. Mor, Sylvia Jeney, László Forró, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Photonic crystal cavities (PhC) have the ability to confine light in very small mode volumes, allowing them to generate strong gradient forces. Particularly, bidimensional hollow photonic crystal cavities (HPhC) allow a strong overlap between the optical field gradient and the open space, allowing trapping at very low power level [1]. The interaction between the trapped object and the optical field generates remarkable features such as self-trapping and back-action [1]. Nanospheres with diameter less than 500 nm are trapped with less than 100 µW of guided power. These HPhC consist of silicon structures, immersed in water using a thin microfluidic layer on top, which allows us to image and record the position of the nanosphere in the cavity through the perturbation of the emitted cavity field.

Here we characterize the influence of the nanosphere size on its dynamics within the trap. Other parameters such as the material of the nanosphere, the Q-factor and the power that is coupled in the cavity are also investigated. The force exerted on the particle is derived and compared to the existing trapping techniques. Finally, we show the possibility to control the number of nanoparticles trapped in the cavity as well as to trap particles selectively regarding its size and index, which is cumbersome to achieve with standard optical tweezers.

Inducing forced and auto oscillations in one-dimensional photonic crystals with light

J. Eduardo Lugo, Rafael Doti, Jocelyn Faubert, Univ. de Montréal (Canada); Noemi Sanchez, Facultad de Ciencias Físico Matemáticas, Benemérita Universidad Autónoma de Puebla, Av. San Claudio (Mexico)

Optical tweezers is an example how to use light to generate a physical

force. They have been used to levitate viruses, bacteria, cells, and sub cellular organisms. Nonetheless it would be beneficial to use such force to develop a new kind of applications. However the radiation pressure usually is small to think in moving larger objects. Currently, there is some research investigating novel photonic working principles to generate a higher force. Here, we studied theoretically and experimentally the induction of electromagnetic forces in one-dimensional photonic crystals when light impinges on the off-axis direction. The photonic structure consists of a micro-cavity like structure formed of two one-dimensional photonic crystals made of free-standing porous silicon, separated by a variable air gap and the working wavelength is 633 nm. We show experimental evidence of this force when the photonic structure is capable of making auto-oscillations and forced-oscillations. We measured peak displacements and velocities ranging from 2 up to 35 microns and 0.4 up to 2.1 mm/s with a power of 13 mW.

9164-50, Session 11

New techniques in optical trapping and sensing

Lulu Liu, Harvard School of Engineering and Applied Sciences (United States); Alexander J. Woolf, Harvard Univ. (United States); Federico Capasso, Harvard School of Engineering and Applied Sciences (United States)

Total internal reflection microscopy is a powerful technique for high resolution sensing near the interface of two dielectrics where a probe particle is allowed or made to move within the evanescent field region generated by total internal reflection. The probe particle, or cell, whatever is being imaged, scatters light by total internal reflection, which gives away its separation from the interface with nanometer precision if the intensity-position relation is known. Current methods for obtaining this relation are cumbersome: generally requiring either a replacement of the system in question with an approximately equivalent analog for which distances are known and controlled, or requiring even further knowledge of parameters such as viscosity, temperature, and mass of the particle. We propose and demonstrate an in situ calibration technique which acts on the actual experimental probe, under actual experimental conditions, with the use of a piezo-controlled optical tweezer, and demonstrate how this calibration fits into a TIRM (or other) measurement.

Additionally, anticipating the usual difficulties performing any kind of tweezing or sensing in the vicinity of a metallic surface due to back reflections and other optical field perturbations, we propose and demonstrate the effectiveness of an ultra-thin anti-reflection coating incorporating the metal itself. We show that in this design the metal interface is maintained, so desired surface chemistry, electrical and thermal conductivity, surface plasmon effects, etc. are generally unchanged, while field perturbations and measurement errors due to back reflections are largely eliminated. We hope this design will enable exciting research in an area which has so far not been extensively investigated.

9164-51, Session 11

Optical trapping of nanoscale plasmonic optical lattice in microfluidic environments

Ya Tang Yang, Jer-Shing Huang, Chia Chun Hung, National Tsing Hua Univ. (Taiwan)

Recent advances in optical manipulation have made it an ideal tool to create one, two, and three dimensional periodic optical potential. Such periodic potentials have found interesting technological and fundamental applications such as micro particle sorting and optical fractionation. Plasmon enhanced optical trapping techniques using metallic nanostructures can overcome the diffraction limits of far-field optical trap techniques and therefore permit trapping of nanoparticle with deep sub wavelength dimensions. Here we report the trapping of nanoparticles for a plasmon-enhanced two dimensional optical lattice. The density of the traps is ~20 times higher than previously reported optical lattice trapping based on holographic techniques. We observe the transport of (both single and multiple) nanoparticles over such an optical lattice. In addition, we will report the experimental progress toward integration of plasmon optical lattice with microfluidic chip. Such an integrated device allows the directional control of nano particles and provides a suitable platform for stochastic transport experiment such as nanoscale optical sorting. Compared to typical holographic techniques based on focusing optics, the plasmonic optical lattice requires much less optical power and is very suitable for lab-on-a-chip applications. Finally, the plasmonic optical lattices, when properly scaled down, will ultimately enable atomic physicists to study novel many-body physics problems.

9164-52, Session 11

Promoting optofluidic actuation of microparticles by plasmonic nanoparticles tagging

Jean-Pierre Delville, Julien Burgin, Univ. Bordeaux 1 (France); Satyabrata Si, Council for Scientific and Industrial Research (India); Marie Helene Delville, Institut de Chimie de la Matière Condensée de Bordeaux (France)

The amplitude of optical forces on flowing dielectric microparticles can be actuated by coating them partially with metallic nanospheres and laser light exposition within the surface plasmon resonance. Here, optical forces on both pure silica particles and silica-gold raspberries are characterized within an optical chromatography setup by measuring the Stokes drag versus laser beam power. Results are compared to the Mie theory prediction for both pure dielectric particles and core-shell ones where the shell is described as a continuous dielectric-metal composite of dielectric constant determined from the Maxwell Garnett approach. The nice observed quantitative agreement demonstrates that radiation pressure forces are directly related to the metal concentration present at the microparticle surface and that nano-metallic objects increase indeed the magnitude of optical forces by several factors compared to pure dielectric particles of the same overall size, even at very low metal concentration. Behaving as “micro-sized nanoparticles”, the benefit of microparticles coated with metallic nanospheres is thus twofold: (i) to enhance optofluidic manipulation and transport at the microscale and, (ii) to increase sensing capabilities at the nanoscale, compared to separated pure dielectric particles and single metallic nanosystems.

Using dark field spectroscopy to measure dynamics and coupling of multiple nanoparticles in a single optical trap

Ana Andres-Arroyo, Wen Jun Toe, Scott Kemp, Fan Wang, Peter J. Reece, The Univ. of New South Wales (Australia)

In the following study we investigate the coupling dynamics and self-organisation of multiple metallic nanoparticles held in a single gradient force optical trap. The use of dark field spectroscopy combined with optical tweezers allows us to probe the localized plasmon resonance (LSPR) spectrum of single and interacting nanoparticles, which provides a highly sensitive probe for sub-diffraction limited motion.

Interacting metallic nanoparticle within an optical field have been explored in a number of optical geometries [1-2] and have a demonstrated tendency to self-organize into particular stable configurations. In some instances these mutual scattering interactions can produce optical binding forces that much greater than the external trapping potential. For the standard gradient force trap resolving interacting particle dynamics is particularly challenging as particle separations are well below the diffraction limit of conventional optical imaging systems.

Near-field optical coupling between adjacent plasmonic particles leads to spectral changes that are dependent on inter-particle spacing as well as the orientation of the scattering objects with respect to the detection system. By trapping two particles independently within separate traps and then letting them combine allows both single LPSR spectra can be recorded before combining them in a single trap. The coupled-particle LSPR occurs at a frequency that is shifted from the single-particle LSPR frequency. Using a double well potential using two separate traps can also lead transient coupling where two-particle hop between coupled and uncoupled states.

9164-54, Session 11

Dynamic plasmonic trapping and manipulation of metallic particles for SERS application

Changjun Min, Wei Shi, Yuquan Zhang, Junfeng Shen, Xiaocong Yuan, Nankai Univ. (China)

We introduce a novel plasmonic tweezers for trapping and manipulating metallic particles and its application on Surface-enhanced Raman scattering (SERS). In the first part, we discuss the interaction mechanism between metallic particles and surface plasmons (SPs) in the plasmonic tweezers excited by a focused radially polarized beam. We show that metallic particles of nanometer to micrometer sizes can be attracted and trapped in such plasmonic tweezers instead of being repulsed by a conventional optical tweezers due to high scattering force. Through numerical analysis, we find that the resultant total force in the plasmonic tweezers is the result not of a stronger gradient force dominating an opposing scattering force, but instead of a dominant gradient force assisted by a weak scattering force acting in the same direction. Then we consider manipulating the metallic particles by modifying the incident beam properties in the plasmonic tweezers. The optical vortices (OV) are chosen to excite the plasmonic vortices and rotate particles in the plasmonic tweezers. We show that metallic particles in plasmonic vortices can be trapped and rotated in a certain radius according to OV's topological charge, due to the optical force provided by the orbital angular momentum (OAM). Finally, we introduce the application of the plasmonic tweezers in SERS. By trapping and dragging a single gold nanoparticle with the plamonic tweezers, we demonstrated a dynamic single-particle-film SERS system, which produces a SERS enhancement factor of ~109, and therefore provides a promising approach to controllable SERS detection and imaging.

9164-55, Session 11

Photothermal heating of silicon nanowires in a single-beam laser trap

Paden B. Roder, Bennett E. Smith, E. James Davis, Peter J. Pauzauskie, Univ. of Washington (United States)

A theoretical model is developed here in tandem with single-beam laser trapping experiments to elucidate the effects of the numerous thermal, optical, and geometric parameters that affect internal temperature distributions within finite nanowires (NWs) during laser irradiation. Analytical solutions to the heat-transfer equation are presented to predict internal temperature distributions within individual nanowires based on numerical calculations of the internal electromagnetic heat source. A new method to extract temperatures of trapped particles during single-beam laser trapping experiments is presented and is used to measure photothermal heating of silicon NWs (SiNWs). Silicon has received little attention to date for photothermal heating applications due to its indirect band gap and low absorption coefficient in the near-infrared tissue-transparency window. We also show that phosphorus ion implantation may be used to increase the optical absorption of SiNWs, leading to significant heating to temperatures greater than 42 °C in an aqueous environment at an irradiance of 3 MW/cm2. Experimental observations of photothermal heating agree well with theoretical predictions. Calculations for comparison with amorphous carbon NWs reveal significantly greater heating effects, as well as internal radial gradients not observed for SiNWs.

9164-56, Session 11

Anomalous dynamic behaviour of optically trapped high aspect ratio nanowires

Wen Jun Toe, Ignacio Ortega Piwonka, Christopher Angstmann, The Univ. of New South Wales (Australia); Hark Hoe Tan, Chennupati Jagadish, The Australian National Univ. (Australia); Bruce I. Henry, Peter J. Reece, The Univ. of New South Wales (Australia)

In the following presentation we experimentally investigate apparent anomalous dynamic behaviour of high aspect ratio nanowires held in a single gradient force optical tweezers. Power spectrum analysis performed on the stochastic trajectory of the optically trapped nanowires indicates that, under certain circumstances, nanowires undergo oscillatory motion analogous to underdamped systems. This motion is characterised by a broad resonance peak of the order of 1 kHz. Auto-correlation measurements confirm a pronounced ringing signature on the millisecond time scales. We investigate the dependence of the peak frequency as a function of optical trapping powers, polarisation, nanowire length and trapping height above the coverslip. We discuss the emergence of resonant behaviour in the context of different possible driving mechanisms, including hopping between local minima and coupling between translation and rotational motion, and first-order non-conservative behaviour arising from the low symmetry of the nanowires.

9164-57, Session 11

Optical trapping with pillar bowtie nanoantennas

Hao Chen, Qing Ding, Brian J. Roxworthy, Abdul M Bhuiya, Kimani C. Toussaint Jr., Univ. of Illinois at Urbana-Champaign (United States)

Plasmonic nanoantennas make effective optical tweezers, owing to their characteristic field enhancement and confinement properties which produce large near-field intensity gradients. The trapping dynamics of plasmonic nanotweezers are strongly affected by their resonant optical absorption, which can produce significant heating and induce rapid convective flows in the surrounding fluid medium. We here consider a new class of plasmonic nanotweezers based on an elevated bowtie nanoantenna (BNA) geometry, whereby BNAs are suspended on optically transparent, 500-nm tall silica pillars. We discuss how the plasmonic properties of these pillar-BNAs (p-BNAs) can be manipulated in large areas of 80 x 80-micron or at the level of an individual p-BNA using either a low-power input optical beam or electron-beam, respectively. This modification in local plasmonic properties is expected to result in a much more complex optical trapping landscape. We also find that the temperature increase in the p-BNAs is more than 10x higher than in comparable substrate-bound structures (for the same input intensity), in which the substrate acts as a heat sink that mitigates temperature increase, and we investigate the role of this enhanced thermo plasmonic heating on plasmonic trapping dynamics.

9164-58, Session 12

Active matter transport on complex landscapes

Cynthia J. Olson Reichhardt, Los Alamos National Lab. (United States); Dipanjan Ray, Los Alamos National Lab. (United States) and Univ. of Notre Dame (United States); Charles M. Reichhardt, Los Alamos National Lab. (United States)

Systems containing self-motile or self-driven particles are commonly referred to as active matter systems, and include swimming bacteria, crawling cells, flocks of animals, and even pedestrian motion. Recently a number of experimental groups have successfully created non-biological active matter with techniques such as light-activated colloids. These systems can exhibit a wealth of nonequilibrium behaviors including clustering, flocking, anomalous diffusion, and pattern formation. Existing studies have generally focused on active matter interacting with a smooth substrate; however, in the wild, active biological matter generally moves through complex environments. Additionally, many applications of colloidal active matter systems will require the particles to interact with a disordered environment. Many studies of non-active colloids examined the effect on the colloidal ordering or dynamics of a periodic or disordered landscape created using optical trapping techniques. Similar techniques could be employed to generate complex substrates for active matter systems. Here we show how the introduction of a random landscape can shift the onset of the clustering phase of active matter systems. In the absence of a substrate, increasing the activity of the system normally increases the mobility; however, when obstacles are present in the landscape, we find that there is an optimal activity level at which the highest particle mobility can be achieved. These results suggest that biological systems may have optimized their activity level in order to move through complex environments.

9164-59, Session 12

Targeted delivery of colloids by swimming bacteria

Roberto Di Leonardo, Nikolaos Koumakis, Consiglio Nazionale delle Ricerche (Italy); Alessia Lepore, Univ. degli Studi di Roma Tre (Italy); Claudio Maggi, Univ. degli Studi di Roma La Sapienza (Italy)

The possibility of exploiting motile microorganisms as tiny propellers represents a fascinating strategy for the transport of colloidal cargoes. However, delivery on target sites usually requires external control fields to steer propellers and trigger cargo release. The need for a constant feedback mechanism prevents the design of compact devices where biopropellers could perform their tasks autonomously. Here we show that holographically fabricated three- dimensional microstructures can define accumulation areas where bacteria spontaneously and efficiently store colloidal beads. The process is stochastic in nature and results from the rectifying action of an asymmetric energy landscape over the fluctuating forces arising from collisions with swimming bacteria. As a result, the concentration of colloids over target areas can be strongly increased or depleted according to the topography of the underlying structures. Besides the significance to technological applications, our experiments pose some important questions regarding the structure of stationary probability distributions in non-equilibrium systems.

9164-60, Session 12

Collective behavior of the optically driven particles on a circular path

Shogo Okubo, Kyushu Univ. (Japan); Shuhei Shibata, Department of Physics, School of Sciences, Kyushu University (Japan); Yasuyuki Kimura, Kyushu Univ. (Japan)

Hydrodynamic interaction is crucial for micrometer-sized objects such as colloids and microorganisms in liquids. Various interesting collective motions including synchronization and rhythmic motion have been reported recently. In this paper, we report experimental study on the collective motion of optically driven particles on a circular path. The micrometer-sized silica colloidal particles are trap on a ring and are forced to rotate with a constant angular velocity by optical vortex which has been realized by a holographic optical tweezers. The characteristic rhythmic motion and the formation of dynamic stable clusters have been observed depending on the number of the particles on a ring and their size.

In the case of the system containing the same-sized particles, a doublet becomes the most stable. When the number of the particles on the ring is even, each of two forms doublet and rotates at constant velocity with almost equal space. On the other hand, when the number of the particles is odd, the formation and decomposition of longer clusters occurs and this induces rhythmic motion. In the case of the system containing different-sized particles, only one or some longer clusters are selectively induced and temporally stable. The final clusters are only determined by the initial arrangement of the particles. These experimental finding are well explained by the simulation with Stokesian hydrodynamics.

9164-61, Session 12

Hydrodynamic synchronisation in arrays of optically controlled rotors *(Invited Paper)*

Simon Hanna, Luke J. Debono, Stuart J. Box, Stephen H. Simpson, Univ. of Bristol (United Kingdom); David B. Phillips, Univ. of Glasgow (United Kingdom)

Hydrodynamic coupling plays a vital role in the coordinated beating of cilia and flagella, and is important for the design of future microscopic machines, artificial swimmers and pumps. In this paper we present a combined theoretical and experimental study of synchronisation effects in two-dimensional arrays of rigid rotors. The rotors are fabricated using 2-photon polymerisation, and are held in an array of optical traps generated using holographic optical tweezers. Rotation is induced by introducing asymmetry either into the optical fields, e.g. with Laguerre-Gaussian beams, or into the shape of the particles. Both the symmetry of the particles and the symmetry of the lattice may be varied, as may the directions of rotation e.g. co-rotating or counter-rotating. The strength of the hydrodynamic coupling, and the resultant synchronisation, is found to depend on all of these factors. Intriguingly, specific couplings are also observed between distant, but symmetrically related, rotors. The mechanisms of phase-locking and synchronisation will be explored and comparisons drawn between theory and experiment.

9164-62, Session 12

Optical trapping and lifting of plasmonic Janus microparticles

Spas N. Nedev, Paul Kühler, Ludwig-Maximilians-Univ. München (Germany); Sol Carretero-Palacios, Ludwig-Maximilians-Univ. München (Germany) and Instituto de Ciencia de Materiales de Sevilla (Spain); Lindsey L. Anderson, Theobald Lohmüller, Jochen Feldmann, Ludwig-Maximilians-Univ. München (Germany)

Janus particles with a plasmonic and a dielectric face have opened up a wide field of applications. Heat generated due to strong absorption of radiation by the metal part can induce an asymmetrical thermal gradient in the environment, which can be employed for self-propulsion in a liquid media. Here we combine this optothermal self-propulsion effect of Janus particles with our methodologies [1, 2] to manipulate gold nanoparticles in focused laser beams.

We explore the balance of optical and thermal forces acting on gold/silica Janus microparticles which are optically trapped in an aqueous medium. By varying the trapping laser power, we see a shift in the particle position as it finds an equilibrium point between the experienced optical and thermal forces, leading to self-propulsion. Lowering laser power leads to relaxation of the Janus particle from this elevated state. Finally, we optically control the distance between a Janus particle and other micro- and nano-objects based on this novel concept. This photonic micron-scale "elevator" might find future applications in thermal force studies as well as in optical micromanipulation experiments.

9164-63, Session 12

3-axis digital holographic microscopy for high speed volumetric imaging

Filippo Saglimbeni, Silvio Bianchi, Univ. degli Studi di Roma La Sapienza (Italy); Roberto Di Leonardo, Consiglio Nazionale delle Ricerche (Italy)

Digital Holographic Microscopy allows to numerically retrieve three dimensional information encoded in a single 2D snapshot of the coherent superposition of a reference and a scattered beam. Since no mechanical scans are involved, holographic techniques have a superior performance in terms of achievable frame rates. On the other hand direct numerical reconstructions usually lead to a poor axial resolution. Here we show that overlapping the three numerical reconstructions obtained by tilted red, green and blue beams results in a great improvement over the axial resolution and sectioning capabilities of holographic microscopy. A strong reduction in the coherent background noise is also observed when combining the volumetric reconstructions of the light fields at the three different wavelengths. We discuss the performance of our technique with two test objects: an array of four glass beads optically trapped along the optical axis and a swimming rod shaped E. coli bacterium.

9164-64, Session 13

Maxwell´s demon with optical tweezers

Regina K. Schmitt, Heiner Linke, Jonas Johansson, Lund Univ. (Sweden)

Ever since Maxwell proposed his Gedankenexperiment in 1871 it has had great impact in theoretical physics but its experimental realization is after 250 years still an ongoing challenge. Optical tweezers have proven to be a very powerful tool in various fields where biophysics is the most prominent. In this investigation we use optical tweezers in order to realize a Maxwell´s Demon. A major step in that direction has already been undertaken by Toyabe et al [Nature Physics 6 (2010) 988]. However, our approach offers the opportunity to investigate a Maxwell´s Demon in its purest form, where the effect of applied work can be avoided. Our system is based on a feedback controlled optical line trap, realized using an acousto optical deflector, restricting the thermal motion of a silicon bead to a linear potential under the influence of a constant external force. Depending on the particles position which is monitored with a CCD camera, potential barriers can be set up at specific predetermined positions. Both the positions and shape of the barrier can be varied. Thus it allows to gradually investigate the interplay of "power stroke" and work extracted from the heat bath. Furthermore our experiments can be analyzed with a rather simple theoretical model. The gained knowledge on these energy conversion processes may lead to a better understanding not only of thermodynamic processes but also of the functionality of molecular motors.

9164-66, Session 13

Spatial measurement of spurious forces with optical tweezers

Ignacio A. Bordeu, Univ. de Concepción (Chile); Giovanni S. Volpe, Bilkent Univ. (Turkey); Juan Pablo Staforelli, Univ. de Concepción (Chile)

The study of diffusion in a crowded and complex environment, such as inside a cell or within a porous medium, is of fundamental importance for science and technology. Combining blinking holographic optical tweezers and sub-pixel video microscopy permits one to study Brownian motion in confined geometries. In this work, in particular, we have studied the Brownian motion of two colloidal particles interacting hydrodynamically with each other. The proximity between the two microspheres induces a space-dependence in the particles diffusion coefficient and, therefore, a spurious drift. We measure this drift and evaluate the magnitude of the spurious force associated with it. We present the optoelectronic tools employed in the experiment and we discuss the experimental results.

9164-67, Session 13

Einstein's osmotic equilibrium of colloidal suspensions in conservative force fields *(Invited Paper)*

Daniel H. Ou-Yang, Jinxin Fu, Lehigh Univ. (United States)

Predicted by Einstein in his celebrated 1905 paper on Brownian motion, and experimentally demonstrated by Perrin and won him Nobel Prize in Physics in 1926, colloidal particles in suspension reach osmotic equilibrium under gravity. The shape of the number density profile depends on particle mass, gravitational acceleration, temperature and the interactions between the particles. Also, in 1926, Theodore (The) Svedberg won Nobel Prize in Chemistry for his "work on disperse systems" leading to the determination of hemoglobin molecular weight. We show Einstein's equation for osmotic equilibrium can be applied to colloids in conservative force fields other than gravity. We demonstrate experimentally that coupling between quasi-conservative force of light and nanoparticles in suspensions as well as interactions between colloidal nanoparticles can be determined by the particle number density distributions alone. The former can be determined from the Boltzmann distribution of the particle number density for dilute solutions when interactions between the particles are negligible. Once the optical force field is determined, interactions between the interacting particles or more specifically, the osmotic equation of state of the colloids can be determined from the known force field. An implication of the idea presented here is the potential of generalization from gravity to other conservative force fields, and from colloidal systems to macromolecular solutions to active colloids.

9164-68, Session 14

Micro-rheology and interparticle interactions in aerosols probed with optical tweezers

Jonathan P. Reid, Rory M. Power, Chen Cai, Stephen H. Simpson, Univ. of Bristol (United Kingdom)

Using optical tweezers for micro-rheological investigations of a surrounding fluid has been routinely demonstrated. In this work, we will demonstrate that rheological measurements of the bulk and surface properties of aerosol particles can be made directly using optical tweezers, providing important insights into the phase behaviour of materials in confined environments and the rate of molecular diffusion in viscous phases.

The use of holographic optical tweezers to manipulate aerosol particles has become standard practice in recent years, providing an invaluable tool to investigate particle dynamics, including evaporation/condensation kinetics, chemical aging and phase transformation. When combined with non-linear Raman spectroscopy, the size and refractive index of a particle can be determined with unprecedented accuracy (<+/- 0.05%). Active control of the relative positions of pairs of particles can allow studies of the coalescence of particles, providing a unique opportunity to investigate the bulk and surface properties that govern the hydrodynamic relaxation in particle shape. In particular, we will show how the viscosity and surface tension of particles can be measured directly in the under-damped regime at low viscosity. In the over-damped regime, we will show that viscosity measurements can extend up close to the glass transition, allowing measurements over an impressive dynamic

range of 12 orders of magnitude in relaxation timescale and viscosity. Indeed, prior to the coalescence event, we will show how the Brownian trajectories of trapped particles can yield important and unique insights into the interactions of aerosol particles.

9164-69, Session 14

The study of thin films on solid aerosol particles using optical trapping and Mie scattering from a broadband white LED

Stephanie H. Jones, Univ. of London (United Kingdom); Andrew D. Ward, Rutherford Appleton Lab. (United Kingdom); Martin D. King, Univ. of London (United Kingdom)

A counter-propagating optical trap has been used to study the oxidation of thin organic films on the surface of solid particulates levitated in air. Micron sized silica and polystyrene spheres, have been trapped in air between opposed 1064 nm laser beams, and illuminated with a broadband white LED. Backscattered light from the trapped particle was collected to obtain a Mie spectrum over the 480-700 nm wavelength range and this was used to determine particle radius and wavelength dependent refractive index (Jones et al., 2013). The trapped particle was coated using a flow of organic vapour and the resultant thin film oxidised by introducing ozone, a common atmospheric oxidant, into the gaseous medium. Resonance positions in the Mie spectrum were monitored with time and analysed using a coated sphere model. Analysis indicated initial film formation followed by film oxidation on the introduction of ozone. Currently, film oxidation is associated with a decrease in film thickness, however, this observation is complicated by the optical properties of products formed.

Whilst thin films are believed to form naturally on atmospheric aerosols (Tervahattu et al., 2002), a debate remains as to whether the organic component completely coats the aerosol surface or partially engulfs it. Such films are readily oxidised in the atmosphere causing a change in aerosol properties and knowledge of aerosol properties is required to understand their effect on the climate. The use of optical trapping combined with Mie spectra acquisition to study and characterise coated solid particulates is therefore an important step in atmospheric science.

9164-70, Session 14

Aerosol optical chromatography and measurements of light extinction by single particles

Jonathan P. Reid, Bernard J. Mason, Michael I. Cotterell, Thomas C. Preston, Andrew Orr-Ewing, Univ. of Bristol (United Kingdom)

To resolve some of the significant uncertainties in the impact of aerosols on global climate, new tools are required to probe light scattering and absorption by aerosol particles. Ideally, such tools should allow direct measurements on individual particles over extended periods of time, providing data to better constrain the optical properties of aerosol, how they depend on the environmental conditions (relative humidity and temperature) and how they change with time. Here, we will present a new technique using a combination of a Bessel beam to manipulate individual particles and cavity ringdown spectroscopy for ultrasensitive measurements of the optical extinction.

We will show that particles can be spatially separated along the propagation direction of a Bessel beam according to their size and refractive index when confined by a Bessel beam core and a counter-propagating gas flow, referred to as optical chromatography. The time-dependent position of a particle will be shown to be a consequence of the differing size dependencies of the forces arising from Stokes drag and radiation pressure. We will also show that particles captured in a Bessel beam can be moved in and out of an optical cavity formed by two highly reflective mirrors. The time constant for the ringdown in light coupled within the cavity can then be used to measure the optical cross-section of the individual particle with extremely high accuracy. An individual particle can be captured indefinitely and its change in optical cross-section measured with change in environmental conditions.

9164-71, Session 14

Microparticle conveyor belt and particle-based sensing in hollow-core photonic crystal fiber

Tijmen G. Euser, Oliver A. Schmidt, Max-Planck-Institut für die Physik des Lichts (Germany); Dmitry S. Bykov, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Philip St. John Russell, Max-Planck-Institut für die Physik des Lichts (Germany)

We review our recent work on microparticle manipulation in air-filled hollow-core photonic crystal fiber (HC-PCF). First, we show that a coherent superposition of co-propagating spatial modes, balanced by a backward-propagating fundamental mode, creates a series of trapping positions spaced by half the beat-length between the forward-propagating modes (typically 1 mm). The system allows a trapped microparticle to be moved along the fiber by continuously tuning the relative phase between the two forward propagating modes. This mode-based “optical conveyor belt” combines long range transport of microparticles with a positional accuracy of ~1 µm [1]. Recently, we also demonstrated that microparticles can be used as microscopic sensors that probe, for instance, the electric field strength along a HC-PCF [2]. Here, the optical conveyor is used to position a charged microparticle along the fiber. Transverse electric fields displace the microparticle, the resulting change in transmitted power is found to be linear with fields in the 0.1-50 kV/m range, with a flat frequency response from 0.01 to ~1 kHz. In a first test, the field pattern near a multi-element electrode was resolved with a spatial resolution of 1 mm. This unique “flying particle” sensor allows electric field mapping over long distances and is suitable for otherwise inaccessible or harsh environments [2].

9164-73, Session 15

Ordering of colloids with competing interactions on quasi-one-dimensional periodic substrates

Charles M. Reichhardt, Los Alamos National Lab. (United States); D. McDermott, Univ. of Notre Dame (United States); Cynthia J. Olson Reichhardt, Los Alamos National Lab. (United States)

There have been numerous studies of colloids interacting with both one- and two-dimensional periodic substrates, showing the occurrence of order-disorder transitions as well as dynamical phenomena such as depinning transitions and frictional effects. Existing studies focused on systems in which the colloid-colloid interaction potential is strictly repulsive; however, there are many other possible colloidal interactions including potentials that combine attractive and repulsive components. In the absence of a substrate, particles with competing interactions can exhibit transitions among crystal, stripe, bubble, clump and void states, each of which can be ordered or disordered. Here we investigate a system of colloids with a long range repulsive and short range attractive interaction potential in the presence of periodic one-dimensional substrates. The substrates stabilize colloidal orderings that do not occur in the absence of a substrate. For strong substrates, the particles adopt a one-dimensional periodic stripe pattern, and as the substrate strength is reduced, we observe the formation of periodically arranged kink structures. For weak substrates, stripes with a different orientation appear. We discuss the dynamics of these states under an external drive and show that effective pinning or friction in the moving states is correlated with transitions observed in the pinned state.

9164-74, Session 15

Hybrid optical and acoustic force based sorting

Paul O'Mahoney, Institute for Medical Science & Technology (United Kingdom); Graham W. Brodie, Univ. of Dundee (United Kingdom); Han Wang, Christine E. M. Demore, Sandy Cochran, Institute for Medical Science & Technology (United Kingdom); Gabriel C. Spalding, Illinois Wesleyan Univ. (United States); Michael P. MacDonald, Institute for Medical Science & Technology (United Kingdom)

Optical and acoustic micromanipulation have both proven to be capable of label free cell sorting. This paper discusses a hybrid optical/acoustic sorting approach designed to meet the demands for quality control in the industrial scale production of stem cell derived RBCs, where non-fully differentiated stem cells are removed from fully differentiated erythrocytes.

Passive sorting using optical forces has been used in the past for sorting cells, including RBCs. In those approaches an optical gradient force [MacDonald, Nature 2003] or radiation pressure [Hart, Applied Physics Letters 2003] is typically set in opposition to a fluid drag, leading to particle motion which is size, shape and refractive index dependent. In this paper we discuss sorting which arises from the opposition of an acoustic gradient force against either an optical gradient force or optical radiation pressure.

We have investigated the effect of deflecting particles out of the acoustic standing wave nodes - which both levitates particles/cells and laterally confines them - using vertical or lateral optical deflection where the optical force is produced either by a gradient force in an optical lattice, or a radiation pressure from a weakly focussed Gaussian beam. If and by how much a particle is deflected depends on the interaction strength with both the optical and acoustic fields, hence giving hybrid optical and acoustic sorting.

By combining optical and ultrasonic forces we have produced a system with potentially greater selectivity, able to sort optically by size, shape and refractive index; or acoustically by compressibility and density.

9164-75, Session 15

Advanced optical particle manipulation on an integrated optofluidic platform

Holger Schmidt, Kaelyn D. Leake, Damla Ozcelik, Univ. of California, Santa Cruz (United States); Brian S. Phillips, Aaron Hawkins, Brigham Young Univ. (United States)

We will review recent progress in on-chip particle manipulation on a liquid-core waveguide optofluidic platform. We will discuss, particle trapping techniques as well as optical particle sorting.

9164-76, Session 15

Real-time and high-throughput mechanical phenotyping of suspended cells

Oliver Otto, Philipp Rosendahl, Stefan Golfier, Alexander Mietke, Salvatore Girardo, Technische Univ. Dresden (Germany); Stefano Pagliara, Ulrich F. Keyser, Univ. of Cambridge (United Kingdom); Jochen R. Guck, Technische Univ. Dresden (Germany) and Univ. of Cambridge (United Kingdom)

The mechanical properties of cells have been emerging as label-free, inherent marker of biological function and disease. Concerted utilization has so far been hampered by the availability of a convenient and robust measurement technique. We report the development and characterization of a microfluidic system for mechanical single cell classification in real-time with analysis rates of several hundred cells per second.

A cell suspension is driven through the constriction zone of a microfluidic chip resulting in cell deformation due to hydrodynamic interactions only. Our custom-built image processing software is capable of performing image acquisition, image analysis and data storage on the fly allowing for mechanical phenotyping of several hundred cells per second in real-time.

The ensuing deformations can be described by an analytical hydrodynamic model. Experiments based on our novel technology with different cell types are in agreement with results obtained with atomic force microscopy and optical stretcher. Our method allows continuous mechanical phenotyping of large and heterogeneous cell populations with a throughput previously only known from flow cytometry.

9164-77, Session 15

Optical deformation of red blood cells trapped on a narrow waveguide

Balpreet S. Ahluwalia, Peter McCourt, Univ. of Tromsø (Norway); James S. Wilkinson, Univ. of Southampton (United Kingdom); Thomas R. Huser, Univ. Bielefeld (Germany); Olav G. Hellesø, Univ. of Tromsø (Norway)

The evanescent field of an optical waveguide can trap and propel red blood cells along the waveguide. A method to optically squeeze red blood cells (RBCs) using an optical waveguide is reported. We demonstrate that the intensity gradient of the evanescent field at the edge of narrow waveguides (1-3 µm) can be used to squeeze a blood cell. The RBCs are squeezed to a size comparable to the waveguide width. When the laser is switched on the cell is attracted towards the waveguide and is held in place. Subsequently, the part of the cell not on the waveguide is pulled in across the waveguide. The result is a cell (7-8 µm in diameter) squeezed down to a significantly smaller width (typically 3 µm). The cell regains its original shape when laser is switched-off. A tapered waveguide (8 µm to 1 µm) was used to bio-mimic the sudden change in the stress level acting on RBCs encountering micro-capillaries during blood circulation. Optical forces and pressure distributions on the cells are numerically computed and are used to explain the squeezing process. The proposed method is used to monitor minute loss of blood deformability during blood storage lesion. The method was found to be highly sensitive and a fast and significant loss of blood deformability during storage was found. Squeezing of red blood cells on waveguide works simultaneously on several cells making the method suitable for monitoring cell population.

9164-78, Session 15

Optoelectronic cell lysis

Steven L. Neale, Christian Witte, Alasdair W. Clark, Julien Reboud, Jonathan M. Cooper, Univ. of Glasgow (United Kingdom)

In this paper we show how the electrical lysis of cells can be controlled through the use of an optoelectronic device. We describe how the lysis process is affected by the size and shape of the cell, which enables the specific selection of individual cell types amongst a mixed population, as well as by the geometry of the device and the light patterns used.

Cell membranes consist of a phospholipid bi-layer which is transfixed by membrane proteins, some of which form channels allowing the membrane to be selectively permeable to ions. By controlling these

channels, the cell can keep the voltage across its membrane (the transmembrane potential) constant. For living cells, the membrane is a good electrical insulator to applied electrical fields of low frequencies with its impedance only dropping at higher frequencies.

When sufficient voltage is applied to a cell, however (on the order of 100s of mV across its membrane), pores form in the membrane and if the voltage is further increased, this electroporation turns into electrical lysis as the pores enlarge and merge together. Here we examine the factors that affect this process within an optoelectronic device that allows us to precisely control the fields the cells experience, through the creation of light induced "virtual electrodes". We show how the size, shape and position of the cell within different device geometries affect these processes. We demonstrate how this can be used to gain access to intracellular contents including organelles and discuss how this can be used for analysis.

Pulsed laser activated cell sorter (PLACS) for high-throughput fluorescent mammalian cell sorting

Yue Chen, Ting-Hsiang Wu, Univ. of California, Los Angeles (United States); Aram Chung, Rensselaer Polytechnic Institute (United States); Michael A. Teitell, Dino Di Carlo, Pei-Yu E. Chiou, Univ. of California, Los Angeles (United States)

We present a Pulsed Laser Activated Cell Sorter (PLACS) realized by exciting laser induced cavitation bubbles in a PDMS microfluidic channel to create high speed liquid jets to deflect detected fluorescent samples. The bubble expands to largest diameter in a few microseconds and has internal pressure of tens of MPa. This ultrafast switching mechanism has a complete on-off cycle of less than 20 µsec with a small liquid perturbation volume. Two schemes are used to achieve 3D focusing. One utilizes multilayer PDMS channels with added vertical pathways to achieve 3D hydrodynamic focusing. The 3D sheath flow focusing offers accurate timing control of fast (2 m/sec) passing particles or cells, enabling high purity sorting at high throughput. 3D PLACS is capable of sorting at 11,000 cells/sec with >95% purity or at 45,000 cells/sec with 45% purity within a single channel.

We also demonstrate integration of PLACS with 3D sheathless inertial focusing, which uses 10 times lower initial concentration cell samples than that in sheath-based PLACS in order to avoid severe dilution effects from high volume sheath flows at the same throughput. Fluid inertia and secondary flows induced by stepped microchannels are used to focus samples in 3 dimensions. An expansion chamber will enlarge the inter-particle distance of closely positioned particles. The PLACS with 3D sheathless inertial focusing is capable of sorting at 10,000 particles/sec with >90% sort purity and 6,000 cells/sec with >80% sort purity.

Dynamics of two atoms undergoing collisions and molecule formation in an optical microtrap

Yin Hsien Fung, Pimonpan Sompet, Alicia V. Carpentier, Mikkel F. Andersen, Univ. of Otago (New Zealand)

Photo-association provides a promising route to the ability to construct individual molecules in particular quantum states. We study the dynamics of atoms in a far off resonance optical trap when exposed to laser light that induces molecule formation and light-assisted collisions. We implement the idealised collision experiment in which only two atoms are present in the trap so that we can observe individual atom loss events and their evolution when exposed to red-detuned light. Due to the simplicity of the system (with just two atoms in the microtrap) we can directly simulate the two-atom dynamics, thereby revealing detailed insight into it. We find that light-assisted collisions can result in only one of the colliding partners being expelled from the optical trap, besides the pair loss often assumed. Generally both channels are present; but which is more likely depends on the dynamics of the atoms in the trap under the influence of laser cooling. This finding highlights the importance of studying microscopic processes at the individual event level as it allows us to discriminate between different outcomes of event. Finally, the existence of collisional single atom ejection allows us to exceed the 50% isolation efficiency of individual atoms previously reported when using red-detuned light-assisted collisions. The onset of other loss mechanisms still limits our single atom loading efficiency to 63%.

Computational toolbox for optical tweezers in geometrical optics

Agnese Callegari, Mite Mijalkov, A. Burak Gököz, Giovanni S. Volpe, Bilkent Univ. (Turkey)

Optical tweezers have found widespread application in many fields, from physics to biology. Here, we explain in detail how optical forces and torques can be described within the geometrical optics approximation and we show that this approximation provides reliable results in agreement with experiments for particles whose characteristic dimensions are larger than the wavelength of the trap- ping light. Furthermore, we provide an object-oriented software package implemented in MatLab for the calculation of optical forces and torques in the geometrical optics regime: OTGO - Optical Forces in Geometrical Optics. We provide all source codes for OTGO as well as the documentation and code examples – e.g., standard optical tweezers, optical tweezers with elongated particle, wind- mill effect, Kramers transitions between two optical traps – necessary to enable users to effectively employ it in their research and teaching.

Micro-particles self-arrangement in shapeable counter-propagating beams

Oto Brzobohaty, Jan Kaňka, Lukas Chvatal, Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Daniel H. Ou-Yang, Lehigh Univ. (United States)

The very first experiments with light trapping of particles were performed by A. Ashkin using counter propagating laser beams. We use the geometry of counter-propagating beams but enhanced with spatial light modulator to shape the intensity profile and number of counter-propagating beams. We observed self-arrangement of sub-micrometer size particles into colloidal waveguides long tens of micrometers, we investigated particles positions and tested theoretical models describing their behaviour.

Rapid fabrication of polymeric micro lenses for optical fiber trapping and beam shaping

Ana Rita S. Rodrigues Ribeiro, Raquel B. Queirós, INESC TEC (Portugal); Carole Ecoffet, Ecole Nationale Supérieure de Chimie de Mulhouse (France); Olivier Soppera, Institut de Sciences des Matériaux de Mulhouse (France); Abel González Oliva, Instituto de Tecnologia Química e Biológica (Portugal); Ariel R. Guerreiro, Univ. do Porto (Portugal) and INESC TEC (Portugal); Pedro A. S. Jorge, INESC TEC (Portugal)

The ability to trap and accurately manipulate either cells or dielectric particles without physical contact is a key aspect of optical tweezers. In 1995 one of the first single optical fiber tweezer was proposed by

M. Ikeda, and since then several others have been developed. Through fiber-end micro machining/fabrication technologies, distinct structures and designs have been investigated to use optical fibers as trapping instruments. However, most of them do not allow an accurate control of the produced lenses, are time consuming and sometimes expensive.

In this work, we report a new type of optical fiber tweezers based on polymeric micro-lenses. The lenses are achieved by means of a low cost and fast fabrication process, using an in-fiber photo-polymerization technique. The polymerization radiation is guided towards the fiber tip creating a polymeric waveguide, by self-guiding effect. The method allows tailoring the geometry of the tip (eg. curvature radius, length) by adjusting fabrication parameters such as the exposure time, the composition of the polymer or the power of the polymerization laser. In addition, more complex shapes can be fabricated by exploring modal effects at the polymerization and trapping wavelengths. Therefore, using a simple setup it is possible to fabricate optical fiber micro tips for different applications such as trapping, beam shaping and patterned illumination. The design and fabrication of the micro lenses are supported by 3-dimensional numerical simulations, using the Finite Differences Time Domain method.

Generation of shock waves in a medium with absorbing particles

Vira R. Besaga, Oleg V. Angelsky, Andrew P. Maksimyak, Peter P. Maksimyak, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

This work is dedicated to the generation of shock waves in a disperse medium with absorbing particles using continuous laser radiation.

In our investigations we utilized the mechanism of explosive boiling, when an explosive evaporation of the liquid occurs. For carrying out the experiments we used continuous laser radiation of low power and the aqueous suspension of black pigment particles.

It turned out that the emergence of shock waves and corresponding medium blooming while focusing laser radiation on the cell with the disperse medium is periodic in time and runs the following way: the particles absorb radiation, heat themselves, heat the water, the water boils, cavitation occurs, a shock wave is generated, medium blooming takes place, and then the particles occupy the bloomed volume and absorb radiation again.

As the result of the experimental investigation it was found that the illuminating beam diameter growth at the constant laser power results in the decrease of the signals' modulation frequency, improving their stability and increasing their amplitudes. In its turn, the decrease of the signal's modulation frequency is caused by the growth of time, which is needed for heating the medium to the critical temperature of cavitation. Improving the stability and the increase of optical and acoustic signals' amplitudes take place due to the growth of the medium volume, and hence the number of pigment particles that participate in cavitation.

The results of these investigations will become the basis for the diagnostic technique of absorbing disperse media.

Viscoelasticity measurements inside liposomes

Shu Zhang, Lachlan Gibson, Daryl C. Preece, Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Microrheology?the study of the behavior of fluids on the microscopic scale?has been and continues to be one of the most important areas of study which can be applied to characterize the behaviour of biological fluids.

It is extremely difficult to make rapid measurements of the viscoelastic properties of the interior of living cells. Liposomes are widely used as model systems for studying different aspects of cell biology as they closely mimic cellular membranes. We propose to develop a microrheometer, based on real-time control of optical tweezers, to investigate the viscoelastic properties of the fluid inside liposomes. This will give a greater understanding of the viscoelastic properties of the fluids inside cells.

In our experiment, the liposomes are prepared by a modified electroformation procedure. Instead of originally preparing a dry lipid film deposited on an electrode, we use hydrogel stamps to prepare lipid deposits. During the procedure of lipid formation in which we produce a large number of monodisperse giant liposomes, the birefringent microspheres are added to buffer solution and are encapsulated inside liposomes. By rotating the vaterite inside a liposome via spin angular momentum, the optical torque can be measured by measuring the change of polarization of the transmitted light, which allows the direct measurement of viscous drag torque since the optical torque is balanced by the viscous drag

We present an initial feasibility demonstration of trapping and manipulation of a microscopic vaterite inside a liposome. The applied method is simple and can be extended to sensing within living cells.

natural user interface as a supplement of the holographic Raman tweezers

Zoltan Tomori, Institute of Experimental Physics (Slovakia); Jan Ka?ka, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Peter Kesa, Institute of Experimental Physics (Slovakia) and P. J. Safarik Univ. (Slovakia); Petr Jákl, Mojmir Sery, Silvie Bernatova, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Marian Antalik, Institute of Experimental Physics (Slovakia) and P. J. Safarik Univ. (Slovakia); Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

Holographic Raman tweezers (HRT) manipulates with microobjects by controlling the positions of multiple optical traps via the mouse or joystick. Several attempts have appeared recently to exploit touch tablets, 2D cameras or Kinect game console instead. Natural User Interface (NUI) is a progressive way of a man-machine communication based on gestures, hand and body pose, speech etc.

Proposed method accepts inputs from various NUI devices and sends them to HRT using specific network protocol messages (OSC). We have tested 3D cameras (Kinect, Leap Motion, Creative Gesture Camera, MyGaze) detecting 3D coordinates of fingertips, hand joints, head, eye gaze vector etc. System also recognizes voice commands and gestures sending them to HRT which subsequently controls the positions of trapping beams, micropositioning stage and the acquisition system of Raman spectra. This, of course, required adaptation of HRT firmware to interpret received OSC messages. We have proposed also an indirect control alternative which doesn't require any modification of existing HRT firmware because the software simulates mouse and keyboard messages. Any HRT should accept simulated messages by the same way as these coming from the real mouse or keyboard.

Our system does not try to replace the traditional control of HRT but to extend it - e.g. mouse in one hand combined with gestures of the second hand is possible. We present various modes of operation proper for specific tasks. Proposed methods not only make manual control of HRT more efficient but they are also a good platform for its future semi-automated and fully automated work.

Laser tweezers for determining liquid crystal properties under the influence of external stimuli

David Wei, Helen F. Gleeson, Mark R. Dickinson, The Univ. of Manchester (United Kingdom)

The dynamic response characteristics of a liquid crystal (LC) device are dependent upon its viscosity coefficients and dielectric anisotropy. Optimisation of these properties allows for LC devices with faster response times. With such a wide variety of LC materials, information regarding the viscous properties is often incomplete. The effect of external stimuli, including temperature and electric fields, on these properties provides valuable information for device behaviour. Laser tweezers provide alternate routes to determine this information, as the dimensions are well suited to these techniques.

Manipulation of micron-sized particles with optical tweezers provides a unique method for LC systems to be studied. Dispersed colloidal particles can be trapped and used to probe the fundamental properties of these systems, particularly anisotropic viscosity coefficients in the low Ericksen regime. These properties can be explored under a variety of external conditions, and with different tweezing techniques such as viscous drag measurements or particle tracking.

Optical tweezers also allow the forces acting on colloidal particles in these systems to be explored. The response of trapped particles can provide insight into the behaviour and motion of particles in such systems. The influence of anisotropic LC properties, and of external stimuli, on this behaviour can be studied for a wide variety of materials.

Anomalous diffusion of active brownian particles in random potentials

Giorgio Volpe, Institut Langevin (France); Sabareesh K. P. Velu, Ercag Pince, Bilkent Univ. (Turkey); Sylvain Gigan, Institut Langevin (France); Giovanni S. Volpe, Bilkent Univ. (Turkey)

Brownian particles undergo stochastic and random motion due to the thermal agitation in the surrounding medium. In recent years, a lot of attention has been devoted to the study of active Brownian particles, i.e., microscopic particles capable of self-propelling. These active particles are out-of-thermal equilibrium and, therefore, they explore their environment differently from passive Brownian particles. Recently, the properties of such active particles in complex environments have started to be explored. For example, it has been shown that the interaction of active Brownian particles with a complex environment can be used to develop novel sorting, classification and dialysis techniques based on the swimming style of these particles. In this work, we study experimentally and numerically the motion of Brownian particles in complex potentials and in complex media. The complex potentials are generated by using speckle light fields, while complex media are obtained by adding some bio-propellers (E-coli bacteria) to the solution. We show that both the presence of complex potentials and the presence of complex media have an influence on the motion of the particles. In particular, we demonstrate the gathering and segregation of Brownian particles in the region of interest by speckle light fields and bio-propellers making them suitable for target delivery applications.

Simulation of active brownian particles in optical potentials

Giorgio Volpe, Sylvain Gigan, Institut Langevin (France); Giovanni S. Volpe, Bilkent Univ. (Turkey)

Differently from passive Brownian particles, active Brownian particles, also known as microswimmers, are capable of driving themselves out of equilibrium by taking up energy from their environment and converting it into directed motion. Therefore, understanding their motion can provide insight into out-of-equilibrium phenomena associated both to biological entities such as bacteria and to artificial microswimmers. In particular, it is interesting to consider how these active particles can interact with a complex optical potential. Here, we discuss how to mathematically model their motion using a set of stochastic differential equations and how to numerically simulate it by using the corresponding set of finite difference equations both in homogenous and complex environments. In particular, we show how active Brownian particles do not follow the Maxwell-Boltzmann distribution –a clear signature of their out-of-equilibrium nature– and how, differently from passive Brownian particles, microswimmers can be funnelled, trapped and sorted taking advantage of the out-of-equilibrium nature of their motion.

Multiplexed spectroscopy with holographic optical tweezers

David H. McIntyre, Matthew A. Cibula, Oregon State Univ. (United States)

We are developing a multiplexed spectroscopy system incorporating holographic optical tweezers with an imaging spectrometer to manipulate optically trapped sensor particles and detect their fluorescence spectra. The system builds on previous work in which we have trapped single pH-sensitive fluorescent microspheres. Sensor particles, which incorporate quantum dots or fluorescent dyes, are capable of measuring local environmental properties including pH, ion concentration, temperature, and voltage by monitoring changes in the fluorescence spectrum. We plan to use these sensors to detect such properties in microfluidic devices and cells.

Our system uses a spatial light modulator (SLM) to control the positions of optical traps so that sensors can be positioned into regions of interest. The fluorescent sensors are excited with a wide field source or by alternating the SLM control between the trapping laser and the excitation laser to excite individual sensors locally. Use of a 532 nm excitation laser with a 1064 nm trapping laser opens a wide spectral window to study fluorescence. The spectra of multiple sensors are detected simultaneously in our system with the use of an imaging spectrometer. We obtain accurate measurements of changes in the fluorescence spectra by calibrating the spectra to the locations of the sensors when the zeroth-order image is viewed through the spectrometer on the CCD. The spectrometer slit must remain open to view sensors distributed across a sample; therefore, the spectral resolution is limited by the size of the particles. Results will be presented to display the capabilities of our system.

Numeric modeling approximation of the fluid dynamics in an optical fiber trap

Jenny E. Hernández-Zavala, Univ. Veracruzana (Mexico); Héctor H. Cerecedo-Nuñez, Univ. Autonoma Veracruzana (Mexico); Marco O. Vigueras Zuñiga, Patricia Padilla-Sosa, Univ. Veracruzana (Mexico)

This document presents a first approach to study the behavior of a static fluid radiated by infrared light (980 nm, 100 mW) transmited by a single-mode optical fiber, for this simulation temperature and radiation pressure are calculated based on the Intensity delivered by a laser diode. The Computing Fluid Dynamics (CFD) results were base on a mesh Tet/Hybrid, TGrid for a Silica micro-particle and a mesh Hex/Wedge, Cooper for the beam. The results show that as the particle moves along the axis, temperature and pressure decreases, having the points of mayor temperature and pressure around the axis. The conclusion of this work

is that it is possible to simulate the interactions between the beam, the micro-particle and the surrounded medium in terms of temperature and pressure using the energy and viscous model.

Holographic generation of vector beams with upper-bound diffraction efficiency

Rafael Páez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico); Guadalupe Méndez, Maximino L. Arroyo-Carrasco, Benemérita Univ. Autónoma de Puebla (Mexico); Rubén Ramos-García, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

Vector beams (VB) have attracted significant interest due to its unique characteristics. In particular, the presence of a strong longitudinal component of the electric field and tighter focusing in comparison to homogeneously polarized beams. Several generation methods for obtaining VB have been reported, however, most of them are unstable, complicated and/or the output efficiency is small. One promising method of generation of vector beams is synthetic phase holograms (SPH) due to its versatility and flexibility. We recently demonstrated that when the SPH called kinoform is used to encode an arbitrary nondiffractive optical field, its Fourier the spectra and its corresponding noise do not overlap. Consequently, the desired nondiffractive optical field is generated with upper bound-diffraction efficiency and high quality of reconstruction (Mendez, G.; Fernandez-Vazquez, A.; Generation of an arbitrary nondiffractive optical field with upper bound diffraction efficiency: Theory and experimental generation of Parabolic fields; Optics Communications vol. 309 November 15, 2013. p.p. 175-179). In this work we present numerical and experimental generation of reconfigurable vector beams employing SPH that provide the optimum diffraction efficiency and high quality of reconstruction. The vector beams with spatially variable polarization are generated by the linear recombination of two orthogonally homogeneous polarized scalar modes. The scalar modes are generated with a SPH displayed in a phase-only Spatial Light Modulator (SLM) and superimposed using a common-path interferometer which consists of a 4-f system. We demonstrate the generation of high order TE and TM vector Bessel, Mathieu and Weber beams which could be used for optical trapping applications.

Studying biofuel aerosol evaporation rates with single particle manipulation

Stella Corsetti, Univ. of Aberdeen (United Kingdom) and Univ. of Dundee (United Kingdom); Rachael Miles, Jonathan P. Reid, Univ. of Bristol (United Kingdom); Johannes Kiefer, Univ. of Aberdeen (United Kingdom); David McGloin, Univ. of Dundee (United Kingdom)

The significant increase in the greenhouse effect, air pollution, and the impact on climate change due to the burning of fossil fuel has led to the research of alternative energies. Bio-ethanol, obtained from a variety of feedstocks can provide a feasible solution [1]. Mixing bio-Ethanol with gasoline leads to a reduction in CO emission and in NOx emissions compared with the use of gasoline alone [2]. However, adding ethanol leads to a change in the fuel evaporation [3]. Here we present a preliminary investigation of evaporation times of single ethanol-gasoline droplets. In particular, we investigated the different evaporation rate of the droplets depending on the variation in the percentage of ethanol inside them. Two different techniques have been used to trap the droplets. One makes use of an electrodynamic balance (EDB), the other a 532nm optical tweezers set up. The mean size of the droplets trapped by the use of the first technique was ~25 microns, while of those trapped by the use of the second one was ~13 microns. The droplets decreasing size was measured using elastic light scattering and video analysis respectively. In both cases measurements were conducted at 7oC and a controlled environment has been preserved by flowing nitrogen into the chamber. Binary phase droplets with a higher percentage of ethanol resulted in longer droplet lifetimes (0.2s for pure gasoline, 0.4s for 30% of ethanol, 0.8s for 70% of ethanol). Our work also highlights advantages and disadvantages of each technique for such studies. In particular it is challenging to trap droplets with low ethanol content (such as pure gasoline) by the use of EDB. Conversely such droplets are trivial to trap using optical tweezers. We also present data outlining the difficulties in trapping such aerosols in different temperature regimes, and how fuller data sets can be acquired by using both types of instruments.

Optical nanofiber integrated into an optical tweezers for particle manipulation and in-situ fiber probing

Ivan Gusachenko, Okinawa Institute of Science and Technology (Japan); Mary Frawley, Univ. College Cork (Ireland); Viet Giang Truong, Síle G. Nic Chormaic, Okinawa Institute of Science and Technology (Japan)

We present an integrated platform for particle manipulation consisting of a combined optical nanofiber and optical tweezers system. Individual silica microspheres are introduced to the nanofiber at arbitrary points using the optical tweezers, thereby producing pronounced dips in the fiber transmission. We show that such consistent and reversible transmission modulations depend on both particle and fiber diameter, and may be used as a reference point for in-situ nanofiber or particle size calibration. Particles can be prepared in various arrangements prior to releasing from the optical tweezers onto the nanofiber, and are propelled along the fiber length; upon propulsion, they self-arrange into structured arrays, induced by inter-particle optical forces. Integration with an optical tweezers is promising for detailed studies of the optical binding, which is a fundamental phenomenon observed in many optical systems. We also demonstrate a 'particle jet' created by a strong optical trap in optical tweezers, and use it to feed a supply of microspheres to the nanofiber surface, forming a particle conveyor belt. Combining those two trapping devices can be promising for high throughput cytometry or particle sorting and recognition. In conclusion, the demonstrated integrated optical platform provides a method for selective evanescent field manipulation of micron-sized particles, including cell sorting, and facilitates studies of optical binding and light-particle interaction dynamics.

Towards polarization-sensitive trapping of metal nanoparticles in double nanohole apertures

Ivan Gusachenko, Viet Giang Truong, Síle G. Nic Chormaic, Okinawa Institute of Science and Technology (Japan)

Double nanohole apertures in metal films have proven to be efficient plasmonic devices for trapping nanoparticles as small as single proteins [Y. Pang, R. Gordon, Nano Letters, 12, 2012]. Moreover, other contrasts such as fluorescence spectroscopy and Raman scattering

can be implemented on those systems. We exploit similar structures to optically trap fluorescent nanoparticles, and are developing a system for fluorescent lifetime and correlation spectroscopy of trapped objects using TCSPC hardware. A combination of time-resolved spectroscopies with single molecule trapping can be promising for studying single molecule interactions via FRET or fluorescence quenching observations. Not only does time resolution add substantially new information about the sample behaviour, but also it allows for increasing SNR because contamination from the excitation light can be temporally filtered. We propose the application of this system for studying the interaction of flagellar motor complex proteins in bacterium Salmonella.

Multi scale manipulation of microbubbles employing simultaneous optical and acoustical trapping

Chris Fury, National Physical Lab. (United Kingdom) and Univ. College London (United Kingdom); Philip H. Jones, Univ. College London (United Kingdom); Gianluca Memoli, National Physical Lab. (United Kingdom)

Micrometer-sized gas-filled bubbles, primarily used for improving ultrasound imaging contrast, are finding ever wider use in the field of medicine. As these fields grow, so do the safety implications for the bubbles' manufacture. This drives the need for experimental facilities capable of manipulating the position of bubbles over long ranges (>1000x bubble radii) and with fine resolution (<1x bubble radii) to allow for the directing of bubbles into the path of instruments capable of probing the bubbles' mechanical properties. We present a dual-modality microbubble trapping system that incorporates the fine spatial resolution of optical tweezers, operating in a Laguerre-Gaussian (LG) mode, with the long range, high force manipulation of an acoustic tweezer, in a single microfluidic system. Through back focal plane interferometry we characterise the tweezers in terms of the spring constant and measure the forces involved, including acoustic pressures in the liquid. The response of the trapped microbubbles is observed during the control of the optical trap diameter (LG mode), acoustic frequency and power supplied to each trap. We note the differences between the effect of these parameters on high refractive index particles and low refractive index microbubbles. Further development of the system to include acoustic emission measurement is presented, with the goal of having a multi-purpose mechanical and cavitation detection set-up combined into a single system.

9164-112, Session PWed

Micro- and nano-particle trapping using fibered optical nano-tweezers

Jean-Baptiste Decombe, Institut NÉEL (France); Géraldine Dantelle, Ecole Polytechnique (France) and Institut NÉEL (France); Thierry Gacoin, Ecole Polytechnique (France); Francisco J. Valdivia-Valero, Lab. Interdisciplinaire Carnot de Bourgogne (France); Gérard Colas des Francs, Univ. de Bourgogne (France); Serge Huant, Jochen Fick, Institut NÉEL (France)

Micro- and nano-particles were trapped in aqueous suspension using our fiber-based optical tweezers. Compared to conventional experiments, our main motivation is to understand the involved forces, and to use this as a tool for the manipulation of small nanoparticles that can hardly be trapped under usual conditions.

For 1µm commercial polystyrene particles, transient trapping was obtained with a single fiber nano-tip, whereas stable trapping over hours was realized with two fiber tips facing each other. The particle position was controlled by modifying the relative light intensities in the two fiber tips. Using Boltzmann statistics of the particle position fluctuations the trap potential was found to be harmonic, both in transverse (perpendicular to fiber axis) and longitudinal directions. The maximal trap stiffness was estimated to 1fN/nm for a tip-to-tip distance of 6µm and 6mW light intensity in each fiber tip. This value was confirmed applying Einstein–Ornstein–Uhlenbeck and autocorrelation approaches.

Nanoparticle trapping was studied using luminescent Ce:YAG particles to allow for direct optical observation. A specific glycothermal synthesis route was successfully developed to elaborate 300nm sized spherical particles with high colloidal stability in water (ζ-potential=43mV). In this case stable trapping with stiffness of 0.3fN/nm was observed for a tip-to-tip distance of 9µm and 8mW. The trapping potential was harmonic in the transverse direction. In the longitudinal direction three minima at about half the wavelength distances were observed.

Finally, using a 3D-finite-elements method (Comsol), some simulations of these configurations have been performed to be compared with experimental results.

Object-adapted trapping and shape-tracking to probe a bacterial protein chain motor

Matthias Koch, Julian Roth, Albert-Ludwigs-Univ Freiburg (Germany); Alexander Rohrbach, Albert-Ludwigs-Univ. Freiburg (Germany)

The locomotion of swimming bacteria is normally related to rotary motors as e.g. flagella motors. This study concentrates on the helical bacterium Spiroplasma melliferum, a plant and arthropod pathogen which lacks a stiff cell wall in contrast to most other bacteria. It is able to deform itself intensively, a property that is used for propulsion by generating a pair of kinks propagating down the length of the cell body - thus representing a linear motor. Kinks are generated by a cytoskeletal ribbon made of the unique protein Fibril, whose subunits can change their length through conformational changes. However, the functional principle and the mechanics of the Fibril ribbon have not yet been completely understood.

We use the recently developed object-adapted optical trapping and shape-tracking technique [1] to image the shape deformations of the only 200nm thin cell body while it is hold by an optical line trap. Based on space-resolved light scattering and interference, we are able to record 3D movies of the trapped, self-propelling cell at nanometer precision and frame rates up to 1 kHz. We then analyze the response of the linear motor complex on different external stimuli such as different poisons and optical forces, which are smoothly distributed along the cell body. These observations can be linked to a physical model of the underlying potential landscape of the motor, describing the switching of individual subunits by Kramer's rate theory. We further test this model by exerting forces via optically trapped beads attached to the cell.

Visco-elastic properties of artificial cytoskeletal networks with optically trapped anchor points

Matthias Koch, Dominic Ruh, Alexander Rohrbach, Albert-Ludwigs-Univ. Freiburg (Germany)

Microtubules are biopolymers which self-organize over a large spatial and temporal scale in living cells as a response to a variety of external stimuli. Most of the highly complex intracellular processes like cell-division or mechanotransduction are based on microtubule networks. However, there is only little knowledge about the role of the meshwork geometry on the transport of mechanical momentum in a two dimensional microtubule network.

We use time-multiplexed optical tweezers to generate an array of anchor points for the microtubule network. Fluorescently labeled microtubules are then attached to and spanned between individually trapped 1µm neutravidin beads. We use one trap as actor to exert varying forces on one bead and resolve the positions of all beads by back focal plane interferometry [1]. Despite acting as anchors, the beads are also used as sensors for the response of the network on the actor, thus resolving momentum propagation. This configuration allows probing the visco-elastic properties of biopolymers in synthesized networks in a bottom-up approach and might reveal deeper insights in their complex interaction as part of the cytoskeleton.

We present a mechanical model and simulations of different network topologies and compare these to experimental results. First basic configurations are presented that can be regarded as elementary network elements.

Holographic optical tweezers: microassembling of shape-complementary 2PP building blocks

Sarah Isabelle Ksouri, Jannis Köhler, Andreas Aumann, Reza Ghadiri, Andreas Ostendorf, Ruhr-Univ. Bochum (Germany)

Based on an ongoing trend in miniaturization and due to the increased complexity in MEMS-technology new methods of assembly need to be developed. Recent developments show that particularly optical forces are suitable to meet the requirements. The unique advantages of optical tweezers (OT) are attractive due to their contactless and precise manipulation forces. Spherical as well as non-spherical shaped preforms can already be assembled arbitrarily by using appropriate beam profiles generated by a spatial light modulator (SLM), resulting in a so called holographic optical tweezer (HOT) setup. For the fabrication of shape-complementary preforms, a two-photon-polymerization (2PP) process is implemented. The purpose of the process combination of 2PP and HOT is the development of an optical microprocessing platform for assembling arbitrary building blocks. Here, the optimization of the 2PP and HOT processes is described in order to allow the fabrication and 3D assembling of interlocking components. Results include the analysis of the manufacturing accuracy as well as an optimization of the localization process of 2PP microstructures in the fluid. In conjunction, the related transport and storage processes for complex microcomponents have been realized. Besides, the applied detachable interlocking connections of the 2PP building blocks are visualized by an application example. In the long-term a full optical assembly method without applying any mechanical forces can thus be realized.

Microfluidic chip for cell sorting

Mojmír Šerý, Zdeněk Pilát, Jan Ježek, Jan Ka?ka, Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

We will demonstrate specially constructed microfluidic platform for optical sorting application. The main advantage of the chip system is fabrication by combination of two photon nano-litography technique (TPP) and cryo temperature deep reactive ion etching technique (DRIE) into biocompatible glass type substrates. These techniques give us certain freedom in construction of the chip system and therefore very complicated structures can be created. Microfluidic chip was incorporated into our active optical sorting system based on fast galvano-optics steering of the optical trapping beam. As the decision level for sorting we used specific Raman signal peaks that correspond to vitality of the cells. Efficiency and throughput of the chip for sorting was evaluated for various types living microorganisms.

The authors acknowledge support from MEYS CR (LO1212) together with EC (ALISI No. CZ.1.05/2.1.00/01.0017).

Force dependence of phagosome trafficking in retinal pigment epithelial cells

Rebekah Daniel, Willamette Univ. (United States); Andrew T. Koll, Willamette University (United States); David Altman, Willamette Univ. (United States)

Retinal pigment epithelial (RPE) cells play an integral role in the renewal of photoreceptor disk membranes. As rod cells shed their disk membranes, they are phagocytosed and degraded by the RPE, and a failure in this process can result in retinal degeneration. We have studied the role of myosin VI in phagocytosis in a human RPE primary cell line (ARPE-19), testing the hypothesis that this motor generates the forces required to traffic phagosomes in these cells. Experiments were conducted in the presence of forces through the use of in vivo optical trapping. Our results support a role for myosin VI in phagosome trafficking and demonstrate that applied forces modulate rates of phagosome trafficking.

9164-118, Session PWed

Anomalous behavior of a three-dimensionally optically trapped super-paramagnetic particle

Martin Siler, Petr Jákl, Oto Brzobohatý, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic); Jan Jezek, Institute of Scientific Instruments of the ASCR (Czech Republic); Pavel Zemánek, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

Superparamagnetic particles are used extensively in diagnostics and other research applications for the purification of cells and biomolecules, etc. Here, we demonstrate full 3D optical manipulation of such sub-micrometer sized particle using optical tweezers. Due to the presence of of absorbing iron oxides in the polymer matrix the particle is heated by the laser light. We discuss properties of the optical trap and particle heating for various laser power in the sample space.

9164-119, Session PWed

Sub-micron optical manipulation through phase tuning of light

Jisu Kim, Jung H. Shin, KAIST (Korea, Republic of)

Optical trapping by the evanescent field, as it overcomes diffraction limits of optical tweezers, can be a promising tool for developing lab-on-a chip devices for sorting and analyzing particles at nanoscale. While transporting methods have been studied extensively, methods for positioning and manipulating particle are not as well known. However, developing technique which can control the position of a trapped particle would enable investigation of the fundamental properties of bio particles, as well as integration of the optical analysis with and imaging of particles at nanoscale. Here, we propose and demonstrate a design to precisely control the trapping position of a particle through phase tuning of light. Device is composed of a SU8 waveguide with an intended gap in a PMMA/PDMS fluidic channel. By coupling counter-propagating beams into the SU8 waveguide, a standing wave pattern is generated in the gap to trap a particle. Use of two separate counter-propagating beam allows arbitrary variation of the relative phase and intensity of the two input light into the gap, enabling trapping at, and moving to, of particles at arbitrary positions within the gap. Simulation of E-field distribution in the gap predicts that trapping of 2 um sized particle at with 100 nm accuracy is possible at room temperature. We have achieved trapping of particle at a stationary point using the counter-propagating beams, and will present results of sub-micron control of particle location via phase control.

Singular optics in tractor beams

Dongliang Gao, Tianhang Zhang, Cheng-Wei Qiu, National Univ. of Singapore (Singapore)

The recently found optical pulling force achieved by illuminating a nondiffraction beam on dielectric particles can be explained by momentum conservation: when the forward scattering exceeds the backward one, the particle receives the backward recoil momentum. So far this momentum enhancement is explained by interference between dipoles or higher orders and optical pulling force is represented by integrating stress tensor at a black box enclosing the object. Being a basic concept in electrodynamics, the Poynting vector plays a dramatic role in understanding the physics of light scattering and optical force. Meanwhile singular points of Poynting vector can reveal the change of energy flow in the near field. In this proceeding, singular optics of nonparaxial light beams in the near field is investigated when the light behaves as a tractor beam. We showed the distributions of Poynting vector for various radiuses of the sphere under nonparaxial beam and expounded how optical pulling force is achieved in term of singular points. Forward momentum enhancement is interpreted as the transfer of the stored azimuthal Poynting vector to longitudinal component redirected by these singular points. The results can be useful to give a clear physical picture of the light-matter interaction and significance of singular optics in manipulating the optical force.

Beam-splitting waveguides induced in nanocolloids

Karen P. Volke-Sepúlveda, Luis A. López-Peña, Cristian R. Velasco-Gutiérrez, Emma C. Brambila-Tamayo, Univ. Nacional Autónoma de México (Mexico); Roland A. Terborg, ICFO - Institut de Ciències Fotòniques (Spain)

It has been shown that a spatial soliton can be created when a CW laser travels through a suspension of dielectric nanoparticles, provided its power is above a critical value [Opt. Lett. Vol. 7: 276 (1982)]. Recently, it was demonstrated that these soliton-like beams can be used as waveguides for controlling an additional low-power laser (probe beam) [Opt. Lett. Vol. 38: 5284 (2013)]. Here, we present an experimental study of the interaction between two soliton-like beams propagating through a nanocolloid. Moreover, we analyze the possibility to use these solitons to create a beam splitter for a probe beam.

Generation of hollow optical beams for optical manipulation

Alexey P. Porfirev, Samara State Aerospace Univ. (Russian Federation) and Image Processing Systems Institute (Russian Federation); Roman V. Skidanov, Image Processing Systems Institute (Russian Federation) and Samara State Aerospace Univ. (Russian Federation)

We demonstrate a technique for the generation of hollow optical beams (HOB's), the cross-section intensity distribution of which has a predetermined shape. This technique is based on using multimodal Bessel beams. We can generate Bessel-like non-diffracting beams by varying parameters of individual beams and adjusting their individual energy contribution to the generated light distribution. This technique allows designing transmission functions for elements that shape both non-rotating and rotating beams. Designed diffractive optical elements simulated using Fresnel transform. HOB's, the cross-section intensity distribution of which has a predetermined shape were successfully formed by using spatial light modulator. Experimental results agree well with the theoretical analysis. Such laser beams can be used for the controlled manipulation of non-spherical objects in liquids or air (the non-spherical particle is trapped in the dark region on axis).

9164-125, Session PWed

Plasmonic Archimedes spiral for selective optical trapping and rotation of optically isotropic particles

Wei-Yi Tsai, Jer-Shing Huang, Chen-Bin Huang, National Tsing Hua Univ. (Taiwan)

Optical manipulation of very small particles has long been challenging due to reduced gradient force. Rotation of particles by light is even more difficult since that requires the particle to be absorbing or to exhibit large polarizability and optical anisotropy. Recently surface plasmon-enhanced optical near field has been used to effectively trap small particles. However, rotation and spinning of isotropic dielectric and transparent particles by optical near field remain challenging. Here, we report the first experimental demonstration of selective trapping or rotation of isotropic dielectric micro-particles using one single plasmonic device, a plasmonic Archimedes spiral. Depending on the handedness of the input circularly polarized light, we show selective generation of a near field focusing hot spot for particle trapping or a plasmonic near-field vortex for particle rotation. Such functionality is of great interest and may find applications in various fields, such as protein folding analysis and local mixing in microfluidic channels.

9164-126, Session PWed

Trapping and manipulation using Rayleigh convection generated by laser-induced heating of an absorbing thin film

Susana A. Torres-Hurtado, INAOE (Mexico); Eddy Flores-Flores, Benemérita Univ. Autónoma de Puebla (Mexico); Georgina Beltran-Perez, Facultad de Ciencias Físico Matemáticas, Benemerita Universidad Autonoma de Puebla (Mexico); Steven L. Neale, Univ. of Glasgow (United Kingdom); Julio Ramirez-San-Juan, Rubén Ramos-García, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

In previous works [1] large gas bubbles trapped in oil were manipulated by thermocapillary forces due to high absorbing films using a low power semiconductor laser (10 mW at 635nm). More recently, microparticles dissolved in water were manipulated using a metallic substrate but at much higher power (>100 mW at 532 nm) resulting in the creation of vapor bubbles [2]. The convection current modulated by the presence of the vapor bubble leads to trapping and manipulation of microparticles a ring around the beam and bubble center. Here we show that vapor bubbles can be avoided but trapping it is still possible using low power laser (<10 mW). The device consist of a thin film of a:Si (1micron and absorption coefficient of ~5e4 cm-1) deposited on glass substrate. Particles are dissolved in water contained between the a:Si film and a cover glass plate separated by an spacer of 120 microns. Light absorption at the a:Si film generates the convection currents. For low power (~1 mW) particules are trapped in the center of the beam but for higher power (~3 mW) particles form a ring around the beam due to two competing forces: Stokes and thermophoretic forces. We calculated these forces and the speed at which the particles were trapped. Numerical simulations confirm that thermal gradients are responsible for the trapping mechanism.

Various superpositions of Bessel beams for capture and controlled rotation of microobjects

Alexey P. Porfirev, Andrey A. Morozov, Mikhail A. Rykov, Roman V. Skidanov, Image Processing Systems Institute (Russian Federation); Sofia V. Ganchevskaya, Samara State Aerospace Univ. (Russian Federation)

The authors present a technique for modulation laser beams into beams with special properties, capable of trapping and rotating objects of micro-size. There are two approaches covered: the first one utilizes zero-order Bessel beams superposition for light tubes shaping, and the second one forms Bessel beams superpositions with diffractional optical elements with spatially partitioned topological charge or, alternatively, with vortex axicones.

Diffractional optical elements simulated using FFT and are brought to binary form for easy manufacture. Binary form DOE are manufactured as quartz-plate etched reliefs, while multi-level DOE forms are studied using SLM.

The authors also cover micromechanical object manufacturing, optimized for rotating in vortex Bessel beams superposition. Such microobjects are manufactured by photolitography. Results of numerical simulations and experimental data are presented and then discussed.

Study of light extraction efficiency of QWIP-LED enhanced by photonic crystal slab based on simulation

Yihe Hou, Dongdong Zhang, Shanghai Institute of Technical Physics (China)

QWIP-LED is a new type of infrared up-converter, which can up-convert mid-infrared(9μm) incident light to near-infrared(870nm) output radiation. QWIP-LED/CCD is capable of mid-infrared imaging detection with remarkable advantage of low cost compared with traditional infrared sensor, such as HgCdTe. Unfortunately, the low light extraction efficiency(≈2%) of QWIP-LED prevent this technology from wide application.

In this paper, we introduce Photonic Crystal Slab (PCS) into QWIP-LED to improve light extraction efficiency specifically to its radiation wavelength of 870nm. First, the possible mechanism beneath light extraction enhancement is introduced. And then the model of QWIP-LED containing PCS structure is built using simulation software EastFDTD. The PCS introduced is basically air hole array in triangular arrangement. The structural parameters (lattice constant a, the ratio of radius to lattice constant r/a, PCS thickness d) of the PCS can be changed in certain ranges. Using FDTD (Finite Difference Time Domain) method we calculate the enhancement of the light extraction efficiency under various PCS parameters, and get a combination of optimized PCS structure parameters under which the efficiency is enhanced 2.32 times. The mechanism underneath the enhancement of the light extraction is analyzed based on PCS band theory and effective medium theory. Based on the analysis, a conclusion was drawn that light extraction efficiency can be enhanced to some extent by single PCS structure, but other measures are needed for further enhancement.

Photonic clusters: potential energy surfaces and reaction pathways for optical assembly of nanoparticles

Zijie Yan, The Univ. of Chicago (United States); Stephen K. Gray, Argonne National Lab. (United States); Norbert F. Scherer, The Univ. of Chicago (United States)

Potential energy surfaces and the associated reaction paths they define have played an important role in understanding the assembly of molecules. Here we show that similar mechanistic effects exist in light-driven self-organization of metal nanoparticles; by analogy, atoms are replaced by silver nanoparticles and optical trapping/optical binding interactions serve as “covalent bonds”. Structurally stable 2D and 3D clusters with various geometries were photonically synthesized with nanometer scale precision in their inter-particle separations using simple Gaussian optical fields. We demonstrate that the formation of specific clusters is ‘path-dependent’, i.e., the assembly depends on the initial positions and hence paths the nanoparticles take upon entering the optical field. The equilibrium geometries and pathways for assembly measured in experiment agree with what is expected from electrodynamic simulations and, in particular, the electrodynamic potential energy surface constructed from these simulations. This work paves the way for rational design of photonic clusters in optical fields with appropriate optical beam shapes and gradients.

9164-81, Session 16

Optical binding between nanoparticles of complex shape

Simon Hanna, Stephen H. Simpson, Univ. of Bristol (United Kingdom)

The optical binding forces between clusters of non-spherical particles of varying symmetry are examined using a computational model. Previous studies have focussed on binding of spheres and nanowires. Here we examine the interactions occurring between particles of varying symmetry in counter-propagating plane waves. We examine, in particular, the 2-dimensional optically-induced self-assembly of particles with 2-fold, 3-fold and 4-fold rotational symmetry, demonstrating the formation of stable ordered clusters. The optical binding calculations are incorporated into Brownian dynamics simulations, including hydrodynamic interactions, enabling the thermal stability of these clusters to be studied. The introduction of structural heterogeneities, in the form, for example, of Janus particles, allows dynamically disordered structures to be examined. Comparisons are drawn with recent experimental results.

9164-82, Session 16

Waveguides in colloidal nanosuspensions

Karen P. Volke-Sepúlveda, Luis A. López-Peña, Yadira Salazar-Romero, Univ. Nacional Autónoma de México (Mexico); Roland A. Terborg, Institute of Photonic Sciences (Spain); Juan Hernández-Cordero, Univ Nacional Autónoma de México (Mexico); Juan P. Torres, ICFO - Institut de Ciències Fotòniques (Spain)

We present and discuss a set of experiments based on the application of the nonlinear properties of colloidal nanosuspensions to induce waveguides with a high-power CW laser beam (532nm) and its use for controlling an additional probe beam. The probe is a CW laser of a different wavelength, whose power is well below the critical value to induce nonlinear effects in the colloidal medium. We also discuss a diagnosis technique for the characterization of the induced waveguides and their performance.

9164-83, Session 17

Formation and manipulation of L-phenylalanine crystal by a laser beam focused at a solution surface

Ken-ichi Yuyama, National Chiao Tung Univ. (Taiwan); Teruki Sugiyama, Instrument Technology Research Ctr. (Taiwan); Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

Laser trapping of molecular clusters due to radiation pressure of a focused laser beam has attracted much attention as a high potential method for spatial-temporally controllable crystallization. In the past several years, we have successfully demonstrated glycine and L-alanine crystallization by trapping their liquid-like clusters at a surface of the D2O solution. In this paper, we report on the formation and manipulation of single L-phenylalanine crystal by laser trapping at a surface of the unsaturated H2O solution. When a continuous-wave laser beam of 1064 nm was focused at the surface through an objective lens (60 magnification, NA = 0.9), the single anhydrous crystal was formed from the focal spot. The further irradiation directly into the crystal led to continuous crystal growth on the solution surface, giving thin plate-like crystal. During its growth, the growth rate could be also controlled arbitrarily by changing the power, which indicates that the amount of L-phenylalanine molecules/clusters trapped and adsorbed at the crystal edge is controllable with laser trapping. It was also possible to stop the growth completely and dissolve the crystal by optimizing the power. Moreover, the crystal trapped at the focal spot could be spatially manipulated on the solution surface. During the manipulation, changing polarization of the trapping laser could control the direction of the crystal. These spatial-temporally controlled nucleation, size control, and crystal manipulation will be one of new application techniques of laser trapping.

9164-84, Session 17

Manipulation of particles by laser tweezers-induced gradient of order in the nematic liquid crystal

Igor Musevic, Jožef Stefan Institute (Slovenia); Miha Skarabot, Univ. of Ljubljana (Slovenia); Natan Osterman, Ziga Lokar, Jožef Stefan Institute (Slovenia)

We demonstrate manipulation and transport of microparticles and molecules by the thermally induced gradient of the order parameter in the nematic liquid crystal. We use IR light absorption of the laser tweezers to heat locally a thin layer of the nematic liquid crystal by several degrees. This creates a spatial gradient of temperature of the nematic liquid crystal over tens of micrometers, which not only generates force on the particles, but also induces flow of the liquid crystal. We show that colloidal particles are attracted into the hot spot of the tweezers. The depth of the trapping potential scales linearly with particle radius, indicating that the trapping mechanism is due to elastic self-energy of the distorted nematic liquid crystal around the particle and softening of the elasticity with increased temperature of the liquid crystal. We also demonstrate that this thermal trapping mechanism is efficient down to the nanoscale, as fluorescent molecules are also transported into hotter regions of the liquid crystal. This effect is absent in the isotropic phase, which calls into question particle transport due to the Soret effect. The flow is governed by the dynamic thermal expansion in a gradient of viscosity, local decrease and melting of the nematic order.

9164-85, Session 17

The break-up dynamics of liquid threads revealed by laser radiation pressure and optocapillarity

Jean-Pierre Delville, Univ. Bordeaux 1 (France); Julien Petit, Technische Univ. Darmstadt (Germany); Matthieu Robert de Saint Vincent, Univ. de Rennes 1 (France); David Rivière, Hamid Kellay, Univ. Bordeaux 1 (France)

We show how optofluidics (radiation pressure or optocapillary stresses) in two-phase liquids opens the way for investigating the difficult problem of liquid thread breakup at very small scales when the roughness of the surface becomes important or when surfactant are present at the interface. The production of monodisperse droplets is indeed desirable, and the exact breakup mechanism needs to be clarified as it determines the size and polydispersity of the drops. The first case happens with nanojets or when nanowires fragment during thermal annealing. Considering near critical interface, where the roughness of the interfaces may be tuned, we use the radiation pressure of a laser wave to produce fluctuating liquid columns and study their breakup. We show how classical visco-capillary breakup, usually governed by a balance between viscosity and surface tension, crosses over to a fluctuation dominated regime. We fully describe this new regime, demonstrate its universality and characterize the transition. On the other hand, using thermocapillary stresses driven by light to actuate the breakup of liquid thread and produce droplet of surfactant laden liquids, we observe deviations from the expected visco-capillary law. We suggest that these deviations are due to the presence of a time varying interfacial tension at the minimum neck location. We extract this quantity from a simple ansatz which incorporates the temporal change of the interfacial tension and allows understanding the dynamics of thinning. These experiments suggests that opto-hydrodynamics becomes a new route to reveal new physics of fluids.

9164-86, Session 18

Dynamic motion of semicircular optical wings

Alexandra B. Artusio-Glimpse, Daniel G. Schuster, Mario W. Gomes, Grover A. Swartzlander Jr., Rochester Institute of Technology (United States)

Conventional work in optical micromanipulation utilizes carefully sculpted laser beams for optical trapping affording unprecedented control of the microscopic world; however, the extent of applications is far from exhausted. Fashioning an object to be forced by uniform light is gaining enthusiasm as the dynamics of these objects while in flight is realized. Working as devices that measure small scale surface characteristics or as space flying microscopic satellites, cambered refracting particles (or optical wings) present a potential for a wide range of applications. This work defines the dynamics of particles with semicircular cross-sections. A simple theory is developed and supported by numerical simulation and preliminary experimentation. Two specific shapes are analyzed while uniformly illuminated - 1) a semicylinder rocking curved side down on a flat surface when gravitational effects persist and 2) a hemisphere floating in gravity-free space. Both of these semicircular optical wings are mirrored on the flat surface. The semicylinder is found to behave as a parametrically driven nonlinear harmonic oscillator such that radiation pressure changes the frequency of rocking oscillation. What is more, we find that above a critical intensity the equilibrium orientation of the wing bifurcates so that the wing stably oscillates about some raised orientation. Solutions to the equation of motion are given for both constant and time varying illumination conditions. In addition, we analyze the hemisphere as it spins about its symmetry axis. Due to the radiation pressure induced torque, the spinning hemisphere will precess in an intensity dependent manner.

9164-87, Session 18

Optical field interactions with non-spherical optical particles

David M. Carberry, Vincent L. Y. Loke, Daryl C. Preece, Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Non-spherical optical probes generated via two-photon photopolymerisation have several advantages over traditional microspheres. For example: their interactions with the optical field can be optimised to a desired function, the contact area with specimens can be minimised, and they be designed to operate over multiple force ranges. Here we present our latest results showing how non-spherical optical probes interact with optical fields, and how the added complexity of the probe is more than offset by increases in functionality.

9164-88, Session 18

Optical tweezers as manufacturing and characterization tool in microfluidics

Jannis Köhler, Reza Ghadiri, Sarah Isabelle Ksouri, Evgeny L. Gurevich, Andreas Ostendorf, Ruhr-Univ. Bochum (Germany)

Pumping and mixing of small volumes of liquid samples are basic processes in microfluidic applications. Among the number of different principles for active transportation of the fluids, microrotors have been investigated from the beginning. The main challenge in microrotors, however, has been the driving principle. In this work a new approach for a very simple magnetic driving principle has been realized. More precisely, we take advantage of optical grippers to fabricate various microrotors and introduce an optical force method to characterize the fluid flow generated by rotating the structures through magnetic actuation. The microrotors are built of silica and magnetic microspheres, which are initially coated with Streptavidin or Biotin molecules. Holographic optical tweezers (HOT) are used to trap, position, and assemble the microspheres with the chemical interaction of the biomolecules leading to a stable contact. Using this technique, complex designs of microrotors can be realized. The magnetic response of the magnetic microspheres enables the rotation and control of the structures through an external magnetic field. The generated fluid flow around the microrotor is measured optically by inserting a probe particle next to the rotor. While the probe particle is trapped by optical forces, the flow force leads to a displacement of the particle from the trapping position. This displacement is directly related to the flow velocity and can be measured and calibrated. Variations of the microrotor design and rotating speed lead to characteristic flow fields. Using this method, the fabrication of a microrotor with adjustable size and flow properties can be realized. With the implementation into a microfluidic system it can be used correspondingly as a micropump or for mixing applications.

Measurements of motor-driven viral DNA packaging with optical tweezers: Evidence that the packaged DNA indirectly modulates motor function

Douglas E. Smith, Zachary Berndsen, Nicholas A. Keller, Damian J. delToro, Univ. of California, San Diego (United States)

e use force-measuring optical tweezers to directly measure the motor-driven packaging of single DNA molecules into single bacteriophage phi29 virus capsids. We have previously shown that the packaging rate slows with increasing capsid filling, suggesting that large forces build up resisting DNA confinement. Here we present preliminary evidence suggesting that packaging is also slowed by an indirect interaction between the packaged DNA and the motor propagated though the portal complex. In addition, of potential technical interest to researchers using optical tweezers, we describe an improved method for accurate calibration of force and displacement measurements using DNA molecules as metrology standards.

9164-123, Session 20

Optical trapping of isolated mammalian chromosomes

Nima Khatibzadeh, Beckman Laser Institute and Medical Clinic (United States); Ann A. M. Bui, Alex B. Stilgoe, The Univ. of Queensland (Australia); Yesenia Rocha, Gladys Cruz, Beckman Laser Institute and Medical Clinic (United States); Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia); Michael W. Berns, Beckman Laser Institute and Medical Clinic (United States)

We have investigated optical trapping of isolated mammalian chromosomes, and based on these measurements, we have estimated the forces exerted on them during cell division. A continuous wave ytterbium fiber laser at 1064 nm was used to create an optical trapping system to perform chromosome manipulation experiments. Briefly, the optical system consisted of an inverted Zeiss Axiovert-135 microscope with a 100X/1.4 oil immersion objective through which the laser beam converged to form the optical trap. The laser beam was collimated, steered, and coupled to the microscope through the epifluorescence port. The laser power at the trap focal spot was determined by measuring the input power at the back aperture of the objective lens multiplied by the objective transmission factor at 1064 nm of ≈25%.

Individual isolated chromosomes with mean±s.d. diameter values of ≈0.95±0.16 μm, length of ≈6.71±1.74 μm, and aspect ratio (length/radius) of ≈14.42±3.89 were suspended in liquid media with 1 and 3 cP viscosity prior to trapping. Individual chromosomes were trapped at different trapping powers in the range of ≈20-55 mW. Fluidic viscous drag forces where applied by driving a computer controlled motorized microscope stage at known velocities. Based on the Stokes' equation for flow around cylindrical objects, the drag forces were calculated at the velocities at which the chromosomes escaped from the trap. The preliminary data show a linear relationship between chromosome trapping force and power within the range of the power and suspension media viscosity values used in this study. Our study includes calculation of the dimensionless trap efficiency coefficient (QEscape) at 1064 nm and the corresponding effects of media viscosity and trapping power on that value. The results of this study validate optical tweezers as a non-invasive and precise technique to determine intracellular forces in general, and specifically, the spindle forces exerted on the chromosomes during cell division.

9165-1, Session 1

Ultrafast and two-dimensional electronic spectroscopy of singlet exciton fission in nanoparticle dispersions of functionalized pentacene derivatives *(Invited Paper)*

Ryan D. Pensack, Andrew J. Tilley, Tia S. Lee, Dong Gao, Univ. of Toronto (Canada); Marcia M. Payne, John E. Anthony, Univ. of Kentucky (United States); Dwight S. Seferos, Gregory D. Scholes, Univ. of Toronto (Canada)

Singlet exciton fission has the potential to become a new paradigm in organic photovoltaic devices. While efficient singlet fission has been observed in a number of molecular systems, details regarding the mechanism are only beginning to emerge. Here, we apply pump–probe and two-dimensional electronic spectroscopy to elucidate the mechanism of singlet fission in nanoparticle dispersions of functionalized pentacene derivatives. We find that the nanoparticle absorption spectrum does not vastly differ from that of the constituent molecules suggesting the molecules are weakly electronically coupled and the nanoparticles are disordered. Regardless of this apparent lack of electronic coupling and structural order, we observe the rapid evolution of singlet to triplet transient signatures in the pump–probe spectra on the ultrafast timescale. The formation of triplets is consistent with marked fluorescence quenching that occurs upon nanoparticle formation. Taken together, these observations implicate singlet fission as the mechanism of triplet formation and suggest the efficient conversion of singlet to triplet populations. We have performed pump–probe anisotropy and two-dimensional electronic spectroscopy experiments to understand more clearly the nature of triplet formation in the nanoparticles. In particular, the aim is to differentiate between other physical phenomena that may complicate interpretation of time constants obtained directly from the transient measurements in terms of the intrinsic rate of singlet fission. We also intend to discuss the observation of vibrational coherences in two-dimensional electronic spectroscopy experiments and how monitoring their time evolution may serve to provide additional insight into the mechanism of singlet fission in disordered systems.

9165-2, Session 1

How molecular packing affects the rate of singlet exciton fission

Christopher J. Bardeen, Univ. of California, Riverside (United States); Katharina Broch, Eberhard Karls Univ. Tübingen (Germany); Valerie Nichols, Geoffrey Piland, Univ. of California, Riverside (United States); Frank Schreiber, Eberhard Karls Univ. Tübingen (Germany)

Singlet exciton fission is a spin-allowed process in which a singlet excited state spontaneously splits into a pair of triplet excitons. This process may provide an avenue to higher efficiency solar cells by making it possible to generate two electron-hole pairs per absorbed photon. But a predictive understanding of how molecular-level packing affects the rate of fission has been elusive. In order to clarify the role of intermolecular interactions in this process, we have studied how the rate of singlet fission depends on molecular arrangement in well-defined crystalline systems. In diphenylhexatriene, we compare the fission rates of two different crystal polymorphs, monoclinic and orthorhombic. We find the rate of fission is 50% greater in the monoclinic form, most likely due to the decreased intermolecular separation and better spatial overlap of the molecules in this crystal form.[1] Pentacene has only one polymorph, but the average separation between pentacene molecules can be varied by dilution with an inert molecule, in this case diindenoperylene, while maintaining the overall crystal packing motif. We find that the fission rate and possibly its mechanism both change as the pentacene separation increases. In both molecular systems, the fission rate changes but remains competitive with other relaxation processes. Our results suggest that singlet exciton fission is reasonably robust with respect to molecular packing arrangements.

[1] "Different Rates of Singlet Fission in Monoclinic Versus Orthorhombic Crystal Forms of Diphenylhexatriene," R. J. Dillon, G. B. Piland and C. J. Bardeen, J. Am. Chem. Soc., 135, 17278–17281 (2013).

Johnson, National Renewable Energy Lab. (United States)

Efficient singlet fission, which is the generation of two triplet excitons from one absorbed photon in molecular systems, has been observed in polycrystalline thin films of 1,3-diphenylisobenzofuran (1). Solution grown single crystals of two conformational polymorphs of 1 have been characterized by x-ray diffraction (XRD) for full structure determination and fluorescence spectroscopy. Thin films of 1 were prepared by thermal evaporation and solution dropcasting and were characterized by powder XRD, steady-state absorption, steady-state fluorescence, time-resolved fluorescence, and ultrafast transient absorption spectroscopy. Two polymorphs exist in the bulk and in thin films, labeled α and β here. Although the films are likely a mix of α and β crystallites, predominantly α-type films generate 2.0 triplets per absorbed photon at 77 K and 1.4 triplets per absorbed photon at room temperature, whereas β-type films have much lower triplet quantum yields. Fitting of UV-vis absorption spectra corrected for reflection and scattering revealed a 600 cm-1 redshift of the absorption onset of β-type with respect to α-type films. The β-type singlet vibronic state lies too low in energy to access the coupled triplet state necessary for the system to undergo singlet exciton fission. Enhanced stabilization of a rapidly formed excimer state in ?-1 can also account for low efficiency of triplet formation. Cibalackrot (2), a stable indigo derivative which has been shown to exhibit conformational polymorphism, also generates multiple triplet excitons per absorbed photons. Current work focuses on quantifying triplet formation in solution as well as in thin films of 2.

9165-4, Session 2

Towards determining the factors controlling photocurrent generation in low bandgap polymer/fullerene solar cells *(Invited Paper)*

Stoichko D. Dimitrov, Imperial College London (United Kingdom)

The most efficient organic solar cells are now reaching power conversion efficiencies of 10%, but further device improvements are needed for this technology to become commercially viable. A major obstacle to achieve this is our poor understanding of the relationship of charge photogeneration with materials energetics and film morphology.

In this talk, I will present our recent advances in understanding these relationships in polymer:PCBM solar cells. Using femtosecond to millisecond transient absorption spectroscopy, we compared the charge photogeneration dynamics in indacenodithiophene and diketopyrrolopyrrole copolymer: PCBM blends with differing energy

offsets and film morphologies. For the blend with the low energy offset, we observed ultrafast formation of bound-polaron-pair states that geminately recombine to the polymer triplets on a sub-nanosecond timescale. For the higher energy offset blends, device photocurrent was not limited by such geminate recombination, but instead by non-geminate recombination losses. Our analysis of charge photogeneration as a function of film composition revealed that the yield of charges on the picosecond and microsecond timescales correlate with the device photocurrent densities measured under different applied bias.

In addition to charge generation from polymer excitons, we investigated the kinetics of fullerene excitons in diketopyrrolopyrrole:PC70BM blends. Our femtosecond transient absorption spectroscopy results demonstrated that PC70BM excitons can contribute strongly to device photocurrent but are often limited by exciton diffusion to the polymer-fullerene interface. By fractionating the diketopyrrolopyrrole copolymers, we optimised the morphology of the active layer to reduce PC70BM exciton diffusion losses and thus achieved ~7 mA/cm2 photocurrent from PC70BM excitons.

9165-5, Session 2

The roles of bulk and interfacial molecular orientations in determining the performance of organic bilayer solar cells

Guy O. Ngongang Ndjawa, King Abdullah Univ. of Science and Technology (Saudi Arabia); Kenneth R. Graham, King Abdullah Univ. of Science and Technology (Saudi Arabia) and Stanford Univ. (United States); Sarah Conron, Patrick Erwin, The Univ. of Southern California (United States); Ruipeng Li, King Abdullah Univ. of Science and Technology (Saudi Arabia); Kang Wei Chou, Lawrence Berkeley National Lab. (United States); George Burkhard, Stanford Univ. (United States); Lethy Krishnan Jagadamma, King Abdullah Univ. of Science and Technology (Saudi Arabia); Eric T. Hoke, Michael D. McGehee, Stanford Univ. (United States); Mark E. Thompson, The Univ. of Southern California (United States); Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Molecular orientation has been shown both experimentally and theoretically to play a significant role in determining the performance of small molecule solar cells. In these cells processes such as light absorption, exciton transport, and exciton dissociation are strongly dependent on how the molecules are oriented both in the bulk and at the donor-acceptor interface. While the influence of molecular packing and molecular orientation on the device performance has long been investigated, it remains experimentally challenging to isolate contributions arising from the bulk molecular orientations vs. those from interfacial orientations. This difficulty in part is due to complexities such as molecular rearrangements at the donor-acceptor interface, interaction induced disorder, and intermixing. In this work we use ZnPc/C60 bilayer systems whereby the orientation of the ZnPc molecules is altered by using a thin copper iodide layer to achieve a predominantly face on (on CuI) vs. edge on (on ITO) packing configuration. To independently alter the bulk and interfacial molecular orientation, we conduct very low temperature deposition during the deposition of the donor and/or the acceptor to suppress ordering in the bulk and/or interdiffusion at the interface. These experiments allow us to probe the contributions of the bulk ZnPc layer and the ZnPc/C60 interface by comparing device pairs in which only the bulk or the interface differ. We find that by controlling the orientation in the bulk the short circuit current can be strongly modulated, whereas controlling the interfacial molecular orientation and degree of intermixing mediate the open circuit voltage of the devices.

9165-6, Session 2

Consequence of thermal annealing on PCDTBT-based solar cells performance and composition profile

Olesia Synooka, Kai-Rudi Eberhardt, Chetan R. Singh, Gernot Ecke, Technische Univ. Ilmenau (Germany); Bernhard Ecker, Elizabeth von Hauff, Albert-Ludwigs-Univ. Freiburg (Germany); Gerhard Gobsch, Harald Hoppe, Technische Univ. Ilmenau (Germany)

As reported earlier, the photovoltaic performance of PCDTBT:PCBM polymer solar cells drastically decreases upon thermal annealing. It was demonstrated in the literature, that thermal annealing leads to increased trap formation and as a consequence disturb solar cell performance, especially via a reduced fill factor. This has been demonstrated by space-charge-limited-current analysis and ellipsometry, as well as, structural changes analyse of PCDTBT upon annealing. However, we decided in addition to investigate morphological changes occurring within PCDTBT:PCBM photoactive blend layers upon thermal annealing, as these must have an impact on charge transport. By application of several characterizations techniques, and especially supported by results of Impedance Spectroscopy and Auger Electron Spectroscopy (AES), indeed the existence of an unfavourable compositional gradient within the photoactive layer could be revealed. This compositional gradient may be in part accounted for harming the transport of electrons and holes in either direction.

9165-7, Session 2

Charge separation and recombination dynamics in organic semiconducting photovoltaic systems: role quantum tunneling, delocalization and spin statistics *(Invited Paper)*

Eric R. Bittner, Univ. of Houston (United States)

We present a fully quantum-mechanical model of the electronic dynamics of primary photoexcitations in a polymeric semiconductor heterojunction, which includes both polymer stacking and phonon relaxation. By examining the phonon-induced fluctuations in the state-to-state energy gaps and the exact golden-rule rate constants, we conclude that resonant tunnelling between the primary exciton to delocalized interchain charge-transfer states may be the initial step in the formation of charge-carriers in polymer-based bulk-heterojunction photovoltaic diodes. Using the same theoretical approach, we explore the role of quantum state delocalization in suppressing bimolecular recombination of triplet polarons pairs.

9165-8, Session 3

New insights on the nature of two-dimensional polarons in semiconducting polymers: infrared absorption in poly(3-hexylthiophene) *(Invited Paper)*

Frank C. Spano, Chris M. Pochas, Temple Univ. (United States)

The nature of charges in semiconducting conjugated polymer films has continued to receive a great deal of attention, motivated primarily by the promise of plastic solar cells. In this talk, the IR/NIR absorption spectrum of positive charges (holes) in poly(3-hexylthiophene) - or P3HT -thin films is revisited. P3HT is a semicrystalline polymer which forms ?pi-stacks of cofacially-oriented polymers or polymer segments, separated by intervening layers containing the hexyl side-chains. The existence of

holes delocalized in two dimensions – along the polymer backbone as well as across polymers within a pi-stack, has been associated with the emergence of an IR peak near 0.1 eV due to hole transfer between neighboring chains.[1,2] This talk presents new insights regarding the detailed vibronic structure of the IR band, based on an analysis of a Holstein-style Hamiltonian which includes electronic coupling both along and across chains, vibronic coupling involving the main symmetric ring-stretching mode, and diagonal (site energetic) and off-diagonal disorder. Utilizing the two-particle approximation configurationally-averaged IR spectra are computed which accurately reproduce the vibronic structure observed in the measured spectra. The impact of diagonal and off-diagonal ("paracrystalline") disorder is shown to be polarization sensitive. Short-range disorder along the polymer backbone selectively attenuates the intrachain polaron peaks (P1), while short-range disorder across polymers within a stack selectively attenuates the interchain polaron peak (DP1). The impact of interchain interacitons on polaron coherence is also discussed.

9165-9, Session 3

Influence of acceptor structure and aggregation on mechanisms of charge generation at organic interfaces

John B. Asbury, The Pennsylvania State Univ. (United States)

We examine the mechanisms of charge photogeneration in archetypal classes of electron acceptors in organic photovoltaics (OPVs) using ultrafast infrared spectroscopy. The molecular structures and crystalline order of acceptors blended with conjugated polymers are found to determine whether hot CT state dissociation can influence the dynamics and yield of photo-generated electrons and holes. Furthermore, the degree of aggregation and therefore charge carrier delocalization within amorphous acceptor phases influences the yield of photogenerated charge carriers. Enhancing the degree of carrier delocalization leads to more efficient charge generation on ultrafast time scales – suggesting that hot CT state dissociation may be most important when OPV materials are able to support extended carrier delocalization. Findings about efficient charge carrier generation in OPV materials that do not contain fullerenes are presented.

9165-10, Session 3

Charge separation in an n-p-n triad forming Lamellar structure

Damien Rolland, Lucia Hartmann, Natalie Banerji, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Martin Brinkmann, Institut Charles Sadron (France); Holger Frauenrath, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Since charge separation in organic photovoltaics takes place between n- and p-type semiconductors, their interface should be maximized within the active layer, while charge percolation pathways to the electrodes should be ensured. One way to obtain an ideal and thermodynamically stable morphology is to covalently link n- and p-type semiconductors, provided a sufficiently high internal order is achieved. To this end, we have synthesized a perylene-quaterthiophene-perylene triad substituted with poly(isobutene) segments that induce order at the nanoscale via microphase segregation. Charge separation under selective illumination on the quaterthiophene or perylene moiety was investigated by steady state and transient absorption spectroscopy, and related to the molecular packing and phase morphology deduced from electron and grazing incidence X-ray diffractions. Photoluminescence was quenched due to charge separation within the triad. In solution, these charges quickly recombined, but were shown to have a longer lifetime in films, which is beneficial for charge collection in photovoltaic devices. We have also investigated whether alignment of the supramolecular aggregates affects the photophysics.

9165-11, Session 3

X-ray photoemission spectroscopy study of vertical phase segregation in polymer: PDI blends

Alberto Brambilla, Alberto Calloni, Politecnico di Milano (Italy); Eduardo Aluicio-Sardui, Istituto Italiano di Tecnologia (Italy); Giulia Berti, Politecnico di Milano (Italy); Zhipeng Kan, Istituto Italiano di Tecnologia (Italy); Serge Beaupré, Mario Leclerc, Univ. Laval (Canada); Hans-Jürgen Butt, Max-Planck-Institut für Polymerforschung (Germany); George Floudas, Univ. of Ioannina (Greece); Panagiotis E. Keivanidis, Istituto Italiano di Tecnologia (Italy); Lamberto Duò, Politecnico di Milano (Italy)

In the context of research on organic photovoltaics (OPVs), the realization of photoactive layers based on bulk heterojunctions (BHJ) of electron donor and acceptor materials forming an interpenetrating network has received significant attention due to their low cost, high efficiency and ease of fabrication. Among most explored materials, poly(3-hexylthiophene) and C61-butyric acid methyl ester (PCBM) blend films have yielded the highest power conversion efficiencies (PCEs) to date, with the drawback of relatively high realization costs. Perylene diimide (PDI) derivatives are a potential candidate for PCBM replacement, being cheaper, showing visible absorption and high electron mobility [1-3]. However, the device performance of PDI-based OPVs is still inferior to that of the PCBM-based cells.

In order to provide a rationale for PDI device improvement, we present here a systematic study on PDI molecules blended with semiconducting polymers, such as (for brevity) F8BT, TFB, PCDTBT and PBDTT-E-O. In particular, we investigated the vertical phase separation in the polymer:PDI blends by means of X-ray photoemission spectroscopy (XPS) and its influence on the PCEs of working devices. According to XPS results, an enhanced segregation of the PDI component at the hole-collecting electrode of PEDOT:PSS is responsible for the low PCE of the 'conventional' OPV devices.

9165-12, Session 3

What structural features do charge transfer states depend on? *(Invited Paper)*

Natalie Stingelin, Imperial College London (United Kingdom)

We will present a discussion on how microstructural changes affect the electronic landscape of organic solar cells, including charge generation, charge recombination and charge transfer states. We will show, for instance, that the evolution of well-defined interfaces between intermixed and relatively phase-pure domains of the donor and acceptor is required for spatial separation of the electron and hole. This structural characteristic largely controls the yield of free charges. Moreover, we should that the intensity of CT absorption is directly correlated with the presence of a molecularly intermixed donor:acceptor phase and discuss what structural features determine the CT energy.

9165-13, Session 4

Charge recombination in organic and hybrid solar cells: probing buried interfaces *(Invited Paper)*

David S. Ginger, Univ. of Washington (United States)

Control of surface chemistry at buried interfaces has been shown to improve the performance of organic bulk heterojunctions, quantum dot solar cells, and planar heterojunction OPVs. We combine transient photovoltage, transient photocurrent, and scanning probe based surface photovoltage experiments to explore the role of chemical modifiers at the organic/inorganic interface on non-geminate recombination losses in various solution processed solar cells. We show that in selected BHJs chemical modification of the hole extracting contact can increase carrier lifetimes and improve open circuit voltage. Furthermore, we demonstrate the use scanning probe microscopy methods to reveal spatial heterogeneity in carrier lifetimes due to variable surface chemistry at the buried semiconductor/electrode interface.

9165-14, Session 4

Charge separation and energy transfer at inorganic/organic semiconductor interfaces: a case study with ZnO

Francesco Bianchi, Sylke Blumstengel, Stefan Hecht, Fritz Henneberger, Björn Kobin, Norbert Koch, Raphael Schlesinger, Mino Sparenberg, Humboldt-Univ. zu Berlin (Germany)

ZnO is currently attracting significant interest as a candidate for hybrid photovoltaic and light-emitting devices. We studied - in an all-ultrahigh vacuum approach - the interfacing of ZnO with various conjugated organic molecules, including oligo-phenylenes and perylene derivatives, whose fundamental optical excitation is (fully) resonant to the ZnO band gap. The morphology and electronic structure of the hybrid interfaces were determined by in-situ electron diffraction, scanning probe microscopies, photoemission and reflection spectroscopy, complemented by ex-situ transmission electron microscopy and X-ray diffraction analyses. By appropriate interfacial design, we are able to demonstrate (diffusion-limited) electron-hole separation and, alternatively, excitonic energy transfer with efficiencies of up to 80 %.

9165-15, Session 4

Interfacial charge-transfer processes in polymeric organic nitroxy-radical energy storage materials

Madison Martinez, Barbara K. Hughes, Wade A. Braunecker, Ross Larsen, Heather Platt, Thomas Gennett, National Renewable Energy Lab. (United States)

Organic radical batteries (ORBs) comprise a relatively new technology that uses cathodes based on stable polymeric organic radical-based polymers. These materials show great promise as cathodes in batteries because the neutral, radical species (at left, Figure 1) is remarkably stable and the one-electron oxidation depicted is fully reversible. The rate at which charge can be pushed into or extracted from an electrode is determined by the timescales on which charges are able to move within an electrode and across an electrode-electrolyte, electrode-current collector interface. This work focused on various test-cell pressures to determine how the charge/discharge processes based on the radical polymer's redox interfacial and intramolecular mass-transfer processes would be influenced by the external pressure on the organic radical polymer electrode matrix.

With the Redox process shown in Figure 1, the expansion-contraction of the polymer by the inclusion-exclusion of the solvated anions during charge-discharge can have a direct affect on the mass transfer mechanism with the electrode matrix. Therefore, the rate of the interfacial charge transfer may be affected by; nitroxide radical concentration i.e. cathode capacity, pendant group chain length, cathode thickness and the current collector surface.

AC impedance measurement of the composite electrodes at pressure from 25 to 85 inch-lbs revealed a correlation between: the overall electron transfer resistance of the composite electrode and the material of the current collector; capacity of nitroxide polymer; and the charge-discharge rate limits. These data suggest that the ionic conduction pathways both across the solvent-electrode interface and within the electrode matrix can be altered by pressure.

Overall, our results indicate that the interfacial electron transfer processes both within the electrode matrix, and across the electrolyte-electrode interface can dominate the charge/discharge performance of an organic radical battery system. Therefore, the overall performance of these new organic cathode materials could be improved by suitably designing the interfacial structure for specific charge-discharge rate requirements to maximize interfacial charge transfer through distinct composition for maximal pressure, correct polymer expansion and maximized redox sites.

9165-16, Session 4

Photoluminescence investigation of fundamental charge transfer processes in stable nitroxyl radical-containing polymers

Barbara K. Hughes, Andrew J. Ferguson, Wade A. Braunecker, Thomas Gennett, National Renewable Energy Lab. (United States)

The electrochemical redox reactions of stable organic polymer materials with unpaired electrons is a relatively new and exciting area of battery research. Specifically, stable nitroxyl radical-containing polymers have displayed excellent characteristics as the cathode-active material and have presented themselves as low-cost and environmentally friendly alternative to the current Li-ion battery technologies. However, there is a lack of fundamental understanding of the dynamics of charge transfer processes within organic radical-containing polymers.

Since nitroxyl radicals are known fluorescence quenchers, we have investigated photoinduced charge transfer processes between radical polymers and an organic fluorophore. Using extensive photoluminescence studies, we probed charge transport by the incorporation of fluorescent perylene markers into the radical-containing polymer matrix. We have investigated the interplay between collisional and static quenching processes using steady-state and time-resolved photoluminescence quenching studies of perylene by TEMPO (TE2,2,6,6-tetramethylpiperidinyloxyl), radical-containing species. Quenching studies for these model systems, including both free TEMPO monomers and non cross-linked, solution-phase PTMA-nitroxy polymers, (poly(4-methacryloyloxy-2,2,6,6-tetramethylpiperidine-N-oxyl) have allowed us to determine how such polymer properties as average chain length, spacing between pendant groups, proclivity for polymer folding, and solvent swelling affect both the mechanism of quenching as well as the efficiency of charge transfer. As a function of polymer length, we observe a change in quenching mechanism, while the density of radical moieties has significant affects on quenching/charge transfer efficiency. The quenching sphere of action and thus the optimal distance between radical moieties and fluorophores for the most efficient charge transfer has also been determined and will be discussed at length.

9165-17, Session 4

Nano-multilayer V/ZnO transparent conduction thin films

Yu Shan Wei, Yen-Shuo Liu, Cheng-Yi Liu, National Central Univ. (Taiwan)

Nano-multilayer V/ZnO TCLs (transparent conductive layer) were prepared by sandwiching nano V and two ZnO layers by sputtering processes. The total thickness of the V/ZnO nano-multilayer is fixed at 200nm. The electrical properties (resistivity, mobility, carrier concentration) of the V/ZnO nano-multilayer were investigated by Hall measurement. With XPS and HR-TEM analysis on the V/ZnO nano-multilayer, we conclude that the high mobility and carrier concentration of the V/ZnO nano-multilayer attribute to the interface layer forms between the V and ZnO layers: we determine that the Zn and O atoms diffused into immobile V layer and the nano-ZnVxOy layers were formed. Also, we produced several nano-multilayer by splitting V layer into the ZnO layer, which are 1x2, 3x4, 4x5, 6x7, 9x10. The front digit means the layer number of the V metallic layer and the later digit means the layer number of the ZnO layer. The 3x4 structure shows the best electrical conduction among all multi-layer samples. In this talk, we will explain how the nano interfacial layers between V and ZnO contribute the carrier concentration and serve as the carrier mobility path.

9165-18, Session 5

Exciton hopping in carbon nanotube solar cells studied with 2D white-light spectroscopy *(Invited Paper)*

Martin T. Zanni, Univ. of Wisconsin-Madison (United States)

We report a new multidimensional technique, 2D-White-Light Spectroscopy, that is capable of monitoring charge and energy flow over the entire visible and near-IR wavelength range. Using this new technique, we will present data on thin films of semiconducting carbon nanotubes. These thin films are a promising mesoscale architecture for next generation solar cells. We map all possible energy pathways, observe delocalized electronic states, and anti-correlated energy levels. By simultaneously spanning 400 to 1400 nm, 2D-WL provides an unprecedented view of energy flow in carbon nanotubes and other light harvesting materials.

9165-19, Session 5

Direct measurement of energy transport in organic nanosystems *(Invited Paper)*

Katie Clark, Katherine Koen, Emma L. Krueger, David A. Vanden Bout, The Univ. of Texas at Austin (United States)

Energy transport in organic systems is of interest for a variety of applications such as light harvesting for solar energy conversion. Results are presented for two fluorescence spectroscopy experiments that allow for direct measurement of energy transport in individual isolated organic nanosystems. Both take advantage of single particle spectroscopy techniques to examine the individual systems and quantify the maximum transport lengths. First, fluorescence imaging is used to probe the energy transport in tubular J-aggregates of well separated and bundled cylindrical 3,3'-bis- (2-sulfopropyl)-5,5',6,6'-tetrachloro-1,1'-dioctylbenzimida-carbocyanine (C8S3) dye. Transport was measured by exciting the aggregates with highly localized excitation followed by imaging the fluorescence emitting along aggregate. The one-dimensional average energy transport length was found to be 60 nm along well-separated cylindrical C8S3 J-aggregates. In sharp contrast, the bundle nanotubes exhibited transport on much longer length scales up to hundreds of nanometers. Second, transport was measured in single conjugated polymer chains and aggregates using super-resolution fluorescence microscopy combined with quenching by oxidation sites. Single chains of 1,049 kDa poly[2-methoxy-5-2-(ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) were studied as their fluorescence was reversibly quenched by an applied bias to a capacitor-like device surrounding the molecules. By directly measuring the centroid of the emission from the polymer chain before and after quenching the spatial extent of the quenched regions could be measured in real space. The results show that large energy transfer distances (greater than 25nm) in single MEH-PPV chains were only observed in highly anisotropic conformations, and that these shifts are aligned with the longitudinal axis of the polymer.

9165-20, Session 5

The optical properties of conjugated materials and their aggregates: towards imaging films and devices

Linda A. Peteanu, Carnegie Mellon Univ. (United States); Jiyun Hong, Carnegie Mellon Univ. (United States) and Northwestern Univ. (United States); SuKyung Jeon, Janice Kim, Diane Devi, Carnegie Mellon Univ. (United States); Jurjen Wildeman, Zernike Institute for Advanced Materials (Netherlands); Matthew Y. Sfeir, Brookhaven National Lab. (United States); James H. Werner, Los Alamos National Lab. (United States); Andrew P. Shreve, The Univ. of New Mexico (United States)

Applications of conjugated polymers in photovoltaics and displays drive the need to understand how morphology affects emission and charge migration. A detailed analysis of the interactions that lead to aggregate-induced fluorescence quenching in conjugated polymers is challenging due to the heterogeneity of their structures. This drives recent efforts to analyze the effects of chain-chain interactions on the emission spectra via a detailed study of short-chain PPV- and thiophene-based oligomers and their aggregates. These are formed in solution by 'poisoning' a solution of the oligomers in a good solvent with a small amount of a poor solvent. They exhibit remarkably uniform spectral properties that vary reproducibly with the oligomer chain length and amount of poor solvent used in the preparation. This is verified by dispersed fluorescence microscopy of single aggregates. A more detailed probe of aggregate morphology is provided by fluorescence lifetime imaging (FLIM). The aggregate images are found to be consistent with the formation of "core-shell" structures in which the chains at the aggregate core are tightly packed and the chains at the surface are weakly interacting. This structural model of the single chain-aggregate interface rationalizes the bulk spectroscopic and lifetime data as well as data on the polymeric system. Our recent ultrafast studies probing the wavelength dependence of exciton-exciton annihilation dynamics and charge separation are also consistent with this morphological picture.

9165-21, Session 5

Carrier injection and dynamics from photoexcited transition metal containing porphyrins *(Invited Paper)*

Charles A. Schmuttenmaer, Rebecca L. Milot, Yale Univ. (United States); Gary F. Moore, Lawrence Berkely National Lab (United States) and Joint Ctr. for Artificial Photosynthesis (United States); Christian F. A. Negre, Victor S. Batista, Robert H. Crabtree, Gary W. Brudvig, Yale Univ. (United States)

Terahertz spectroscopy has proven itself to be an excellent non-contact probe of charge injection and conductivity with sub-picosecond time resolution. I will describe the charge injection time scale and efficiency for a selection of high-potential photoanodes (HPPAs) for photo-electrochemical cells. The anodes consist of bis- and tris-pentafluorophenyl free-base and metallo-porphyrin sensitizers anchored to TiO_2 and SnO_2 nanoparticles. Photoelectrochemical measurements demonstrate that the photosensitizers extend the absorption of the bare anode well into the visible region. THz spectroscopic studies demonstrate the sensitizers used in these HPPAs are capable of injecting electrons into the conduction band of the metal-oxide materials in those cases where the energies of the donor (excited state dye) and acceptor (metal oxide conduction band minimum) components are appropriate. The time scales and efficiencies are interpreted in terms of the identities

(singlet vs. triplet) and energetics of excited electronic states.

We have also investigated axially complexing bis-pentafluorphenyl Zn-porphyrin sensitizers to an isonicotinic acid anchor or variants thereof rather than binding them directly to the metal oxide surface. I will compare their binding stability in water, as well as their photoexcited interfacial electron transfer efficiency when using carboxylic acid, hydroxamate, acetylacetonate and phosphonate the anchoring group.

9165-22, Session 6

Two-electron photo-oxidation of betanin on titanium dioxide and potential for improved dye-sensitized solar energy conversion *(Invited Paper)*

Fritz J. Knorr, Washington State Univ. (United States); Deborah J Malamen, Washington State University (United States); Jeanne L. McHale, Washington State Univ. (United States); Arianna Marchioro, Jacques E. Moser, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Dye-sensitized solar photovoltaic cells based on plant pigments in the betalain family show promise for enhanced efficiency of solar energy conversion through two-electron photoredox chemistry of these pigments on nanoparticule TiO2. Solution phase betanin extracted from plants of the order Caryophylalles (such as beets and cactus pears) is known to undergo enzymatic and electrochemical two-electron oxidation. We have previously reported incident photon-to-current conversion efficiencies that suggest two electron photo-oxidation of betanin on TiO2. In this work, we pursue the spectroelectrochemistry and transient absorption spectroscopy of the violet pigment betanin adsorbed on nanocrystalline TiO2 to elucidate the mechanism of sequential or simultaneous two-electron injection. We report spectroelectrochemical evidence for two-electron proton-coupled oxidation of betanin on TiO2, resulting in a product with an absorption band in the blue. Transient absorption spectroscopy measurements on the nanosecond and femtosecond time scales were performed on betanin adsorbed on TiO2 and compared to similar measurements on non–injecting ZrO2 to reveal the spectral signatures and dynamics of oxidized species. Resonance Raman spectroscopic experiments of the photo-oxidation products will be presented in order to provide molecular insight into the photo-induced electron injection process.

9165-23, Session 6

The fate of photoinduced excitons and free carriers at carbon nanotube-fullerene interfaces

Andrew J. Ferguson, Anne-Marie Dowgiallo, Kevin S. Mistry, Bryon W. Larson, Jeffrey L. Blackburn, National Renewable Energy Lab. (United States); Dominick J. Bindl, Meng-Yin Wu, Michael S. Arnold, Univ. of Wisconsin-Madison (United States); Tyler T. Clikeman, Olga V. Boltalina, Steven H. Strauss, Colorado State Univ. (United States)

Photovoltaic active layers comprised of semiconducting single-walled carbon nanotubes (s-SWCNTs) in conjunction with buckminsterfullerene (C60) have realized power conversion efficiencies of around 1%, demonstrating their potential for low cost solar energy conversion applications. We employ a non-contact transient photoconductivity technique, time-resolved microwave conductivity (TRMC), to probe photoinduced free carrier generation, transport and decay at the s-SWCNT-C60 “bilayer” interface. Measurements of the mono-chiral (7,5) s-SWCNT-C60 interface highlight carrier generation and recombination rates that are dependent on the thickness of the (7,5) s-SWCNT layer. The former is due to the need for excitons in the SWCNTs to reach the interface with C60, whereas the latter can be attributed to partial penetration of the C60 into the s-SWCNT network, resulting in the formation of a graded or mixed interface. We subsequently turn our attention to the thermodynamics of free carrier generation at the s-SWCNT-fullerene interface. A study of a multi-chiral s-SWCNT/C60 interface shows that the efficiency of free carrier generation is determined by the diameter-dependent s-SWCNT bandgap, which alters the energetic offset between the electron affinities of the s-SWCNTs and C60 and hence the driving force for exciton dissociation to free carriers. We then remove uncertainties due to the presence of multiple s-SWCNT chiralities, by measuring (7,5) s-SWCNTs in conjunction with various perfluoromethylfullerene derivatives. Here we probe the dependence of free carrier generation on the electron affinity of the fullerene derivative. These two studies allow us to make further refinements to estimates of diameter-dependent electronic properties of s-SWCNTs.

9165-24, Session 6

Ultrafast electron transfer from low band gap conjugated polymer to quantum dots in hybrid photovoltaic materials *(Invited Paper)*

Elsa Couderc, Matthew J. Greaney, The Univ. of Southern California (United States); William Thornbury, USC (United States); Richard L. Brutchey, Stephen E. Bradforth, The Univ. of Southern California (United States)

We investigate the coupling of semiconductor quantum dots to complex organic environment. In organic materials, bound excited species are formed upon photo-excitation, and must be dissociated into free charge carriers for photovoltaic applications. Charge separation is typically achieved at an interface obtained by nanoscale mixing of electron accepting and donating phases. Hybrid solar cells contain quantum dots (QDs) as electron acceptors, but the performances of these heterojunctions remain low compared to those of all-organic cells. To better understand this discrepancy, we use ultrafast transient absorption to track the excited species on the QDs and polymer chains in the fs-ns range. Here, we study CdSe quantum dots blended with a low band gap polymer, poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b?]dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)]. Through selective excitation of the polymer, we show that the photo-generation of excitons on the polymer chains results in ultrafast electron transfer onto the quantum dots, detectable as an emerging spectral feature within our time resolution (65 fs). The yield of electron transfer depends on the QD surface chemistry, which participate in explaining the differences observed in photovoltaic performances for hybrids with different ligands. Finally, we find that very fast recombination (in the picosecond range) occurs in the hybrids. These results indicate that the performances of hybrids solar cells are not limited by charge carrier generation when ligands are properly chosen, but could be due to recombinations at longer times and to charge carrier extraction.

9165-25, Session 6

Quantum confinement-tunable ultrafast charge transfer at the PbS quantum dot and PCBM Fullerene interface

Omar F. Mohammed Abdelsaboor, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Flexible solar panels made from semiconductor quantum dots have great potential to be useful light-harvesting materials, opening up an optimistic view to utilize this new technology in third-generation photovoltaic devices1-3. More specifically, quantum dot (QD) solar cells have emerged as a promising low-cost alternative to existing photovoltaic technologies. Here, we investigate charge transfer and separation at PbS QDs and phenyl-C61-butyric acid methyl ester (PCBM) interfaces using a combination of femtosecond (fs) broadband transient absorption

(TA) spectroscopy and steady-state photoluminescence quenching measurements4. We analyzed ultrafast electron injection and charge separation at PbS QD/PCBM interfaces for four different QD sizes and as a function of PCBM concentration. The results reveal that the energy band alignment, tuned by the quantum size effect, is the key element for efficient electron injection and charge separation processes. More specifically, the steady-state and time-resolved data demonstrate that only small-sized PbS QDs with a bandgap larger than 1 eV can transfer electrons to PCBM upon light absorption. We show that these trends result from the formation of a type-II interface band alignment, as a consequence of the size distribution of the QDs. Transient absorption data indicate that electron injection from photoexcited PbS QDs to PCBM occurs within our temporal resolution of 120 fs for QDs with bandgaps that achieve type-II alignment, while virtually all signals observed in smaller bandgap QD samples result from large bandgap outliers in the size distribution. In other words, the electron injection process can be tuned from highly efficient and ultrafast (<120 fs) for PbS QDs with a bandgap of more than 1 eV to nearly or completely absent for QDs with larger diameters and a bandgap of less than 1 eV (See Scheme 1).

This information is of central importance to the design of photovoltaic devices employing QDs to harvest the near-IR solar spectrum. More generally, understanding the dynamics of the electron injection at the surface of the semiconducting QD is a key factor in determining the utility of these materials in applications that principally rely on the interfacial dynamics such as light-emitting diodes, p-n junctions, and photocatalysis.

9165-26, Session 7

Optical studies on metal oxide nanoparticles

Muneeswaran Muniyandi, National Institute of Technology, Tiruchirappalli (India); Mohammed Ghouse Munavary, National Institute of Technology Delhi (India); Giridharan Nambi Venkatesan, National Institute of Technology, Tiruchirappalli (India)

Multiferroic materials are attracting much attention due to their potential applications and their fascinating fundamental physics. $BiFeO_3$ (BFO) is the most intensively studied material due to its high ferroelectric Curie temperature (T_C)~1103K and antiferromagnetic Neel temperature (T_N)~643K. It has rhombohedrally distorted perovskite structure crystallized in space group of R3c. We here report the effect of the trivalent rare-earth ion, Dy^{3+}in the stabilization of the BFO phase, and investigating its structural, magnetic and optical properties. A soft chemical method has been adapted to synthesis single phase [$Bi_{1-x}Dy_xFeO_3$(BDFO x=0.0, 0.05, 0.10 and 0.15)] powders.The reaction precursors used were $Bi(NO_3)_3$•$5H_2O$, $Fe(NO_3)_3$•$9H_2O$ and $Dy(NO_3)_3$. H_2O powders. Distilled water was used as the solvent. By precisely controlling the chemical precipitation process, the reaction product was obtained. The product was washed and filtered by deionized water for several times then dried at 100 °C for 4 h and annealed at 600°C. The prepared BDFO powders were characterized by XRD, FT-IR, DRS and TEM. The details of the result will be presented and discussed.

Effect of atomic under-coordination on the properties of Ag and Cu nanoclusters

Shideh Ahmadi, Xi Zhang, Nanyang Technological Univ. (Singapore); Yinyan Gong, China Jiliang Univ. (China); Changqing Sun, Nanyang Technological Univ. (Singapore)

Metallic nanostructures have attracted enormous interest recently due to their unique properties, which cannot be observed in the bulk counterparts, such as transition from conductor to insulator and nonmagnetic to magnetic and extraordinary high capability of catalysis. Density functional theory (DFT) calculations have been conducted to investigate the effect of the under-coordinated atoms in the surface region of the Cuboctahedral (CO) and the Marks decahedral (MD) structures of Ag and Cu nanoclusters. The calculation results are in good agreement with the experimental observations including X-ray-absorption fine structure (EXAFS), scanning tunneling microscope/ spectroscopy (STM/S), X-ray photoelectron spectroscopy (XPS), and ultraviolet photoelectron spectra (UPS). This consistency confirmed the predications based on bond order-length-strength correlation (BOLS) theory [1] and nonbonding electron polarization [2], suggesting that the shorter and stronger bonds between under-coordinated atoms in the surface skin of nanostructures induce local densification, entrapment of the core electrons, and valence charge polarization, which provide perturbation to the Hamiltonian and cause the new properties in Cu and Ag nanoclusters.

9165-28, Session 7

Spectroelectrochemical photoluminescence of titanium dioxide nanosheets and nanoparticles in aqueous and nonaqueous environments

Riley E. Rex, Jeanne L. McHale, Fritz J. Knorr, Washington State Univ. (United States)

Spectroelectrochemical photoluminescence is used to investigate surface electron and hole traps on two different anatase particle morphologies in aqueous and nonaqueous environments. Trap state photoluminescence of nanocrystalline TiO_2 in aqueous environment under Fermi level control reveals the pH-dependent redox Fermi levels of the surface $Ti^{3+/4+}$ couple associated with five-fold coordinated titanium. In aqueous environment, this trap state distribution is populated at lower energy in TiO_2 nanosheets rich in exposed (001) surfaces, compared to commercial anatase TiO_2 nanoparticles with exposed (101) surfaces. Lower energy traps appear to be partially passivated in the case of nanosheets in acetonitrile environment. Self-modeling curve resolution of the photoluminescence under Fermi level control reveals three spectral components in aqueous and acetonitrile environments, the red and green photoluminescence we have previously associated with electron and hole traps, respectively, and a third intermediate (yellow) component that may result from a separate distribution of electron traps. An apparent overvoltage, which is larger for nanoparticles than nanosheets, is found for occupation of surface electron traps in aqueous environment. In contrast, electron traps in acetonitrile are occupied at potentials consistent with their energetic position within the band gap as determined by the photoluminescence spectrum. Our results reveal the solvent-dependent redox potential of electron traps and lend insight into the effects of contacting solvent on performance of nano-TiO_2 in applications such as dye–sensitized solar cells.

9165-29, Session 7

Charge trapping and intraband relaxation in colloidal quantum dot and perovskite photovoltaic materials *(Invited Paper)*

Artem A. Bakulin, FOM Institute for Atomic and Molecular Physics (Netherlands); Zhuoying Chen, Ctr. National de la Recherche Scientifique (France) and Ecole Supérieure de Physique et de Chimie Industrielles (France)

Solution-processed organic-inorganic hybrid materials like colloidal quantum dots (QD) or perovskites hold promise for cost-effective thin-film solar cells. The carrier dynamics in these materials is determined by the conduction and valence band structure, distribution of trapping states and the pathways for carrier relaxation. In current contribution, we apply a set of novel ultrafast electro-optical techniques, including Vis-pump – IR-probe, pump-push photocurrent, and 3-pulse transient absorption spectroscopies to elucidate the carrier relaxation and trapping dynamics in PbS QD and methylammonium lead halide perovskite films. The material properties were controlled by the QD ligand-exchange and perovskite surface passivation.

We show that the carrier relaxation in the studied systems can occur on a variety of timescales form 200 fs to longer than 10 ps. The particular charge relaxation and recombination rates strongly depend on the presence of defect states and the strength of electron-hole coupling. In QD photovoltaic device we observed that some photogenerated electron-hole pairs are intrinsically weakly bound. At the same time, charge diffusion in the QD films leads to substantial charge trapping on the ~ns timescale. Our study provides important information for the development and implementation of hot-electron extraction and carrier multiplication in third-generation photovoltaic devices.

9165-30, Session 7

Band-edge photophysics of emerging organic-inorganic photovoltaic materials

Robert J. Stewart, John B. Asbury, The Pennsylvania State Univ. (United States)

In both quantum dot and perovskite hybrid organic-inorganic photovoltaic materials, localized sub-gap states below the band edge may play important roles in mediating charge transport and in limiting the maximum obtainable photovoltage in solar cells. We present a systematic study examining the importance of these sub-gap states and their function in charge transport processes in quantum dot and perovskite materials using time-resolved infrared (TRIR) spectroscopy. Approaches are presented to eliminate sub-gap states by tuning the structure and composition of these hybrid materials in an effort to improve the short-circuit current and open-circuit voltage of the corresponding solar cells.

9165-31, Session 8

Time-resolved spectroscopy insights into charge transfer processes in organo-lead iodide perovskite solar cells *(Invited Paper)*

Jacques Moser, Arianna Marchioro, Ahmad A. Oskouei, Arun A. Paraecattil, Adrian Pulgarin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Hybrid organic-inorganic lead halide perovskite semiconductors have recently been successfully applied as light absorbers in novel solid-state solar cells displaying a power conversion efficiency reaching 16% and an unprecedented open circuit voltage of 1.1 Volt. Ultrafast transient absorption spectroscopy and time-resolved terahertz photoconductivity measurements unraveled the mechanisms and dynamics of charge transfer processes taking place in titania and alumina mesoporous films impregnated with methylammonium triiodoplumbate (II) perovskite and the organic hole-transporting material (HTM) spiro-MeOTAD.

In photovoltaic systems based on a titanium dioxide | perovskite | HTM architecture, primary charge separation was observed by transient absorption in the NIR to occur at both junctions with the electron-transporting oxide and the HTM simultaneously, with ultrafast electron- and hole-injection taking place simultaneously.

The effect of the excitation wavelength upon the transient THz absorption amplitude and spectrum allowed evidencing the formation of excitons, polarons and bipolarons during the first picoseconds following pulsed excitation of the perovskite, on a time-scale slower than interfacial charge transfer. We thus conclude that the exceptionally large carrier diffusion lengths in the semiconductor allow photogenerated electrons and holes to reach the selective contacts separately, where they are readily injected, before they could associate in the form of excitons and eventually recombine. This unique charge separation mechanism makes perovskite hybrid solar cells a new type of photovoltaic converter of its own and a new realm of scientific investigation and technological development.

9165-32, Session 8

Ferroelectric domain walls as nanoscale pathways to novel functional properties *(Invited Paper)*

Patrycja Paruch, Univ. de Genève (Switzerland)

In ferroelectrics, domain walls separate regions with different polarization. At domain walls, modified symmetry and electronic structure, or chemical segregation can lead to unusual, extremely localized functional properties, quite different from those of the parent phase.

Particularly exciting has been the discovery of domain-wall-specific electrical conductivity in multiferroic $BiFeO_3$ [1]. Here, I will present our generalization of these observations to $Pb(Zr,Ti)O_3$ [2], highlighting the key role of oxygen vacancies, whose distribution can be modulated to reversibly control domain wall transport. For these studies, we have also developed carbon-nanotube-based probes with exceptional performance [3].

9165-33, Session 8

The photophysics of perovskite solar cells *(Invited Paper)*

Tze Chien Sum, Nanyang Technological Univ. (Singapore)

Solution processed hybrid organic-inorganic perovskite solar cells have recently been identified as one of the breakthroughs of 2013. Power conversion efficiencies exceeding 15% from these devices have been reported.1, 2 These solar cells offer the promise of low-cost photovoltaics that is compatible with large-scale, low temperature processing. Remarkably, these phenomenal efficiencies were achieved in a matter of 4 years – up from ~3.8% back in 2009. Comparatively, dye-sensitized solar cells needed more than two decades of intensive research to achieve similar breakthroughs. In this talk, I will review the developments in these nanostructured perovskite solar cells and focus on the photo-physics and charge dynamics studies. I will discuss about our findings of long range balanced electron-hole diffusion lengths and the hot-hole cooling dynamics in $CH_3NH_3PbI_3$.3 I will also highlight some of our latest work on unravelling the charge dynamics and charge transfer mechanisms in these devices.

9165-34, Session 9

Optical properties of low bandgap copolymer PTB7 for organic photovoltaic applications *(Invited Paper)*

Uyen Huynh, Tek P. Basel, The Univ. of Utah (United States); Luyao Lu, Tao Xu, Tianyue Zheng, Luping Yu, The Univ. of Chicago (United States); Z. Valy Vardeny, The Univ. of Utah (United States)

We have measured the photoexcitation transient dynamics and magnetic field effect in pristine and donor-acceptor blends based on various low bang-gap polymers. We found that triplet excitons dominate the photoexcitation dynamics in both pristine and D-A blends. Therefore the charge photogeneration in the blends need not be simple exciton dissociation at the D-A interface, but may involve several novel avenues.

9165-70, Session 9

Exciton dynamics in disordered molecular environments *(Invited Paper)*

Adam P. Willard, Massachusetts Institute of Technology (United States)

For organic conjugated molecules details of the electronic structure such as excited state energy levels or spatial distribution of electronic charge depend sensitively on nuclear configuration. Consequently, for microscopically disordered systems like the bulk heterojunction predicting macroscopic electronic properties is a challenging and unsolved problem. We use molecular simulation to characterize the relationship between molecular disorder, both static and dynamic, and transient behavior of excitons in organic conjugated polymers and at donor-acceptor interfaces. In particular we carry out novel mixed quantum/classical simulations that are capable of providing a molecular-level basis for the interpretation of time-resolved ultrafast spectroscopic data.

9165-36, Session 10

Photoinduced charge separationp processes: from natural photosynthesis to organic photovoltaic cells

Oleg G. Poluektov, Argonne National Lab. (United States)

Photovoltaic (PV) cells are the most promising man-made devices for direct solar energy utilization. Detailed knowledge of the charge separation and charge transport in PV materials is crucial for improving the efficiency of the solar cells. Advanced EPR spectroscopy, especially light-induced multi-frequency EPR, has been essential for understanding the mechanisms of the light-induced generation, separation, and recombination of the charge carriers in natural photosynthesis. Here, we use light-induced EPR spectroscopy combined with DFT calculations to study mechanisms of charge separation and charge stabilization in active organic PV materials based on the composites of multiple polymers (P3HT, PCDTBT, and PTB7) and fullerene derivatives (C60-PCBM and C70-PCBM). Time-resolved EPR spectra show strong polarization pattern for all polymer-fullerene blends under study, which is caused by non-Boltzmann population of the electron spin energy levels in the radical pairs. Similar polarization patterns were first reported in molecular donor-acceptor systems, such as natural and artificial photosynthetic assemblies, and were understood within the models of spin-correlated radical pairs (SCRP) and sequential electron transfer. These models were used by us to explain the polarization pattern of the SCRP in polymer-fullerene blends and describe the charge separation process like electron jumps or tunnelling between neighbouring fullerene molecules. The first step of the charge separation process is exciton dissociation and electron transfer to the fullerene molecule neighbouring to the polymer. In order to outcompete the recombination process this state cannot live longer than a few picoseconds. Forward electron transfer forms an intermediate radical pair, with the separation distance within 15-20 Å. The third step is electron transfer to the secondary radical pair with a separation of 25-30 Å which is stable for tens-hundreds microseconds. The following electron transfer steps are on the slower time-scale and lead to further charge separation or charge recombination. The analysis presented here helps to improve our understanding of the mechanism of charge separation processes in the active organic photovoltaic materials.

9165-37, Session 10

Understanding electronic and optical properties of organic semiconductors from first principles *(Invited Paper)*

Leeor Kronik, Weizmann Institute of Science (Israel); Sahar Sharifzadeh, Lawrence Berkeley National Lab. (United States); Sivan Refaely-Abramson, Weizmann Institute of Science (Israel); Jeff B. Neaton, Lawrence Berkeley National Lab. (United States) and Univ. of California, Berkeley (United States)

Understanding the electronic and optical properties of organic semiconductors, with an emphasis on transport and optical gaps, is essential to the design of modern organic electronic and photovoltaic devices. Here, we show how this is achieved using a combination of density functional theory and many-body perturbation theory approaches. We then show how this sheds light on issues of direct relevance to device performance, such as inter-molecular hybridization, band dispersion, polarization phenomena, exciton formation and delocalization, and more.

9165-38, Session 11

Detection, tracking, and manipulation of individual biomolecules at interfaces *(Invited Paper)*

Jens Ehrig, Susann Spindler, Marek Piliarik, Ji Tae Kim, Vahid Sandoghdar, Max-Planck-Institut für die Physik des Lichts (Germany)

Some of the exciting challenges of modern biology and biophysics concern efforts to surpass the limits of conventional optical imaging. In particular, novel contrast mechanisms, sensitivity, signal acquisition rate and spatial resolution have been substantially improved over the past two decades. Over the past decade, we have developed interferometric scattering (iSCAT) microscopy as a fluorescence-free technique, which relies on measuring the interference of the Rayleigh scattering with a reference light beam.

In the first part of the talk, we report on using iSCAT to study the diffusion of very small gold nanoparticles (typically 20 nm) attached to GM1 or DOPE lipids in DOPC lipid bilayers at frame rates up to 1 MHz with nanometer precision [1]. We, thus, present a very powerful single particle tracking approach, with the potential to resolve some of the long-standing issues of the heterogeneities in lipid and protein compositions of cell membranes. Furthermore, we show that the sensitivity of iSCAT suffices to push the limits of biosensing by orders of magnitude to the detection of individual proteins as small as 60 kDa [2].

In the second part of the talk, we will introduce an electrostatic trap that is created in an aqueous medium between the aperture of a glass nanopipette and a glass substrate [3]. We demonstrate trapping and manipulating of nanoparticles or small biological entities like lipid vesicles. The ease of tuning the trap stiffness in real time by adjusting the height of the pipette allows on-command capture, displacement and release of nanoparticles.

Super-resolution imaging reveals cooperativity and dynamics in live bacteria *(Invited Paper)*

Yi Liao, Krishanthi Karunatilaka, Julie S. Biteen, Univ. of Michigan (United States)

Single-molecule fluorescence brings the resolution of optical microscopy down to the nanometer scale, allowing us to unlock the mysteries of how biomolecules work together to achieve the complexity that is a cell. This high-resolution, non-destructive method for examining subcellular events has opened up an exciting new frontier: the study of macromolecular localization and dynamics in living cells. We have developed methods for single-molecule investigations inside live bacteria, and here, we discuss our investigations of DNA repair in Bacillus subtilis and starch digestion in Bacteroides thetaiotaomicron.

In the first case, we have examined mismatch repair (MMR), which corrects base-pairing errors in B. subtilis. Based on Photoactivated Localization Microscopy (PALM) of MutS-PAmCherry, two-color single-particle tracking (SPT), and mutant MutS defective for mismatch recognition and mismatch unbinding, we reveal the in vivo single-molecule distributions and dynamics of MutS, as well as the MutS-replisome interactions. Our results provide strong evidence that MutS recruitment to the replisome is required for MMR and precedes mismatch binding in vivo. In the second case, we have monitored the dynamics and cooperativity of recruits Starch-Utilization System (Sus) proteins in the prominent human gut symbiont B. thetaiotaomicron. By measuring the dynamics and stoichiometry of starch-induced Sus complex assembly on the molecular scale, we find that polymeric starches dynamically recruit Sus proteins, serving as an external scaffold for bacterial membrane assembly of the Sus complex, which in turn efficiently captures and degrades starch. Additionally, based on Sus protein knockout strains, we discern the mechanism of starch-induced Sus complex assembly.

9165-40, Session 11

Studies of structure and dynamics of protein-DNA complexes by single molecule and two-dimensional fluorescence spectroscopy (2DFS) *(Invited Paper)*

Andrew H. Marcus, Univ. of Oregon (United States)

The properties of biological macromolecules are greatly influenced by local soft interactions between proteins, nucleic acids, sugars and lipids. Such interactions affect the stability of biomolecular complexes, as well as the barriers that must be surmounted for molecular motions to occur. In this talk, I will present fluorescence based nonlinear spectroscopic measurements that determine the three-dimensional shapes, or local conformations, adopted by electronically coupled molecular dimers in biological environments. I will describe studies of the assembly of dimers of square-shaped metal tetraphenyl porphyrin (TPP) molecules embedded in a phospholipid bilayer membrane, in which we show that the assembled dimers exist as a “T-shaped” conformation. When a flexible linker is used to connect two TPP molecules, the “folded” form of the dimer is favored at elevated temperatures, which we show is due to entropic interactions between the TPP molecules and the local membrane environment. Similar experiments performed on dimers of fluorescent nucleic acid bases, which may be substituted for natural bases within model DNA constructs, reveal the structures of local base stacking conformations, and provide information about the balance of thermodynamic forces that contribute to nucleic acid stability. I will also describe single-molecule fluorescence experiments to investigate DNA ‘breathing’ fluctuations, in which nucleotide residues near single-stranded (ss) – double-stranded (ds) DNA forks and junctions temporarily adopt local conformations that depart from their most stable structures. Such fluctuations may comprise important mechanistic steps on the reaction pathways of a number of biological reactions important in DNA replication and RNA transcription.

9165-41, Session 12

Harmonic nanoparticles for nonlinear imaging and photo-interaction *(Invited Paper)*

Luigi Bonacina, Univ. de Genève (Switzerland)

The term harmonic nanoparticles designate a family of inorganic nanometric crystals (size < 100 nm) of different materials ($KNbO_3$, $BiFeO_3$, $LiNbO_3$, KTP, …) sharing the characteristic of noncentrosymmetric structure. This property determines their large nonlinear optical efficiency, and, in fact, in the last years they have been mostly investigated as localized sources for second harmonic generation. After introducing this approach and comparing it with respect to other nanoparticles-based labelling strategies (quantum dots, upconversion NPs), I will highlight some recent applications in the field of (multi-photon) imaging and optical detection of biological samples together with NPs-mediated photo-interaction with cellular DNA.

9165-42, Session 12

Effect of solvent environment on colloidal quantum dot solar cell manufacturability and performance

Ahmad R. Kirmani, King Abdullah Univ. of Science and Technology (Saudi Arabia); Graham H. Carey, Univ. of Toronto (Canada); Buyi Yan, Maged Abdelsamie, Dongkyu Cha, King Abdullah Univ. of Science and Technology (Saudi Arabia); Lisa R. Rollny, Univ. of Toronto (Canada); Xiaoyu Cui, Canadian Light Source Inc. (Canada); Edward H. Sargent, Univ. of Toronto (Canada); Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

State-of-the-art colloidal quantum dot (CQD) solar cells have been shown to achieve power conversion efficiencies (PCEs) approaching 9%. However, deposition of the CQD absorber layer is tedious requiring a layer-by-layer (LbL) buildup and is a major obstacle to industrial scale-up. Understanding why the LbL process is needed to achieve state-of-the-art devices is crucial to improving manufacturability and to improving solar cells further. In this study we have sought to evaluate the solvent-QD interactions in terms of physical and chemical changes to the CQD absorbing layer in order to identify an alternative and more facile ligand

exchange route. We have demonstrated that an extended exposure of CQD films to methanol (MeOH) is harmful for the overall performance. This explains why the standard CQD solar cells made with MeOH require tedious LbL buildup involving nearly a dozen steps. Understanding of solvent interactions with QD films has led us to develop more efficient processing conditions based on use of acetonitrile (ACN) which allow us to achieve state-of-the-art performance in only three steps. This work could shed light on ways to achieve a single step deposition and solid-state ligand exchange.

9165-43, Session 12

Exciton and carrier dynamics in quantum confined materials *(Invited Paper)*

Xiaoyang Zhu, Columbia Univ. (United States)

The best-understood property of quantum confined semiconductor systems, such as quantum dots, wires, and wells, is the quantization of charge carrier energies near the band edges. In contrast, much less is known about how quantum confinement and dimensionality affect carrier relaxation dynamics. Here we present recent efforts in our lab to quantitatively probe exciton and carrier relaxation dynamics in quantum confined systems. We apply femtosecond nonlinear spectroscopic techniques to directly follow the dynamics in energy and time domains. We show how charge carrier dynamics can be bulk like at high energies and how quantum confinement comes into play as these carriers cool down to near the band edges. We discuss the central role of enhanced Coulomb interaction in quantum confined systems in differentiating their dynamic behavior from those in bulk solids.

9165-44, Session 12

Quantum dots: using the known as well as exploring the unknown *(Invited Paper)*

Ron Tenne, Osip Schwartz, Ayelet Teitelboim, Pazit Rukenstien, Maria Dyshel, Weizmann Institute of Science (Israel); Taleb Mokari, Ben-Gurion Univ. of the Negev (Israel); Dan Oron, Weizmann Institute of Science (Israel)

Colloidal quantum dots (QDs) are a research focus in materials science as well as a promising building block for applications in optics and microscopy. I will describe two works portraying these two aspects in QDs research. In the first, synthesis of novel hetero-structures shed light on a long-lasting question regarding QD blinking. In a second work the “good-old” QDs serve as building blocks in a new superresolution microscopy technique relying on the quantum nature of light.

Single QDs exhibit switching between a dark and a bright emission state, a phenomenon termed blinking. While still a matter of debate, many models link this darkening to the Auger recombination in charged QDs. To investigate this claim a single inorganic hole trap was grown onto CdSe/CdS nanorods, stochastically charging the QD. Although charging indeed introduced an Auger recombination route, the trap addition increased only the occurrence of a third intermediate brightness (“grey”) level [1]. Together with other blinking studies, this work hints on the conditions required to avoid blinking and use QDs in new imaging applications.

Superresolution microscopy techniques, imaging of features below the Abbe diffraction limit, rely on breaking one of the assumptions made in the Abbe limit. While uniform illumination, linearity and time independence are the most common cornerstones of the Abbe limit bypassed, we have harnessed quantum fluctuations in light in order to achieve superresolution imaging, breaking the ‘classicality-of-light’ assumption [2].

9165-45, Session 13

High efficiency Perovskite solar cells based on organolead iodide *(Invited Paper)*

Nam-Gyu Park, Sungkyunkwan Univ. (Korea, Republic of)

(Invited Talk) Perovskite solar cell based on organolead halide has been considered as a promising photovoltaic technology because of very low cost and high efficiency, and thereby regarded as a potential alternative to silicon or CIGS solar cells. In this talk, technologies for perovskite solar cells with power conversion efficiency exceeding 16% are presented. Since the first report on long-term durable perovskite solar cell with power conversion efficiency (PCE) of 9.7% in 2012 by Park’s group, PCE increased rapidly, as a result, 15% was achieved by Gratzel and Snaith groups in 2013. However, the average PCE was as low as 12%. Deposition method was found to be critical to high efficiency devices. We compare the photovoltaic performance of methylammonium lead iodide perovskite solar cells prepared by one-step and two-step deposition methods, where one-step showed low PCE of about 8-9%, on the other hands, two-step methods showed higher PCE with average value of more than 15% and best value of 17%. Substitution of other organic cations for methylammonium led to lower band gap and higher absorption coefficient, which consequently resulted in PCE of 16% and average PCE of 15.5% with better photostability and little I-V hysteresis.

9165-46, Session 13

P-contact metal oxide in efficient $CH_3NH_3PbI_3$ perovskite/PCBM planar-heterojunction hybrid solar cells

Tzung-Fang Guo, Peter Chen, Jun-Yuan Jeng, Kuo-Cheng Chen, Tsung-Yu Chiang, Pei-Ying Lin, National Cheng Kung Univ. (Taiwan)

Applying a thin nickel-oxide (NiOx) interlayer between glass/ITO electrode and light absorbing CH3NH3PbI3 perovskite significantly enhances the photovoltaic performance of perovskite/fullerene-derivative heterojunction hybrid solar cells. The efficient hole transfer at NiO/perovskite heterojunction was verified by photo-induced absorption spectroscopy, showing a broad spectral feature above 800 nm, the long-lived charge-separation state of NiO+/P-. We successfully demonstrate the efficient hole transfer between NiO/perovskite junction and apply p-contact NiO for fabricating perovskite-based solar cells with decent efficiency. First, NiOx electrode-interlayer is a p-type semiconductor of high work function of 5.4 eV, which is close to the valence band edge level of CH3NH3PbI3 perovskite (5.4 eV). The alignment of energy level minimizes the interfacial energy losses for the hole transfer and optimizes the photovoltage output of device. Second, CH3NH3PbI3 perovskite films prepared by the spin-coating process on glass/ITO/NiOx substrate exhibit a relatively smooth morphology than those deposited on glass/ITO/PEDOT:PSS substrate. The conformal coverage of the perovskite film enhances the light harvesting, reduces the leakage current, increases JSC, and elevates the PCE of the devices. The best performing cell with the configuration of glass/ITO/NiOx/CH3NH3PbI3 perovskite/PCBM/bathocuproine/Al presents an VOC= 0.92 V, a JSC = 12.43 mA/cm2, and a FF = 0.68, corresponding to a PCE of 7.8 % under standard 1 sun AM 1.5G simulated solar irradiation. Our findings reveal the design principle for enhancing the photovoltaic performance of CH3NH3PbI3 perovskite/PCBM hybrid heterojunction solar cells through the judicious selection of metal oxide p-contact material.

Quantum-chemical calculations of hybrid inorganic-organic perovskites

Wichard J. D. Beenken, Mezhoura Oussadou, Harald Hoppe, Erich Runge, Technische Univ. Ilmenau (Germany)

We will present quantum-chemical calculations of hybrid organic-inorganic perovskites usable for photovoltaic devices using the programpackage VASP. Based on XRD structures for the inorganic part of the perovskite (e.g. PbI2) we will demonstrate the optimal positions of the organic cations (e.g. CH3NH4+), which are almost invisible for XRD, within this structure. Furthermore we will present band-structure calculations of the optimized structures.

9165-48, Session 13

Progress and fundamental insights into perovskite solar cells *(Invited Paper)*

Nripan Mathews, Nanyang Technological Univ. (Singapore)

Solid-state organic-inorganic perovskite (CH3NH3)PbX3 (X =Cl, Br, I) based nanostructured solar cells have recently gained a lot of attention due to their superior performance and ease of fabrication. At the lab scale, power conversion efficiencies over 15 % have already been achieved utilizing a solution based two-step method to deposit the perovskite A power conversion efficiency of ~ 17 % has been identified as a realistic target. Now that it has been shown conclusively that the CH3NH3PbX3 perovskite layers can form highly efficient solar cells, efforts must focus on two areas (i) Unravelling the reasons for the high efficiency and (ii) focussing on technologically relevant challenges.

The talk will cover these two broad areas. Physical and photophysical characterization of these classes of compounds will be presented. The relevance of these properties in determining the high efficiencies as well as in predicting newer structures of perovskites will be shown. Photophysical characterization results showing the excellent carrier lengths in these classes of compounds will also be described. On the technological side, a cost effective low cost roll-to-roll production of solid state devices is only possible when the processing temperatures are brought down to 100-150 oC. A low temperature approach can have other interesting advantages such as the fabrication of flexible devices, due to the instability of plastic substrates at high temperatures. The utilisation of a ZnO compact layer formed by electrodepositon and ZnO nanorods grown by chemical bath deposition (CBD) allow the processing of low-temperature, solution based and flexible solid state perovskite CH3NH3PbI3 solar cells. Conversion efficiencies of 8.90 % were achieved on rigid substrates processed at low temperatures. Other efforts to utilise various mesoporous architectures will also be covered.

Drug/protein interactions studied by time-resolved fluorescence spectroscopy *(Invited Paper)*

Thomas L. Gustavsson, Dimitra Markovitsi, Lab. Francis Perrin (France); Ignacio Vayá, Maria-Consuelo Jiménez, Miguel A. Miranda, Univ. Politècnica de València (Spain)

The transport and distribution of drugs in the body is a complex mechanisms governed by many different processes. An important role is played by specific transport proteins, responsible for the fixing and release of the drugs. Obtaining a better understanding of the factors that govern the structure and dynamics of drug-protein complexes is therefore of great interest.

Among the various experimental approaches used, time-resolved fluorescence spectroscopy has proven to be a particularly powerful tool. This technique informs on the excited state interactions occurring between the photo-excited drug and the protein, which in turn brings detailed information regarding the structural dynamics of the complex. In our laboratory, we use a combination of various fluorescence techniques, notably femtosecond fluorescence upconversion.

We report here on a recent time-resolved fluorescence study of the interaction between flurbiprofen (FBP), a chiral non-steroid anti-inflammatory drug, and human serum albumin (HSA), the main transport protein in the human body. We compare the results obtained for the drug-protein complex with those of various covalently linked flurbiprofen-tryptophan dyads having well-defined geometries. In all cases stereoselective dynamic fluorescence quenching is observed, varying greatly from one system to another. In addition, the fluorescence anisotropy decays also display a clear stereoselectivity. For the drug-protein complexes, this can be interpreted in terms of the protein microenvironment playing a significant role in the conformational relaxation of FBP, which is more restricted in the case of the (R)-enantiomer.

Protein structure following adsorption on nanoparticles: importance for cellular binding and uptake *(Invited Paper)*

Christine K. Payne, Sabiha Runa, Georgia Institute of Technology (United States)

Nanoparticles offer exciting new approaches for biomedicine ranging from drug delivery to cellular imaging. In the course of these applications, nanoparticles are exposed to a complex mixture of extracellular proteins that adsorb onto the surface of the nanoparticle. This “protein corona” dominates the interaction of nanoparticles with cells. We have investigated how proteins found in blood serum affect the cellular binding of protein-nanoparticle complexes. Using fluorescence microscopy, we find that the cellular binding of cationic nanoparticles is enhanced by the presence of serum proteins while the binding of anionic nanoparticles is inhibited. Competition assays confirm that these protein-nanoparticle complexes use distinct cellular receptors. Circular dichroism spectroscopy, fluorescence spectroscopy, and isothermal titration calorimetry show that the secondary structure of the adsorbed serum albumin is altered following adsorption on the surface of cationic nanoparticles. These structural changes redirect the albumin-nanoparticle complex to scavenger receptors. In comparison, the secondary structure of albumin is preserved following adsorption on anionic nanoparticles. The cellular binding trend is independent of nanoparticle composition: quantum dots, colloidal gold nanoparticles, and low-density lipoprotein particles all show the same behavior. This link between protein structure and cellular outcomes will provide a molecular basis for the design of nanoparticles for use in biomedical applications.

9165-51, Session 14

Interfacial self-assembly of the bacterial hydrophobin BslA *(Invited Paper)*

Cait MacPhee, Keith Bromley, Ryan Morris, Giovanni Brandani, Laura Hobley, The Univ. of Edinburgh (United Kingdom); Nicola Stanley-Wall, Univ. of Dundee (United Kingdom)

The Gram-positive soil bacterium, Bacillus subtilis, can assemble to form a biofilm, a community of bacteria supported and protected by a self-produced extracellular matrix. Biofilms created by B. subtilis are highly hydrophobic, a property that arises from the surface active protein BslA. The high interfacial activity and hydrophobic properties of BslA are due to its unusual amphiphilic structure, which was recently determined by X-ray crystallography. BslA in its purified form also forms stable, viscoelastic films at air- and oil-water interfaces, and has been likened to the fungal hydrophobins. I will describe the novel mechanism of self-assembly of BslA, and present the physical properties of the interfacial films.

9165-71, Session 14

Role of ZnS shell on stability, cytotoxicity and photocytotoxicity of water-soluble CdSe semiconductor quantum dots surface modified with glutathione

Salwa Ali Ibrahim, National Institute of Laser Enhanced Sciences - Cairo University (Egypt); Wafaa Ahmed, National Institute of Cancer - Cairo University (Egypt); Tareq Youssef, National Institute of Laser Enhanced Sciences - Cairo University (Egypt)

Great efforts are currently devoted to fabricate high-quality quantum dots (QDs) in aqueous solutions for biomedical applications. Two biocompatible systems consisting of core (CdSe) and core/shell (CdSe/ZnS) QDs surface modified with glutathione (GSH), named CdSe-GSH and CdSe/ZnS-GSH respectively, were built. Upon photoirradiation using low laser power, both systems in HEPES buffer (pH:7.2) showed significant photoluminescence (PL) enhancements. CdSe/ZnS-GSH showed much less blue shifts in excitonic absorption and emission peaks without photobleaching compared with CdSe-GSH QDs system. X-ray diffraction showed that there is no change in the crystalline phase structure of the CdSe/ZnS-GSH QDs system after 1 h irradiation. Cell viability assessment, in the dark and following laser exposure, demonstrated that no cytotoxic effects were shown upon incubation CdSe/ZnS-GSH QDs with normal human skin (HFB4) or human adenocarcinoma (MCF-7) cell lines for periods up to 72 h and at concentrations up to 400 nM. The present study demonstrates that CdSe/ZnS-GSH QDs system exhibits a high photostability with a relatively high PL efficiency in aqueous medium following low intensity photoexcitation, without significant cytotoxic effect making this system attractive for several important biomedical applications.

Contribution of weak localization and electron-electron interaction in corrective term mT1/2 of the metallic conductivity in p-type 70Ge:Ga

Abdelhamid El Kaaouachi, Mohamed Errai, Univ. Ibn Zohr (Morocco); Hassan El Idrissi, Jamal Hemin, Univ. Hassan II Mohammedia - Casablanca (Morocco)

We present measurements of the electrical conductivity of metallic samples 70Ge: Ga driven to the metal-insulator transition by impurity concentration, in the temperature range 0.53 to 0.017 K and with impurity concentration up to 2.6251017cm-3.The Electrical conductivity is found to behave like $\sigma=\sigma 0+mT1/2$ inferior to 17 mK. Physical explanation to the temperature dependence of the conductivity is given by considering the competition between two effects involved in the mechanisms of conduction, like electron-electron interaction effect, and weak localization effect. The data are for 70Ge: Ga sample prepared and reported by Kohei M. Itoh et al in reference ["Itoh, K. M,and al, Phys. Rev. Lett.77, 4058-4061 (1996)."].

9165-54, Session PWed

Crossover from Efros-Shklovskii to Mott variable range hopping in amorphous thin NixSi1-x films

Jamal Hemine, Univ. Hassan II Mohammedia - Casablanca (Morocco); Mohamed Errai, Abdelhamid El Kaaouachi, Univ. Ibn Zohr (Morocco); Hassan El Idrissi, Univ. Hassan II Mohammedia - Casablanca (Morocco)

The temperature dependence of electrical conductivity of insulating amorphous NixSi1-x alloys is studied in the temperature range 1-160 K. At low temperatures, Efros-Shklovskii (ES) variable range hopping (VRH) is observed. This is assumed to occur because of the creation of the Coulomb Gap (CG) in the vicinity of Fermi level. With increasing temperature, CG vanishes and the measured conductivity can be described by Mott VRH model where the density of state is constant. The criterion of the crossover ES from to Mott VRH is assessed by extracting the related parameters.

9165-55, Session PWed

Transport phenomenon in two dimensional hole gas GaAs/AlGaAs

Hassan El Idrissi, Asmaa Chakhmane, Univ. Hassan II Mohammedia - Casablanca (Morocco); Abdelhamid El Kaaouachi, Univ. Ibn Zohr (Morocco)

In this work, we have studied the magnetoresistance in a dilute two-dimensional hole gas in GaAs/AlGaAs versus parallel magnetic field. To do this, we tried to define the normalized resistivity P(B)/P(0) as a function as B/Bx and B/Bcross, where Bx is a scaling parameter, and Bcross is determined by the crossover of B^2 dependence of theof the resistivity. This study shows that there is a dependence between the two curves of Bx and Bcross for various hole densities. Later, we were interested to extract the product m*g* for some values of hole density, in order to examine the variation of susceptibility x. The later is found to be almost constant for those values.

9165-56, Session PWed

Synthesis, Mössbauer spectroscopy and magnetic measurements of FeGa2O4 nanoparticles

Chun-Rong Lin, National Pingtung Univ. of Education (Taiwan); N. E. Gervits, I. S. Lyubutin, Russian Academy of Sciences (Russian Federation); Yaw-Teng Tseng, National Pingtung Univ. of Education (Taiwan)

FeGa2O4 nanoparticles with mean crystallite sizes ranging from 1.8 to 28.0 nm were prepared by the combustion method. Room temperature Mössbauer spectra indicate that all iron ions in the sample of 1.8 nm are in the paramagnetic high spin ferric state Fe3+. The magnetic component appears in the spectra for the samples 2.4 nm, 5.4 nm, 12.3 nm and 28.0 nm along with the paramagnetic doublet. Relative content of the magnetic component increases with the increase in crystallite sizes. The appearing magnetic component has the isomer shift value typical of ferrous ions. This means that only Fe2+ ions are in a magnetically ordered state, while Fe3+ ions are paramagnetic in all samples at room temperature. The values of magnetic hyperfine field Hhf at Fe2+ ions are very low, which could be explained by superparamagnetic properties of small particles. Low temperature Mössbauer spectra of the 1.8 nm size particles indicate a magnetic ordering of all iron ions. The spectra can be fit to two magnetic components with different values of magnetic hyperfine fields. According to isomer shift values both components belong to Fe3+. At 5 K the values of the field Hhf are 463 and 402 kOe. These values can be attributed to Fe3+ ions in octahedral and tetrahedral sites of the spinel structure, respectively. We define the cation distribution over tetrahedral and octahedral sites: (Fe1/3Ga2/3)tet [Fe2/3Ga4/3]oct O4. With temperature increasing the value of Hhf decreases, and one can plot the temperature dependence of Hhf for both sites and indicate a Neel temperature of 20 K.

Theoretical study in energy absorption in the systems zinc-macrocycles-nanocluster of TiO2 in solar-cells

Fernando Mendizabal, Univ. de Chile (Chile)

Many different principles have been proposed for constructing efficient solar-energy capturing devices. One of the more successful and promising approaches is dye-sensitized solar cells (DSSCs), proposed by Grätzel [1,2]. The chemical and physical processes of the Grätzel cells are largely known, whereas the details at the atomic level are less elucidated. To improve the efficiency of the dye-sensitized solar cells it is necessary to find suitable molecular chromophores for the light capturing process. We have studied from a point of view of quantum chemistry the process of interaction reduction of metallomacrocycles of Zn on cluster of TiO2 that represents the anatase surface [3-5]. Through calculations based on theoretical density functional (TDF) at the B3LYP, PBE y TPSS levels with dispersion effect, we study and quantify the interaction of the metallomacroclycle on the cluster of TiO2 and electronic spectra of the complexes in the energy absorption process.

Acknowledgments:

This work has been funded and prompted by the Conicyt-Aka-ERNC-001, Fondecyt N°1140503 project, Millenium Nucleus RC120001 and Basal Financing Program CONICYT-FB0807 (CEDENNA).

A striking mobility improvement of C_{60} OFET by inserting diindenoperylene layer between C_{60} and SiO_2 gate insulator

Jinpeng Yang, Keiichiro Yonezawa, Alexander Hinderhofer, Fabio Bussolotti, Satoshi Kera, Nobuo Ueno, Chiba Univ. (Japan)

Gap states in organic semiconductors play a crucial role in determining Energy-Level Alignment and in many cases they act as charge trapping centers to result in serious lowering of charge mobility. Thus origin of gap states has gained increasong attention in order to realize higher mobility organic devises[1-4]. Bussolotti et al. have demonstrated recently that gap states in a pentacene thin film increase even by exposing the film to inert gas and confirmed that the gas exposure madiates structural defects in the film thus gap states[4]. The results have also indicated that preparation of better-ordered organic thin films is necessary to improve the device performance, namely to decrease trapping states.

Here we demonstrate a dramatic improvement of electron mobility (μn) of a C60-based OFET by using ultrathin diindenoperylene (DIP) as the template layer between the C60 layer and SiO2 gate insulator [5]. μn of the DIP-template C60 OFET shows 2.9 cm2V-1s-1, which is higher by about 15 times than the reference device without the DIP. Moreover striking device stability was also found for the DIP-template C60 OTFT upon air exposure. The DIP-template C60 OFET showed μn of 1.9 cm2V-1s-1 in air, whereas the C60 OFET without the DIP degraded completely in air. Grazing incidence X-ray diffraction revealed that the ultrathin DIP inter-layer between the C60 film and the SiO2 improves the C60 film quality in the crystallinity, crystal orientation and grain size at least factor of 3. Furthermore ultrahigh sensitivity UPS measurements demonstrated that lowering of the density of trap states in the C60 film as well as at the C60 interface for the DIP-template C60 film.

Preparation of flexible TiO_2 photoelectrodes for dye-sensitized solar cells

Wen-Ren Li, National Central Univ. (Taiwan); Hsiu-Hsuan Wang, National Ilan Univ. (Taiwan); Chia-Feng Lin, National Taipei Univ Tech (Taiwan); Chaochin Su, National Taipei Univ. of Technology (Taiwan)

Dye-sensitized solar cells (DSSCs) based on nanocrystalline TiO2 photoelectrodes on indium tin oxide (ITO) coated polymer substrates have drawn great attention due to its lightweight, flexibility, and advantages in commercial applications. However, the thermal instability of polymer substrates limits the process temperature to below 150 °C. In order to assure high and firm interparticle connection between TiO2 nanocrystals (TiO2-NC) and polymer substrates, the post-treatment of flexible TiO2 photoelectrodes (F-TiO2-PE) by mechanical compression was employed. In this work, Degussa P25 TiO2-NC was mixed with tert-butyl alcohol and DI-water to form TiO2 paste. F-TiO2-PE was then prepared by coating the TiO2 paste onto ITO coated polyethylene terephthalate (PET) substrate using doctor blade followed by low temperature sintering at 120 °C for 2 hours. To study the effect of mechanical compression, we applied 50 and 100 kg/cm2 pressure on TiO2/PET to complete the fabrication of F-TiO2-PE. The surface morphology of F-TiO2-PE was characterized using scanning electron microscopy. The resultant F-TiO2-PE sample exhibited a smooth, crack-free structure indicating the great improvement in the interparticle connection of TiO2-NC. Increase of compression pressure could lead to the increase of DSSC photoconversion efficiency. The best photoconversion efficiency of 4.19 % (open circuit voltage (Voc) = 0.79 V, short-circuit photocurrent density (Jsc) = 7.75 mA/cm2, fill factor (FF) = 0.68) was obtained for the F-TiO2-PE device, which showed great enhancement compared with the F-TiO2-PE cell without compression treatment. The effect of compression in DSSC performance was vindicated by the electrochemical impedance spectroscopy measurement.

The influence of harmful gases on pentacene complexes

Luciano Leal, Univ. de Brasília (Brazil)

We concentrated our efforts on the absorption of the harmful gases cited below. Analyzing the dissociation energy of PEC we found that just ultraviolet rays can dissociate the gas-pentacene bound. This is an important result because the absorption is effective. We observed that when we substitute some carbons of pentacene for inorganic compounds the absorption increases.

9165-61, Session PWed

Geometrical functionalization of carbon nanotubes

Jonathan Teixeira, Univ. de Brasília (Brazil) and Federal Institute of Brasilia (Brazil); Wiliam F. Cunha, Pedro Oliveira Neto, Ricardo G. Gargano, Geraldo Magela, Univ. de Brasília (Brazil)

Due to the importance of phenomena associated to carbon dioxide, this gas has since long ago attracted the attention of the scientific community. In order to solve this CO2 related environmental problems an accurate and reliable detection of this gas in a scale that allows mapping its concentration in any media is highly desirable. An efficient method to do so is the nanostructural arrestment of carbon dioxide (1). In this sense, carbon nanotubes stands (SWNT) up as a promising structure. Provided an important adsorption energy is observed between the gas molecule and the nanotube lattice, the other physical and chemical features of this system are favorable to this nanotechnology application. In a previous study, we observed that, whereas pristine SWNT present low reactivity, the effect of doping this system with transition metals yielded excellent results [2].In the present work, we propose a new route to functionalize SWNT in order to arrest carbon dioxide. By means of electronic structures calculations in the scope of the Density Functional Theory, we applied structural deformations to the lattice and conducted an analysis on whether or not the originated system was suitable to CO2 detection. The feasibility of this system to the actual application is measured in terms of the interaction energy, energies levels profiles and spectroscopic constants. By means of this procedure we observed a reasonable adsorption energy, of about an order of magnitude higher than that of the pristine nanotube. This indicate that the conformational functionalization is an reasonable choice to obtain efficient gas sensors.

Silver nanoparticles on titanium dioxide through Linker molecules and its photocatalytic performance

Lorena Barrientos, La Univ. Pedagógica de Chile (Chile)

The development of metal-semiconductor photocatalyst through linker molecules makes innovation in catalytic materials. A controlled decoration of silver nanoparticles (AgNPs) through a linker molecule (HOOC-CH2-SH) on a titanium dioxide (TiO2) by Magnetron Sputtering was achieved. The structure, chemical nature, surface morphology and chemical bonding between the linker molecule, silver and titania have been characterized by UV-Vis Absorption Spectroscopy, Powder X-Ray Diffraction, Raman Spectroscopy, High Resolution Transmission Electron Microscopy and Field Emission Scanning Electron Microscopy. Combining the efficient photocatalytic activity of titania with the excellent absorption and electron acceptor abilities of AgNPs, it was possible to get a methylene blue (MB) photo-degradation of 100% at 150 min. The stability, particle-size and distribution of silver nanoparticles were controlled via chemical bonding to linker molecules and the sputter time.

The UV-Vis light photocatalytic activities were tested for the photocatalyst materials using the decoloration of MB solution. It was found that the best photocatalytic activity was obtained for TiO2-OOC-CH2-S-AgNPs with 30s of sputter time. The rest of photocatalysts prepared at different sputter times showed low performances, but higher than pure TiO2 nanoparticles. These results suggest that the use of linker molecules permit to control the particles size and distribution of AgNPs onto TiO2, allowing to modulate and improve the photocatalytic performance of TiO2.

This research was possible thanks to the financial support of the grant FONDECYT No. 11110138. L.B.P wants to thanks Basal Financing Program CONICYT, FB0807 (CEDENNA).

The ESR and MCD studies of spinel $CuCr_2Se_4$ nanocrystals

Chun-Rong Lin, Tzu-Fang Hsu, Hua-Shu Hsu, Yaw-Teng Tseng, National Pingtung Univ. of Education (Taiwan)

A facile solution based method involving the thermal decomposition of metal chloride precursors in selenium using oleyamine (OLA) as a solvent and stabilizing agent is used to synthesize spinel CuCr2Se4 nanocrystals. The Cu–Cr–OLA complex prepared at 175°C and cooled to room temperature (RT) is rapidly injected into Se–OLA mixture which has been heated to 330°C. The temperature of Se–OLA at time of injection is varied from 330°C down to RT. Transmission electron microscopy (TEM) images show 24.8 nm average size cubic to tetrahedron shaped nanocrystals prepared when the metal precursors were injected into the Se mixture at 330°C. Moreover, nearly monodisperse 68.1 nm hexagonal crystals prepared when injection was done at RT. X-ray diffraction (XRD) patterns show well defined crystalline peaks for samples provided the Cu: Cr: Se ratio was 1:2:8-10 (lack of excess selenium resulted in formation of secondary phases). The mean crystallite size from XRD matched well with TEM results. Hysteresis loops measurements show a soft ferromagnetic behavior with higher retentivity and magnetic saturation as the crystal size increased. A superparamagnetic relaxation is observed as the field-cooled (FC) and zero-field-cooled (ZFC) curves bifurcate while lower than bulk Curie temperature is a result of surface spin canting. The electron spin resonance (ESR) data shows hybridization between localized 3d3 electrons of Cr3+ and delocalized holes of Se 4p band, confirming correct phase formation. Broad magnetic circular dichroism (MCD) signals with similar shapes indicate magneto-optical effects of different crystal sizes.

Ultrafast carrier trapping of metal-doped titanium dioxide semiconductor revealed with femtosecond transient absorption spectroscopy

Jafar I. Khan, King Abdullah Univ. of Science and Technology (Saudi Arabia)

We explored for the first time the ultrafast carrier trapping of metal-doped titanium dioxide (TiO2) semiconductor using broadband transient absorption (TA) spectroscopy with 120 femtosecond (fs) temporal resolution. The titanium dioxide was successfully doped layer-by-layer with two metals namely Tungsten (W) and Cobalt (Co). The time-resolved data demonstrate clearly that the carrier trapping time decreases progressively with increasing the metal deposition time. A global fitting procedure for the carrier trapping indicates appearance of two time components: a fast one is directly associated with carrier trapping to the defect state in the vicinity of the conduction band while a slow component is attributed to carrier trapping to the deep level state from the conduction band. For a high doping deposition time in the range of 30 s, a carrier lifetime of about 1 picosecond is obtained. Interestingly, a significant effect not only of the doping deposition time but also the metal size on the carrier recombination dynamics is observed, indicating the crucial role of metal size in the carrier trapping in semiconductor oxides. Consequently, the findings reported here may potentially be implemented for high-speed optoelectronic applications and for ultrafast switching devices.

The preparation of Pt nanoparticle counter electrode for dye-sensitized solar cells

Chaochin Su, National Taipei Univ. of Technology (Taiwan); Hsiu-

Hsuan Wang, National Ilan Univ. (Taiwan); Wen-Ren Li, National Central Univ. (Taiwan)

In dye-sensitized solar cells (DSSCs), a thin layer of platinum (Pt) on counter electrode (Pt CE) catalyzes the electron transfer process to hole conducting medium, such as iodide/triiodide redox couple. The surface microstructure of Pt CE is thus an important factor to determine the efficiency of DSSCs. In this work, the optimal condition for preparation of nanoparticle platinum (Pt) film was investigated in order to use it as the counter electrode for high efficiency DSSCs. Hexachloroplatinic acid (H2PtCl6•(H2O)6) was used as a Pt precursor and it mixed with ethyl cellulose, α-Terpineol, and ethanol, to prepare Pt paste. Pt CE was then prepared by screen printing the Pt paste onto FTO (fluorine-doped tin oxide) glass followed by thermal decomposition to form Pt nanoparticles on FTO (Pt nanoparticles counter electrode - Pt NP CE). The surface morphology of Pt NP CE was characterized using scanning electron microscopy (SEM). The resultant Pt NP CE sample exhibited a porous structure which could provide more active surface area for Pt catalysis process and reduces the charge-transfer resistance as well. The best photoconversion efficiency of 9.05 % (open circuit voltage (Voc) = 0.76 V, short-circuit photocurrent density (Jsc) = 16.93 mA/cm2, fill factor (FF) = 0.70) was obtained for the Pt NP CE device, which was 13 % enhancement compared with the sputter deposited Pt electrode based cell. The effect of Pt nanoparticles in DSSC performance was vindicated by the electrochemical impedance spectroscopy measurement.

9165-66, Session PWed

Interfacial electronic structure of colloidal PbS quantum dots

Tae Gun Kim, Korea Research Institute of Standards and Science (Korea, Republic of) and Univ. of Science and Technology (Korea, Republic of); Hyekyoung Choi, Sohee Jeong, Korean Institute of Machinery & Materials (Korea, Republic of) and Univ. of Science and Technology (Korea, Republic of); Jeong Won Kim, Korea Research Institute of Standards and Science (Korea, Republic of) and Univ. of Science and Technology (Korea, Republic of)

Charge injection barrier and open circuit voltage (VOC) are affected by interfacial electron energy-level alignment in semiconductor Quantum dot (QD) solar cells. To keep the QDs stable and dispersive, surface ligand passivation is necessary, which adversely changes the electronic structure of QDs. Previously, only a few cases of literature have reported such electron structure changes by direct measurement of surface electron density of states, but their information is limited by vulnerable surface oxidation and low signal to noise ratio.

To investigate the electronic structure of lead sulfide (PbS) QDs and its effect of 1,2-Ethanedithiol (EDT) ligand passivation, we prepared colloidal quantum dots (CQDs) of PbS on two different substrates, indium tin oxide (ITO) and TiO2. They were transferred to a measurement stage for ultraviolet photoelectron spectroscopy (UPS) without air exposure and their electron density of states was observed. To discriminate the EDT contribution, we compared it with the results of PbS thin film and EDT exposure processed under vacuum. It is confirmed that the EDT adsorption induces the PbS more p-type characteristic. In addition, the chemical identification of each step was made by X-ray photoelectron spectroscopy (XPS)

The UPS spectrum for PbS CQDs comprises of five peaks from S 3s and 3p orbitals which are sensitive to oxidation. Their evolution and energy level alignment with the QD thickness are systematically observed by UPS and XPS. On ITO (WF = 4.62 eV), the PbS QDs show a slight hole injection barrier for Schottky type solar cells, whereas there is no electron injection barrier for heterojunction type but wide depletion layer on TiO2 (WF = 4.48 eV). However their actual energy level alignment with respect to Fermi level at ground state does not heavily depend on substrate. To enhance charge collection efficiency and increase VOC, a proper buffer layer or substrate treatment seems to be useful.

9165-67, Session PWed

Functionalized BNNTs as candidates to gas sensors

Wiliam F. Cunha, Univ. de Brasília (Brazil)

It is a well-known fact that nanostructured materials are good candidates to gas sensors due to their good surface to volume ratio. Unlike Carbon Nanotubes (CNT), Boron Nitride Nanotubes (BNNT) tend to exhibit constant electronic properties regardless of the diameter, chirality and number of layers considered. Add that to the high oxidation and thermal resistances observed, greater chemical stability when compared to CNT, and fair temperature conductivity and one has an interesting class of system to nanotechnology applications particularly in harmful and oxidative environments in which CNT would not be so efficient. In order to assess the feasibility of a given system to an actual application, one must perform an accurate and thorough investigation of all the properties that might affect the systems behavior. In this sense, we investigate electronic and vibrational properties of pristine and cobalt doped single walled boron nitride nanotubes of different chiralities interacting with a carbon dioxide molecule through the use of the Density Functional Theory and the Discrete Variable Representation. A stronger interaction between the carbon dioxide molecule and the functionalized BN nanotube was observed, when compared to a similar simulation concerning carbon nanotubes. Density of states investigation suggest that the doping induces major changes in the electronic structure pattern in the sense of critically reducing the original gap. From the vibrational point of view we note that the zig-zag chirality tends to present higher values of vibrational frequencies for most of the states considered regardless of the nanotubes being doped or not. Our results leads one to consider functionalized BN nanotubes superior to their carbon equivalents as far as chemisorption phenomena is concerned.

Dynamics of exciton diffusion in organic semiconductors

Pedro H. Neto, Wiliam F. Cunha, Guilherme M. Carvalho, Univ. de Brasília (Brazil)

The phenomenological reasons behind the decay of the luminescence observed in organic based compounds are unclear. By means of time-resolved photoluminescence in conjugated polymer/fullerene heterostructures was suggested that a single exciton diffusion coefficient can be utilized as a descriptive parameter for the dynamics of excitation migration in conjugated polymers. However, the heterogeneous morphology of thin films based on conjugated polymers makes difficult to separate the effects of chain conformation and interchain contacts from the intrinsic electronic properties of the chain. In this context, we investigated the creation of excitons and their dynamics in organic semiconductors with a modified version of the Su-Schrieffer-Heeger model Hamiltonian to include temperature effects and photoexcitations. When it comes to the excitons dynamics solely considering temperature, it was possible to characterize the diffusive process of the quasiparticles as being mainly due to random-walk effect, rather than being primarily originated from a concentration gradient. The good agreement with experimental evidences allows us to conclude that our model is, in many aspects, a fundamental tool to the phenomenological understanding of the charge-transport behavior in this class of new materials

9165-69, Session PWed

Optical tunability of magnetic polaron stability in single-Mn doped bulk GaAs and GaAs/AlGaAs quantum dots

Fabio V. Moura, Univ. de Brasília (Brazil); Fanyao Q. Qu, Univ. de Brasilia (Brazil); Ricardo G. Gargano, Univ. de Brasília (Brazil); Damaso D. Ribeiro, Univ. de Brasilia (Brazil)

Optical control of magnetic property of a magnetic polaron (MP) in Mn-doped bulk GaAs and GaAs/AlGaAs quantum Dots (QDs) have been studied. We have developed basis optimization technique for the method of linear combination of atomic orbitals (LCAO), which significantly improve the accuracy of the conventional LCAO calculation. We have demonstrated that a monochromatic, linearly polarized, intense pulsed laser field induces a collapse of the MP and an ionization of Mn-acceptor in Mn-doped GaAs materials due to a dichotomy of hole wave func tion. We find this optical tunability of MP stability can be adjusted by confinement introduced in GaAs QDs.

9166-1, Session 1

Some emerging directions in 21st century medicine *(Invited Paper)*

Massoud H. Agahi, Harbor-UCLA Medical Ctr. (United States); Farnaz Haji, Midwestern Univ. (United States)

"Nanomedicine" has been a term used loosely to refer to an emerging field of nano-scale technologies and concepts that may enable advances in the health sciences. The Nanomedicine initiative of the NIH Common Fund was established as a 10 year program with the primary goal of "characterizing the molecular components inside cells at a level of precision that leads to re-engineering intracellular complexes." At the midpoint of the Program the Nanomedicine Development Centers were asked to "define their translational goals and the transitional research path needed to reach those goals by the end of the initiative in 2015."

As Nanomedicine develops beyond its infancy stage it is necessary for those involved in related research and development activities to become aware of the general trends and trajectories in the field in order to better align their own efforts. Highlights of the NIH initiative will be discussed along with other leading developments of interest to researchers who envision contributing to this exciting transformation in the health sciences. Finally, some general thoughts and introduction to specific problems in clinical medicine that may be suitable targets for the emerging technologies to address will be presented.

9166-2, Session 1

Intracellular delivery of p53 gene, siRNAs against oncogenes and anti-cancer drugs using pH-sensitive inorganic nanoparticles for induction of apoptosis in breast cancer cells

Tahereh Fatemian, Monash Univ. (Malaysia)

Taking into account the high mortality and relapse rates of breast cancer, a new discipline maneuvering the heterogeneous biology of breast tumors and interfering with the underlying pathways would be an unmet need in breast cancer management.

This study utilizes carbonate apatite nanoparticles, as an efficient macromolecular drug delivery and expression system, for in vitro and in vivo intracellular delivery of p53 gene and siRNAs against HER2, MAP kinase and PI3 kinase pathway genes into breast cancer cells. By enhancing the capacity of the breast cancer cells to undergo apoptosis, this approach is shown to render the cancer cells more sensitive to classical anti-cancer agents.

The efficacy of the proposed treatments is evaluated by means of cytotoxicity assays, western blotting and also tumor regression studies in tumor bearing mice.

9166-3, Session 1

Incorporation of photosenzitizer hypericin into synthetic lipid-based nano-particles for drug delivery and large unilamellar vesicles with different content of cholesterol

Jaroslava Joniova, Pavol Jozef Šafárik Univ. in Kolšice (Slovakia) and Univ. Pierre et Marie Curie (France); Ludmila Blascakova, Pavol Jozef Šafárik Univ. in Kolšice (Slovakia); Zuzana Nadova, Daniel Jancura, Pavol Jozef Šafárik Univ. in Kolšice (Slovakia) and Ctr. for Interdisciplinary Biosciences (Slovakia); Franck Sureau, Univ. Pierre et Marie Curie (France); Pavol Miškovský, Pavol Jozef Šafárik Univ. in Kolšice (Slovakia) and Ctr. for Interdisciplinary Biosciences (Slovakia)

It has been proven that low-density lipoproteins (LDL) are useful vehicles for lipophilic drugs to cancer cells. We have used modified dextran (Dm) as protective coating of the natural LDL (nLDL) as well as of the synthesized LDL (sLDL) surface to make this delivery system even more efficient. In using the hydrophobic natural photosensitizer hypericin (Hyp) we intend to show that such modification can reduce the interaction of the initial [LDL-drug] complex with other serum constituents, such as free lipoproteins, and consequently decrease the drug redistribution processes.

Cryo-electron microscopy was used to characterize the size and structure of the complex. Fluorescence spectroscopy, confocal fluorescence imaging, raman optical tweezer and flow cytometry were used to characterize the redistribution of Hyp, loaded in lipoprotein/Dm complexes to free LDL molecules as well as to monitor cellular uptake of Hyp by U87-MG cells. It was shown that the redistribution process of Hyp between nLDL or sLDL molecules is partially decreased by Dm coating of (n/s)LDL surface. However, dextran coating of LDL-Hyp does not inhibit their recognition by LDL receptors of U-87 MG cells and further uptake of Hyp. Hence, this approach could lead to the construction of effective and selective delivery system of hydrophobic drugs to cancer cells.

9166-4, Session 1

Targeting hepatocellular carcinoma with aptamer-functionalized PLGA/PLA-PEG nanoparticles *(Invited Paper)*

Shannon E. Weigum, Melissa Sutton, Eugenia Barnes, Texas State Univ. (United States); Sarah Miller, New Braunfels High School (United States); Tania Betancourt, Texas State Univ. (United States)

Hepatocellular carcinoma (HCC) is one of the leading causes of cancer-related death worldwide, particularly in regions where chronic Hepatitis B and C infections are common. Nanoparticle assemblies that incorporate high –affinity aptamers which specifically bind malignant hepatocellular carcinoma cells could be useful for targeted drug delivery or enhancing contrast with existing ablation therapies. The in vitro interactions of a tumor-specific aptamer, TLS11a, were characterized in a hepatoma cell line via live-cell fluorescence imaging, SDS-PAGE and Western Blotting techniques. Cell surface binding of the aptamer-AlexaFluor®546 conjugate was found to occur within 20 minutes of initial exposure, followed by internalization and localization to early endosomes using the pH-sensitive LysoSensor™ Green dye and confocal microscopy. Aptamer-functionalized poly(lactide)-b-poly(ethylene glycol) (PLA-PEG) polymer nanoparticles were then prepared by nanoprecipitation and passively loaded with the chemotherapeutic agent, doxorubicin, yielding spherical nanoparticles approximately 70-100 nm in diameter. Targeted drug delivery and cytotoxicity was assessed using live/dead fluorescent dyes and a MTT colorimetric viability assay with elevated levels of cell death found in cultures treated with the aptamer-targeted PLA-PEG nanoparticles. Identification and characterization of the cell surface protein epitope(s) recognized by the TLS11a aptamer are ongoing, but these preliminary studies support the use of this unique aptamer and functionalized nanoparticle conjugates for targeted labeling and drug delivery within malignant hepatocellular carcinomas.

9166-5, Session 1

Nanotechnology-based treatment for chemotherapy-resistant cancer

Abraham H. Abouzeid, Niravkumar R. Patel, Northeastern Univ. (United States); Ilya M. Rachman, Sean Senn, Immix Biopharma, LLC (United States); Vladimir Torchilin, Northeastern Univ. (United States)

Background: Treatment of metastatic cancer remains a formidable clinical challenge. Better therapeutic options with improved tissue penetration and tumor cell uptake are urgently needed. Targeted nanotherapy, for improved delivery, and combinatory drug administration aimed at inhibiting chemo-resistance may be the solution.

Purpose: The study was performed to evaluate the therapeutic efficacy of polymeric PEG-PE micelles, co-loaded with curcumin (CUR) and doxorubicin (DOX), and targeted with anti-GLUT1 antibody (GLUT1) against MDA-MB-231 human breast adenocarcinoma cells both in vitro and in vivo.

Methods: MDA-MB-231 DOX-resistant cells were treated with non-targeted and GLUT1-targeted CUR and DOX micelles as a single agent or in combination. Tumor cells were also inoculated in female nude mice. Established tumors were treated with the micellar formulations at a dose of 6 mg/kg CUR and 1 mg/kg DOX every 2 d for a total of 7 injections.

Results: CUR+DOX-loaded micelles decorated with GLUT1 had a robust killing effect even at low doses of DOX in vitro. At the doses chosen, non-targeted CUR and CUR+DOX micelles did not exhibit significant tumor inhibition versus control. However, GLUT1-CUR and GLUT1-CUR+DOX micelles showed a significant tumor inhibition effect with an improvement in survival.

Conclusion: We showed a dramatic improvement in efficacy between the non-targeted and GLUT1-targeted formulations both in vitro and in vivo. Also, importantly, the addition of CUR to the micelle, has restored sensitivity to DOX, with resultant tumor growth inhibition. Hence, we confirmed that GLUT1-CUR+DOX micelles are effective in vitro and in vivo and deserve further investigation.

9166-6, Session 1

Feedback-mediated cancer therapy: a FRET-based nanoreporter approach

Suproteem K. Sarkar, Conestoga High School (United States) and Brigham and Women's Hospital (United States); Yashika Khater, Brigham and Women's Hospital (United States); Ashish Kulkarni, Shiladitya Sengupta, Harvard Medical School (United States)

A theranostic nanoparticle system was developed by integrating a chemotherapeutic agent with an "activatable" fluorescent tracer. The system signals tumor death by monitoring the activity of caspase-3, a product of apoptosis.

The polymer nanoparticles (Poly [isobutylene-alt-maleic anhydride]) were formed through reprecipitation and contained paclitaxel, a chemotherapy drug, and fluorescein isothiocyanate, a fluorescent dye. The dye's fluorescence was quenched through Förster resonance energy transfer (FRET) by a quencher that was connected to the dye by a peptide chain. With sizes ranging from 250-300 nm, the nanoparticles were stable for two weeks.

The nanoparticles were tested in vitro with responsive Lewis Lung Carcinoma (LLC) cells and taxane-resistant cells. Upon cell death by paclitaxel exposure, caspase-3 cleaved the peptide chain connecting the dye and the quencher, causing the system to fluoresce. When LLC cells were treated with the system, the nanoreporters fluoresced, but when resistant cells were tested, and when the drug was removed from the system, the nanoreporters did not fluoresce.

Since the system screens if a drug can successfully kill a particular tumor, it offers a novel and promising approach to personalized medicine.

9166-8, Session 1

Gold nanorods coupled with upconversion phosphors for simultaneous bladder cancer detection and treatment

Suehyun K. Cho, Univ. of Colorado at Boulder (United States); Lih-Jen Su, Xiaoping Yang, Thomas W. Flaig, Univ. of Colorado Denver (United States); Wounjhang Park, Univ. of Colorado at Boulder (United States)

The development of multifunctional nanoparticle complex composed of upconversion phosphor (UCP) nanoparticles and gold nanorods (AuNR) is presented. The anti-epidermal growth factor receptor antibody (αEGFR) conjugated AuNRs were prepared to demonstrate (1) specific binding to the EGFR-expressing bladder cancer cells (HTB9) and (2) thermal ablation of the cells upon NIR irradiation. The successful conjugation of AuNRs with αEGFR was directly confirmed by the specific binding to the HTB9 cells via NIR darkfield microscopy. In vitro thermal ablation experiments showed effective and selective cell killing by NIR irradiation.

UCPs absorbing NIR light and emitting visible fluorescence have ample potential as a high-contrast bio-imaging agent as the NIR excitation invokes minimal autofluorescence. For bioconjugation, UCPs were grafted with thiol and amine ended heterofunctional polyethylene glycol and poly(maleic anhydride-alt-1-octadecene) (PMAO). PMAO was first attached on UCP by hydrophobic interaction. Subsequent reaction with the amine group of PEG turns PMAO amphiphilic and the UCP nanoparticles water-soluble. The remaining amine-reactive groups allow further functionalization with αEGFR which provides specific, targeted binding with HTB9 cells.

The HTB9 cells treated with αEGFR functionalized UCPs were examined by fluorescence microscopy under 980nm illumination and membrane binding was clearly observed.

Finally, by using the free thiol end of PEG attached on UCP, the αEGFR functionalized UCP was linked to AuNR. The formation of UCP-AuNR complexes was confirmed by both optical microscopy as well as electron microscopy. Successful UCP-AuNR coupling enables simultaneous cellular level detection and ablation of cancer, opening a door to new diagnostic and therapeutic approaches.

9166-9, Session 1

Plasmonic enhanced pulsed laser induced optoporation and transfection of cells *(Invited Paper)*

Michel Meunier, Ecole Polytechnique de Montréal (Canada)

A new technique is introduced to perform optoporation and transfection of living cells using a laser and nanotechnology. Irradiating plasmonics nanostructures by an ultrafast laser beam produces highly localised processes on the nanoscale in the biological surrounding medium, yielding to the optoporation of the cell membrane.. These nanoparticles could be functionalised to target specific biological entities, thus performing multiple targeted processes on the nanoscale. . We are able to perform gene transfection in living cell with an optoporation efficiency as high as 70%. Complete physical model was developed to determine the basic mechanism underlying this new process. Our laser technology shows promises as an innovative tool for fundamental research in biology and medicine as well as an efficient alternative nanosurgery technology that could be adapted to therapeutic tools in the clinic.

9166-10, Session 1

Controlling the intracellular fate of nano-bioconjugates: pathways for realizing nanoparticle-mediated theranostics *(Invited Paper)*

James B. Delehanty III, Christopher M. Spillmann, Jawad Naciri, Kimihiro Susumu, Michael H. Stewart, Alan Huston, U.S. Naval Research Lab. (United States); Philip E. Dawson, Juan B. Blanco Canosa, The Scripps Research Institute (United States); Igor L. Medintz, U.S. Naval Research Lab. (United States)

For nanomaterials to realize their full potential in disease diagnosis and drug delivery applications, one must be able to exert fine control over their cellular delivery, localization and long-term fate in biological systems. Our laboratory has been active in developing methodologies for the controlled and site-specific delivery of a range of nanomaterials (e.g., quantum dots, colloidal gold, nematic liquid crystals) for cellular labeling, imaging and sensing. This talk will feature several examples from these efforts and will highlight the use of peptide- and protein-mediated facilitated delivery of nanomaterials to discrete cellular locations including the endocytic pathway, the plasma membrane and the cellular cytosol.

9166-11, Session 2

Probing protein-nanoparticle interactions using a plasmon waveguide resonance

Farshid Bahrami, Univ. of Toronto (Canada); Mathieu Maisonneuve, Michel Meunier, Ecole Polytechnique de Montréal (Canada); Arthur O. Montazeri, Yujin Kim, Nazir P. Kherani, James S. Aitchison, Mohammad Mojahedi, Univ. of Toronto (Canada)

A plasmon waveguide resonance (PWR) sensor is proposed for studying gold nanoparticle-protein interactions. The polarization diversity of the PWR sensor enables simultaneous measurement of surface reactions with two different light polarizations – TM and TE. Gold nanoparticles are immobilized on the PWR surface using a self-assembled APTMS layer. Then, nanoparticles are biotinylated and two different concentrations of streptavidin are passed over the samples. The response of each mode to streptavidin-biotin interaction at the surface of gold nanoparticles is investigated in real time. Finally, the nanoparticle surface reaction is decoupled from the bulk solution refractive index variations using dual mode spectroscopy.

9166-12, Session 2

Redox colorimetric-polyaniline nanoindicator for in-situ trafficking of intracellular transport

Seo Ryung Bae, Jihye Choi, Hyun-Ouk Kim, Byunghoon Kang, Myeong-Hoon Kim, Jong-Woo Lim, Yonsei Univ. (Korea, Republic of); Jin-Suck Suh, Yong-Min Huh, Yonsei Univ. College of Medicine (Korea, Republic of); Seungjoo Haam, Yonsei Univ. (Korea, Republic of)

Real-time tunable ratiometric fluorescent proton organic sensor that can efficiently measure optical fluorescent-based ratiometric signals in living cells, have attracted much interest in an aspect of understanding diverse cellular processes. In particular, vesicular proton plays a crucial role in cell biology staying generally between 6.8 and 7.4 in the cytosol and between 4.5 and 6.0 in the cell's acidic organelles since proteins depend on the proton level to maintain their structure and function, and cellular dysfunction is often associated with an abnormal proton level in organelles. One promising approach is the assessment of a nanoindicator based on polyaniline (PANI) that exhibits convertible transition states according to proton levels. To synthesize monodisperse silica-coated PANI for trafficking of the intracellular compartment with varying proton gradients, Fe3O4–MnO heterostructured nanoparticles were employed as an oxidant for the polymerization of aniline in an aqueous acidic medium. We synthesized two partially reversible oxidized forms of PANI, the deprotonated EB and protonated ES states, which exhibit distinct absorbance peaks at 750 and 600 nm, respectively. Subsequently, two pH-insensitive fluorophores, Cy3 and Cy7 were further adsorbed onto the PANI surface. The optical-absorbance peak of polyaniline was red-shifted as a result of its transition from the EB state to the ES state in the entire physiologically relevant range of the endosome–lysosome pathway. To assess the feasibility of using a fluorophore-adsorbed silica-coated polyaniline nanoindicator (FPSNI) as an organic nanoquencher, we investigated the quenching effect of FPSNICy3 and FPSNICy7, biocompatibility, and in vitro ratiometric fluorophores intensities.

9166-14, Session 2

Novel nano-optical concepts for sensing and driving helical micro-biological objects

Silke R. Kirchner, Lindsey L. Anderson, Ludwig-Maximilians-Univ. München (Germany); Debora Schamel, Max-Planck Institut für Intelligente Systeme (Germany); Spas N. Nedev, Sol Carretero-Palacios, Andreas Mader, Madeleine Opitz, Theobald Lohmüller, Ludwig-Maximilians-Univ. München (Germany); Peer Fischer, Max-Planck Institut für Intelligente Systeme (Germany) and Univ. Stuttgart (Germany); Jochen Feldmann, Ludwig-Maximilians-Univ. München (Germany)

We report two novel concepts related to optical trapping that have great potential for future applications in theranostics on the micro- and nanoscale.

Recently, an optically based "nanoear" has been introduced by our group [1] which allows for the detection of flagellar motion stemming from an optically trapped bacterium [2]. For this purpose a single bacterial cell either with or without a helical flagellar bundle is optically trapped in a focused laser beam. A second optical tweezer is used to trap a silica particle close to the trapped bacterium. The spatiotemporal diffusion pattern of the microparticle within the tweezer potential is then tracked with the help of a dark field microscope and a high speed camera. The Fast-Fourier spectrum of the particle motion clearly shows a resonance at 62 Hz which is interpreted as the main rotation frequency of the flagellar bundle [2].

Vice versa, we study the light-induced rotation of a helical colloidal silica particle [3, 4] which serves as an inorganic model system of a rotating bacterial flagellum. Here, the inorganic colloidal screw-propellers are held in an optical trap. We obtained the rotation frequency by performing a Fast-Fourier analysis of the optically detected microscrew position versus time. Although the incident light is linearly polarized, the helical shape of the particle results in rotation. We can drive the "micro driller`s" rotation even more efficiently when using circularly polarized light.

9166-15, Session 2

Transfer of electronic excitation energy in determining of structural changes in nanoscale biosystems under the influence of surfactants

Andrey G. Melnikov, Irina V. Alonova, Gennady V. Melnikov, Saratov State Technical Univ. (Russian Federation)

We observed singlet-singlet energy transfer between tryptophanyl of human serum albumin (HSA) and probes from xanthene and acridine series.

We determined the radius of singlet-singlet energy transfer between tryptophanyl and the probes from xanthene series. The values of this radius do not exceed a value of 10 Angstroms. This indicates that the selected hydrophilic probes are localized in deep microregions of protein globule near hydrophobic tryptophanyl. The efficiency of energy transfer between tryptophanyls and probes from xanthene series: eosin, erythrosine is much higher than between tryptophanyls and trypaflavine.

We have studied the interaction of the cationic (cetyltrimethylammonium bromide), anionic (sodium dodecyl sulfate) and nonionic (triton X-100) surfactants with proteins. We observed the decrease in the radius of energy transfer during surfactants addition, which testifies about structural changes in proteins under the influence of surfactants. Hence the radius of energy transfer is a quantitative assessment of structural changes in proteins.

In addition, the binding constants of probes with proteins were identified.

Also we performed studies of triplet-triplet transfer of electronic excitation energy through the exchange- resonance mechanism between the polar probes – energy donor – eosin and nonpolar probes – energy acceptors – anthracene bound to HSA. These studies have revealed interglobular energy transfer due to diffusion of the energy donor – eosin during the lifetime of its excited triplet state in protein solution.

Radius of triplet-triplet energy transfer was defined. The dependence of the radius of energy transfer on the concentration of surfactants that causes structural changes in proteins was observed.

9166-16, Session 2

Portable biosensor based on plasmonic interferometer array

Xie Zeng, Dengxin Ji, Nan Zhang, Haomin Song, Qiaoqiang Gan, Univ. at Buffalo (United States)

High-throughput microarray multiplexed biosensing is important for early detection of disease and drug screening, which currently rely on fluorescent-labeling techniques. However, since fluorescent labels often interfere with molecular binding interactions and lead to inaccurate measurement, there is a significant need for label-free biosensing technique. While prism-based surface plasmon resonance systems have become the archetype for label-free biomolecular and chemical sensing, reductions in size and instrumental complexity are desired for applications requiring low-cost, compact, portable sensors, including routine point-of-care clinical evaluation, real-time diagnosis of diseases in developing countries and fast genetic mapping for personalized care. Nanoplasmonic biosensors employing novel topographies are an attractive miniaturized platform to meet these requirements, which are mainly based on wavelength interrogation in most reports. However, high spatial density multiplexed measurements are difficult to achieve in these designs in that broadband wavelength analysis via spectrometer is required, which inevitably adds the size and cost of the entire sensing system. In this work, we develop a compact plasmonic interferometer biosensor platform constructed by nanogroove-slit pairs or nanogroove rings with a nanohole at their center. Surface plasmon modes generated at the nanogrooves will propagate to the nanoslit or hole to interfere with the free space light transmitted through the nanoslit/hole and enable the surface refractive index sensing. Importantly, this plasmonic interferometer can be fabricated in a large scale array and be directly imaged by miniaturized microscope system coupled with CCD/CMOS imagers to realize low cost and portable sensitive multiplexed biosensor systems.

9166-17, Session 2

Label free detection of phospholipids by infrared absorption spectroscopy

Tahsin Ahmed, Erick Foster, Genevieve Vigil, Aamir A. Khan, Paul W. Bohn, Scott S. Howard, Univ. of Notre Dame (United States)

We present a new compact, label free dissolved lipid sensor by combining capillary electrophoresis separation in a PDMS microfluidic chip online with mid-infrared (MIR) absorption spectroscopy for biomarker detection. In this system, the detection platform is a PDMS microfluidic chip placed on top of a germanium substrate. On-chip capillary electrophoresis is used to separate the biomarkers without introducing any extrinsic contrast agent, which reduces both cost and complexity. The label free biomarker detection is done by interrogating separated biomarkers in the channel by MIR absorption spectroscopy. Phospholipids biomarkers of degenerative neurological, kidney, and bone diseases are detectable using this label free technique. These phospholipids exhibit strong absorption resonances in the MIR and are present in biofluids including urine, blood plasma, and cerebrospinal fluid. MIR spectroscopy of a 12-carbon chain phosphatidic acid (PA) (1,2-dilauroyl-sn-glycero-3-phosphate (sodium salt)) dissolved in N-methylformamide, exhibits a strong amide peak near wavenumber 1660 cm-1 (wavelength 6 μm), arising from the phosphate headgroup vibrations within a low-loss window of the solvent. PA has a similar structure to many important phospholipids molecules like phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and phosphatidylserine (PS), making it an ideal molecule for initial proof-of-concept studies. In conclusions, we present a new detection platform that requires minimal sample preparation and is capable of identifying several biomarkers from the same sample, simultaneously.

9166-59, Session 2

Optical printing and injection of gold nanoparticles into living cells

Miao Li, Theobald Lohmüller, Jochen Feldmann, Ludwig-Maximilians-Univ. München (Germany)

The active delivery of nanoscopic objects to the surface or interior of living cells with light offers promising prospects for the development of novel molecular delivery strategies or intracellular biosensor applications.

Previous works in our group showed that the gold nanoparticles could be not only patterned on glass surface by laser [1], but also be optically pushed through the lipid membrane [2]. In this study, we show that single gold nanoparticles (80 nm) from solution can be optically captured and patterned on Chinese hamster ovary (CHO) cells by using a 532 nm cw laser beam under dark-field microscope. We furthermore demonstrate that the particles can be injected into the cell by focusing the laser on the printed particles on the cell surface. We find that a short exposure time (within one second) is sufficient to perforate the cell membrane and inject the particles into the cell. The cell viability and cytotoxicity during printing and injection are investigated to help explaining the mechanism of the cell-nanoparticle interaction.

9166-61, Session 2

Advanced terahertz imaging and spectroscopy systems based on plasmonic terahertz optoelectronics *(Invited Paper)*

Mona Jarrahi, Univ. of California, Los Angeles (United States)

We present an overview of recent advances in plasmonic photoconductive terahertz sources and detectors, enabling higher performance terahertz imaging and spectroscopy systems. We show that the use of plasmonic contact electrodes in a photoconductive terahertz source and detector manipulates the spatial distribution of photocarriers in the device active area and enhances the number of photocarriers in nanoscale distances from the contact electrodes significantly, enabling efficient collection of the majority of carriers in a sub-picosecond time scale. It also allows increasing photoconductor active area without a considerable impact on device parasitics, boosting the maximum terahertz radiation power and detection sensitivity by preventing the carrier screening effect and thermal breakdown at high optical pump powers. We experimentally demonstrate that the use of plasmonic photoconductive terahertz sources and detectors in a terahertz imaging and spectroscopy system offers more than four orders of magnitude higher signal-to-noise ratio levels compared to existing terahertz imaging and spectroscopy systems. This significant performance enhancement could offer numerous opportunities for e.g., medical diagnostics, biological sensing, pharmaceutical quality control, and medical imaging.

9166-18, Session 3

Computational microscopy, sensing, and diagnostics *(Invited Paper)*

Aydogan Ozcan, Univ. of California, Los Angeles (United States)

My research focuses on the use of computation/algorithms to create new optical microscopy, sensing, and diagnostic techniques, significantly improving existing tools for probing micro- and nano-objects while also simplifying the designs of these analysis tools. In this presentation, I will introduce a new set of computational microscopes which use lens-free on-chip imaging to replace traditional lenses with holographic reconstruction algorithms. Basically, 3D images of specimens are reconstructed from their “shadows” providing considerably improved field-of-view (FOV) and depth-of-field, thus enabling large sample volumes to be rapidly imaged, even at nanoscale. These new computational microscopes routinely generate >1–2 billion pixels (giga-pixels), where even single viruses can be detected with a FOV that is >100 fold wider than other techniques. At the heart of this leapfrog performance lie self-assembled liquid nano-lenses that are computationally imaged on a chip. These self-assembled nano-lenses are stable for >1 hour at room temperature, and are composed of a biocompatible buffer that prevents nano-particle aggregation while also acting as a spatial “phase mask.” The field-of-view of these computational microscopes is equal to the active-area of the sensor-array, easily reaching, for example, >20 mm2 or >10 cm2 by employing state-of-the-art CMOS or CCD imaging chips, respectively.

In addition to this remarkable increase in throughput, another major benefit of this technology is that it lends itself to field-portable and cost-effective designs which easily integrate with smartphones to conduct giga-pixel tele-pathology and microscopy even in resource-poor and remote settings where traditional techniques are difficult to implement and sustain, thus opening the door to various telemedicine applications in global health. Some other examples of these smartphone-based biomedical tools that I will describe include imaging flow cytometers, immunochromatographic diagnostic test readers, bacteria/pathogen sensors, blood analyzers for complete blood count, and allergen detectors. Through the development of similar computational imagers, I will also report the discovery of new 3D swimming patterns observed in human and animal sperm. One of this newly discovered and extremely rare motion is in the form of “chiral ribbons” where the planar swings of the sperm head occur on an osculating plane creating in some cases a helical ribbon and in some others a twisted ribbon. Shedding light onto the statistics and biophysics of various micro-swimmers’ 3D motion, these results provide an important example of how biomedical imaging significantly benefits from emerging computational algorithms/theories, revolutionizing existing tools for observing various micro- and nano-scale phenomena in innovative, high-throughput, and yet cost-effective ways.

9166-19, Session 3

Electron optics of nanoplasmonic metamaterials in bio/opto theranostics *(Invited Paper)*

Donald K. Roper, Univ. of Arkansas (United States) and National Science Foundation (United States); Drew DeJarnette, Department of Mechanical Engineering, University of Tulsa (United States); Greg T Forcherio, Microelectronics-Photonics Graduate Program (United States); Jeremy Dunklin, Keith Berry Jr., Department of Chemical Engineering, University of Arkansas (United States); Gyoung Jang, Oak Ridge National Laboratory (United States); Milana Lisunova, Department of Chemical Engineering, University of Arkansas (United States); Phillip T Blake, Departments of Math and Science (United States); Wonmi Ahn, Department of Chemistry, Boston University (United States)

Opto-electronic coupling of plasmonic nano-antennas in the near infrared water window is of growing interest for biosensing, opto-theranostics, and drug delivery. Dynamic enhancement of opto-electronic coupling could advance synthetic biology and enhance neurotechnologies. Fundamentally, quantized photon-exciton coupling supports induced charge transfer in ordered DNA chains and distance-dependent Forster resonance energy transfer in spectroscopic molecular rulers.

Our lab distinguished contributions of quantized plasmon polarizabilities and photon diffraction to opto-electronic coupling in ordered metal-ceramic and polymeric nanocomposite metamaterials for bio/opto theranostic applications. Metamaterials exhibit tunable electromagnetic functionality (e.g., iridescence in butterfly wings; radiofrequency cloaking) due to coherent interference from multiscale structuring of nanocomposites. We have made rapid progress recently in self-assembling plasmonic metamaterials on ceramic and biocompatible polymeric substrates, and distinguishing coherent and incoherent optical re-radiation and thermal dissipation from plasmonic nano-antennas in biocompatible devices.

Design of dynamical electron optics in bioelectronic systems has been obstructed by computational expense and complexity. Our lab has developed and validated several approximations that integrate near-field polarizability and far-field modal interference to describe electron optic coupling in metamaterials and biodevices. This speeds design and description of new ring nanoarchitectures that show promise for bioapplications.

We characterize our fabricated metamaterials and validate their fundamental descriptions using microspectroscopies (x-ray photoelectron; transmission UV) and transmission/scanning electron and optical microscopies. Such analysis has supported measurable improvements in opto-electronic interactions in nano-scale metallic particles and films for bio/opto theranostics.

9166-20, Session 3

Improving the performance of silicon photonic rings, disks, and Bragg gratings for use in label-free biosensing

Shon A. Schmidt, Univ. of Washington (United States); Jonas Flueckiger, Department of Electrical and Computer Engineering, The University of British Columbia (Canada); WenXuan Wu, Department of Bioengineering, The University of Washington (United States); Samantha M Grist, Sahba Talebi Fard, Department of Electrical and Computer Engineering, The University of British Columbia (Canada); Valentina Donzella, Department of Electrical and Computer Engineering, The University of British Columbia, (Canada); Pakapreud Khumwan, Emily R Thompson, Qian Wang, Pavel Kulik, James T Kirk, Department of Bioengineering, The University of Washington (United States); Karen C Cheung, Lukas Chrostowski, Department of Electrical and Computer Engineering, The University of British Columbia (Canada); Daniel M Ratner, Department of Bioengineering, The University of Washington (United States)

Silicon photonics is emerging as a mainstream technology for high performance computing and telecommunications. As near-infrared light propagates through nano-scale silicon wires on a chip, a portion of the light travels outside the waveguide, sensitive to refractive index changes such as molecules binding on its surface. This feature makes silicon photonics an ideal platform for label-free biosensing and promises the advent of highly-matrixed medical diagnostic lab-on-chip systems at the economies of scale only offered by today's CMOS foundries. In this paper, we describe a myriad of TE- and TM-mode silicon photonic resonators specifically optimized for biosensing applications such as: cascaded micro-rings, micro-disks, and slab- and slot-waveguide Bragg gratings. We demonstrate their biosensing capability and compare their performance in terms of bulk sensitivity, Q, and detection limit. Specifically, we demonstrate the improved bulk sensitivity of TM-mode micro-ring and micro-disk sensors over their TE counterparts and the resulting impact on particle detection and size differentiation. We also report on sensitivity improvements achieved by suspending the resonant sensing portion of Bragg grating sensors, creating more overlap between the evanescent field and bulk media. Finally, the performance of each sensor is compared for the detection of biological analytes for future application in lab-on-a-chip systems.

9166-21, Session 3

Novel 3D plasmonic nano-electrodes for intracellular investigations and neural interfaces

Mario Malerba, Michele Dipalo, Alessandro Simi, Hayder Amin, Luca Berdondini, Francesco De Angelis, Istituto Italiano di Tecnologia (Italy)

We present a novel, advanced and robust approach for the fabrication of 3D high aspect-ratio hollow plasmonic nanoantennas [1].

This not only provides a new fabrication method, which may outdo current limits in many fields, but also introduces a new class of nanostructured devices, to be employed and studied in fundamental and multidisciplinary research fields.

In detail, we report on large-scale matrices of vertical plasmonic hollow nanoantennas, fabricated on different supports. Among its traits, a high electric field enhancement from the architectures' hotspots and a reproducible resonance tunability in a broad range of the spectrum. The 3D nature of the fabricated devices enables us to realize efficient broadband-enhancement plasmonic architectures, electrically connected to an active electronic circuit without affecting its plasmonic functioning. Additionally, the hollow nature of the antennas enables the fabrication of microfluidic devices for intracellular drug-delivery experiments. The outstanding mechanical properties (flexibility and resistance) at last allow us to use the structures as microelectrodes for intracellular recordings [2], porating the outer membrane and accessing the cytosol environment. By fabricating such architectures onto pre-built, commercially available C-MOS multielectrode array circuits (MEAs), it is thus possible to synergistically study and monitor with an unprecedented sensitivity and resolution complex biological systems, such as neuron networks, merging electrical recordings with optoplasmonic spectroscopy.

9166-22, Session 3

The whispering gallery mode biosensor: label-free detection from virus to single protein *(Invited Paper)*

Stephen Holler, Fordham Univ. (United States); Venkata R. Dantham, Stephen Arnold, Polytechnic Institute of New York Univ. (United States); Vasily Kolchenko, New York City College of Technology (United States); David Keng, Polytechnic Institute of New York Univ. (United States); Brigid Mulroe, Milan Paspaley-Grbavac, Fordham Univ. (United States)

The presence of infection or disease may be elucidated through the detection of pathogenic agents or protein markers within the bodily fluids. Such nanobioparticles circulate throughout the body and may serve as an indicator of infection or the reemergence of disease. However, for efficacious treatment to be administered early identification is necessary which requires the ability to ultrasensitive trace species detection. The whispering gallery mode biosensor has developed over the years as a sensitive photonic platform for the label-free detection of trace quantities of biological material. It has been successfully applied to the detection of bacteria, virus and protein. Single virus sensing has been achieved through the integration of plasmonic nanoparticles with the whispering gallery mode sensor. We recently reported label-free single protein detection using this nanoplasmonic-photonic hybrid resonant microcavity. Plasmonic-enhanced resonant systems have proven effective at being highly sensitive and highly responsive to changes in their environment. The textured surface of the plasmonic nanoparticles considerably boosts local electric field in the vicinity of the plasmon resonance. This enhancement facilitates the detection of individual viruses and protein markers making possible the sensitive detection of pathogens (e.g., Human Papillomavirus) and important disease markers (e.g., Thyroglobulin). The enhanced detection capability was demonstrated using small protein molecules (BSA (66 kDa) and Tg (660 kDa)), which resulted in the observation of a larger (2.4x - 15x) response than expected from this smooth surface model and allows us to project the limit of detection of the whispering gallery mode sensor to be 5 kDa.

9166-23, Session 3

Innovative optic sensing concepts towards applications in biotechnology and medicine *(Invited Paper)*

Joerg Opitz, Thomas Härtling, Susan Derenko, Carola E. Gerich, Manuela Reitzig, Olaf Roeder, Fraunhofer IKTS-MD (Germany)

The Fraunhofer Institute for Ceramic Technologies and Systems, Branch Materials Diagnostics (IKTS-MD) covers also fields of biosensing and nanotechnology, from basic research towards applications. This talk will address three optically based methods for sensing.

Improving cancer diagnosis is one of the important challenges at this time. The precise differentiation between benign and malignant tissue is of utmost significance in oncology and oncologic surgery. A diagnostic system based on the analysis of the fractal dimension of time-resolved auto-fluorescence spectroscopy will be illustrated. The results of different multi-clinical studies on prostate and oral tissue will be shown.

Especially in the food and medical sector regulations concerning sterility are increasingly tightened. A promising alternative to low-temperature and dry sterilization of surfaces for sensitive packaging materials is the electron beam treatment. For this, a secure proof for sterilization process is required. However, there does not exist any non-destructive and in

situ method up to now. Our approach is to integrate a suitable marker material based on rare-earth-doped phosphors in the packaging material of the respective product. We present our recent investigations on time-resolved measurements of alterations in the temporal luminescence decay of upconversion phosphors induced by electron beam irradiation.

The monitoring of drinking and waste water quality and water based processes in the chemical industry requires a sensor technology with the capability of being integrated in the process and a distinguished reliability. For this a refractive index sensing with a CCD chip technology based on localized SPR sensing will be discussed.

9166-24, Session 3

A portable surface plasmon resonance biosensor capable of phase interrogation in a large dynamics range *(Invited Paper)*

How-Foo Chen, Hsin-Yuan Chuang, National Yang-Ming Univ. (Taiwan); Chih-Hang Chen, Yun-Hsiang Chang, National Yang-Ming Univ (Taiwan)

Biosensors utilizing surface plasmon resonance (SPR) for drug and antibody screening, clinical examination, food pollution detection, and life science research have received tremendous investigation due to their characteristics of label-free operation, real-time observation, and high sensitivity detection. However, most of the current devices are either bulky with descent sensitivity or compact but with very limited sensitivity. Thus, with the development of a point of care (POC) biosensor in mind, a polymer-molding prism with double parabolic surfaces is invented and developed to implement an ultra-compact SPR biosensor with extremely high sensitivity. The polymer molded free-form prism is cost effective and then disposable, thus cross contamination of biological samples can be avoided. Also because of the low-cost consumable light-coupling part, this biosensor can extend the applications of SPR biosensors from laboratory studies to clinical practices. A highly sensitive biosensor with a form factor less than 15cm*15cm*5cm was received with a tunable excitation angle of light beam for a large dynamic range. The invented optical structure can easily utilize optical phase interrogation, which usually requires a very precise optical alignment, with a tunable light incident angle. A 635nm laser beam and Au coating of around 47.5nm is used to test the sensitivity. Detection of limitation with the value of less than 5.0x10-7 refractive index unit was obtained. The device is also compatible to a modern microscopy platform.

9166-25, Session 3

Optofluidic cellular immunofunctional analysis by localized surface plasmon resonance *(Invited Paper)*

Katsuo Kurabayashi, Bo-Ram Oh, Univ. of Michigan (United States)

Biomolecular motors are nanometer-scale biomaterials that convert chemical energy stored in ATP into mechanical work. They are responsible for mass transport and cell movement in biological systems. The bionanotechnology research community has recently been exploring the development of new hybrid devices that incorporate biomolecular motors in a non-biological engineered material structure. Manipulation of nanomechanical structures using these motors is an excellent example of utilizing life's natural resources to power man-made systems at high fuel-to-power conversion efficiency. This talk discusses our research on nanometer-scale molecular sorting and biosensing utilizing biomolecular motor-integrated micro/nano materials and devices with a fundamental understanding of nanomechanical processes to control their stochastic movements. Expected advantages and technological challenges accompanying the hybrid devices are also discussed.

9166-26, Session 3

Elucidation of protein-small molecule interactions using a single particle aperture optical trap

Ryan M. Gelfand, Ahmed Al-Balushi, Abhay Kotnala, Skylar Wheaton, Reuven Gordon, Univ. of Victoria (Canada)

Current methods for characterizing protein-small molecule interactions are generally assay based and require a significant amount of preparation; for example, fluorescent labeling. By using a double nanohole optical aperture trap a single protein can be trapped and characterized both with and without the addition of a small molecule. These interactions are vital to understanding many drug molecule workings and may help drug discovery. The optical behavior of the trap changes depending on the geometric properties and dynamics of the protein being trapped and by changing these characteristics we can separate one interaction type from another. For example streptavidin and biotinylated streptavidin can be identified based on their respective effects on the optical properties of the transmitted light exiting the aperture trap. Furthermore using a microfluidic flow channel integrated with the double nanohole trap, real time studies of the bonding dynamics between these two analytes can be studied without steric hindrance of the protein. The trapping laser uses less power than conventional gradient force optical trapping, and heat is efficiently removed from the trapping region by the gold film. Therefore, this process is nondestructive, and because the wavelength used is in the near infrared non-resonant Raman studies may be performed in-situ. This technique can be made portable and compact by fabricating the trap onto the end of an optical fiber and multiplexed by bundling many of them together. This new construct would allow researchers to conduct experiments in parallel, being able to then extract large amounts of data quickly and efficiently.

9166-27, Session 4

Nanoscale fiber tip probe for biomedical sensing *(Invited Paper)*

Qimin Quan, Wooyoung Hong, Harvard Univ. (United States); Feng Liang, Diane Schaak, The Rowland Institute at Harvard (United States); Marko Loncar, Harvard School of Engineering and Applied Sciences (United States)

Rapid and sensitive biosensors are gaining increasing importance in biomedicine and public health. Fluorescence based assays (e.g. enzyme-linked immunosorbent assay (ELISA), microarray, green fluorescent protein) have enabled a number of scientific advances and commercial applications. However, the labeling approaches are often difficult to control and may interfere with receptor affinity. I will describe a label-free nanoscale fiber tip probe as a tool for in vitro protein detection. I will compare the sensitivity of the bioprobe with standard assays such as ELISA, and traditional SPR sensors, such as Biacore. Furthermore, I will discuss the application of the nanscale fiber tip probe to detect intracellular proteins.

The fiber tip probe has a 5 micrometer length and sub-100 nanometer-diameter. One single gold nanorod is attached to the end of the tip, and the surface of which was functionalized with antibodies specific to the target analyte. The collective oscillation of the conductive electrons in the gold nanorod couples strongly to polarized light in the visible wavelength range, generating a localized surface plasmon resonance (LSPR) signal, and is sensitive to small perturbations to its optical mode near its surface. Therefore, the fiber tip probe can be used as a bioprobe to detect proteins that are captured on the gold nanorod surface.

9166-28, Session 4

Portable optical sensors imaging systems for biomedical applications *(Invited Paper)*

Ofer Levi, Univ. of Toronto (Canada)

We present the development of miniature optical sensors inside micro-fluidic channels for biomedical diagnosis and molecular studies. We have developed a miniature GaAs-based fluorescence sensor including VCSELs, PIN diode and filters, packaged it with a low noise CMOS readout and demonstrated high sensing sensitivity and the ability to implant it in living mice. In addition, we have shown that using photonic crystal slab (PCS) nanostructures, parameters such as spectral sensitivity (nm/RIU) and quality factor for an index of refraction sensor can be optimized simultaneously, leading to limit of detection better than 10^-7 RIU and to sensing sensitivity >0.8 of the theoretical limit.

We present the development of a multi-modality optical neural imaging system, based on fast coherence reduction techniques applied to Vertical Cavity Surface Emitting Lasers (VCSELs) operating at 680, 795 and 850 nm. We demonstrate a novel system which combines the two techniques of laser speckle contrast imaging (LCSI) and intrinsic optical signal imaging (IOSI) simultaneously, using these compact laser sources, to monitor induced cortical ischemia in a full field format with high temporal acquisition rates. We will also present our initial design and system analysis for a low-cost CMOS-based portable imaging system as a minimally invasive method for long-term neurological studies in un-anesthetized animals. This system will provide a better understanding of the progression and treatment efficacy of various neurological disorders, in freely behaving animals.

9166-29, Session 4

Biologically inspired materials *(Invited Paper)*

Alon Gorodetsky, Univ. of California, Irvine (United States)

Cephalopods are known as the chameleons of the sea – they can alter their skin's coloration, patterning, and texture to blend into the surrounding environment. These capabilities are enabled by unique proteins and self-assembled nanostructures found within cephalopod skin. We will discuss our work on new types of photonic and ionic devices from naturally occurring materials found in cephalopods. Our findings hold implications for the next generation of camouflage and renewable energy technologies.

9166-30, Session 4

Nanocrystal optical sensors and multimodal optical imaging for quantitative nanomedicine *(Invited Paper)*

Jeeseong Hwang, National Institute of Standards and Technology (United States)

Quantitative detection and imaging of pathogens, infectious agents, and cancer plays a vital role in biological threat surveillance, agricultural safety, and medical diagnosis. While there is increasing interest in highly sensitive detection assays involving either fluorescent molecules or light-emitting chemical reactions, they often pose challenges to quantitative optical analysis. I will present our recent results on characterizing and modeling the unique optical properties of novel nanocrystal probes and quantitative imaging of molecular processes in cells and tissues. I will also present our ongoing efforts on developing novel hyperspectral multimodal imaging platforms and standards to apply nanocrystals and molecular sensors in several important biomedical applications. Such applications include visualizing dynamic characteristics of cells in a disease state and developing optical standards for effective and safe hyperthermia cancer treatments.

9166-31, Session 4

Silicon nano-photonic devices optimized for label-free biosensing applications *(Invited Paper)*

Lukas Chrostowski, The Univ. of British Columbia (Canada); Shon A. Schmidt, Univ. of Washington (United States); Jonas Flueckiger, Sahba Talebi Fard, The Univ. of British Columbia (Canada); Valentina Donzella, The Univ. of British Columbia (Italy); Samantha M. Grist, The Univ. of British Columbia (Canada); WenXuan Wu, Qian Wang, Pavel Kulik, James Kirk, Daniel Ratner, Univ. of Washington (United States)

Silicon photonics is emerging as a mainstream technology for high performance computing and telecommunications. As near-infrared light propagates through nano-scale silicon wires on a chip, a portion of the light travels outside the waveguide, sensitive to refractive index changes such as molecules binding on its surface. This feature makes silicon photonics an ideal platform for label-free biosensing and promises the advent of highly-matrixed medical diagnostic lab-on-chip systems at the economies of scale only offered by today's CMOS foundries. In this paper, we describe a myriad of TE- and TM-mode silicon photonic resonators specifically optimized for biosensing applications such as: cascaded micro-rings, micro-disks, and slab- and slot-waveguide Bragg gratings. We demonstrate their biosensing capability and compare their performance in terms of bulk sensitivity, Q, and detection limit. Finally, the performance of each sensor is compared for the detection of biological analytes for future application in lab-on-a-chip systems.

9166-32, Session 4

Plasmonic nanosensors for molecular and functional cancer imaging and therapy *(Invited Paper)*

Konstantin V. Sokolov, The Univ. of Texas M.D. Anderson Cancer Ctr. (United States)

Gold made materials undergo fascinating changes in physicochemical properties when their size is reduced to nanoscale. This phenomenon has been observed as long as some thousands years ago with many famous examples such as the Roman Lycurgus cup from AD400 that makes nanotechnology an ancient filed of human endeavors. Nowadays, we are studying fundamental properties of gold nanoparticles and their interactions with biological environment with the ultimate goal to harness the nanoscale material properties for improved imaging and therapy of devastating diseases such as cancer.

In this talk, I will discuss three interconnected areas of research that are involved in development of plasmonic nanosensors for biomedical applications: (1) synthesis of biocompatible molecular specific gold nanoparticles; (2) studies of mechanisms of nanoparticle interactions with cells and tissues to enable molecular-specific imaging and therapy; and (3) optimization of nanoparticles for clinical translation.

9166-33, Session 4

Probing the nano-bio interface with nanoplasmonic optical probes *(Invited Paper)*

Xinwei Yu, Linxi Wu, Ali Khanehzar, Amin Feizpour, Fangda Xu, Björn M. Reinhard, Boston Univ. (United States)

Noble metal nanoparticles have large cross-sections in both optical and electron microscopy and plasmon coupling between noble metal nanoparticles facilitate the characterization of subdiffraction limit separations through spectral analysis of the scattered light in plasmon coupling microscopy. The size compatibility of noble metal nanoparticles together with the ability to encode specific functionality in a rational fashion by control of the nanoparticle surface makes noble metal nanoparticles unique probes for a broad range of biological processes. Recent applications of the technology include i.) characterization of cellular heterogeneity in nanomaterial uptake and processing through macrophages, ii.) testing the role of viral membrane lipids in mediating viral binding and trafficking, and iii.) characterizing the spatial organization of cancer biomarkers in plasma membranes. This paper reviews some of these applications and introduces the physical and material science principles underlying them. In particular, we will focus in this presentation on the use of membrane wrapped noble metal nanoparticles, which combine the superb photophysical properties of a nanoparticle core with the biological functionality of a membrane, as probes in Plasmon Coupling Microscopy (PCM).

9166-34, Session 4

A prism coupled light sheet microscope for single molecule super-resolution imaging *(Invited Paper)*

Hu Cang, The Salk Institute (United States)

A light sheet microscope, which selectively illuminates a thin plane of a sample with a sheet of light, offers extraordinary signal-to-noise ratio for tissue imaging. The current design of light-sheet microscopes is essentially unchanged since its invention in 1903. This design, which uses an orthogonal configuration of a condenser and an objective lens. has severe limitations on the numerical aperture (NA) of the objective lens that can be used for light sheet microscopy, and is unsuitable for single molecule detection. Here we present a new design of light sheet microscope, which use a prism to couple the light sheet into the sample. this new design relax the angle between the condenser and objective, which allows the use of high NA lens for single molecule imaging. We demonstrate its value by imaging chromatin of stem cells with nanometer scale resolution. In addition, we show that this prism coupled light sheet microscope is also compatible with a recently developed Bayesian microscopy for high-speed live cell imaging.

9166-35, Session PWed

Effect of amine functionalized polyethylene on clay-silver dispersion for polyethylene nanocomposites: mechanical and antimicrobial properties

Saul Sanchez, Centro de Investigacion en Quimica Aplicada (Mexico)

The compatibilization effects provided by Maleic anhydride (MA), Itaconic Acid (IAc), Itaconic anhydride (IA) and 2-[2-(dimethylamine)-ethoxy] ethanol (DMAE) functionalized polyethylenes for forming high density polyethylene-based nanocomposites were studied and compared. IAc, IA were grafted into HDPE by melt mixing to obtain functionalized polyethylenes (HDPEgIAc and HDPEgIA) and amino alcohol functionalized polyethylene was prepared by reaction of commercial HDPEgMA with DMAE in the melt to form polyethylene grafted dimethyl amine ethoxy ethanol (PEgDMAE). Nanocomposites were prepared by melt processing using a twin screw extruder by blending polyethylene and these compatibilizers, with a quaternary ammonium surfactant modified montmorillonite clay (Nanomer I28E) impregnated with silver nanoparticles. FTIR characterization confirmed the formation of these compatibilizers and confirmed the reaction between HDPEgMA and the amino alcohol. All the compatibilized nanocomposites had better clay exfoliation and silver dipersion compared to the uncompatibilized HDPE nanocomposites. Mechanical and barrier properties, X-Ray diffraction, thermo gravimetric analysis and transmission electron microscopy results, as well as antimicrobial behviour against a bacteria (E.Colli) and a fungus (A. Nigger) showed the next order in their decreasing performance behaviour as compatibilizer: PEgDMAE>HDPEgAI>HDPEgAcI>HDPEgMA. This behavior was attributed to the specific interactions between the anionic surface of the clay and the functionality of the compatibilizer. Samples with higher clay content showed poor clay dispersion or intercalation which was attributed to a possible clay saturation when the van der Waals attractive interactions between clay layers becomes dominant when the distance between them is smaller at a certain concentration of clay.It was demonstrated the synergistic effect of both clay and silver nanoparticles on antimicrobial properties of the nanocomposite. Possible interaction between compatibilizer and nanoparticles was schematized.

9166-36, Session PWed

Generation of reactive oxygen species from 5-aminolevulinic acid and glutamate in cooperation with excited CdSe/ZnS QDs

Hong Dinh Duong, Jee Won Lee, Jong Il Rhee, Chonnam National Univ. (Korea, Republic of)

CdSe/ZnS QDs can be joined in the reductive pathway involving the electron transferring to an acceptor or in the oxidative pathway involving the hole transferring to a donor. They were exploited in the oxidation reactions of 5-aminolevulinic acid (ALA) and glutamate (GLU) for the generation of reactive oxygen species (ROS) such as hydroxyl radical (HO•) and superoxide anion (O2••). The fast and highly efficient oxidation reactions of ALA to produce the HO• and in case of GLU to produce the O2•• were observed in the cooperation of mercaptopropionic acid (MPA) capped-CdSe/ZnS QDs. Fluorescence spectroscopy and Electron Spin Resonance (ESR) spectroscopy were used to evaluate the generation of different forms of ROS. Effect of the generated ROS on HeLa cells was real time monitored.

9166-37, Session PWed

Enhancement of singlet oxygen production based on FRET between Coumarin tri-compound and CdSe/ZnS QDs

Hong Dinh Duong, Jee Won Lee, Jong Il Rhee, Chonnam National Univ. (Korea, Republic of)

In this work, CdSe/ZnS QDs were synthesized and then exchanged ligands on their surface by using mercaptopropionic acid (MPA) to produce water-soluble QDs (MPA-QDs). The silica particles-captured coumarin tri-compound (SiC3) were also synthesized as a source of energy transfer for MPA-QDs. Based on FRET from SiC3 to MPA-QDs, the singlet oxygen production from MPA-QDs was significantly enhanced (80%) as compared with that of MPA-QDs without SiC3. Sol-gel of 3-glycidoxypropyl trimethoxysilane (GPTMS), 3-aminopropyltrimethoxysilane (APTMS) was used as the linking between SiC3 and QDs and produced an effective combination and stability in reaction of singlet oxygen production. Effect of the generated ROS on animal cells was real time monitored.

9166-38, Session PWed

Chemical sensors of biopolymers and hydrogen-containing components on the basis of nanodimensional porous Si

Liubomyr S. Monastyrsky, Ivan Franko National Univ. of L'viv (Ukraine)

The research is aimed at the development of nanoelectronic devices such as biosensors and molecular transmitters which are formed by integration of biological materials with micro-and nanoelectronic devices. It is presented spectral sensitivity of porous silicon (PC) to covering and status of biocomponent coatings, such as proteins (interferon, chicken egg protein), hygrogen-containing environment (methane, hydrogen, ammonia, ethanol).

Sensory properties of heterostructures (HS) were studied using the methods of luminescence, thermostimulated depolarization (TSD) and impedance measurements.

We have found changes in the PL spectra of the HS in the visible spectrum and in the spectra of TSD at excitation by nitrogen laser. Comparison of PL spectra of PC and HS of biopolymer (interferon)- PC indicates the quenching of PL maximum intensity, its displacement by 50 nm to 600 nm and the emergence of a new PL band in the vicinity of 500 nm. The dependences of conductivity and capacitance of PC–hydrogen-containing environment HS on the pressure of methane, hydrogen, ammonia and ethanol were obtained. It has been shown that the studied HS are also promising for quality control of food (eg, changes in the luminescence spectra of PS chicken protein HS depending on the quality of the product), for monitoring the environment on content and concentration of some gases (H2, CH4, NH3, C2H5OH) and can be suitable for fabrication of optical (fluorescent) and electro-sensors based on nanostructured por-Si.

9166-39, Session PWed

Multivariate system of orientational tomography of biological crystals birefringence networks

Natalia I. Zabolotna, Vinnytsia National Technical Univ. (Ukraine); Alexander G. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

This work contain the data about methodological algorithm of usage Mueller-matrix tomography in investigation of optically – anisotropic layers. Presented the theoretical algorithms unleashing direct and inverse problems of diagnostics and presentation of anisotropy distribution of biological networks.

Described the system of Mueller-matrix tomography, which contains methods of oriental tomography. Proposed the experimental method of oriental tomography of polycrystalline protein networks of optically-thin layer in biological tissues, which contains from next parts:

• Distribution of optically-thin layer of biological tissues in optical disposition of polarimeter.

• Forming polarization rendering conditions of determined directions of optical axis in polycrystalline network.

• Detecting in CCD-camera plane series of microscopical polarization-filtered images.

• Determination statistical, correlational and spectral moments, which characterize distribution of optical axis direction, autocorrelation functions and spectrums of capacity such distributions.

9166-40, Session PWed

System of the phase tomography of optically anisotropic polycrystalline films of biological fluids

Natalia I. Zabolotna, Vinnytsia National Technical Univ. (Ukraine); Alexander G. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Artem O. Karachevtsev, Yuriy Fedkovych Chernivtsi National Univ (Ukraine)

The article highlights the theoretical algorithms to solve direct and inverse problems of diagnosis and for reproducing distribution of the anisotropy parameters of polycrystalline networks of the biological environments.

It describes the system of complex Mueller-matrix tomography, including methods of the phase tomography.

It is proposed an experimental method of the phase tomography of polycrystalline protein networks of the optical thin layers of biological tissues. The method includes the following stages:

• Placing optical thin layer of biological tissue in the optical polarimeter scheme.

• Creating conditions for polarizing phase visualization of the polycrystalline birefringence optical network.

• Registering the camera of polarizing filtered images in the CCD plane

9166-41, Session PWed

Laser system of the autofluorescence polarimetry of cytologic layers at an early stage of cancer detection

Yuriy A. Ushenko, Maxim Sidor, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

This article presents the research results of the laser polarization fluorescence of biological layers (histological sections, cytological smears). It highlights the discovered and investigated polarized structure of the autofluorescent image layers of biological tissues and fluids. It is proposed a model describing the formation of polarizing inhomogeneous autofluorescence images of the optical biological optically anisotropic layers. Basing on this, the method of laser autofluorescence polarimetry was analytically grounded and experimentally tested. Its efficiency lies in the detection and differentiation of the uterine wall cancer (dysplasia - microinvasive cancer) at an early stage. There were defined the objective criteria (statistical moments) of differentiation of autofluorescent images of the endometrial biopsy histological sections and cytology samples of its mucous. The operational characteristics of this technique (sensitivity, specificity, accuracy) were determined.

9166-42, Session PWed

Fluorescent biopsy of biological tissues in differentiation of benign and malignant tumors of prostate

Yuriy A. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

This paper presents the results of investigation of laser polarization fluorescence of biological layers. Detected and investigated polarization structure of autofluorescent images of human biological tissues and fluids. Proposed the model of description of polarization- heterogeneous images of optically anisotropic biological layers. On this basis analytically founded and experimentally checked the method of autofluorescent polarization-variability. Analyzed efficiency of application in the different tasks of medical diagnostics: detection and differentiation early cancer forms (dysplasia - microinvasive carcinoma) of uterine neck. The objective criteria (statistical moments) of differentiation of autofluorescent images of histological sections, endometrium and cytologic films of mucosal tunic were defined. The operational characteristics (sensitivity, specificity, accuracy) of this technique were determined concerning the positions of probative medicine, and clinical efficiency of the technique was demonstrated.

9166-43, Session PWed

Statistical and fractal analysis of autofluorescent myocardium images in posthumous diagnostics of acute coronary insufficiency

Taras M. Boychuk, Bukovinian State Medical Univ. (Ukraine)

This research presents the results of investigation of laser polarization fluorescence of biological layers (histologic section). Detected and investigated the polarizational structural properties of autofluorescence images of human biological tissues. Analytically founded and experimentally checked the method of autofluorescent polarization-variability. Analyzed the efficiency of application this method in criminal anthropology rapid differentiation reasons of death coming. The objective criteria (statistical moments) of differentiation of autofluorescent images of histological sections of myocardium biopsy, endometry and cytology of mucous were defined. The operational characteristics (sensitivity, specificity, accuracy) of these technique were determined concerning the positions of probative medicine, and clinical efficiency of the technique was demonstrated.

9166-44, Session PWed

Polarization-correlation analysis of maps of optical anisotropy biological layers

Olexander V. Dubolazov, Yuriy A. Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

The theoretical background of azimuthally stable method of the Jones-matrix mapping of histological sections of biopsy of uterine neck on the basis of spatial-frequency selection of the mechanisms of linear and circular birefringence is presented.

It is analytically justified the use of new diagnostic correlation parameter - complex degree of mutual anisotropy (CDMA). The technique of measuring the coordinate distributions CDMA followed by space-frequency filtering of the high-and low-frequency components.

It is found the interaction of such distributions with parameters of the linear and circular birefringence gistologichenskih slices of endometrial uterine wall.

The comparative results of measuring the coordinate distributions of complex degree of mutual anisotropy formed by fibrillar networks of myosin and collagen fibrils of uterine neck tissue of different pathological states – pre-cancer (dysplasia) and cancer (adenocarcinoma) are shown.

The values and ranges of change of the statistical (moments of the 1st – 4th order) parameters of complex degree of mutual anisotropy coordinate distributions are studied. The objective criteria of diagnostics of the pathology and differentiation of its severity degree are determined.

Proton-dependent multi-drugs release using CD44 targeted nanoparticles for the induction of biliary cancer cell death

Ilkoo Noh, Jihye Choi, Hyun-Ouk Kim, Yonsei Univ. (Korea, Republic of); Jin-Suck Suh, Yong-Min Huh, Yonsei Univ. College of Medicine (Korea, Republic of); Seungjoo Haam, Yonsei Univ. (Korea, Republic of)

Multi-drugs delivery, which is focused by different signaling pathways in cancer cell, can generate synergistic effect onto anti-proliferation of cancers. To enhance delivery efficiency with minimal side effect, we developed CD44 targeted multi-drugs nanoparticle (MDNPs) consisting of paclitaxel conjugated poly-L-lysine (PLL-PTX) and gemcitabine conjugated hyaluronic acid (HA-GEM). Paclitaxel, a fraction of PLL-PTX, contributes to hydrophobic interaction during particle formation and exhibit a slightly positive charge. Negatively charged HA, a fraction of HA-GEM, can induce CD44 receptor-mediated endocytosis. Therefore, MDNPs were formed by electrostatic interaction using complementary charge of dual polymers showing advantageous features of not only maintaining similar pharmacokinetic drug efficacy but also accelerating drug release at acidic endosome environment (pH=5.5) in cancer cells. As a proof of concept, we confirmed successful synthesis of PLL-PTX and HA-GEM by NMR and IR spectroscopy, and the formation of MDNPs were analyzed by AFM, DLS and zeta potential. In vitro CD44 specific uptake was analyzed by CLSM using rhodamine B conjugated MDNCs. In vitro cell viability and gene expression of MDNPs showed that they exhibited more inhibition of cell proliferation in CD44 positive cell lines (Hucct-1) than CD44 negative cell lines (SCK) and higher expression of Bax/Bcl-xL in Hucct-t than SCK. Consequently, these results demonstrate that multi-drugs conjugated MDNPs could achieve a synergistic effect and effective cellular uptake at targeted cancer cells compared to free drug.

Optical pre-clinical diagnostics of the cervical tissues malignant changing

Sergey B. Yermolenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Dmytro Voloshynskyi, Olexander Fedoruk, Bukovinian State Medical University (Ukraine); Ion Gruia, University of Bucharest (Romania); Dmitry Zimnyakov, Yury Gagarin State Technical University (Russian Federation)

This work is directed to the investigation of the scope of the technique of laser polarimetry of oncological changes of the human prostate and cervical tissues under the conditions of multiple scattering, which presents a more general and real experimental clinical situation.

To compare the above mentioned scope of biotissue laser polarimetry on the first stage the research of human prostate and cervical tissues in the conditions of single scattering was performed.

Analytical approach to the analysis of polarizationally inhomogeneous images of human prostate tissue is based on the main model theses of laser polarimetry technique, according to which biological tissue (BT) is treated as a monolayer containing the ensemble of optically uniaxial birefringent fibrils.

Statistic moments of the first (M), second ( ), third (A) and fourth (E) orders were used as the analytical tool for estimating the ensemble of random values of z, that characterize the image of biological object (intensity I, polarization azimuths and ellipticities) and its optical-geometrical structure (orientation directions of the protein fibrils and birefringence index of their substance).

It was shown that the difference between the values of average and dispersion of distributions I (0 - 0), I (0 - 90), the intensities of images of various types of prostate tissues are insufficient and are within 10%-25%. The values of the excess of intensity distribution of the images of oncologically changed prostate tissues differ from the similar parameter of a sound tissue by 1-2 times. The third statistic moment proved to be the most sensitive to pathological changes in orientation structure. Its value in the intensity distribution of polarization image I (0 - 90) of oncologically changed tissue is 21 times higher if compared with the similar statistic parameter of the intensity distribution of the healthy tissue.

Diagnostic value spectropolarimetry of blood plazma in patients with breast cancer

Alexander G. Prydiy, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Tetjana Kruk, Bukovinian State Medical University

(Ukraine); Pavlo Ivashko, Yuriy Fedkovych Chernivtsi National Univ (Ukraine); Olga Ushakova, Yury Gagarin State Technical University (Russian Federation)

The aim was to study the possibility of using polarimetry methods of performance evaluation of blood plasma of patients with breast cancer and spectroscopy method in the diagnosis of breast cancer and determine the criteria for their use of non-invasive screening for problems.

This paper presents the results of a comprehensive survey of 101 breast cancer patients aged 27 to 75 years who were hospitalized in Chernivtsi clinical oncology clinic. The paper also used 101 primary surgical specimens of patients with breast cancer. All patients were comprehensive survey of the use of common clinical practices according to the standards of diagnosis and treatment of patients with malignant tumors, adopted in Ukraine. Patients underwent radical surgery. They did not receive neoadjuvant chemotherapy, hormone and radiation therapy. All patients agreed to participate in the study. The control group consisted of 50 patients.

Laser image of inhomogeneous polarization component plasma is a polycrystalline network formed by ensembles excoptically uniaxial crystals albumin and globulin. Depending on the availability of cancer spatial orientation the structure of the network undergoes the following changes :

- blood plasma of healthy women is characterized by the predominance of large-scale, organized in the areas of optical axes of the crystals albumin SSC disordered in the fields of optical axes crystals globulin;

- laser images of human plasma, patients with breast cancer, we noticed the trend - the predominance of small-scale networks disordered crystals globulin;

- polarization properties of polycrystalline chains of amino acids in blood plasma can be defined as a single polycrystal properties and describes a set of static points in the 1st - 4th order and logarithmic dependencies of power spectra of coordinate distributions of the elements of the generalized Mueller- matrix operator.

It is shown that algorithms of statistical analysis, correlation and fractal analysis approaches Mueller-matrix and polarization images of crystalline layers of blood plasma can used as diagnostic methods for patients with breast cancer,

Absorption bands of vibrational transmission spectra of blood plasma of patients of group 1 - 3 were identified; most difference in the behavior of the absorption spectrum manifested in the region 1400- 2900 cm- 1 in patients of group 3.

9166-48, Session PWed

Absorption spectra of adenocarcinoma and squamous cell carcinoma cervical tissues

Pavlo V. Ivashko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Olexander Peresunko, Natalia Zelinska, Bukovinian State Medical University (Ukraine); Marina Alonova, Saratov State Technical University (Russian Federation)

We studied a methods of assessment of a connective tissue of cervix in terms of specific volume of fibrous component and an optical density of staining of connective tissue fibers in the stroma of squamous cancer and cervix adenocarcinoma. An absorption spectra of blood plasma of the patients suffering from squamous cancer and cervix adenocarcinoma both before the surgery and in postsurgical periods were obtained. Linear dichroism measurements transmittance in polarized light at different orientations of the polarization plane relative to the direction of the dominant orientation in the structure of the sample of biotissues of stroma of squamous cancer and cervix adenocarcinoma were carried.

In this study, first used methods of assessment of the connective tissue of the cervix in terms of specific volume of fibrous component and the optical density of staining of connective tissue fibers in the stroma of squamous (keratinizing and nonkeratinizing) cancer (n = 25) and adenocarcinoma of the cervix (n = 19). These results likely allow precise histochemical differential diagnosis of squamous and glandular cancers of different stages of differentiation (G1, G2, G3), indicating the feasibility of using computer microspectrophotometry in terms of additional sensitive diagnostic test .

Studies suggest that there are dependencies between pathological conditions of cervical stroma and performance that takes into account these data to compile prognosis of adenocarcinoma or squamous cell carcinoma. Computer histochemical assessment of connective tissue fibers in nonkeratinizing squamous cell carcinoma and adenocarcinoma of the cervix and is sensitive additional differential diagnostic test that helps objectification assessment of histological preparations and opens new perspectives in the study of the mechanisms and patterns of development of malignancy tumors. It is researched that in all the cases the linear dichroism appears in biotissues with the cancer disease the magnitude of which depends on the type of the tissue and on the time of the cancer process development. The phenomenon of the linear dichroism formation has a selective character: maximum values Δ are observed in the area λ=410 – 430 nm and in the area λ= 500 – 530 nm; for the wavelenth λ< 300 nm and λ> 750 nm Δ is almost zero or zero.

As the linear dichroism is lacking for healthy tissues, then the obtained results can have diagnostic values with the purpose of detection and estimation of the stage of the cancer disease development.

9166-49, Session PWed

Dynamics of blood plazma by spectropolarimetry and biochemical techniques

Sergey B. Yermolenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine); Olexander Prydij, Yuriy Fedkovych Chernivtsi National Univ (Ukraine); Katerina Voloshynska, Tetjana Ilashchuka, Bukovinian State Medical University (Ukraine); Maria Gruia, Oncologic Institute “Al. Trestioreanu” (Romania)

Oxygen, indispensable element of life is very active and toxic by its metabolites. They first action initiates a chain reaction of oxidative degradation of lipids and protein constituents of cell membranes. Lipid and protein peroxidation reactions have direct implications for membrane signaling mechanisms, affectingthe intercellular adhesion, receptors, antibodies, antigens expression. These mechanisms can be considered precursors of malignant transformation.

Early detection of such changes may be useful for early diagnosis for clinicians but also to establish an optimal molecular targeted therapy.

The aim of this paper is the identification of these changes by spectropolarimetry techniques, and completion of results by biochemical techniques.

This has been performed in cell membranes isolated by repeated ultracentrifugation from experimental tumors in their growth dynamics compared to normal tissue membranes. Recorded optical results were compared with quantitative measurements of lipid and protein peroxidation reaction performed on the same biological samples.

These were monitored by quantifying the concentration of MDA (malondialdehyde), being the degradation product of lipid peroxidation and total-SH groups (thiol) as a measure of protein oxidative attack.

The results indicate that the primary source of the attackare the lipid molecules, and only after the initiation of chain reactions and quantitative production of reactive oxygen species will be attack the proteins, while the natural defense systems (endogenous antioxidants) are activated.

Optical measurements are consistent with the biochemical anisotropy measured wavelengths correspond breaks overhead associated protein and lipid oxidative damage.

Light-scattering properties of bacteria Desulfuromonas acetoxidans under the influence of nano silver particles

Oleksandr I. Bilyi, Ivan O. Bordun, Taras Z. Grechukh, Olga D. Maslovska, Svitlana O. Hnatush, Ivan Franko National Univ. of L'viv (Ukraine)

Concentration changes and relative content of bacterial cells of D.acetoxidans in the intervals of sizes 0,2 - 2,0 μm under the influence of nano silver particles have been investigated. Correlation between these changes of light-scattering properties of bacterial cells and growth abilities of bacteria D. acetoxidans under inflence of silver nanoparticles and ions has been shown. The intensity of processes the peroxide oxidize of lipids and change of indexes of the antioxidant system the cells of D.acetoxidans at influence of silver nanoparticles and silver nitrate was the aim with work. A bacteria D.acetoxidans are obligative anaerobic sulfur bacteria of the aquatic sedimental environments that are able to Fe^{3+} dissimilative reduction and Ag^{1+} is able to renew to Ag^0. The influence of various concentrations of ferric (III) citrate, silver nanoparticles and silver nitrate on enzymatic activity of catalase and reduced glutathione synthesis by D. acetoxidans cells under their cultivation with fumarate addition and with absence of sulphur has been determined. Specific catalase activity increased with enhancing of ferric (III) citrate concentration and duration of bacterial cultivation under the addition of this salt. The highest specific catalase activity was determined on the second day of bacterial growth under the influence of all concentration range of investigated metal salt. The reduced glutathione content under silver nitrate and silver nanoparticles exposure varied depending on the cultivation time and metal concentration. The maximum reduced glutathione content has been observed. The mechanism of action the silver on bacterial D.acetoxidans cells has been description.

Synthesis and characterization of fluorene-based NIR fluorescent dyes for in-vivo imaging

ShinJae Woo, Pusan National Univ. (Korea, Republic of); Sungmin Park, Korea Institute of Science and Technology (Korea, Republic of); Han Young Woo, Pusan National Univ. (Korea, Republic of)

Near-infrared (NIR) fluorescent organic dyes have emerged as in vivo fluorescence imaging agents due to deep tissue penetration, less photodamage and low autofluorescence by biomolecules. Here, we designed new water-soluble pi-conjugated NIR fluorescent dyes, which is relatively photo-stable with compared to the double bond-containing cyanine dyes. To obtain the NIR fluorescence signal, three types of fluorene-based donor-acceptor-donor (DAD) fluorescent dyes (Q-FITBTTFI, Q-FIBBTFI and Q-FITBBTTFI) have been designed and synthesized with fluorene as an electron-donating group, and 2,1,3-benzothiadiazole and benzo[1,2-c:4,5-c']bis[1,2,5]thiadiazole moieties as an electron-accepting group. The dyes exhibited relatively low fluorescence quantum yields with a broad fluorescence spectrum and large stoke-shift in water, as compared to commercially available dyes. Polymer vesicles and polymer nanoparticles (Pdots) containing the DAD fluorescent dyes were synthesized to improve the quantum yield and biocompatibility, etc. Among the new dyes presented herein, the vesicle of Q-FITBTTFI displayed the best fluorescence imaging in biological media and in-vivo imaging.

Cationic water-soluble fluorescent probe with 15 crown-5 for potassium ion detection

Hyejin Choi, Bao-Lam Nguyen, Van Sang Le, Han Young Woo, Pusan National Univ. (Korea, Republic of)

We report a highly selective and sensitive potassium detection by cationic water-soluble fluorescent probe. New water-soluble fluorescent probes with a donor-π-acceptor structure based on 1,4-bis(styryl)benzene were synthesized with the 15-crown-5 group for selective binding for K^+ ions. This structure allows efficient intramolecular charge transfer (ICT) in the main backbone from donor to acceptor. In the presence of K^+ ions, the ICT interaction is possibly modulated due to the binding of potassium ions onto the crown ether, resulting in the changes in the fluorescence signal of the probe. The detection limit of potassium was measured to be ~ 1.15 nM.

Graphene/ruthenium nanoparticles as tool for sensor development

Ausra Gustainyte, Ctr. for Physical Sciences and Technology (Lithuania); Isabel Pastoriza-Santos, Elisa Gonzalez- Romero, Univ. de Vigo (Spain)

Biosensors can be applied in various samples including body fluids and environmental samples. We used innovative Screen-Printed Graphene Electrodes (SPGPHEs), because of its high surface area, thermal and electric conductivity. The electrodes were modified with nanoparticles to improve the electrocatalytic properties toward β-Nicotinamide (NADH) oxidation, so that it can be used for electrochemical biosensor device. We prepared triangular ruthenium nanoparticles using hydrothermal synthesis method. First, the electrode surface was covered with a film by electropolimerisation with o-Phenylenediamine onto graphene (SPGPHE/PoPD). Secondly, the SPGPHE/PoPD was modified with RuNPs, SPGPH/PoPD/RuNPs. Cyclic voltammograms of NADH on bare SPGPHE and SPGPH/PoPD/RuNPs modified electrode show that the electrocatalytic current decreased significantly (30%) when the RuNPs were absent from the electrode surface. A remarkable catalytic oxidation current at the modified electrode occurred at ca. 0V, which negatively shifted higher than 400 mV, compared with that at bare SPGPHE (ca. 450 mV). Our results demonstrated that the SPGPH/PoPD/RuNPs maintained a good electrochemical activity toward NADH and could be applied to the field for electrochemical sensors.

Optimization of synthesis of nanosilica fillers for experimental dental nanocomposites

Maedeh Sharifzadeh Baei, Islamic Azad Univ. (Iran, Islamic Republic of)

The aim of this study was to Optimization of synthesise nanosilica fillers for use in the fabrication of experimental dental nanocomposites. Monodispersed, spherical silica nanoparticles were synthesised via a sol-gel process, and different size range of 20-100 nm was obtained. Surface treatment of the nanosilica was carried out with the silane coupling agent y-methacryloxypropyltrimethoxysilane (MPS) to reduce agglomeration of nanosilica. Experimental dental nanocomposites with two different filler contents, 30 and 35 wt%, were fabricated and polymerised with different light curing unit. The surface morphology, surface roughness, flexural strength and elastic modulus were evaluated and compared. A nanocomposite with 35% filler content showed higher filler compaction, lower surface roughness and higher elastic modulus than a nanocomposite filled with 30% filler. However, the nanocomposite in size of 30 nm and light curing of 40 s filled with 30% filler content

showed higher flexural strength. Based on the results obtained, the synthesised nanosilica is a promising material for the fabrication of dental nanocomposites for tooth-filling applications.

A high-sensitivity ellipsometric biosensor under a liquid immersion micro flow paths environment

Hyun Mo Cho, Won Chegal, Yong Jai Cho, Korea Research Institute of Standards and Science (Korea, Republic of); Yong Hee Yoon, Yoon Ho Seo, Dae Suk Kim, Chonbuk National Univ. (Korea, Republic of); Woong Jeong, Jae Heung Jo, Hannam Univ. (Korea, Republic of); Sang Won O, Se-Hwan Paek, Korea Univ. (Korea, Republic of)

Binding kinetics of peptides with immobilized antibody are investigated by ellipsometric biosensor under a liquid immersion environment on silicon substrate. In this work, the experimental setup for ellipsometric biosensor is based on custom-built rotating analyzer ellipsometer which is equipped with a micro flow path on silicon substrate. In conventional surface plasmon resonance sensor, it is difficult to distinguish between a change in the reflective index of the buffer solution and pure binding characteristics, and the changes in the reflective index of the buffer solution can always serve as measurement error factors. This ellipsometric biosensor was insensitive to the changes in the refractive index of the buffer solution, but it showed high sensitivity to the film thickness in p-wave anti-reflective boundary conditions. Accordingly, the binding and dissociation kinetics inherent in only the samples can be accurately measured almost without the influence of a change in the refractive index resulting from a buffer solution. In order to directly monitor the interaction of small molecule-protein, it is necessary to design a high-sensitivity biosensor with a sensitivity of greater than 1 pg/mm2. In this paper, we demonstrate how an ellipsometric biosensor based on silicon wafer in the p-wave anti-reflective condition can be used to directly obtain the interactions and binding kinetics of peptides with immobilized antibodies. We achieved a detection limit of 1.0 x 10-7 RIU, which is equivalent to 0.1 pg/mm2. This method is applicable not only to sensor applications, such as affinity biosensors, but also to highly sensitive kinetics for drug discovery.

Self-assembled clusters of gold nanoparticles for cancer-targeted photothermal therapy

Mi Hwa Oh, Insu Kim, Jeong Heon Yu, Shinyoung Choi, Yoon Sung Nam, KAIST (Korea, Republic of)

We construct genetically programmed T7 bacteriophages (also called phages) as a hybrid nanoplatform to assemble gold nanoparticles (AuNPs) for cancer-targeted bio-imaging and photothermal therapy. To assemble AuNPs on the surface of T7 phages, a Au-binding peptide (MHGKTQATSGTIQS) is displayed on each gp10B capsid protein along with a PC3 human prostate cancer cell surface-binding peptide (IAGLATPGWSHWLAL) in a tandem sequence. We investigate if pre-synthesized AuNPs with a diameter of 5 nm can bind to the recombinant T7 phages, forming a AuNP-clustered hybrid nanostructure, while the cancer-targeting peptide still maintains its specific binding affinity toward target cancer cells. The prepared T7-templated clusters of AuNPs show targeted tumor detection on a dark-field microscope, which is a fast and sensitive tool without staining. In addition, they show a potential as an agent for photothermal therapy originated from gold plasmonics when illuminated by a visible light source with target specificity. We expect that Au-PC3-T7 phages can be widely applied as a multifunctional therapeutic system in the field of biomedical therapeutics.

Synthesis of eco-friendly silver nanoparticles using plant extracts and assessment of their antimicrobial activity

Mohamed M. Ibrahim, Alexandria Univ. (Saudi Arabia) and King Saud Univ. (Saudi Arabia); Amal A. Hazzani, Afaf I. Shehata, Gehan A. El-Gaaly, King Saud Univ. (Saudi Arabia)

Increasing interest for the biosynthesis of metal nanoparticles is under investigation due to their wide biomedical applications and research interest in nanotechnology. Mentha asiatica and Ocimum basilicum leaves extracts were used to evaluate their extra cellular potential synthesis of silver nanoparticles and their bactericidal impact on different kinds of pathogenic bacteria. UV-Visible spectroscopy was utilized to monitor the formation of silver nanoparticles. XRD analysis of the formed silver nanoparticles revealed spherical and cubical shapes structure with different planes ranged between 111 to 311 planes. Scanning electron microscopy (SEM) was used to characterize the morphology of the nanoparticles obtained from plant extracts. The synthesized nanoparticles were found to be active against clinically isolated human pathogens, Staphylococcus aureus and Escherichia coli. Our work proffers an eco-friendly method for biogenic silver nanoparticles production. This could provide a faster synthesis rate comparable to those of chemical methods and potentially be used in areas such as food and medical applications.

Spin-lasers: from optical gain to high-frequency operation *(Invited Paper)*

Paulo Eduardo Faria, Univ. at Buffalo (United States); Guilherme M. Sipahi, Univ. de São Paulo (Brazil); Jeongsu Lee, Igor Zutic, Univ. at Buffalo (United States)

Spin-lasers provide intriguing opportunities for room-temperature spintronic applications, not limited to magnetoresistance. Starting from optical selection rules, we describe desirable properties of semiconductor nanostructures which also enable improving the optical gain, responsible for stimulated emission. We explore the relation between electronic structure of the active region and the operation of spin-lasers that could lead to an improved operation in both static and dynamic properties, as compared to conventional lasers.

9167-2, Session 1a

Polarization dynamics in spin-polarized vertical-cavity surface-emitting lasers *(Invited Paper)*

Nils C. Gerhardt, Henning Höpfner, Markus Lindemann, Martin R. Hofmann, Ruhr-Univ. Bochum (Germany)

Spin-polarized lasers and especially spin-polarized vertical-cavity surface-emitting lasers (spin-VCSELs) are attractive novel spintronic devices providing functionalities and characteristics superior to their conventional purely charge-based counterparts. This applies in particular to ultrafast dynamics, modulation capability and chirp control of directly modulated lasers. Here we demonstrate that ultrafast oscillations of the circular polarization degree can be generated in VCSELs by pulsed spin injection which have the potential to reach frequencies beyond 100 GHz. These oscillations are due to the coupling of the carrier-spin-photon system via the optical birefringence for the linearly polarized laser modes in the micro-cavity and are principally decoupled from conventional relaxation oscillations of the carrier-photon system. Utilizing these polarization oscillations is a very promising path to ultrafast directly modulated spin-VCSELs in the near future as long as an effective concept can be developed to modulate or switch these polarization oscillations. After briefly reviewing the state of research in the emerging field of spin-VCSELs, we present a novel concept for controlled switching of polarization oscillations by use of multiple optical spin injection pulses. Depending of the amplitude and phase conditions of the excitation pulses, constructive or destructive interference of polarization oscillations leads to an excitation, stabilization or switch-off of these oscillations. Furthermore even short single polarization bursts can be generated with pulse width only limited by the resonance frequency of the polarization oscillation resonance frequency. Consequently, this concept is an important building block for using spin controlled polarization oscillations for future communication applications.

9167-3, Session 1a

Control of light polarization using spin-injected opto-electronic devices with vertical geometries *(Invited Paper)*

Julien Frougier, Unité Mixte de Physique CNRS/Thales (France); Tiantian Zhang, Institut National des Sciences Appliquées de Toulouse (France); Shiheng Liang, Institut Jean Lamour (France); Phillipe Barate, Pierre Renucci, Xavier Marie, Institut National des Sciences Appliquées de Toulouse (France); Ghaya Baili, Thales Research & Technology (France); Mehdi Alouini, Univ. de Rennes 1 (France) and Thales Research & Technology (France); Isabelle Sagnes, Lab. de Photonique et de Nanostructures (France); Arnaud Garnache, Institut d'Électronique Fondamentale (France); Yuan Lu, Univ. Henri Poincaré Nancy (France); Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France); Jean-Marie George, Unité Mixte de Physique CNRS/Thales (France)

In the past decade, a continous interest and a research effort have been dedicated to the study of spin injection into Semiconductor-based Light Emitting Device such as Spin-Light Emitting Diodes (Spin-LEDs) [1,2] and more recently Spin-LASERs such as Vertical Cavity Surface Emitting LASERs (VCSELs) [3].

We will first focus on structural characterization and optical polarization efficiency of Ta/CoFeB/MgO spin injector grown on the top of an InGaAs-QW LED. We will show that for very thin layer of CoFeB it is possible to induce Perpendicular Magnetic Anisotropy leading to emission of polarized light at remanence (i.e. without external magnetic field). A natural extension of this magnetic bit conversion into circularly-polarized light via spin-polarized current is to extend the Spin-LED principle to Spin-LASER.

Based on our expertise on Spin-LEDs, we fabricated and characterized an optically pumped (100)-oriented InGaAs/GaAsP MQW Vertical External Cavity Surface Emitting Laser (VECSEL). Using an optical spin injection we were able to demonstrate a switching between two highly circular polarization states [4]. We will discuss the condition for the control of the electromagnetic field polarization.

Ultrafast adiabatic rapid passage in a single semiconductor quantum dot *(Invited Paper)*

Kimberley C. Hall, Reuble Mathew, Eric Dilcher, Angela Gamouras, Ajan Ramachandran, Dalhousie Univ. (Canada); Sabine Freisem, Dennis Deppe, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Adiabatic rapid passage (ARP) provides a robust optical control strategy for solid state qubit systems such as semiconductor quantum dots due to the insensitivity of this process to variations in optical parameters such as the transition energy and dipole moment. In this work, we present the demonstration of ARP on a single self-assembled InAs quantum dot. Through the use of broad bandwidth optical control pulses, our experiments explore a new regime of strong (and rapidly-varying) Rabi energies. We achieve ARP on a subpicosecond time scale, representing a 20 fold reduction in gate time relative to previous experimental demonstrations [1]. Our experiments also reveal a reduction in the efficiency of exciton inversion for negatively-chirped pulses in comparison to results for positive pulse chirp, confirming the dominance of resonant coupling to acoustic phonons in exciton dephasing during the control pulse. Calculations of the exciton dynamics using a density matrix treatment including coupling to LA phonons suggest the importance of multi-phonon emission processes and/or non Markovian effects. Together with the recent demonstration of parallel single qubit gates using optimal quantum control techniques [2], these results highlight the power and flexibility of optical pulse shaping for the control of solid state

qubits. [1] Wu et al. Phys. Rev. Lett. 106, 067401 (2011); Simon et al. Phys. Rev. Lett. 106, 166801 (2011). [2] Gamouras et al. Nano Letters 13, 4666 (2013).

Thermoelectric transport through nano-devices: interplay between resonance spin scattering and strong spin-orbit interaction *(Invited Paper)*

Mikhail Kiselev, The Abdus Salam International Ctr. for Theoretical Physics (Italy)

We investigate the interplay between effects of Zeeman field and strong Spin-Orbit (SO) interaction in the single electron transistor (SET) built on a quantum dot strongly coupled to one of the leads by a single-mode quantum point contact (QPC). The quantum transport through such a device is described by Kondo physics. The role of the impurity spin in the ordinary Kondo problem is played by the orbital degrees of freedom: the left/right movers at QPC stand for the impurity spin-up/down projections in the conventional Kondo problem while two spin projections of an electron account for the scattering channels.

The impurity spin-flip process in the ordinary Kondo effect is represented in this model by the reflection in the QPC, with the Kondo coupling determined by the reflection coefficient.

The charging energy of a Coulomb blockaded quantum dot plays the role of a Kondo temperature.

On one hand, the external magnetic field applied to the SET in the strong-coupling regime is responsible for the Non-Fermi liquid -to-Fermi liquid crossover in the transport properties. A parallel magnetic field applied to SET results in the channel up/down asymmetry and thus changes the universality class from the two-channel Kondo to the single-channel Kondo regimes. On the other hand, if external magnetic field is smaller compared to effective field associated with the spin-orbit interaction, the thermoelectric coefficients depend on an angle between the Zeeman and SO fields allowing a fine-tuning a Fermi-liquid to Non-Fermi-liquid crossover by the in-plane magnetic field.

It is shown that the strong spin orbit interaction in QPC “protects” the Non-Fermi liquid regime associated with the two-channel Kondo effect and modifies the thermoelectric coefficients. We discuss how the effects of strong electron interaction and resonance scattering influence the thermoelectric transport through the nano-devices and present some suggestions for experimental verification of our theoretical predictions.

Room-temperature initialization, dynamics, and measurement of coherent electron spins in strongly confined quantum dots *(Invited Paper)*

Jesse Berezovsky, Ahmad K. Fumani, Michael Wolf, Case Western Reserve Univ. (United States)

Semiconductor quantum dots provide a platform for studying and exploiting individual electron spins as they interact with a complex solid state environment. Colloidal nanocrystal quantum dots are of particular interest for potential applications, because they can achieve sufficient confinement to operate at room temperature with relatively robust electron spin coherence. The strong confinement in these nanostructures leads to significant effects caused by electron-hole exchange interactions, mixing of valence subbands, variation in particle size and shape, and surface defects. These effects all influence the processes of carrier spin initialization, dynamics, and detection. We have performed ensemble time-resolved Faraday rotation experiments as well as single-dot photoluminescence measurements to study how the strong quantum confinement affects the spin physics in these systems. We find that the mixing of valence subbands in the confined hole states largely determines the efficiency of optical spin pumping and Faraday-rotation-based spin detection. The intermittent charging of the quantum dots results in both photoluminescence blinking and changes to the coherent spin dynamics. Significant splitting of the exciton ground state due to the electron-hole exchange interaction and crystal fields leads to spin decoherence effects that depend sensitively on quantum dot size and shape. By studying these effects, we take a step towards controlling and exploiting spin coherence in this flexible room temperature platform.

9167-7, Session 1b

Epitaxial growth of CdMnTe quantum dots directly on Si(111) *(Invited Paper)*

Marielle H. Lage, Sukarno O. Ferreira, Univ. Federal de Viçosa (Brazil); Angelo S. Malachias, Univ. Federal de Minas Gerais (Brazil)

The presence of magnetic ions in a diluted magnetic semiconductor (DMS) leads to a variety of electronic, optical and magneto-optical properties. For instance, the exchange interaction between the magnetic ions spin and the spin of carriers leads to formation of bound magnetic polarons (BMPs). In a diluted magnetic quantum dot (DMQD), the possibility of tuning the three dimensional confinement originates new magnetic effects not present in bulk or quantum wells and makes MPs a very interesting system. Recently, formation of robust MPs has been observed in type-II DMQDs, due to the spatial separation of electrons and holes. In this work, we report the growth and structural characterization of CdMnTe/Si quantum dots. The samples were grown by molecular beam epitaxy directly on Si(111) substrates, in contrast with the previously studied systems, where the DMS islands were grown on II-VI buffers layers. The use of Silicon as substrates is advantageous for its compatibility with most processes of the microelectronic industry. We have used atomic force microscopy, high-resolution transmission electron microscopy and high-resolution x-ray diffraction to investigate the effect of growth time and temperature on the morphology and structural characteristics of the quantum dots. Our results show that this system follows the Volmer-Weber growth mode and almost perfect epitaxial islands can be grown despite a lattice mismatch around 19%. The introduction of a small concentration Mn ions reduces the lattice mismatch and improves the structural quality of the islands, as observed by reciprocal space maps around the (111) Bragg reflection.

Optical spin orientation and depolarization in Ge: from near infrared to visible *(Invited Paper)*

Christian Rinaldi, Matteo Cantoni, Stefano Bertoli, Cristian Manzoni, Marco Marangoni, Giulio Cerullo, Massimiliano Bianchi, Roman Sordan, Riccardo Bertacco, Politecnico di Milano (Italy)

Ge-based spintronic devices have recently deserved great attention, thanks to the compatibility with Si-based electronics, the large carrier mobility, the opportunity of electrical spin manipulation and optical spin pumping.

In this work we employ fully epitaxial Fe/MgO/Ge heterostructures [1] to investigate the spectral dependence of the optical spin orientation in germanium at room temperature from near infrared (1550 nm) to visible (400 nm) [2].

We fabricated spin-photodiodes by optical lithography. Spin-polarized carriers are photo-excited in the semiconductor by monochromatic circularly polarized light. The spin-dependent tunneling at the Fe/MgO interface is employed to measure the degree of spin polarization (DSP) of both electrons and holes in Ge. Changing the photon energy and measuring the variation of the photocurrent upon reversal of light helicity, we were able to obtain the spectral dependence of DSP.

We found the expected maximum in the spin polarization of photocarriers [3] for excitation at the direct gap in Gamma (1550 nm) and a second sizable peak due to photo-generation in the L valleys (530 nm). Our data suggest distinct spin depolarization mechanisms for excitation at Gamma and L point of the Brillouin zone, with shorter spin relaxation times whether the X point is involved.

Ge-based spin-photodiodes pave the way to integrated detection of light helicity over a wide spectral range in novel spin-optoelectronics systems.

Optical orientation of electron spins in GaAs L-valleys *(Invited Paper)*

Andrea Balocchi, Phillipe Barate, Tiantian Zhang, Thierry Amand, Pierre Renucci, Hélène Carrère, Bernhard Urbaszek, Xavier Marie, Institut National des Sciences Appliquées de Toulouse (France)

Electron spin dynamics are more commonly performed with optical excitation energies close to the band gap yielding the photo-generation of spin-polarized electrons in the Γ valley. Information on the electron spin dynamics in the upper valleys could be of interest for devices based on electrical injection such as spin light-emitting diodes and spin lasers, where electrons populate not only the Γ valley but also the satellite L and X ones. Here we present an all-optical investigation of the electron spin dynamics of L-valleys in GaAs based on the optical orientation of L-valley electrons and a detection of the variation of the luminescence polarization at the fundamental gap transition. We demonstrate that a significant fraction of the electron spin memory can be conserved when the electron is scattered from the L to the Γ valley following an energy relaxation of several hundreds of meV. These measurements allow us to precisely quantify the energy-dependent optical orientation of L-electrons and the significant remaining polarization of electrons that relaxed to the bottom of the Γ valley. From both CW and time resolved measurements we deduce a typical L-valley electron spin relaxation time of 200 fs, in agreement with theoretical calculations.

9167-10, Session 2a

Demonstration of the spin solar cell effect *(Invited Paper)*

Dominique Bougeard, Bernhard Endres, Mariusz Ciorga, Maximilian Schmid, Martin Utz, Dieter Weiss, Günther Bayreuther, Christian H. Back, Univ. Regensburg (Germany)

Optical spin orientation is a well-known method to create spin accumulations in semiconductors. The mechanism is particularly efficient in direct bandgap semiconductors but requires the use of circularly polarized light and resonant excitation. Here, we present the demonstration of a spin-generating photovoltaic effect, which creates a spin accumulation in n-GaAs, using unpolarized and non-resonant illumination [1,2].

The device consists of a p-n junction built from n-doped GaAs and ferromagnetic (Ga,Mn)As as the p-side. The illumination of this junction creates a photo-voltage, causing electrons to tunnel across the junction. Due to the spin-dependent tunneling probability, a spin accumulation is then created in the n-GaAs. The spin solar cell effect is demonstrated both via complementary polar magneto-optic Kerr effect experiments and electrical non-local voltage detection. When applying a large negative bias the sign of the photo-induced spin polarization is reversed, as expected, due to the suppression of the tunneling current. This mode of operation corresponds to a spin photodiode. Both effects are expected to also be efficient at room temperature in indirect bandgap semiconductors, paving the way for efficient optical spin injection into silicon or germanium.

Spin-dependent transport as a consequence of Pauli blockade in a degenerate electron gas *(Invited Paper)*

Fabian Cadiz, Daniel Paget, Alistair Rowe, Ecole Polytechnique (France)

Degeneracy of a photoelectron gas strongly affects spin transport. The momentum relaxation time becomes spin dependent because of the Pauli Principle, resulting in a spin dependence of the mobility (μ) and the diffusion constant (D). In addition D is further modified because the usual Einstein relations are no longer valid. We report the observation of these phenomena in p+ GaAs as a function of photoelectron density and electronic temperature using a polarized microluminescence technique. In this method a highly spin-polarized photoelectron gas is locally created by a continuous, tightly-focused circularly-polarized laser and images of the resulting radial distribution of the spin polarization, P(r), are recorded. In non-degenerate conditions P decreases during transport (i.e. with increasing r) due to the usual spin relaxation processes. In contrast, at low temperatures and high excitation intensities the photoelectron gas becomes degenerate and the spin dependence of D and μ results in a spin filter effect in which P increases during transport. The results are interpreted, without any adjustable parameters, by solving the coupled spin and charge diffusion equations. Relative differences of 50 % and 30 % are found for the spin-dependent values of D and μ. The spin-dependence of the luminescence intensity profile is also explored, and the observation of a spin-dependent increase in the photoelectron volume confirms the central role played by the quantum degeneracy pressure.

9167-12, Session 2b

Spin-orbit interaction and spin coherence in narrow-gap semiconductor and semimetal wires *(Invited Paper)*

Jean J. Heremans, Virginia Polytechnic Institute and State Univ. (United States); R. L. Kallaher, M. Rudolph, Virginia Tech (United States); Michael B. Santos, The Univ. of Oklahoma (United States); Willem Van Roy, Gustaaf R. Borghs, IMEC (Belgium)

The narrow-gap semiconductors InSb, InAs, and InGaAs, and the semimetal Bi have substantial spin-orbit interaction. We discuss spin-dependent quantum transport experiments on these materials, particularly in mesoscopic geometries on heterostructures and thin films, where spin-orbit interaction and quantum coherence determine the properties. The antilocalization signature in magnetoresistance results from spin-orbit interaction and is sensitive to spin- and quantum phase coherence lengths. Using antilocalization we determine the dependence of spin coherence lengths on the wire width in narrow nanolithographic ballistic InSb wires, InAs wires, and diffusive Bi wires. In all three different systems we find that the spin coherence lengths increase with decreasing wire widths if other parameters stay constant, an observation of technological importance for spin-based devices. A united understanding of the experiments can moreover be achieved via the duality between the Aharonov-Bohm and the Aharonov-Casher phases, the latter resulting from spin-orbit interaction. The experiments also indicate that Bi has surface states with strong Rashba-like spin-orbit interaction. In side-gated narrow channels of mesoscopic dimensions on InGaAs/InAlAs heterostructures, we study the tunable spin-orbit interaction induced by the electric field laterally confining electrons. The channel magnetoresistance due to antilocalization provides a measure of the confinement-induced spin-orbit interaction, if, as measurements

indicate, the variation in conducting width of the channel is also taken into account. This linear spin-orbit interaction, equivalent to an Aharonov-Casher vector potential, suggests the use of effective gauge fields to generate new quantum states of matter, with emphasis on edge states potentially robust against decoherence.

9167-13, Session 2b

Electron and hole spin transport in InSb nanowire quantum dots *(Invited Paper)*

Vlad S. Pribiag, S. Nadj-Perge, J. W. G. van den Berg, S. M. Frolov, I. van Weperen, Kavli Institute of Nanoscience Delft (Netherlands); S. R. Plissard, Erik P. A. M. Bakkers, Eindhoven Univ. of Technology (Netherlands); Leo P. Kouwenhoven, Kavli Institute of Nanoscience Delft (Netherlands)

The spin-orbit interaction enables fast all-electrical control of individual spins in quantum dots. The presence of very large spin-orbit coupling thus makes InSb nanowires a highly promising platform for spin-based qubits. We rely on electric dipole spin resonance (EDSR) to demonstrate single electron spin rotations, measure the strength of the spin-orbit coupling and extract the anisotropic g-factor.

A promising approach to enhancing qubit coherence is to use hole spins as qubits instead of electron spins, since hole spins have weaker hyperfine coupling. Here we take advantage of the small bandgap of InSb to readily gate-tune our nanowire devices between few-electron and few-hole quantum dots. In the few-hole regime we demonstrate rotation of single hole spin states via EDSR and use this to extract the hole g-factors. Thanks to the high tunability of these devices we are able to compare important properties of electrons and holes, such as effective masses, g-factors and spin-blockade anisotropies. The ability to control and read out hole spin states paves the way for more coherent, all-electrical hole-spin qubits.

9167-14, Session 2b

High magnetic field spectroscopy of silicon donors for quantum information applications *(Invited Paper)*

Benedict Murdin, Ellis Bowyer, Univ. of Surrey (United Kingdom)

Shallow donor impurities in silicon, once frozen out at low temperature, share many properties in common with free hydrogen atoms [1]. They have long been the subject of spectroscopic investigation, but it is only very recently [2,3] that it has been possible to investigate the time-domain dynamics of orbital excitations such as the 1s to 2p, due to the difficulty of obtaining short, intense pulses in the relevant wavelength range. These new techniques make shallow donors, and also acceptors [4], attractive for studying atomic physics effects, and for applications in quantum information. We have measured the population dynamics [2] of electrons orbiting around phosphorus impurities in commercially-available silicon, and shown that the lattice relaxation lifetime is about 200ps, only 1 order of magnitude shorter than the radiative lifetime of free hydrogen. Recently we also showed that high magnetic fields can introduce enormous changes in the electron wavefunction [1], and that easily available fields could be used for spatial control of the Rydberg orbital, and hence the overlap with adjacent atoms.

9167-15, Session 3a

Postselection-free entangled photons from highly symmetric quantum dots grown by droplet epitaxy *(Invited Paper)*

Takashi Kuroda, Takaaki Mano, Kazuaki Sakoda, National Institute for Materials Science (Japan); Bernhard Urbaszek, Institut National des Sciences Appliquées de Toulouse (France); Xavier Marie, Thierry Amand, Univ. de Toulouse (France); Hideaki Nakajima, Hidekazu Kumano, Ikuo Suemune, Hokkaido Univ. (Japan)

Entanglement is an essential resource for the implementation of quantum information processing. An efficient source of high-purity entangled photons is of particular importance since it would play a key role in realizing practical quantum key distributions. Semiconductor quantum dots have attracted much attention due to their appealing aspects such as the capability of on demand photon pair generations. Despite the concept being straightforward and analogous to that of an atomic cascade, experimental implementation has long been problematic due to inherent asymmetry in a common class of dots. The fine structure splitting of the intermediate exciton states makes radiative transition paths distinguishable, and thus strongly degrades or even dissolve quantum correlations in the emitted photons. Various attempts have been devoted to restoring the isotropic characteristics, but these methods would limit the potential scalability of dot-based photon sources. Here we report the generation of highly-entangled photons using a naturally symmetric quantum dot cascade. Our source consists of strain-free GaAs dots self-assembled on a triangular symmetric (111)A surface. The measured photons strongly violate Bell's inequality without postselection (S = 2.33 +- 0.06), which is an important step towards scalable quantum communication applications. The remaining decoherence channel of the photon source is ascribed to random nuclear spin fluctuations in and near the dot. Recent progress on the growth of telecommunication quantum dots on (111)A InP will be also reported.

9167-16, Session 3a

Spin-resolved study of direct band-gap recombination in bulk Ge *(Invited Paper)*

Fabio Pezzoli, Anna Giorgioni, Emanuele Grilli, Univ. degli Studi di Milano-Bicocca (Italy); Giovanni Isella, Politecnico di Milano (Italy); Mario Guzzi, Univ. degli Studi di Milano-Bicocca (Italy); Mario Guzzi, University of Milano-Bicocca (Italy)

Germanium and silicon-germanium alloys have found entry into Si technology thanks to their compatibility with Si processing and their ability to tailor electronic properties by strain and band-gap engineering. Noticeably, the quasi-direct band structure of Ge allows for optical spin orientation bridging the fields of spintronics and Si photonics where Ge is increasingly applied. Despite recent progress in the investigation of spin dynamics in Ge, very little is known about spin flip scattering by dopants and the role played by impurities in determining spin properties in different temperature regimes. Here we present a combined experimental and theoretical investigation of the spin and energy relaxation of electrons in Ge. By taking advantage of polarization-resolved photoluminescence measurements and Monte Carlo simulations of carrier dynamics we unveil a unique and very rich spin physics and highlight the importance of the multi-valley conduction band of this material. We demonstrate full control over the angular momentum of the direct gap emission with a complete reversal between right- and left-handed circular polarization. In the low temperature regime, the observed state of light polarization is ascribed to the so-far overlooked carrier cooling process that stems from the Coulomb scattering originated within the X-valleys. In the high temperature range, we disclose the role of backscattering from the L-valley in defining the depolarization of direct gap luminescence. This detailed investigation of spin properties of Ge is expected to open new opportunities connected to photonics and spintronics on a CMOS-compatible platform.

9167-17, Session 3a

Photonic spin Hall effect for precision metrology *(Invited Paper)*

Xinxing Zhou, Shizhen Chen, Yachao Liu, Hailu Luo, Shuangchun Wen, Hunan Univ. (China)

The photonic spin Hall effect (SHE) is generally believed to be a result of an effective spin-orbit interaction, which describes the mutual influence of the spin (polarization) and the trajectory of the light beam. For optical wavelengths, the photonic SHE is very weak and the corresponding spin-dependent splitting is restricted to a few tens of nanometers. However, using the quantum weak measurement, this tiny phenomenon can be detected with the desirable accuracy. The photonic SHE holds great potential for precision metrology owing to the fact that the spin-dependent splitting in photonic SHE are sensitive to the structural parameter variations of different physical systems. We should firstly establish the quantitative relationship between the spin-dependent shifts and the structural parameters. After detecting the spin-dependent displacements with weak measurement method, we can accurately determine these structural parameters. Here, we will present some of our works on using photonic SHE for precision metrology, such as determining the photon momentum in a transparent dielectric, measuring the thickness of nanometal film, identifying the graphene layers, and detecting the strength of axion coupling in topological insulators.

9167-18, Session 3a

On the charge-magnet paradoxes of classical electrodynamics *(Invited Paper)*

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

A number of charge-magnet paradoxes have been discussed in the literature, beginning with W. Shockley's famous 1967 paper, where he introduced the notion of hidden momentum in electromagnetic systems. We discuss all these paradoxes in a single, general context, showing that the conservation laws of energy, momentum, and angular momentum can be satisfied “without” the need for hidden entities, provided that the Einstein-Laub law of force and torque is used in place of the standard Lorentz law. Einstein and Laub published their paper in 1908, but the simplicity of the conventional Lorentz law overshadowed the subtle features of the Einstein-Laub formulation which, at first sight, appears overly complicated. However, that slight complication turns out to lead to subsequent simplifications in light of the discovery of hidden momentum by Shockley in 1967, more than a decade after Einstein had passed away. In this presentation, we will show how the Einstein-Laub law solves the underlying problems associated with several paradoxes of classical electrodynamics -- without contradicting the existing body of knowledge that has been confirmed by 150 years of theoretical work and experimental observations in electrodynamics.

9167-19, Session 3b

Individual cobalt and manganese ions in semiconductor quantum dots and photonic structures *(Invited Paper)*

Wojciech Pacuski, Univ. of Warsaw (Poland)

This work presents fabrication and optical study of diluted magnetic semiconductors (DMS) and two kind of quantum dots (CdTe and CdSe) with individual ions of transition metals: cobalt and manganese [1,2]. The most surprising findings are related to exciton recombination channels. For DMS structures where exciton energy is larger than intraionic transition energy, we observe excitonic photoluminescence which is weak due to quenching by magnetic ions. However, for single magnetic ions in QDs, effect of quenching is negligible, as shown by exciton photoluminescence decay measurements [1].

QDs containing exactly one magnetic ion exhibit characteristic photoluminescence spectrum modified by s,p-d exchange interaction. Exciton line is split by 6 in case of single Mn2+ in CdSe QD [1] (due to 6 spin projection of Mn2+ [3]). In case of CdTe QD with individual Co2+, exciton line is split by 4 [1] (due to 4 spin projection of Co2+). Using on/off modulated non-resonant laser excitation we are determining spin relaxation of individual magnetic ions and we find the longest relaxation times for single Mn2+ in CdSe QDs [1].

Permanent marking of quantum dots position enable multiple studies on selected magnetic ion and fabrication of a micropillar cavity with a QD containing exactly one magnetic ion [2].

Conventional versus unconventional magnetic polarons: ZnMnTe/ZnSe and ZnTe/ZnMnSe quantum dots *(Invited Paper)*

Biplob Barman, Athos Petrou, Yutsung Tsai, Thomas A. Scrace, James M. Pientka, Joseph R. Murphy, Alexander N. Cartwright, Igor Zutic, Bruce D. McCombe, Univ. at Buffalo (United States); Rafal Oszwaldowski, Andre Petukhov, South Dakota School of Mines and Technology (United States); Ian R. Sellers, The Univ. of Oklahoma (United States); Wu-Ching Chou, W. C. Fan, National Chiao Tung Univ. (Taiwan); C. S. Yang, Tatung Univ. (Taiwan)

A magnetic polaron (MP) can be viewed as a cloud of localized magnetic ion spins, aligned through exchange interaction with the spin of a confined carrier. A conventional understanding suggests that the MP formation energy E(MP), measured from the red-shift of the band-edge photoluminescence (PL), decreases rapidly with an increase in temperature and applied magnetic field. Our time-resolved photoluminescence studies reveal differences in MP behavior in two related, spatially indirect, (II,Mn)VI, epitaxially grown quantum dot (QD) structures. In type-A ZnTe/(Zn,Mn)Se samples we observe E(MP) with a conventional temperature and magnetic field dependence. However, in type-B (Zn,Mn)Te/ZnSe samples there is only a weak dependence of E(MP) on temperature and magnetic field; E(MP) is also larger than that in type-A samples. We attribute these differences to the difference in the strength of the exchange interaction between the Mn and the hole spins, which are spatially separated in type-A, but in close proximity in type-B samples. Our theoretical analysis of the PL data in type-B samples suggest the presence of antiferromagnetic coupling of Mn spins which leads to an unusual form of magnetic ordering.

9167-22, Session 4a

Direct observation of non-thermal influence in the process of photo-induced ferromagnetic resonance in (Ga,Mn)As *(Invited Paper)*

Takashi Matsuda, Kazuhiro Nishibayashi, Hiro Munekata, Tokyo Institute of Technology (Japan)

Some works [1, 2] concerning the photo-induced ferromagnetic resonance (phi-FMR) in (Ga,Mn)As assumed that the resonance was triggered by the ultrafast spin heating (UFSH), despite of the fact that only a small fraction of photon energy could be released to spin and lattice sub-systems in ps time scale because of the presence of the

band gap. We report here that, through studying the initial stage of phi-FMR, magnetization precession is not accompanied by the UFSH but is triggered by the modulation of hole-mediated exchange interaction, in particular crystal magnetic anisotropy, through the repopulation of photo-excited holes. Our findings are based on time-resolved magneto-optical and reflectivity signals obtained from a Ga0.98Mn0.02As epilayer by pump-probe technique with fs-laser source in the regime of weak excitation (0.34 - 3.4 μJ/cm2 per pulse). One of the most remarkable results is a clear observation of the onset of the precession together with pump-probe autocorrelation signals in the sub-ps time scale with excitation wavelengths of $\lambda > 820$ nm. Analysis with the gyromagnetic model reveals a change in the direction of crystal anisotropy with duration of 10 – 20 ps. A characteristic exponential decay washes out the autocorrelation signals when excited with $\lambda > 820$ nm. Furthermore, duration of excited crystal anisotropy is extended up to 90 – 140 ps in this case. Since 820 nm corresponds to the photon energy equivalent to the band gap of a host GaAs, effects occurring with $\lambda \leq 820$ nm are attributed to the excitation of delocalized carrier system.

9167-23, Session 4a

Modeling optically pumped NMR and spin polarization in GaAs/AlGaAs quantum wells *(Invited Paper)*

Christopher J. Stanton, Dipta Saha, Ryan Wood, Clifford R. Bowers, Univ. of Florida (United States); Erika L. Sesti, Sophia E. Hayes, Washington Univ. in St. Louis (United States)

Optically-pumped nuclear magnetic resonance (OPNMR) spectroscopy is an emerging technique to probe electronic and nuclear spin properties in bulk and quantum well semiconductors. In OPNMR, one uses optical pumping with circularly polarized light to create spin-polarized electrons in a semiconductor. The electron spin can be transferred to the nuclear spin bath through the Fermi contact hyperfine interaction which can then be detected by conventional NMR. The resulting NMR signal can be enhanced four to five orders of magnitude or more over the thermal equilibrium signal. In previous work, we studied OPNMR in bulk GaAs were we investigated the strength of the OPNMR signal as a function of the frequency of the pump laser. This allowed us to study the spin-split valence band. Here we report on OPNMR studies in AlGaAs/GaAs quantum wells. We will focus on the theoretical calculations for the average electron spin polarization at different photon energies for different values of external magnetic field in both unstrained and strained quantum wells. Our calculations allow us to identify the Landau level transitions which are responsible for the peaks in the OPNMR signal intensity. The calculations are based on the 8- band Pidgeon-Brown model generalized to include the effects of the quantum confinement potential as well as pseudomorphic strain at the interfaces. Optical properties are calculated within the golden rule approximation. Detailed comparison to experiment allows one to accurately determine valence band spin splitting in the quantum wells including the effects of strain.

9167-24, Session 4a

Experimental measurements of optically pumped NMR and spin polarization in bulk GaAs and AlGaAs/GaAs quantum wells *(Invited Paper)*

Sophia E. Hayes, Erika L. Sesti, Washington Univ. in St. Louis (United States); Dipta Saha, Ryan Wood, Clifford R. Bowers, Christopher J. Stanton, Univ. of Florida (United States)

Optically-pumped nuclear magnetic resonance (OPNMR) spectroscopy uses optical pumping of a direct-gap semiconductor (such as GaAs in bulk or quantum well form) to orient the electron spins. These electron spins couple to the surrounding nuclei through a Fermi-contact hyperfine interaction, thereby polarizing these as well. OPNMR uses the detection of 69Ga and 71Ga NMR resonances at low temperatures (4-10K) and at relatively low magnetic fields (3T – 7T). In previous work, we varied the photon energy used for optical pumping, as well as the polarization of the laser, to determine the behavior of the OPNMR resonances as a function of each of these parameters. These studies yielded information on the spin-split valence band. Here we report on OPNMR studies in AlGaAs/GaAs quantum wells. The talk will focus on new measurements of the quantum well and bulk signals at 3T and 4.7T, in particular as a function of laser intensity. In conjunction with theoretical calculations, Landau level transitions which are responsible for the peaks in the OPNMR signal intensity can be identified. The calculations, described in a separate paper from Stanton et al., are based on the 8- band Pidgeon-Brown model. Optical properties are calculated within the golden rule approximation. Detailed comparison to experiment allows one to accurately determine valence band spin splitting in the quantum wells, and a comparison to the behavior in bulk GaAs. This work was supported by the NSF through grants DMR-1206447, DMR-1105437, and the NHMFL In-House Science Program (DMR-1157490).

9167-25, Session 4a

Deviation from the Landau-Lifshitz-Gilbert equation in the inertial regime of the magnetization *(Invited Paper)*

Enrick Olive, Univ. de Tours (France)

The inertial dynamics of uniform magnetization is investigated in the framework of a generalized Landau-Lifshitz-Gilbert (LLG) equation wich introduces a characteristic time that accounts for fast degrees of freedom. Unlike the usual LLG equation where the dynamics is limited to the precession of the magnetization around a static field, a fast nutation dynamics coupled to the precession is evidenced in the generalized LLG equation. As a consequence, the resulting resonance curves in the frequency domain show two different peaks associated with both dynamics. Another consequence of the inertial model is the displacement of the ferromagnetic resonance (FMR) compared to the usual LLG equation. We present analytical and numerical simulation results on the expected resonance curves within the inertial model which is investigated while varying the fast characteristic time Ÿ, the damping and the static field.

9167-26, Session 4b

Domain walls in multiferroic oxides as nanoscale functional elements *(Invited Paper)*

Jan Seidel, The Univ. of New South Wales (Australia)

Interfaces and topological defects in complex oxide materials, such as domain walls, have recently received increasing attention due to the fact that their properties, which are linked to the inherent order parameters of the material, its structure and symmetry, can be completely different from that of the bulk material [1]. I will present an overview of recent results on electronic and optical properties of ferroelectric phase boundaries, domain walls, and topological defects in multiferroic BiFeO3 [2, 3]. The origin and nature of the observed confined nanoscale properties is probed using a combination of nanoscale transport measurements, high resolution transmission electron microscopy and first-principles density functional computations. I will also give an outlook on how these special properties can be found in other material systems and discuss possible future applications [4].

9167-27, Session 4b

Resonant Raman scattering in $BiFeO_3$ *(Invited Paper)*

Mads Weber, Ctr. de Recherche Public - Gabriel Lippmann (Luxembourg) and Univ. du Luxembourg (Luxembourg); Mael Guennou, Ctr. de Recherche Public - Gabriel Lippmann (Luxembourg); Constance Toulouse, Maximilien Cazayous, Univ. Paris 7-Denis Diderot (France); Jens Kreisel, Ctr. de Recherche Public - Gabriel Lippmann (Luxembourg) and Univ. du Luxembourg (Luxembourg)

BiFeO3, being one of the very few materials having at ambient conditions both magnetic ordering and ferroelectricity, has been adopted as a model multifunctional material. Recent investigations have revealed notably its potential as a photoferroelectric, or the ubiquitous properties of its domain walls, thought of as basic functional elements in the currently emerging field of “domain-wall nanoelectronics”. Raman spectroscopy has been amply used in the past for characterization of BiFeO3 single crystals, ceramics and thin films. Its potential for characterization of domain-walls or nanostructures is unquestioned, but requires a thorough understanding of the Raman spectra of the bulk material and the many factors that influence it (excitation wavelength, skin layer, penetration depth etc.).

Here, we discuss the Raman spectrum of BiFeO3 with a focus on resonant Raman phenomena measured with a collection of exciting laser lines from 325 to 785 nm. Resonant Raman scattering occurs when the exciting laser light approaches an electronic excitation, and is usually of little significance in classical insulators with band gap lying well above the visible range. In BiFeO3 however, resonance phenomena are shown to be particularly pronounced with blue or green laser light and to affect both the first-order and the second-order phonon spectrum. The temperature dependence of these features enables us to link these observations to current understanding on the behaviour of the band gap and electronic phenomena in BiFeO3. We expect resonant Raman studies to be a very useful tool for investigations of interaction of light with BiFeO3.

9167-28, Session 4b

Low-dimensional antiferromagnetic transition metal oxides coupled to magnetic substrates *(Invited Paper)*

Alberto Brambilla, Andrea Picone, Michele Riva, Alberto Calloni, Giulia Berti, Gianlorenzo Bussetti, Marco Finazzi, Lamberto Duò, Franco Ciccacci, Politecnico di Milano (Italy)

Intriguing magnetic properties can be obtained in systems containing antiferromagnetic (AF) transition metal oxides both by low-dimensionality and by proximity to ferromagnetic (F) layers, giving rise to well-known exchange coupling phenomena. The tailoring of such properties towards spintronics applications must pass through a sound understanding of the correlations between their magnetic, chemical, structural and morphologic features.

So far, we have collected a rich record of investigations on AF/Fe layered structures [1]. Several issues, such as chemical interactions at the interfaces, magnetic couplings in AF/Fe and Fe/AF/Fe systems, spin reorientation transitions, development of nanometer sized domains and very sharp domain walls, have been investigated.

We are currently pursuing new efforts towards the nanoscale understanding of AF/F structures by studying the early stages of formation of oxide nanostructures coupled to Fe substrates. Such systems contain appealing ingredients, such as high chemical reactivity, stabilization of unusual stiochiometries, presence of metastable phases. Our presentation will focus on Scanning Tunneling Microscopy/Spectroscopy investigations of transition metal oxides nanostructures based on Co, Ni and Cr [2,3]. Such investigations are supported by electron spectroscopies – also with spin resolution –by x-ray magnetic dichroism and magneto-optical Kerr effect measurements. The results will be discussed in the perspective of a comparative study aimed to identify the key features to develop new nanostructured magnetic structures with a bottom-up approach.

Magnetization dynamics and Gilbert damping properties of Co_2FeAl film grown by molecular beam epitaxy *(Invited Paper)*

Shuag Qiao, Shuaihua Nie, Institute of Semiconductors (China); Yan Huo, Yizheng Wu, Fudan Univ. (China); Jianhua Zhao, Xinhui Zhang, Institute of Semiconductors (China)

Co-based full-Heusler alloys have been revealed to behave like half-metals even at room temperature. The highly ordered Co2FeAl with an ideal L21 structure has been predicted to be half-metal, with a well-defined band gap in the minority spin channel. However, its magnetic and damping properties, which are fundamental for spintronics application, have not been investigated in detail before. In this work, the thickness and growth temperature dependent magnetocrystalline anisotropy of MBE-grown Co2FeAl films were first investigated by employing the rotating magneto-optical Kerr effect (ROTMOKE). Then the magnetization dynamics and Gilbert damping property for high quality Co2FeAl films were investigated in detail by combining both the ferromagnetic resonance (FMR) and time-resolved magneto-optical Kerr effect (TR-MOKE) techniques. The apparent damping parameter was found to show strong dependence on both the strength and directions of the applied magnetic field at low field regime, but decrease drastically with increasing magnetic field for all studied films with different thickness and eventually become a constant value of 0.004 at high field regime. The inhomogeneity of effective magnetocrystalline anisotropy and two-magnon scatterings are suggested to be responsible for the observed abnormal damping properties observed especially at low field regime. The intrinsic damping parameter of 0.004 is deduced for our highly ordered Co2FeAl film. Our results provide essential information for highly ordered MBE-grown Co2FeAl film and its possible application in spintronic devices.

Ultra-low-energy straintronics using multiferroic composites *(Invited Paper)*

Kuntal Roy, Purdue Univ. (United States)

The primary impediment to continued improvement of traditional charge-based electronic devices in accordance with Moore's law is the excessive energy dissipation that takes place in the device during switching of bits. One very promising solution is to utilize multiferroic composites, i.e., ferroelectric-ferromagnet heterostructures, where the magnetoelectric effect arises from the strain-mediated interaction between the ferroelectric and ferromagnetic constituents. The voltage applied across the heterostructure generates a strain in the magnetostrictive ferromagnet and thereby the induced magnetic anisotropy can rotate its magnetization. With suitable choice of materials, the required voltage for magnetization switching can be a few millivolts, that incurs a miniscule amount of energy dissipation of ~1 attojoule [1-4]. Such devices have been proposed not only for memory bits, but also for building logic [5,6] leading to a new field named straintronics [7]. Apart from digital computing, it is shown that the multiferroic devices can be also utilized for analog signal processing, e.g., voltage amplification with a gain and input-output isolation, filter, rectifier. It is also shown that in a magnetostrictive nanomagnet, it is possible to achieve the so-called Landauer limit (or the ultimate limit) of energy dissipation. According to

Landauer's principle, postulated by the famous scientist R. Landauer back in 1961, it necessarily dissipates an energy of amount kT ln(2) compensating the entropy loss while erasing a bit of information, thereby linking information and thermodynamics. The simulation results are based on the study of magnetization dynamics using the stochastic Landau-Lifshitz-Gilbert (LLG) equation in the presence of room-temperature thermal fluctuations.

Persistent optically induced magnetism in oxygen-deficient strontium titanate *(Invited Paper)*

William D. Rice, Los Alamos National Lab. (United States); Palak Ambwani, Univ. of Minnesota (United States); M. Bombeck, Technische Univ. Dortmund (Germany); Joe D. Thompson, Los Alamos National Lab. (United States); Greg Haugstad, Univ. of Minnesota, Twin Cities (United States); Chris Leighton, Univ. of Minnesota (United States); Scott A. Crooker, Los Alamos National Lab. (United States)

Strontium titanate ($SrTiO_3$) is a foundational material in the emerging field of complex oxide electronics. $SrTiO_3$ has recently become a renewed materials research focus due to observations of extremely high interfacial charge densities that form between $SrTiO_3$ and other wide bandgap semiconducting oxides. Investigations of $SrTiO_3$ heterostructure interfaces were further catalyzed in part by the unexpected discovery of the coexistence of magnetism and superconductivity. The formation and distribution of oxygen vacancies, especially in $SrTiO_3$, is thought to play an essential but as-yet-incompletely understood role in these effects.

Using magnetic circular dichroism spectroscopy and SQUID magnetometry, we find that oxygen-deficient $SrTiO_{3-\sigma}$ exhibits persistent, optically induced magnetization [1]. We find that when oxygen vacancies are introduced via thermal annealing in UHV, we are able to optically induce magnetization at zero magnetic field with sub-bandgap (400-500 nm) circularly polarized light; this magnetization inverts when the circular polarization is reversed. Interestingly, we observe that the relaxation dynamics strongly depend on temperature: the induced magnetization exhibits hours-long decay times when the temperature is below 10 K, but only persists for seconds near 18 K, the temperature where the magneto-optical effects first appear. Utilizing the remarkably long relaxation times and all-optical magnetization control, we demonstrate that $SrTiO_{3-\sigma}$ can be used as optical magnetic memory. The magneto-optical phenomena described here, which only occur in oxygen-deficient samples, reveal the detailed interplay between magnetism, lattice defects, and light in an archetypal oxide material and may yield new insights into the physics of oxide interfaces.

Skyrmions are topologically protected particle-like configurations, with a topological complexity described by their Skyrmion number. In magnetic systems, they have been numerically predicted to exhibit rich dynamics, such as the gyrotropic and breathing modes, dominated by their topology. Recent experimental advances brought their static manipulation well under control. However, their dynamical behaviour is largely unexplored experimentally. In this work, we provide with the first direct observation of eigenmode skyrmion dynamics. In particular, we present dynamical imaging data with high temporal and spatial resolution to demonstrate the GHz gyrotropic mode of a single skyrmion bubble, as well as the breathing-like behaviour of a pair of skyrmionic configurations. We use the observed dynamical behaviour to confirm the skyrmion topology and show the existence of an unexpectedly large inertia that is key for accurately describing skyrmion dynamics. Our results demonstrate new ways for experimentally observing skyrmion dynamics and provide a framework for describing their behaviour. Furthermore, the results outline a link between the dynamical behaviour of skyrmions and their distinct topological properties, with possible ramifications for skyrmionic spin structures research including technological applications.

Micromagnetics with Dzyaloshinskii-Moriya interaction: from domain walls to skyrmions *(Invited Paper)*

Stanislas Rohart, Univ. Paris-Sud 11 (France)

Recent observation using have shown that in ultrathin films in asymmetric multilayer stacks, chiral magnetic textures may appear, due to the Dzyaloshinskii-Moriya interaction (DMI) [1,2]. This opens the way to high efficiency current induced domain wall motion [2,3] or new type of memories based on skyrmions [4].

In this talk, we review different manifestations of DMI on these films. We first consider moderate DMI which doesn't destabilize the ferromagnetic ground state. The symmetry of DMI imposes a Néel structure with a unique chirality. These walls have unique properties such as increases Walker velocity and high sensitivity to the spin Hall effect spin-transfer torque [3]. Another manifestation occurs at the nanostructure edges where a chiral magnetization tilt develops [6], which has practical consequences on edge domain wall nucleation [7].

In a second part we consider skyrmions which may appear for stronger DMI, and describe the conditions to obtain them as soliton states, in the perspectives of race-track memory type applications. We also show that the DMI induced edge micromagnetic state creates a confining potential for skyrmions which are then stable in nanostructures [6].

Writing and deleting single magnetic skyrmions *(Invited Paper)*

Niklas Romming, Christian Hanneken, Matthias Menzel, Jessica E. Bickel, Boris Wolter, Kirsten von Bergmann, André Kubetzka, Roland Wiesendanger, Univ. Hamburg (Germany)

Magnetism in thin films can significantly deviate from commonly known magnetic configurations in bulk systems due to low dimensionality, hybridization effects, a change of the lattice constant, stacking and broken inversion symmetry at interfaces. This can lead to non-collinear spin states such as spin spirals or skyrmions. Especially magnetic skyrmions with their nontrivial topology are interesting objects for both fundamental as well as application-related research due to their possible utilization in data storage concepts.

Here, we report on an ultrathin magnetic film in which individual skyrmions can be written and deleted in a controlled fashion with locally injected spin-polarized currents from a scanning tunneling microscope [1]. An external magnetic field is used to tune the energy landscape, and the temperature is adjusted to prevent thermally activated switching between topologically distinct states. Switching rate and direction can then be controlled by the parameters used for current injection. The creation and annihilation of individual magnetic skyrmions demonstrates the potential for topological charge in future information-storage concepts.

Skyrmions and helicoids in epitaxial thin film helical magnets *(Invited Paper)*

Theodore L. Monchesky, Murray N. Wilson, Dalhousie Univ. (Canada); Filipp N. Rybabov, Institute of Metal Physics (Russian Federation); Anna B. Butenko, Alexei B. Bogdanov, Ulrich K. Rossler, Leibniz-Institut für Festkörper- und Werkstoffforschung Dresden (Germany); Helmut Fritzsche, Canadian Neutron Beam Centre (Canada); Kathryn Krycka, Brian J. Kirby, National Institute of Standards and Technology (United States); James C. Loudon, Univ. of Cambridge (United Kingdom); Michael D. Roberston, Acadia Univ. (Canada); Simon Meynell, Eric A. Karhu, David Lake, Andrew S. Quigley, Dalhousie Univ. (Canada); Charles F. Majkrzak, National Institute of Standards and Technology (United States)

Currently, nanolayers of cubic chiral magnets are the only material system where magnetic skyrmions and helicoids are observed over a broad range of thermodynamic parameters. These magnetic states are promising candidates for novel spintronic applications. I will present an overview of the structure and magnetic properties of chiral magnet epilayers grown on Si(111), including MnSi, FeGe and (Fe,Co)Si, which opens the study of skyrmions to a broad range of characterization tools [1,2] that enables the resolution of a controversy in the literature about these nanolayers.

The presence of surfaces produce novel discrete helicoidal states in the epilayers that can be read by electrical means, which shows that in principle they could be used for information storage. The epitaxy induced out-of-plane uniaxial anisotropy is another key component that influences the magnetic texture. The sign of the anisotropy dictates how the skyrmions are stabilized. In contrast to films with an easy-axis, the hard-axis anisotropy entirely suppresses skyrmions in out-of-plane magnetic fields, as predicted by theoretical calculations.[2] An easy-plane anisotropy, however, stabilizes a novel skyrmion state consisting of elliptically distorted skyrmion gratings with their core magnetizations pointing in the plane of the film. Collectively, these results help to understand the general problem of skyrmion formation in chiral magnets. In this talk I will overview neutron scattering, magnetometry, and Lorentz microscopy measurements to provide a comprehensive view of skyrmions in chiral magnet epilayers.

Interaction between vortex walls and asymmetric notches in Permalloy nanowires *(Invited Paper)*

Luiz Sampaio Lima, Centro Brasileiro de Pesquisas Físicas (Brazil)

We have investigated the injection and transmission of vortex domain walls in Permalloy (Py) nanowires through triangular notches. We have used magneto-optical Kerr microscopy and micromagnetic simulations. The nanowires have the width varying from 300 to 800nm and were grown by e-beam lithography. The triangular notches are asymmetric and have in both sides the slope phi varying from 15 to 45 degrees, so two sets of samples were used: 45-phi and phi-45. The Kerr system is able to measure a single nanowire.

Measuring the hysteresis after the notch we observed that the domain wall pinning by the notch depends upon the vortex chirality, independent of the size and the symmetry of the notch. Counterclockwise (CCW) chirality always exhibit larger coercivity than clockwise (CW) one, and this effect was found more pronounced to the phi-45 set. It was also noticed different probabilities for the CCW and CW chiralities to be observed after the notch although both are produced with the same probability. For example, measured histograms of the CCW and CW coercivities show that CW has 9 times more probability than the CCW to be observed after the notch. It was measured for the 15-45 notch in head-to-head walls. It means that the interaction between the vortex wall and the notch is able to change the vortex chirality. Using the experimental results and micromagnetic simulations we were able to obtain the potential produced by the notch on the vortex wall.

Current-driven dynamics of chiral domain walls *(Invited Paper)*

Geoffrey S. Beach, Massachusetts Institute of Technology (United States)

In most ferromagnets the magnetization rotates from one domain to the next with no preferred handedness. However, broken inversion symmetry can lift the chiral degeneracy, leading to topologically rich spin textures such as spin-spirals and skyrmions via the Dzyaloshinskii-Moriya interaction (DMI) [1,2]. Here we show that in ultrathin metallic ferromagnets sandwiched between a heavy metal and an oxide, the DMI stabilizes chiral domain walls (DWs) whose spin texture enables extremely efficient current-driven motion [3]. We show that spin torque from the spin Hall effect drives DWs in opposite directions in Pt/CoFe/MgO and Ta/CoFe/MgO, which can be explained only if the DWs assume a Néel configuration with left-handed chirality. We directly confirm the DW chirality and rigidity by examining current-driven DW dynamics with magnetic fields applied perpendicular and parallel to the spin spiral [3,4]. This work identifies the origin of efficient current-driven domain wall motion in heavy metal/ferromagnet bilayers, and highlights a new path towards interfacial design of spintronic devices. In collaboration with S. Emori, U. Bauer, S.-M. Ahn, and E. Martinez.

Helical order in one dimensional semiconductors *(Invited Paper)*

Peter Stano, RIKEN (Japan)

I will talk about the helical spin order which arises in the thermodynamical equilibrium in a one-dimensional (semi)conductor with spin impurities (e.g., nuclear spins, or spins of localized magnetic impurities). The helical order in localized spins is a consequence of the dimensionality, and thus very general, arising in metals, semiconductors, and even gapped phases, like superconductors.

I will show that the order follows from the resonant peak of the response (spin susceptibility) of a one-dimensional system. I will discuss recent low temperature transport experiments with semiconducting wires which suggest that such helical order was established in nuclear spins of atoms of the wire.

I will explain how such a helical order can be useful in the semi-super hybrid platform to stabilize Majorana fermions and to produce even more exotic many body excitations like fractionally charged fermions and parafermions.

Brookes, ESRF - The European Synchrotron (France); Riccardo Bertacco, Politecnico di Milano (Italy); Amina Taleb, Synchrotron SOLEIL (France); Mebarek Alouani, Eric Beaurepaire, Institut de Physique et Chimie des Matériaux de Strasbourg (France)

Toward the design of large-scale electronic circuits that are entirely spintronics-driven, organic semiconductors have been identified as a promising medium to transport information using the electron spin. This requires an organic current source that is highly spin-polarised at and beyond room temperature, but this key building block is still lacking. We experimentally and theoretically show how the interface between Co and phthalocyanine molecules constitutes a promising candidate. Spin-polarised direct and inverse photoemission experiments reveal a high degree of spin polarisation at room temperature at this interface. We measured a magnetic moment on the molecule's nitrogen ? orbitals, which substantiates an ab-initio theoretical description of highly spin-polarised charge conduction across the interface due to differing spinterface formation mechanisms in each spin channel. We propose, through this example, a recipe to engineer simple organic-inorganic interfaces with remarkable spintronic properties that can endure well above room temperature.

Molecular nanomagnetics for spintronic devices *(Invited Paper)*

Marco Affronte, Univ. degli Studi di Modena e Reggio Emilia (Italy)

The possibility of tailoring their functionalities at the molecular scale makes molecular nanomagnets interesting for applications in information technologies where the race for extreme miniaturization will soon lead at requiring components of few nanometers in size. Properties like the magnetic bistability or the switchability by external stimuli actually allow to mimic, at the molecular scale, basic operations commonly used in computers while embedding magnetic molecules in suitable electronic circuits allows the fabrication of novel spintronic devices. Even more challenging is the control and the exploitation of quantum properties in molecular spin clusters that may allow the encoding of quantum information with molecules. These concepts are substantiated by many achievements obtained in the recent years and they will be briefly reviewed in the first part of my talk [1]. Then, I shall focus on some viable molecular paths to fabricate novel spintronic devices made of carbon allotropes and molecular nanomagnets. As a first step, we have explored different strategies to efficiently graft molecular nanomagnets on carbon surfaces [2, 3]. Secondly, I shall present the design and the realization of hybrid devices made by graphene nano-constrictions with sizes down to 10nm decorated with TbPc2 magnetic molecules. The magnetization reversal of the molecules in proximity with graphene is detected by the magnetoconductivity of these hybrid devices, which shows the uniaxial magnetic anisotropy typical of the TbPc2 SMMs. These results depict the behavior of multiple-field-effect nano-transistors with sensitivity at the single-molecule level [5].

Cyclotron resonance in ferromagnetic semiconductors at ultrahigh magnetic fields *(Invited Paper)*

Yasuhiro H. Matsuda, The Univ. of Tokyo (Japan)

Electronic states of ferromagnetic InMnAs and InMnSb films have been studied by the cyclotron resonance (CR) in ultrahigh magnetic fields of up to 140 T. [1] We used four MOVPE-grown InMnAs and InMnSb films and two MBE-grown InMnSb films. The three MOVPE-grown InMnAs films have the Mn contents x =1, 2, 4%, respectively, and the Currie temperatures (TC) are all 330 K, and the MOVPE-grown InMnSb film with x =5.6% has the Tc=590 K. The MBE grown InMnSb films with x=2% have the TC=10 K. The hole densities are around 10^18 cm-3 and 10^20 cm-3 for MOVPE films and MBE films, respectively.

CR is a powerful tool to investigate the electronic state of semiconductors. Since the mobility of the ferromagnetic semiconductors is typically as low as μ=100 cm2/(Vs), the CR experiment requires an ultrahigh magnetic field as high as B=100 T to satisfy the condition μB > 1. In the present study, we utilize the single-turn coil technique [2] that generates pulsed fields over 100 T with the coil destruction.

By analyzing the CR spectra using a model based on the 8-band k•p Pidgeon-Brown model, it is found that the CR features are well explained by the transitions in the valence band. [1] Our findings indicate that the impurity band is absent in the midgap and that the difference of the TC between the MOVPE-grown and MBE-grown films can be due to the difference of the hole densities.

Magneto-optical spectroscopy of narrow gap ferromagnetic semiconductors *(Invited Paper)*

Giti A. Khodaparast, Virginia Polytechnic Institute and State Univ. (United States); Yasuhiro H. Matsuda, The Univ. of Tokyo (Japan); Dipta Saha, Gary D. Sanders, Christopher J. Stanton, Univ. of Florida (United States); Bruce W. Wessels, Northwestern Univ. (United States)

We present experimental and theoretical studies of the magneto-optical properties of p-type

narrow gap ferromagnetic semiconductors in ultrahigh magnetic fields. Samples were fabricated by Metal-Organic Vapor Phase Epitaxy (MOVPE) and demonstrate Curie temperatures above the room temperature. We compared Landau level and band structure calculations with observed Cyclotron Resonance measurements. To model the results, we used an 8-band Pidgeon-Brown model generalized to include the wave vector dependence of the electronic states along kz as well as the s-d and p-d exchange interactions with the localized Mn d-electrons. The Curie temperature is taken as an input parameter and the average Mn spin is treated in mean field theory. Our calculations indicate that the lower carrier densities in this material system can result in a much larger average spin compared to the MBE grown structures. This fact could be responsible for higher Curie temperatures in the MOVPE grown narrow gap ferromagnetic semiconductors.

9167-43, Session 7

g-factor anisotropy driven spin relaxation in germanium *(Invited Paper)*

Pengke Li, Jing Li, Univ. of Maryland (United States); Song Yang, Lan Qing, Hanan Dery, University of Rochester (United States); Ian Appelbaum, Univ. of Maryland (United States)

In semiconductors possessing more than a single conduction band valley, g-factor anisotropy opens a new channel of electron spin relaxation. This unusual mechanism arises in a magnetic field because the effective Zeeman field is tilted along the valley axis, and is randomized when electrons undergo intervalley scattering. This fluctuation depolarizes electron spins, similar to the Dyakonov-Perel mechanism in noncentrosymmetric semiconductors where spin relaxation is driven by a wavevector dependent magnetic field. We study the unique nature of g-factor anisotropy spin relaxation by spin transport measurements from long-distance germanium devices in a magnetic field aligned to the initial spin orientation. The confluence of electron-phonon scattering (leading to Elliott-Yafet spin relaxation) and this previously unobserved physics enables the extraction of spin lifetime solely from spin-valve measurements. We find spin lifetimes in Ge up to several hundreds of ns at low temperature, far beyond any other available experimental results. such long spin lifetime in Ge is governed by the space inversion symmetry and time reversal symmetry of electrons near the Brillouin zone L-point. Electric field and magnetic field are used to manipulate the spin signal by accelerating the spin polarized electrons and generating carrier heating, or by inducing Hanle spin precession.

9167-44, Session 7

Time resolved magneto-optical studies of InAsP ternary alloys *(Invited Paper)*

Brenden A. Magill, Michael A. Meeker, Travis R. Merrit, Giti A. Khodaparast, Virginia Polytechnic Institute and State Univ. (United States); Stephen A. McGill, National High Magnetic Field Lab. (United States); Chris J. Palmstrom, Univ. of California, Santa Barbara (United States)

Recently, g-factor engineering [1] has attracted much attention for potential applications in in the area of spintronics. InAsP ternary alloys can offer a unique feature, where a wide range of g- factors, including g=0 can be achieved. In this work, we employ magneto-PL, time-resolved magneto-PL, in addition to the time and polarization-resolved differential transmission measurements, to probe the band structure as well the carrier and spin relaxation dynamics in several InAsxP1-x alloys with compositions ranging from x=0.4 to 0.75. The samples were grown on Fe-doped semi-insulating InP(001) by chemical beam epitaxy.

To probe the band structure of these materials, we measured their photoluminescence (PL) in the near-infrared range at 4K and 300K and performed magneto-PL measurements from 0-25T between 4-90K. We observed two peaks in the PL which we attribute to free and bound excitons in the material. The wavelength of these peaks is blue shifted with increasing field as we would expect from theory.

We also report on time resolved differential transmission measurements using an ultra-fast laser with the pump and probe pulses tuned to range of wavelengths between 1280nm and 1350nm at 77 and 300K. To probe the spin relaxation as well as the carrier relaxation we can take advantage of interband selection rules to create spin polarized charge carriers with circularly polarized light. The polarization (P) is then given by P=(SCP-OCP)/(SCP+OCP) and we can use the decay of the polarized transmission to find the spin relaxation time.

Our results presented here demonstrate the tunability of the spin and carrier lifetimes in InAsP alloys as a function of alloy concentration, temperature, and external magnetic field.

Properties of CoFeB-MgO magnetic tunnel junctions down to 11 nm *(Keynote Presentation)*

Hideo Ohno, Tohoku Univ. (Japan)

Properties of perpendicular CoFeB-MgO magnetic tunnel junction down to 11 nm in diameter are presented and discussed. The recording layer employed here consists of two CoFeB layers separated by a thin (0.4 nm) Ta layer. Tunnel magnetoresistance does not depend on the junction size while the thermal stability start to decrease at 30 nm. Scaling properties will be discussed.

9167-46, Session 8

Characterization of retention times and critical currents of STT-MRAM cells *(Invited Paper)*

Alexey Khvalkovskiy, Volodymyr Voznyuk, Sebastian Schafer, Dmytro Apalkov, Robert Beach, Vladimir Nikitin, SAMSUNG Electronics Co., Ltd. (United States)

The retention times t_ret and the critical switching current I_c0 of a STT-MRAM cell may be characterized by measuring the switching current I_c as a function of the switching pulse duration tsw for relatively long pulses (microseconds to seconds) and then extrapolating it to short pulses (tens of ns) to get I_c0 and to zero current to get the retention times. For the in-plane MTJs it has been well established, both theoretically and experimentally, that log(t_sw) is a linear function of I_c, which is successfully used to extract t_ret and I_c0 from the switching data for long pulses. For the perpendicular cells, it is also often assumed that this linear relationship is valid ([1] and references therein). However, it was shown recently that solution of the Fokker-Planck equation [2] and numerical simulations [3] predict quadratic relationship between log(t_sw) and I_c for the perpendicular cells. Indeed, we find experimentally, that the relationship between log(t_sw) and I_c is strongly non-linear, yet is not exactly quadratic. We will discuss the impact which the Joule heating and other artifacts have on determination of t_ret and I_c0 from the switching data.

Status and outlook of STT-MRAM development *(Invited Paper)*

Tai Min, IMEC (Belgium)

Spin torque transfer (STT) MRAM has emerged as the most promising candidate for future L2/L3 cache and DRAM replacement due to its non-volatility, fast read and write time, small size, infinite endurance and compatibility with CMOS technology. There still many remaining challenges to be overcome for STT-MRAM to be commercialized as disruptive memory technology, especially at sub-20nm dimension and dense array: lowering the critical switching current while maintaining adequate thermal energy barrier, increasing tunneling magneto-resistance(TMR) and controlling the resistance distribution, developing re-disposition-free and edge-damage-free patterning process and robust MgO barrier for enough separation between switching and the breakdown voltage. In this talk, we will review the recent progress and future outlook of IMEC's STT-MRAM program. We have developed super smooth bottom electrode process: 0.5A roughness via optimization of CMP process and selection of electrode material. Positive effects on MTJ's PMA, TMR and 400oC post annealing stability observed. Reactive-Ion-Etching process with dynamic in-situ encapsulation for 100nm pitch dense array was developed with demonstration of reliable stop-on-MgO capability. MgO and CoFeB edge damage and its detrimental effect on device properties was observed and improved via process optimization. Effect of lithography technologies like 193i versus EUV on MTJ cell area hence resistance variation were investigated: substantial improvement can be achieved if EUV Self-Aligned Double Patterning process is utilized. Test chip with 1.6 Giga-bit 25nm MTJ at 100nm pitch array to investigate the tail bit behavior and etching process robustness at small-size-dense-array was developed and results will be discussed at the conference.

9167-48, Session 9

Progresses on STT-MRAM technology and normally-off system *(Invited Paper)*

Hiroaki Yoda, Toshiba Corp. (Japan)

Progress on STT- MRAM

Field writing MRAMs were developed. But the density has been limited to be below 64 Mbits which was far smaller than that of DRAM. Furthermore, the write speed was not as fast as that of SRAM. As a result, SRAM/DRAM hierarchy has been used for most of the systems. The challenges for MRAMs are density and speed.

STT MRAMs with perpendicular MTJs were proposed and developed to overcome the challenges. Recently, write current smaller thabt 50 micro-amperes with 2-3 nono-second pulse-width was also demonstrated by using perpendicular MTJ.

Progress on Normally-off memory systems

Systems with MRAM/MRAM can get data very fast and store data very fast. Supply electricity can be turned off very often (even between typing). Normally-off systems which uses MRAM proved 70% reduction of power consumption.

9167-49, Session 9

Perpendicular magnetic tunnel junction material optimization for MRAM cells and spin transfer torque field and bias dependence *(Invited Paper)*

Ricardo C. Sousa, Lea Cuchet, Bernard Rodmacq, Stéphane Auffret, Bernard Dieny, Commissariat à l'Énergie Atomique (France)

Magnetic tunnel junctions with perpendicular magnetic anisotropy are particularly attractive to realize devices of reduced lateral dimension due to their large values of perpendicular anisotropy. This work shows the optimization of bottom and top CoFeB electrodes in perpendicular magnetic tunnel junctions to determine the electrode's "dead layer" and critical thicknesses, where the magnetization anisotropy goes from out-of-plane to in-plane orientation. Magnetic properties are then correlated to transport properties on full-sheet samples with the Current In-Plane Tunneling (CIPT) technique. The optimum magnetic and transport properties are obtained for top FeCoB and bottom CoFeB thicknesses of about 1.5 and 1.2 nm, respectively, for which magnetic layers on both side of the MgO barrier are perfectly perpendicular-to-plane in zero external magnetic field. The critical current for spin transfer torque switching was determined from voltage-field state diagrams using pulses below 100ns. The minimum critical current for enabling both AP to P and P to AP switching by STT can be determined using the phase diagram data. Plotting the transition boundaries corresponding to switching from parallel P to antiparallel AP state, and from AP to P, it can be shown that to a first approximation the critical current density reduces linearly with applied field above a critical pulse voltage. These boundaries cross at a field point where the switching between AP(P) and P(AP) states is possible with the same current density, representing the minimum current density. In this device is found to be 2.9MA/cm^2 at a bias field of 33Oe.

9167-50, Session 9

Materials challenges in perpendicular magnetic tunnel junctions for embedded spin-transfer-torque MRAM *(Invited Paper)*

Kangho Lee, Jimmy Kan, Qualcomm Inc. (United States); Matthias Gottwald, Qualcomm Inc. (Belgium); Chando Park, Seung Kang, Qualcomm Inc. (United States)

Embedded spin-transfer-torque MRAM (STT-MRAM) has tremendous potential to innovate mobile industry, enabling cost-effective and power-efficient mobile chips. In this talk, we will discuss material challenges in optimizing perpendicular magnetic tunnel junctions (pMTJs) for scalable STT-MRAM technology and present the latest results from our full-stack pMTJ films that are suitable for early embedded STT-MRAM products in emerging mobile markets

9167-51, Session 9

Characteristics of orthogonal spin transfer magnetic tunnel junction devices *(Invited Paper)*

Mustafa Pinarbasi, Spin Transfer Technologies, Inc. (United States)

Spin transfer torque magnetic random access memory (STT-MRAM) devices are of great interest for non-volatile memory applications. Most of the effort has been concentrated on collinear magnetic structures where the switching process is stochastic with broad switching times. We will report on the recent results for devices based on the orthogonal spin transfer torque (OST) structures. This structure includes an additional polarizer compared to the standard MTJ structures where the magnetization of the polarizer is perpendicular to the freelayer. Having an orthogonal polarizer provides certain advantages such as instantaneous initiation of the magnetization reversal as a result of large initial spin transfer torque. The processing of such devices, the structure, and switching times will be presented.

9167-52, Session 10

Properties of CoFeB/MgO systems with perpendicular anisotropy *(Invited Paper)*

Jean-Paul Adam, Karin Garcia, Adrien Le Goff, Rémy Soucaille, Capucine Burrowes, Nicolas Vernier, Dafiné Ravelosona, Joo-Von Kim, Thibaut Devolder, Univ. Paris-Sud 11 (France); Stéphane Guilet, Lab. de Photonique et de Nanostructures (France); Berthold Ocker, SINGULUS TECHNOLOGIES AG (Germany)

Magnetic tunnel junctions with ultrathin CoFeB free layers in contact with MgO can exhibit both a Perpendicular Magnetic Anisotropy and a reasonably low damping, which makes them suitable for spin torque applications. However material research is needed to optimize this system. We studied the composition dependence of the magnetic properties of CoFeB free layers with perpendicular anisotropy, the dependence of these properties on the degree of intermixing at a given Ta/CoFeB interface and we have included them in full magnetic tunnel junctions to compare wafer-level to device properties.

Using ferromagnetic resonance and magnetic microscopy, we studied the dependence of the anisotropy and the damping upon the FeCo ratio in both amorphous and crystalline states. The damping increases by 0.001 upon crystallization but vary little with composition on the Fe-rich side, with a minimum of 0.011 in amorphous Co40Fe40B20 film. At high cobalt content, the anisotropy lowers while the damping increases [1]. The domain wall velocities evolve consistently [2].

The degree of intermixing at a CoFeB/Ta interface affects the magnetic properties. It is detrimental to all properties except the anisotropy field since the growth of dead layer at the Ta interface reduces the demagnetizing energy while leaving the interface anisotropy unchanged [3].

Finally we have included our free layers in magnetic tunnel junction nanopillars. The free layer is essentially unaffected by the patterning, apart from the expected coercivity increase. In contrast the Reference layers properties evolve substantially, in particular they loose part of their anisotropy and of their interlayer exchange coupling.

Switching time distributions of orthogonal spin transfer devices at nanosecond time scales *(Invited Paper)*

Georg Wolf, Gabriel D. Chaves-O'Flynn, Andrew D. Kent, New York Univ. (United States); Bartek Kardasz, Spin Transfer Technologies, LLC (United States); Steve Watts, Mustafa Pinarbasi, Spin Transfer Technologies, Inc. (United States)

Spin transfer torque operated magnetic memory cells are promising candidates to replace modern random access memory concepts. In particular, orthogonal spin transfer (OST) devices, formed by a collinear magnetized magnetic tunnel junction (MTJ) and an additional polarizing layer magnetized perpendicular to the free layer of the MTJ, offer certain advantages. Specifically, this type of structure leads to a spin current with an effective angle to the free layer magnetization, which provides a large initial spin torque that can initiate a faster magnetization reversal [1,2]. However, switching is always to some degree a stochastic process, due to thermal fluctuations of the magnetization. It is important to directly determine the switching time and its distribution to assess the impact of fluctuations in spin transfer devices, particularly at short time scales.

We investigate the magnetization reversal of OST devices with time-resolved single shot experiments. A fast real time oscilloscope enables the observation of the magnetization reversal on sub-nanosecond time scales. From the measured time profile of the current flowing through a device in response to an applied voltage pulse we can extract the switching time. Acquiring the respective distribution of the switching time as a function of pulse amplitude gives insight into the interplay of spin torque initiated magnetization reversal and thermal fluctuations. We will contrast these results to those of a purely collinear magnetized device. We will also discuss our micromagnetic simulations of respective structures.

9167-54, Session 10

Time-resolved magnetization dynamics in perpendicular STT-MRAM devices *(Invited Paper)*

Luc Thomas, Guenole Jan, Son Le, Yuan-Jen Lee, Huanlong Liu, Jian Zhu, Ru-Ying Tong, Keyu Pi, Yu-Jen Wang, Tom X. Zhong, Terry Torng, Po-Kang Wang, Headway Technologies, Inc. (United States)

In this talk, we will discuss current-driven magnetization dynamics in perpendicularly magnetized (PMA) STT-MRAM devices. We have performed time-resolved resistance measurements to probe the behavior of single Magnetic Tunnel Junction (MTJ) devices in response to voltage pulses of varying amplitudes and lengths. We find that the magnetization of these PMA-MTJ devices can be switched reliably with sub-nanosecond long voltage pulses. However, we also find that magnetization dynamics in response to voltage excitations can be more complex than anticipated. We will discuss the different behaviors that we observe depending on the device diameter and the structure of the MTJ stack.

9167-55, Session 10

High-performance computing based on spin-diode logic *(Invited Paper)*

Joseph S. Friedman, Bruce W. Wessels, Northwestern Univ. (United States); Damien Querlioz, Univ. Paris-Sud 11 (France); Alan V. Sahakian, Northwestern Univ. (United States)

The application of spintronics to computing has been impeded by the difficulty in cascading spintronic logic gates. While binary switching in response to a magnetic field has been demonstrated in a variety of materials and devices, the identification of an efficient mechanism for dynamically creating the required magnetic fields has been a confounding challenge. Here we discuss spin-diode logic, a cascaded spintronic logic family in which the current through the logic devices is used to create the controlling magnetic field for other logic devices. This logic family is based on spin-diodes, magnetoresistive devices exhibiting strong switching in response to an applied magnetic field above its characteristic threshold field.

Spin-diode logic, which can be applied to both positive and negative magnetoresistance devices, uses current as the binary state variable. All spin-diodes are connected to constant voltages, and the current through each spin-diode is modulated by the applied magnetic field. This current is used as the source of a magnetic field across another spin-diode in a cascading mechanism that can be extended to large complex circuits. The computing speed is related to the speed of electromagnetic wave propagation rather than the speed of electron motion, providing exceptionally high performance.

An additional paradigm for efficient spintronic computing is based on Bayesian probability. Early results on the spintronic implementation of this non-deterministic system are promising, leveraging the unique characteristics of newly available spintronic devices for non-Von Neumann computing. These novel circuit structures provide an opportunity for spintronics to replace CMOS in general-purpose computing.

9167-56, Session 11

Magnon Hall effect: A theoretical investigation *(Invited Paper)*

Ingrid Mertig, Martin-Luther Univ. Halle-Wittenberg (Germany) and Max-Planck-Institut für Mikrostrukturphysik (Germany); Alexander Mook, Martin-Luther Univ. Halle-Wittenberg (Germany); Juergen Henk, Max-Planck-Institut für Mikrostrukturphysik (Germany)

Ferromagnetic insulators with Dzyaloshinskii-Moriya interaction show the magnon Hall effect (Y. Onose et al, Science 329 (2010) 297), i.e., a transverse heat current upon application of a temperature gradient. Our theoretical investigation is based on semiclassical transport theory, the Berry curvature and a quantum mechanical Heisenberg model. For two-dimensional kagomé lattices, we establish a close connection of the magnon Hall effect with the topology of the magnon dispersion relation. From the calculated topological phase diagram, we predict a change of sign of the transverse thermal conductivity with temperature. The bulk-boundary correspondence is proven by topologically non-trivial edge magnons. Moreover, we provide a figure of merit for the transverse thermal conductivity and compare our results with experimental data for the pyrochlore syste $Lu_2V_2O_7$.

9167-57, Session 11

Various methods of spin current generation and manipulation *(Invited Paper)*

Sadamichi Maekawa, Japan Atomic Energy Agency (Japan)

The flow of electron spin, the so-called “spin current”, is a key concept in the recent progress in spintronics [1,2]. When the spin current interacts with the magnetic moment in a ferromagnetic metal, the angular momentum and energy conservations give rise to the spin transfer torque and spinmotive force, respectively. When it is injected into a non-magnetic metal attached to ferromagnet, the electric current is induced through the spin-charge conversion mechanism (inverse spin Hall effect). The generation and manipulation of the spin current and a variety of novel phenomena given by the spin current, including the spin Seebeck effect and spinmotive force, are discussed [3-6].

Anomalous spin and charge Seebeck effect in a quantum well with spin orbit interaction *(Invited Paper)*

Catalina Marinescu, Clemson Univ. (United States); Andrei Manolescu, Reykjavik Univ. (Iceland); Jeremy Capps, Clemson Univ. (United States)

In a semiconductor quantum well with linear Rashba and Dresselhaus spin-orbit interactions of equal strengths, the low temperature ground state obtained in the presence of the Coulomb interaction is shown to correspond to a long-range antiferromagnetic spin alignment. This situation is obtained on account of the opposite-spin single-particle state degeneracy at $mb k = 0$ that makes the spin instability possible. A theory of the resulting magnetic phase is formulated within the Hartree-Fock approximation of the Coulomb interaction by means of a canonical transformation to new quasiparticle states of variable spin orientation, separated by an energy gap that depends on the strength of the spin-orbit coupling and electron density . In the itinerant anti-ferromagnetic phase, we employ a Boltzmann transport formalism to show that scattering on magnetic impurities of the newly created quasiparticles leads to an energetic imbalance that favors the apparition of a large charge and spin thermopower estimated to be up to an order

of magnitude larger than in a regular system. The experimental detection of the anomalous Seebeck effect can be seen therefore as a probe of the ground state magnetization.

9167-59, Session 11

Spin-caloritronics in magnetic nanodevices *(Invited Paper)*

Santiago Serrano-Guisan, International Iberian Nanotechnology Lab. (Portugal); Niklas Liebing, Patryk Krysteczko, Xiukun Hu, Physikalisch-Technische Bundesanstalt (Germany); Karsten Rott, Gunter Reiss, Univ. Bielefeld (Germany); Judith Kimling, Tim Böhnert, Kornelius Nielsch, Univ. Hamburg (Germany); Michael Czerner, Christian Heiliger, Justus-Liebig-Univ. Giessen (Germany); Hans-Werner Schumacher, Physikalisch-Technische Bundesanstalt (Germany)

Spin-caloritronics is a new emerging field of spintronics where thermal gradients developed in nanostructured devices can play an active role to control and manipulate spin-based effects like thermally driven spin currents and heat driven magnetization reversal. Such effects are very promising to improve energy efficiency in future devices as well as to develop novel applications for industry and metrology such as magnetic heat valves. However, to date, many concepts have only theoretical basis and need to be studied experimentally. Moreover, the large current densities involved in spin transfer torque effects in magnetic tunnel junction (MTJ) nanodevices imposes a better knowledge of the interplay of heat, charge and spin currents at such conditions.

Here we will present a compilation of the observed spin-caloric properties in MTJ nanodevices like the large Tunneling Magneto-Seebeck ratios and its angular dependence, the Tunneling Magneto-Thermocurrent and the possibility to explore thermal spin transfer torque effects on magnetization dynamics. We will also discuss the uncertainty of input parameters and its large influence on the calculated temperature profile through the nanostructure (and hence on the derived Seebeck coefficients), and we will show some different approaches to minimize it. Moreover, in order to establish a reliable method to derive Seebeck coefficients different experimental techniques for magneto-thermoelectric measurements in MTJ nanodevices (optical heating, electrical heating and ohmic non-linear correction) will be considered.

Finally magneto-thermoelectric figure of merit ZT studies in metallic magnetic multilayer nanostructures will be presented and the possibility to develop magnetic switchable thermoelectric devices will be addressed.

9167-60, Session 12

Anisotropic magneto-thermal transport: theory and experiments *(Invited Paper)*

Jean-Eric Wegrowe, Do Chung Pham, Henri-Jean Drouhin, Ecole Polytechnique (France); Daniel Lacour, Michel Hehn, Univ. Henri Poincaré Nancy (France)

The anisotropic properties of thermal transport in insulating or conducting ferromagnets are derived on the basis of the Onsager reciprocity relations applied to a magnetic system. It is shown that the angular dependence of the temperature gradient takes the same form as that of the anisotropic magnetoresistance, including anomalous and planar Hall contributions [1].

The experimental study [2] shows that the voltage measured between the extremities of the non-magnetic electrode in thermal contact to the Py or YIG ferromagnetic layers follows the predicted angular dependence. Furthermore, the sign and the amplitude of the magneto-voltaic signal measured is in agreement with the thermocouples calculated from the corresponding Seebeck coefficients, for the three different electrodes used in the study (Pt, Cu, Bi).

9167-61, Session 12

Spin-dependent thermoelectric transport in magnetoresistive nanowires *(Invited Paper)*

Kornelius Nielsch, Univ. Hamburg (Germany)

The anisotropic magneto-thermal resistance (AMTR) effect is the thermal analogue of the anisotropic magneto-resistance (AMR) effect observed in ferromagnetic conductors. We have investigated the AMTR effect in Ni nanowires. We present measurements of electrical and thermal transport properties of cylindrical Ni nanowires in the temperature range between 78 K and 380 K. The determined AMTR ratios lie below the AMR ratios, resulting in an anisotropic Lorenz number. To explain this observation, we apply a simple model that considers spin mixing due to electron-magnon scattering. In comparison, we will present measurements of the magneto-thermal resistance (AMTR) on GMR Co/Ni multi-layer multilayers under thermal transport in-plane, where a Field-independent Lorenz number over the entire temperature range is observed.

The magneto-thermopower (Seebeck coefficient) is measured and correlated to the anisotropic magneto-resistance of Co-Ni alloyed nanowires. By a micrometer setup, three magneto-thermoelectric quantities are determined along the nanowire in magnetic fields applied perpendicularly to the nanowire axis: temperature difference, thermovoltage and electrical conductivity. The highest absolute and relative variation of the Seebeck coefficient are determined to be 1.5 μVK-1 at RT for Co0.24Ni0.76 nanowires and 10.9 % at 100 K for Ni nanowires. Power factors of 3.7 mW/mK2 have been achieved, which is competitive with common thermoelectric materials like TiS2 and Bi2Te3.

More recent experiments have been performed on the magneto-Seebeck effect on multilayer CoNi/Cu multilayered nanowire, which exhibited the GMR effect. In detail the Mott relation between the magneto-Seebeck effect and the magneto-resistance have been analyzed.

9167-62, Session 12

Probing fundamental physics and materials properties of spincaloritronic systems with suspended thermal platforms *(Invited Paper)*

Barry L. Zink, Univ. of Denver (United States)

Interest in spincaloritronics, the interaction of heat, charge, and spin currents in ferromagnetic (FM) systems, continues to grow. This is driven by potential applications not only in spin current generation for future spintronic circuits, but possible energy-harvesting devices that could use transport in the spin channel to overcome the coupling of thermal and electrical conductivity that has long confounded the search for more efficient thermoelectric materials. However, potential optimization of these effects and eventual applications of spincaloritronic devices is possible only if the fundamental interactions are understood. Furthermore, the effect of materials and interface structure on the resulting spincaloritronic properties must be determined. Our research focuses on advancing this understanding, with a particular emphasis on accurate control and measurement of thermal gradients on the thin films or nanostructures often of greatest interest. Reliable measurements of thermally-driven effects in such samples with tiny thermal mass often require great care. In this talk Prof. Zink will present recent measurements of Peltier, Seebeck, and Nernst effects in FM thin films, made using unique micromachined thermal isolation platforms. These allow “zero substrate” heating of thin films, which eliminates unintended thermal gradients that can often complicate probes of the fundamental physics and materials properties. We will clarify the role of the anomalous Nernst Effect and transverse thermopowers, such as the planar Nernst effect, in FM metals as well as describing early steps toward “zero substrate” experiments on ferromagnetic insulating films. We will also describe

efforts to better understand the nature of the FM/paramagnet interfaces used to detect or convert spin currents in spincaloritronic devices.

This work was performed in collaboration with D. Wesenberg, and A. Hojem, and supported by the NSF CAREER award (DMR-0847796).

9167-63, Session 13

Chiral spin torque at magnetic domain walls *(Keynote Presentation)*

Stuart S. P. Parkin, IBM Research - Almaden (United States)

Spin-polarized currents provide a powerful means of manipulating the magnetization of nanodevices, and give rise to spin transfer torques that can drive magnetic domain walls along nanowires. In ultrathin magnetic wires, domain walls are found to move in the opposite direction to that expected from bulk spin transfer torques, and also at much higher speeds. We show that this is due to two intertwined phenomena, both derived from spin–orbit interactions. By measuring the influence of magnetic fields on current-driven domain-wall motion in perpendicularly magnetized Co/Ni/Co trilayers, we find an internal effective magnetic field acting on each domain wall, the direction of which alternates between successive domain walls [1]. This chiral effective field arises from a Dzyaloshinskii–Moriya interaction at the Co/Pt interfaces and, in concert with spin Hall currents, drives the domain walls in lock-step along the nanowire. Elucidating the mechanism for the manipulation of domain walls in ultrathin magnetic films will enable the development of new families of spintronic devices such as Racetrack Memory [2].

9167-64, Session 13

Spin-orbit torques in ferromagnetic heterostructures: fundamentals and applications *(Invited Paper)*

Kevin Garello, Can Onur Avci, ETH Zürich (Switzerland); Mihai Miron, Olivier Boulle, SPINTEC (France); Frank Freimuth, Forschungszentrum Jülich GmbH (Germany); Yuriy Mokrousov, Stefan Blügel, Max-Planck-Institut für Festkörperforschung (Germany) and Forschungszentrum Jülich GmbH (Germany); Gilles Gaudin, SPINTEC (France); Pietro Gambardella, ETH Zürich (Switzerland)

Current-induced spin torques are of great interest to manipulate the orientation of nanomagnets without applying external magnetic fields. Recent demonstrations of perpendicular magnetization switching induced by in-plane current injection in ferromagnetic heterostructures have drawn attention to a class of spin torques based on orbital-to-spin momentum transfer (SOTs), which is alternative to pure spin transfer torque (STT) between noncollinear magnetic layers and amenable to more diversified device functions.

In this talk, we will report on the quantitative vector measurement of SOTs in Pt/Co/AlOx and Ta/CoFeB/MgO trilayers using harmonic analysis of the Hall Voltage as a function of the applied current and magnetization direction. We find that both the field-like and antidamping-like spin-orbit torques are composed of constant and magnetization-dependent contributions revealing a scenario that goes beyond simple models of the spin Hall and Rashba contributions to SOTs. Further, we show that these parameters vary strongly with annealing. Such variations correlate with changes of the saturation magnetization and magnetic anisotropy and are assigned to chemical and structural modifications of the layers.

After describing the main spin-orbit interactions observed in ferromagnetic heterostructures, we will present their straightforward impact on magnetic memory technologies and recent advances to build the first SOT-based perpendicular MRAM device.

9167-65, Session 13

Spin orbit torques and chiral magnetic texture in magnetic heterostructures *(Invited Paper)*

Masamitsu Hayashi, National Institute for Materials Science (Japan)

Spin orbit torques in ultrathin magnetic heterostructures are attracting great interest since it enables magnetization manipulation which is not possible with conventional spin torque devices. We have studied the size and sign of spin orbit torques in ultrathin magnetic heterostructures to reveal the underlying physics of the generation of such torques. Special focus is paid on the torque driven by the spin Hall spin current. Current induced domain nucleation and domain wall motion in related structures will be discussed in connection with the chiral magnetic texture developed in magnetic heterostructures.

Spin orbit torque in these systems can be represented by the “effective magnetic field”, which illustrates the strength and direction of the force exerted on the magnetic moments from the generated spin currents via the spin orbit effects (e.g. the spin Hall effect). We find that the effective field is sensitive to the layer thickness and the material of the heterostructure. The effective field has damping-like and field-like components, similar to those in magnetic tunnel junctions, and the relative size between the two varies with the layer thickness. The size of each component affects the efficiency of magnetization switching and current induced domain wall motion.

For domain wall motion, we find that Neel walls emerge owing to the chiral magnetic exchange interaction that develops at interfaces. The size and sign of such anisotropic exchange interaction, i.e. the Dzyaloshinskii-Moriya interaction, shows significant dependence on the material adjacent to the magnetic layer.

New Heusler compounds for spin transfer torque *(Invited Paper)*

Claudia Felser, Daniel Ebke, Max-Planck-Institut für Chemische Physik Fester Stoffe (Germany); Gerhard H. Fecher, Max-Planck-Institut für Chemische Physik Fester Stoffe (Germany) and Johannes Gutenberg Univ. (Germany); Siham Ouardi, Ajaya K. Nayak, Max-Planck-Institut für Chemische Physik Fester Stoffe (Germany)

Heusler compounds are a remarkable class of materials with more than 1,000 members and a wide range of extraordinary multifunctionalities including half-metallic high-temperature ferri- and ferromagnets, multiferroic shape memory alloys, and tunable topological insulators with a high potential for spintronics, energy technologies and magnetocaloric applications. Recent development of efficient spintronic devices is based on the spin transfer torque (STT) phenomenon. In 2007 Mn3-xGa was identified as a potential electrode for STT applications [1,2]. In general tetragonal Heusler compounds Mn2YZ as potential materials for STT and spincaloric applications can be easily designed by positioning the Fermi energy at the van Hove singularity in one of the spin channels. The Mn3+ ions in Mn2YZ cause a Jahn Teller distortion [3]. High calculated magnetic anisotropy energy (MAE) is the sufficient condition for a material with perpendicular magneto-crystalline anisotropy (PMA). Materials with saturation magnetizations (MS) of 0.2 – 4.0 μB, high Curie temperatures (TC) of 380 – 800 K, high spin polarizations, PMA, and required lattice constant matching with MgO can be realized with ferri- or ferromagnetic Heusler-related compounds. Additional properties can be designed in tetragonal Heusler compounds with three magnetic sublattices. Mn2PtGa is a tetragonal Heusler compound with a large exchange bias behavior [4] and Mn2CoAl a spingapless semiconductor [5]. A novel non-collinear tetragonal Mn2RhSn Heusler material undergoes a spin-reorientation transition, induced by a temperature change and suppressed by the external magnetic field. Because of the non-centrosymmetric structure, Dzyaloshinskii-Moriya exchange and magnetic anisotropy, Mn2RhSn is supposed to be a promising candidate for realizing the skyrmion state [6].

A simple and highly efficient in-line magnetic domain wall injector *(Invited Paper)*

Timothy Phung, Aakash Pushp, Luc Thomas, Charles T. Rettner, See-Hun Yang, Kwang-Su Ryu, John Baglin, Brian Hughes, Stuart S. P. Parkin, IBM Research - Almaden (United States)

The manipulation of domain walls in magnetic nanowires forms the basis of several promising memory and logic nano-devices. Key to the operation of these devices is the controlled injection of domain walls in nanowires at low power. It is known that the magnetic anisotropy of perpendicularly magnetized nanowires can be tailored to create in-plane magnetized regions, thereby leading to the formation of 90° magnetic boundaries. Here we show that by passing a sequence of uni-polar, nanosecond long current pulses across these boundaries, a series of domain walls can be injected into the nanowires. The creation of these domain walls involves utilizing the spin transfer torque obtained from the currents flowing across the 90° magnetic boundary. Remarkably, we find that the currents needed for this domain wall injection process are at least one hundred times smaller than conventional methods that use local magnetic fields from current injection lines fabricated orthogonal to the nanowires. Moreover, we show that the footprint of in-line injection geometry is significantly smaller than that of conventional injection. We shall lastly unravel the physics behind this novel injection scheme.

Theory of spin injection from a half-metal at finite temperatures *(Invited Paper)*

Kirill D. Belashchenko, James K. Glasbrenner, Univ. of Nebraska-Lincoln (United States); Aleksander L. Wysocki, Univ. of Nebraska-Lincoln (United States)

Spin injection from a half-metallic electrode in the presence of thermal spin disorder is analyzed using a combination of random matrix theory, spin-diffusion theory, and explicit simulations for the tight-binding s-d model. It is shown that efficient spin injection from a half-metal is possible as long as the effective resistance of the normal metal does not exceed a characteristic value, which does not depend on the resistance of the half-metallic electrode, but is rather controlled by spin-flip scattering at the interface. This condition can be formulated as $alphalesssim l/l^N_{sf}T_c^{-1}$, where $alpha$ is the relative deviation of the magnetization from saturation, l and l^N_{sf} the mean-free path and the spin-diffusion length in the non-magnetic channel, and T_c the transparency of the tunnel barrier at the interface (if present). The general conclusions are confirmed by tight-binding s-d model calculations. A rough estimate suggests that efficient spin injection from true half-metallic ferromagnets into silicon or copper may be possible at room temperature across a transparent interface.

Eindhoven (Netherlands); Stefan Eisebitt, Technische Univ. Berlin (Germany) and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Mathias Kläui, Johannes Gutenberg Univ. Mainz (Germany)

A wide range of future spintronic memory and logic devices require the ability to carefully control the motion of magnetic domain walls (DWs) [1]. Conventional DW manipulation approaches via in-plane magnetic fields are not suitable for the required synchronous propagation of multiple in-plane magnetized DWs in a single wire, since adjacent walls have opposite spin-orientations and hence move in opposing directions, which leads to a loss of data when the DWs annihilate. An alternative is the use of current driven DW motion, which does facilitate synchronous DW motion, yet requires prohibitively large current densities. Here we demonstrate a radically different DW propagation scheme using out-of-plane field pulses which combines the efficiency of field-induced motion with the ability to move multiple walls synchronously. This is achieved for in-plane magnetized transverse DWs of the same chirality through the application of asymmetric field pulses to a wire which incorporates regularly spaced pinning sites. An analytical model is developed to describe the system which reveals that the force on the DW is independent of the wall orientation but crucially depends on the time derivative of the applied magnetic field. It is therefore possible to tailor the force on the DW by choosing the pulse rise and fall times and by applying asymmetric field pulses achieve net DW motion. This scheme is then analyzed in a realistic geometry via micromagnetic modelling. Finally, the concept is experimentally demonstrated using scanning transmission x-ray microscopy.

Mainz (Germany) and Univ. Konstanz (Germany)

Magnetic logic and, in particular, sensing devices based on the motion of magnetic domain walls rely on the precise and deterministic control of the position and the velocity of individual magnetic domain walls along curved nanowires. However, varying domain wall velocities have been predicted to result from intrinsic effects, such as periodic domain wall spin structure transformations above the Walker breakdown and extrinsic effects, such as pinning due to imperfections and defects in the nanowire. We use Scanning Transmission X-ray Microscopy (STXM) to directly and dynamically image the nanoscale domain wall spin structure, which allows us to directly check these predictions. We present first direct experimental visualization of the precessional motion of vortex domain walls even below the Walker breakdown in nanometer sized ferromagnetic rings controlled by rotating magnetic fields. The periodic oscillations of the vortex domain wall velocity are consequences of the interplay between the rotating driving field and the periodically changing domain wall spin structure. In addition, we show that the extrinsic pinning from imperfections in the nanowire only affects slow domain walls and we identify the magnetostatic energy, which scales with the domain wall velocity, as the energy reservoir for the domain wall to overcome the local pinning potentials. Our pump and probe experiment demonstrates precise control of the domain wall position at high domain wall velocities, enabling reliable and reproducible high-speed domain wall manipulation in magnetic logic and sensing devices.

9167-71, Session 14

Kondo physics in nanoscopic metallic non-local spin transport devices *(Invited Paper)*

L. O'Brien, Univ. of Minnesota (United States) and Univ. of Cambridge (United Kingdom); M. J. Erickson, D. Spivak, Univ. of Minnesota (United States); Haile Ambaye, Rick Goyette, Valeria Lauter, Oak Ridge National Lab. (United States); Paul A Crowell, Univ. of Minnesota, Twin Cities (United States); Chris Leighton, Univ. of Minnesota (United States)

Despite the maturity of metallic spintronics there remain large gaps in our understanding of spin transport in metals, particularly with injection of spins across ferromagnetic/non-magnetic (FM/NM) interfaces, and their subsequent diffusion and relaxation. Unresolved issues include the limits of applicability of the Elliott-Yafet spin relaxation mechanism, the influence of defects, surfaces, and interfaces on spin relaxation at nanoscopic dimensions, and the importance of magnetic and spin-orbit scattering. The non-local spin-valve is an enabling device in the study of such problems as, in addition to offering potentially disruptive applications, it allows for the separation of charge and spin currents. One particularly perplexing issue in metallic non-local spin valve devices is the often observed non-monotonicity in the temperature-dependent spin accumulation, where the spin signal actually decreases at low temperatures, in contrast to expectations. In this work, by studying an expanded range of FM/NM combinations (encompassing Ni80Fe20, Ni, Fe, Co, Cu, and Al), we demonstrate that this effect is not a property of a given FM or NM, but rather of the FM/NM pair. The non-monotonicity is in fact strongly correlated with the ability of the FM to form a dilute local magnetic moment in the NM. We show that local moments, formed by FM/NM interdiffusion, suppress the injected spin polarization and diffusion length via a novel manifestation of the Kondo effect, thus explaining all observations associated with the low temperature downturn in spin accumulation. We further show: (a) that this effect can be promoted by thermal annealing, at which point the conventional charge transport Kondo effect can be simultaneously detected in the NM, and (b) that this suppression in spin accumulation can be quenched, even at interfaces that are highly susceptible to the effect, by insertion of a thin non-moment-supporting interlayer. Important implications, potentially even for room temperature devices, will be discussed.

Magnetic field effects and nodal ground states in InP nanowires

Tiago de Campos, Univ. de São Paulo (Brazil); Paulo Eduardo de Faria Jr., Univ. de São Paulo (Brazil) and Univ. at Buffalo (United States); Guilherme M. Sipahi, Univ. de São Paulo (Brazil); Igor Zutic, Univ. at Buffalo (United States)

Semiconductor nanowires have attracted great interest in the last decade because of their unique optical, electronic, and spin-dependent properties. They also are among the leading candidates to observe exotic states, such at the Majorana Fermions [1]. In a seemingly trivial situation of a single particle confined in a quantum dot, it was predicted that the valence band ground state with a node is possible and was attributed to the formation of orbital textures [2]. This peculiar behavior, may also be present in wurtzite InP nanowires with diameter less then 10 nm [3]. We have systematically explored the possibility for observing such nodal ground state in various nanowires. The presence of this state modifies the basic optical properties of the nanowire, such as the degree of linear polarization. Here we study the change in these states when an external magnetic field is applied along the nanowire axis. We compare the degrees of spin polarization in wurtzite [0001] and zincblende [111] InP nanowires calculated within a k.p method formulation that describes both crystal phases in a single Hamiltonian [4] and accounts for the applied magnetic field.

Probing Majorana-like states in quantum dots and quantum rings

Benedikt Scharf, The State Univ. of New York (United States); Baris Pekerten, Inanc Adagideli, Sabanci Univ. (Turkey); Igor Zutic, Univ. at Buffalo (United States)

Engineering chiral p-wave superconductivity in semiconductor structures offers fascinating ways to obtain and study Majorana modes in a condensed matter context. For example, p-wave superconductivity can be induced in semiconductors with strong Rashba spin-orbit coupling by placing them next to s-wave superconductors and exploiting proximity effects. Here, we theoretically investigate chiral p-wave superconductivity in quantum dots and quantum rings. Using both analytical as well as finite-difference methods we calculate the quasi-particle excitation spectra in these structures and the corresponding excitation amplitudes and charge densities. In the topological regime we can observe the chiral edge modes localized at the boundaries and possessing finite energy in quantum dots and quantum rings. By applying a magnetic field which is expelled from the quantum ring, but which creates a flux that is an odd integer multiple of $\phi\_0/2 = \pi h/e$ Majorana modes, that is, (approximately) degenerate edge modes with zero energy and zero charge density,

become possible in the topological regime. Furthermore, we investigate finite-size effects that split these degenerate edge modes as well as the effect of a magnetic field penetrating into the superconducting region that can under certain circumstances still support edge modes with approximately zero energy and charge.

Spin polarization of Co(0001)/graphene junctions from first principles

Guilherme M. Sipahi, Univ. at Buffalo (United States) and Univ. de São Paulo (Brazil); Igor Zutic, Univ. at Buffalo (United States); Nicolae Atodiresei, Forschungszentrum Jülich GmbH (Germany); Roland K. Kawakami, The Ohio State Univ. (United States); Predrag Lazic, Institut Ruder Boškovic (Croatia)

Junctions comprised of ferromagnets and nonmagnetic materials are one of the key building blocks in spintronics [1]. With the recent breakthroughs of spin injection in ferromagnet/graphene junctions it is possible to consider spin-based applications that are not limited to magnetoresistive effects [2,3]. However, for critical studies of such structures it is crucial to establish accurate predictive methods that would yield atomically resolved information on interfacial properties. By focusing on Co(0001)/graphene junctions and their electronic structure, we illustrate the inequivalence of different spin polarizations [4]. We show atomically resolved spin polarization maps [4] as a useful approach to assess the relevance of Co(0001)/graphene for different spintronics applications.

New directions for engineering quantum spin states: ultracold atomic gases with optically induced synthetic spin-orbit coupling *(Invited Paper)*

Vito Scarola, Virginia Polytechnic Institute and State Univ. (United States)

Materials with strong spin-orbit coupling offer the potential to explore fundamentally new physics in the context of spintronics, the spin Hall effect, and topological insulators. The viability of these new states of matter in solids is typically difficult to asses because strong disorder and defects complicate identification of delicate quantum states. But recent developments in atomic, molecular, and optical physics have demonstrated the ability to engineer pristine environments to mimic spin orbit coupling found in solids. In this talk I will review experimental and theoretical work on ultracold atomic gases as new routes to exotic forms of strongly correlated quantum degenerate matter. I will discuss, in particular, recent experiments using Raman laser coupling to implement synthetic spin-orbit coupling in ultracold atomic gases. By coupling atomic spin states to momentum using lasers, atoms in gases experience artificial Rashba and Dresselhaus spin-orbit couplings. I will discuss models of extreme limits that explore the interplay of strong interactions and strong spin-orbit coupling. Modeling in our group shows that ultracold atoms can be taken into fascinating new regimes that display exotic new spin states, including helical vortex states and spinor Wigner crystals with fractionally charged excitations. Prospects for engineering spiral spin states using synthetic Dzyaloshinskii-Moriya interactions will also be discussed.

Spin control and manipulation in (111) GaAs quantum wells *(Invited Paper)*

Paulo V. Santos, Alberto Hernández-Mínguez, Klaus Biermann, Rudolf Hey, Paul-Drude-Institut für Festkörperelektronik (Germany)

The control of spin dephasing is an essential requirement for quantum information processing using electron spins. Among the different spin scattering processes in III-V semiconductor nanostructures, spin dephasing via the spin-orbit (SO) interaction is a major mechanism limiting the lifetime as well as the transport and manipulation of electron spins. The special symmetry of quantum wells (QWs) grown along the non-conventional crystallographic directions [111] and [110] offer interesting possibilities for the control of SO interaction. In this contribution, we review the spin dynamics in these structures as well as concepts for spin storage, transport and manipulation, which combine the long spin lifetime with the control of the electron orbital motion on a micrometer scale. In particular, by enclosing the electron spins in moving potential dots produced by acoustic waves, it becomes possible to transport spins over several tens of micrometer along the plane of a QW. (110) QWs exhibit long spin lifetimes for spins oriented perpendicular to the QW plane, which persist up to temperatures exceeding 100K. These spins can be transported over tens of micrometer by moving potentials produced by acoustic waves. In (111) QWs, the lifetime of spins with arbitrary orientation can be enhanced to values exceeding 100 ns at low temperature by using a transverse electric field to compensate different contribution to the SO interaction. The compensation mechanism is limited at high temperatures (>50 K) by non-linear terms in electron momentum of the SO interaction. Approaches to overcome this limitation as well as to transport and manipulate spins in these structures will be discussed.

9167-74, Session 15a

Spin-orbit induced currents and g-factors in semiconductor quantum dots *(Invited Paper)*

Andrei Silov, Joost van Bree, Paul M. Koenraad, Technische Univ. Eindhoven (Netherlands); Michael E. Flatté, The Univ. of Iowa (United States)

Spin-correlated orbital currents dramatically modify the magnetic moment of an electron spin in many semiconductors, often enhancing the moment by an order of magnitude over its free-electron value. This modified magnetic moment also controls the spin dynamics in nanostructures, and is usually parameterized in the literature as a shape, size and composition dependent g tensor. Despite the central nature of g tensors to high-speed spin manipulation and spin lifetimes, the spatial structure of the spin-correlated orbital currents that determine these g tensors has not been investigated. We describe the spatial distribution of spin-correlated orbital currents for the lowest-energy electron spin states of a quantum dot at zero magnetic field within an analytically-solvable envelope-function formalism, and show that itinerant currents are extended throughout the quantum dot, peaking about midway out from the center of the dot. The resulting magnetic moment is primarily due to these itinerant currents originating from coherent superpositions of conduction and valence envelope functions, rather than from magnetic moments associated with the Wannier functions of each unit cell. We demonstrate that the correct form of the magnetic moment's value differs greatly from the probability density of the spin. For example, the spin of a quantum dot with g=0 will still evince a local magnetic moment that could interact with localized magnetic systems such as ferromagnets or nuclear moments through the hyperfine interaction.

9167-75, Session 15a

Spin injection and spin-orbit coupling in low-dimensional semiconductor nanostructures *(Invited Paper)*

Sebastian Heedt, Isabel Wehrmann, Thomas Gerster, Forschungszentrum Jülich GmbH (Germany); Paul Wenk, Univ. Regensburg (Germany); Stefan Kettemann, Jacobs Univ. Bremen (Germany); Kamil Sladek, Hilde Hardtdegen, Jürgen Schubert, Andreas Bringer, Natalia Demarina, Detlev Grützmacher, Thomas Schäpers, Forschungszentrum Jülich GmbH (Germany)

Narrow-gap semiconductors with strong spin-orbit coupling represent a natural system for spintronic devices, since they provide the ability for electrical spin-manipulation. Quasi one-dimensional nanostructures made from these materials exhibit a strongly suppressed angular dispersion of the electron momenta, which results in an enhancement of spin coherence. Hence, electrical spin injection and signatures of spin-orbit coupling in electrical transport are studied in epitaxially grown semiconductor nanowires. The creation of nonlocal spin-currents in InN nanowires is demonstrated using ferromagnetic metal injectors and tunnel barriers in order to tailor the interface resistance. Furthermore, weak antilocalization quantum corrections to the conductivity are studied for a large variety of differently doped InAs nanowires, establishing comprehensive control of spin-orbit coupling. On the one hand, spin-orbit coupling can be essentially switched on and off via choosing the desired doping conditions during nanowire growth. On the other hand it is shown to be tunable on-chip via electric gating using high-k dielectrics and top gate electrodes. The Rashba effect related to the charge accumulation layer at the nanowire surface as well as the externally applied electric fields together with the Dresselhaus effect are responsible for the lifting of spin degeneracy. By carefully modeling spin transport in these nanowires, the mechanisms responsible for spin relaxation are understood. Beyond that, confinement is further increased by the formation of quantum dots along the axial direction of the nanowires via top and bottom gates. Thus, the few-electron regime can be accessed and the spin coherence properties are extracted by excited states spin spectroscopy.

9167-76, Session 15a

Spin orbit interaction in semiconductor heterostructures *(Invited Paper)*

Makoto Kohda, Tohoku Univ. (Japan)

The spin-orbit interaction (SOI) induces an effective magnetic field (Beff) for an electron, enabling us to control spin states solely by electrical means. However, the SOI inevitably induces the spin relaxation, disrupting a long spin transport. Such a crucial problem is overcome by employing two different types of SOIs; Rashba and Dresselhaus SOIs. The spin relaxation is completely suppressed when both SOIs are in an equal strength, known as persistent spin helix (PSH) state. As a result, precise control and detection of Beff pave the way for future spintronics and quantum information technology. Here, we experimentally demonstrated fitting-free determination of Beff direction in transport measurement under the coexistence of Rashba and Dresselhaus SOIs. In narrow wires, application of in-plane magnetic field (Bin) modulates the amplitude of magneto-conductance, i.e. weak localization, through the additional spin relaxation induced. Since the anisotropic weak localization depends on the relative angle between Bin and Beff, it enables us to evaluate Beff direction with being independent of model fittings. By applying the proposed method to InGaAs based wire structures, we demonstrated the PSH state as the evidence of Rashba / Dresselhaus SOI ratio to be 1.07 ± 0.04 by controlling the top gate.

9167-77, Session 15b

All optical control of magnetic thin films and nanostructures *(Invited Paper)*

Eric E. Fullerton, Univ. of California, San Diego (United States)

The interplay of light and magnetism has been a topic of interest since the original observations of Faraday and Kerr where magnetic materials affect the light polarization. While these effects have historically been exploited to use light as a probe of magnetic materials there is increasing research on using polarized light to alter or manipulate magnetism. For instance deterministic magnetic switching without any applied magnetic fields using laser pulses of the circular polarized light has been observed for specific ferrimagnetic materials. Here we demonstrate optical control of ferromagnetic materials ranging from magnetic thin films to multilayers and even granular films being explored for ultra-high-density magnetic recording. Our finding shows that optical control of magnetic materials is a much more general phenomenon than previously assumed. These results challenge the current theoretical understanding and will potentially have a major impact on data memory and storage industries via the integration of optical control of ferromagnetic bits.

9167-78, Session 15b

Voltage controlled barriers in tunneling anisotropic magnetoresistance devices *(Invited Paper)*

Georg Schmidt, Martin-Luther-Univ. Halle-Wittenberg (Germany)

We demonstrate that in an organic spin valve with a $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) electrode and a non-magnetic counter electrode voltage pulses can change the resistance by almost two orders of magnitude. Additionally tunneling anisotropic magnetoresistance (TAMR) up to 17% can be observed. Our experiments show that the width and height of the injection barrier between the LSMO and the organic semiconductor are changed by applied voltage pulses. Our observations can be explained by the creation of oxygen vacancies in the LSMO whose spatial distribution can be modified by electric fields. Large reverse voltages can reset the device to its original state.

9167-79, Session 15b

Electric-field modulation of spin-wave phase in yttrium iron garnet film *(Invited Paper)*

Tianyu Liu, The Univ. of Iowa (United States); Xufeng Zhang, Hong Tang, Yale Univ. (United States); Michael E. Flatté, The Univ. of Iowa (United States)

An electric field has been predicted to manipulate the phase of spin waves in yttrium iron garnet (YIG) through the spin-orbit interaction, which couples the electric field with the gradient of the magnetization [1?2]. We have observed an electric-field-dependent phase shift in the propagation of surface spin waves in a YIG waveguide. In addition to the spin-orbit effect there is a first-order magnetoelectric effect on the phase shift caused by the change of the magnetization of the YIG due to the applied electric field. The contributions of the two effects can be distinguished by varying the direction of the electric field relative to the YIG magnetization. This work was supported by DARPA MESO.

9167-80, Session 15b

Recent progress in III-V based ferromagnetic semiconductors: N-type (In,Fe)As and its heterostructures *(Invited Paper)*

Masaaki Tanaka, Pham Nam Hai, Le Duc Anh, The Univ. of Tokyo (Japan)

Carrier-induced ferromagnetic semiconductors (FMSs) generate much attention from the viewpoint of both fundamental physics and potential device applications. Since FMSs are compatible with existing semiconductor heterostructures, we can apply the band-structure engineering to control the properties of FMSs. The most well-studied FMSs are Mn-doped III-V semiconductors. However, the Mn-based FMSs have unsolved problems: (1) They are all p-type, but there is no reliable n-type Mn-based FMS. (2) There is a controversy on the origin of ferromagnetism (whether it is mediated by holes in an extended valence band or in an impurity band). (3) The Curie temperature (TC) is still much lower than room temperature. (4) The coherency of holes are very weak, making their applications to quantum devices difficult.

Here, we show that by introducing iron (Fe) and donors into InAs, it is possible to fabricate a new FMS that can avoid the major problems in the conventional Mn-based FMSs. We demonstrate that (In,Fe)As doped with electrons is an n-type electron-induced FMS, a missing piece of semiconductor spintronics for decades[1,2]. Furthermore, we demonstrate new phenomena in (In,Fe)As and its hetrerostructures: Novel crystalline anisotropic magnetoresistance with two fold and eight fold symmetry[3], and control of ferromagnetism by strain, quantum confinement, and wavefunction engineering in quantum heterostructures with a (In,Fe)As quantum well[4].

Spin pumping and inverse spin Hall effect in Platinum and other 5d metals: the essential role of spin-current discontinuities at interfaces *(Invited Paper)*

Juan-Carlos Rojas-Sánchez, III-V Lab. (France); Nicolas Reyren, Piotr Laczkowski, III-V Lab. (France) and Ctr. National de la Recherche Scientifique (France); Williams Savero, Univ. Joseph Fourier (France) and CEA-INAC (France); Jean-Philipe Attané, Commissariat à l'Énergie Atomique (France); Cyrile Deranlot, Unité Mixte de Physique CNRS/Thales (France); Serge Gambarelli, INAC/SP2M, CEA-Université Joseph Fourier (France); Matthieu Jamet, Commissariat à l'Énergie Atomique (France); Jean-Marie George, Unité Mixte de Physique CNRS/ Thales (France); Laurent Vila, Commissariat à l'Énergie Atomique (France); Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France) and Forschungszentrum Jülich GmbH (Germany)

It was recently realized that the spin Hall effect (SHE) can be very useful in the area of spintronics, due to its ability to generate pure spin current from charge current, without the use of any magnetic materials or magnetic field. The maximum conversion factor is given by the spin Hall angle θSHE, which can take rather important values (up to 30% was reported for W). This phenomenon is usually observed in materials with large spin-orbit coupling, either intrinsic (Pt, β-Ta, W, etc.) or induced by heavy impurities (Cu doped with Bi or Ir). To investigate this property, several groups studied the reciprocal effect, the so-called inverse spin Hall effect (ISHE), converting a pure "pumped" spin current into a charge current (measured by voltage detection in an "open circuit").

We focus here on the 5d Pt material. Values published nowadays for θSHE in Pt are scattered over one order of magnitude, with a clear correlation between the spin diffusion length λsf and the θSHE, both quantities being related to the spin-orbit strength or its inverse. We performed measurements of spin pumping in a cavity and measured the resulting ISHE voltage. We propose a model including spin memory loss at the interfaces that may reconcile all the different observations. In particular, we demonstrate consistent values of spin diffusion length (3.4 ± 0.4 nm) and spin Hall angle (0.05 ± 0.01) for Pt in different metallic multilayer systems.

9167-82, Session 16a

Spin-current transfer between YIG and Pt: effects on the dynamical properties *(Invited Paper)*

Olivier Klein, Commissariat à l'Énergie Atomique (France)

Yttrium iron garnet ($Y_3Fe_5O_{12}$), commonly referred as YIG, is the champion material for magneto-optical applications as it holds the highest figure of merit in terms of low propagation loss. This is why YIG is widely used in high-end microwave and optical-communication devices such as filters, tunable oscillators, or non-reciprocal devices. It is also the material of choice for magnonics, an emerging field, which aims at using spin-waves (SW) (or their quanta magnons) to carry and process information and whose development is presently limited by the damping constant of SW. This field has recently received a renewed interest because of the prospect that spin-current transfer from an adjacent layer can partially or even fully compensate the intrinsic losses of the traveling SW beyond the natural decay time. Recently, an attempt of damping compensation by pure current in the YIG|Pt system was reported by Kajiwara et al. [1]. In this talk, we will report on our progress to control electrically the dynamical properties of YIG|Pt. In this respect it is crucial to work with the highest quality nanometer-thick films of epitaxial YIG. It is crucial as it allows an enhancement of the effect of the interface spin-current transfer, which scales as the inverse YIG thickness. It is crucial as it permits nano-patterning of the YIG and thus the engineering of the spin-wave (SW) spectra through spatial confinement or through the formation of a spatially inhomogeneous magnetic ground state.

Phase-sensitive detection of spin pumping via the ac inverse spin Hall effect *(Invited Paper)*

Mathias Weiler, National Institute of Standards and Technology (United States)

An intriguing feature of spintronics is the use of pure spin-currents to manipulate magnetization, e.g., spin-currents can switch magnetization in spin-torque MRAM, a next-generation DRAM alternative. Giant spin-currents via the spin Hall effect greatly expand the technological opportunities. Conversely, a ferromagnet/normal metal junction emits spin-currents under microwave excitation, i.e. spin-pumping. While such spin-currents are modulated at the excitation frequency, there is also a non-linear, rectified component that is commonly detected using the corresponding inverse spin Hall effect (iSHE) dc voltage. However, the ac component should be more conducive for quantitative analysis, as it is up to two orders of magnitude larger and linear. But any device that uses the ac iSHE is also sensitive to inductive signals via Faraday's Law and discrimination of the ac iSHE signal must rely on phase-sensitive measurements. In this talk, I will demonstrate that the inductive signal is actually beneficial for the quantitative analysis of the ac iSHE as it can be exploited as a reference for the magnitude and phase of the spintronic signal. Our experimental results [1] show a large ac iSHE magnitude in agreement with recent theoretical predictions. Furthermore, the phase of the ac iSHE signal for Pt is retarded by 110 degrees relative to what is expected from existent theory.

Attempting nanolocalization of all-optical switching through nano-holes in an Al-mask *(Invited Paper)*

Matteo Savoini, Radboud Univ. Nijmegen (Netherlands); Alexander H Reid, Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory (United States); Tianhan Wang, Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory (United States) and Department of Materials Science and Engineering, Stanford University (United States); Catherine E Graves, Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory (United States) and Department of Applied Physics, Stanford University (United States); Matthias C Hoffmann, Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory (United States) and Linac Coherent Light Source, SLAC National Accelerator Laboratory (United States); TianMin Liu, Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory (United States) and Department of Physics, Stanford University (United States); Arata Tsukamoto, College of Science and Technology, Nihon University (Japan); Joachim Stöhr, Linac Coherent Light Source, SLAC National Accelerator Laboratory (United States); Hermann Dürr, Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory (United States); Andrei Kirilyuk, Alexey V Kimel, Theo Rasing, Radboud Univ. Nijmegen (Netherlands)

The interaction of sub-picosecond laser pulses with magnetically ordered materials has developed into a fascinating research topic in modern magnetism. From the discovery of sub-picosecond demagnetization over a decade ago to the recent demonstration of magnetization reversal by a single 40 fs laser pulse, the manipulation of magnetic order by ultrashort pulses has become a fundamentally challenging topic with a potentially high impact for future spintronics, data storage and manipulation. A fundamental issue to be addressed is the spatial resolution. It is of key relevance both scientifically and technologically to be able to control the magnetization at the sub-micron level.

Here we present our results on the magnetization control at the sub-micron level using different approaches. We can for example show that strongly focusing the illuminating pulsed beam can lead to the totally unexpected formation of structures with distinct topological properties.

Moreover a further reduction of the optically controlled area dimension may be attempted through different methods, namely the patterning of the sample to limit the sample area and/or the use of plasmonic nano-antennas to further confine the laser excitation. Both approaches are beneficial in the all-optical control of the magnetization and new results will be presented. In particular, it is possible to obtain an energy effective and sub-diffraction switching in patterned area by playing with the shape and the illumination conditions; as a result, all-optical switching as small as 40 nm in size has been achieved thanks to the field confining effects of resonant dipolar antennas.

9167-85, Session 16b

Ultrafast spin dynamics in metallic layers and strongly correlated oxides *(Invited Paper)*

Ettore Carpene, Fabio Boschini, Hamoon Hedayat, Claudia Dallera, Ezio Puppin, Politecnico di Milano (Italy)

The spin dynamics triggered by an ultrashort optical excitation can lead to a variety of behaviors depending on the specific spin and electronic structure of the material. In simple metallic and ferromagnetic layers, electron-quasiparticles (phonons and magnons) interactions takes place on the sub-picosecond timescale and demagnetization is established within 100 fs. In half-metals, such as manganites and other correlated oxides, spin dynamics is much slower (100 ps) due to the inhibition of spin-flip processes. The investigation of spin dynamics in these classes of materials help shed light on the specific mechanism of optically-induced demagnetization, that is still controversial. Furthermore, ultrashort light pulses can strongly modify the magnetic anisotropies in ferromagnets. This phenomenon can be exploited as an effective route to control the spin order. Optically-induced reversible switching of the magnetization under simple experimental conditions has been recently demonstrated in thin magnetic films on the 100 picoseconds timescale.

9167-86, Session 16b

Weak-localization and weak antilocalization of surface electrons in topological insulators *(Invited Paper)*

Shun-Qing Shen, Hai-Zhou Lu, The Univ. of Hong Kong (Hong Kong, China)

The electronic transport experiments on topological insulators exhibit a dilemma. A negative cusp in magnetoconductivity is widely believed as a quantum transport signature of the topological surface states, which are immune from localization and exhibit the weak antilocalization. However, the measured conductivity drops logarithmically when lowering temperature, showing a typical feature of the weak localization as in ordinary disordered metals. Here, we present a conductivity formula for massless and massive Dirac fermions as a function of magnetic field and temperature, by taking into account the electron-electron interaction and quantum interference simultaneously. The formula reconciles the dilemma by explicitly clarifying that, the temperature dependence of the conductivity is dominated by the interaction, while the magnetoconductivity is mainly contributed by the quantum interference. The theory paves the road to quantitatively study the transport in topological insulators, and can be extended to other two-dimensional Dirac-like systems, such as graphene, transition metal dichalcogenides, and silicene.

Weak antilocalisation in topological insulators with strong spin-orbit scattering *(Invited Paper)*

Dimitrie Culcer, Weizhe Liu, The Univ. of New South Wales (Australia); Pierre Adroguer, Julius-Maximilians-Univ. Würzburg (Germany); Xintao Bi, Univ. of Science and Technology of China (China); Ewelina Hankiewicz, Julius-Maximilians-Univ. Würzburg (Germany)

Topological insulators (TI) have revolutionised our understanding of insulating behaviour. They are insulators in the bulk but conducting along their surfaces, thanks to surface states in which the spin and the charge are strongly coupled by means of the spin-orbit interaction. Much of the recent research on TI focuses on overcoming the transport bottleneck [1], namely the fact that surface state transport is overwhelmed by bulk

transport stemming from unintentional doping. The key to overcoming this bottleneck is identifying unambiguous signatures of surface state transport. This talk will discuss one such signature, which is manifest in the coherent backscattering of electrons in TI. Because of the strong spin-orbit coupling in TI one expects to observe weak antilocalisation rather than weak localisation, meaning that coherent backscattering increases the electrical conductivity [2]. The features of this effect, however, are rather subtle, because in TI the impurities have strong spin-orbit coupling as well, greatly increasing the complexity of the problem [3]. I will show that spin-orbit coupled impurities introduce an additional time scale, which is expected to be shorter than the dephasing time, and the resulting conductivity has a logarithmic dependence on the carrier number density, a behaviour hitherto unknown in 2D electron systems. The result we predict is directly observable experimentally and would provide a smoking gun test of surface transport. Furthermore, I will also discuss the effect of electron-electron interactions on transport in this regime.

Room temperature spin transport in condensed matters induced by spin pumping *(Invited Paper)*

Masashi Shiraishi, Kyoto Univ. (Japan); Yuichiro Ando, Osaka Univ. (Japan)

The first success of spin-pumping-induced transport of pure spin current in p-Si at room temperature (RT) opened a door for realizing RT spin transport in condensed matters by the dynamical approach [1]. We have been investigating transport of pure spin current generated by the spin pumping method in various materials, such as graphene [2], Al [3], n-GaAs [4] and so on. In this presentation, we will mainly introduce results on dynamical spin transport in graphene and n-GaAs, and also discuss a possible spurious signals in spin pumping experiments, which comes from self-induced inverse spin Hall effect of ferromagnet [5]

Tree-magnon splitting controlled by temperature *(Invited Paper)*

Kazuya Ando, Takaharu Tashiro, Saki Matsuura, Keio Univ. (Japan)

The spin-orbit interaction in a solid causes a flow of spins, a spin current, to induce an electric field perpendicular to both the spin polarization and the flow direction of the spin current, which is called the inverse spin Hall effect (ISHE). The ISHE has been crucial for exploring the spin physics of inorganic metals and semiconductors, because it enables simple and versatile detection of spin currents in non-magnetic materials. Here we show that a pure spin current can be produced in a solution-processed conducting polymer by pumping spins through a ferromagnetic resonance in an adjacent magnetic insulator, and that this generates an electric voltage across the polymer film [1]. We demonstrate that the experimental characteristics of the generated voltage are consistent with it being generated through the ISHE in the conducting polymer. In contrast with inorganic materials, the conducting polymer exhibits coexistence of high spin-current to charge-current conversion efficiency and long spin lifetimes. Our discovery opens a route for a new generation of molecular-structure-engineered spintronic devices, which could lead to important advances in plastic spintronics.

The field of spintronics is based on the manipulation of the spin degree of freedom. It uses the carrier spin angular momentum as a basic functional unit in addition to the charge. By combining charge and spin, a single electronic device could then integrate both logic and memory functions limiting power consumption and speeding up data processing. The first requirement of a semiconductor-based spintronic technology is the efficient electrical injection of spin-polarized carriers from an appropriate contact into the device heterostructure made of Si or Ge (the materials of mainstream microelectronics) at room temperature. In this presentation, we focus on the generation of a sizeable spin population into Si and Ge by spin pumping. Here, spin pumping corresponds to the generation of a pure spin current in the Si or Ge films by exciting the ferromagnetic resonance of an adjacent ferromagnetic electrode made of CoFeB with microwaves. The pure spin current is then detected using spin-orbit based effects. Our aim is to understand the basic mechanisms of spin pumping into Si and Ge as well as the spin-to-charge conversion by inverse spin Hall effect (ISHE, bulk effect) and Rashba effect (interface effect). In particular, the influence of the doping type (n and p) and interface resistance on spin pumping-ISHE measurements in germanium will be discussed. Finally, in both Si and Ge, we investigated the spin-to-charge conversion using interface states exhibiting giant Rashba splitting.

9167-91, Session 17a

Dual-frequency ferromagnetic resonance to measure spin current coupling in multilayers *(Invited Paper)*

Rohan Adur, Chunhui Du, Hailong Wang, Sergei Manuilov, Fengyuan Yang, P. Chris Hammel, Ohio State Unive. (United States)

Spin pumping, the transfer of spin angular momentum from a ferromagnet into an adjacent material as a consequence of the excitation of the magnetization of the ferromagnet, represents an intriguing phenomenon with substantial technological potential. It is widely believed that the mechanism for spin pumping in ferromagnet/nonmagnet bilayers is the exchange interaction between the ferromagnet and nonmagnetic material. We report exponential decay of spin pumping from thin $Y_3Fe_5O_{12}$ films to Pt across insulating barriers. This signature of quantum tunneling through a barrier confirms the role of exchange coupling for spin pumping and reveals its dependence on the characteristics of the barrier material. The efficiency of spin pumping is largely determined by the spin mixing conductance at the FM/NM interface. Our measurements of spin pumping in $Y_3Fe_5O_{12}$ /

Cu/Pt and Y3Fe5O12 /Cu/W trilayers with varying Cu thicknesses reveal that Y3Fe5O12/Cu interface has a very large intrinsic spin mixing conductance; in fact we find that the insertion of the Cu layer between Y3Fe5O12 and W leads to enhanced spin currents relative to Y3Fe5O12 /W.

Scanned probe magnetic resonance is a powerful tool in this context offering high resolution magnetic resonance imaging, localized spin excitation and measurement of spin relaxation/damping in nanoscale. We report on microscopic scanned probe magnetic resonance studies of spin dynamics, and explore the relationships between spin lifetime and transport. This research is supported by the U.S. DOE through Grant No. DE-FG02-03ER46054, by the NSF MRSEC program through Grant No. 0820414 and by the Army Research Office through Grant W911NF0910147.

9167-92, Session 17b

Novel quantum anomalous Hall effect for spintronics *(Invited Paper)*

Xiao Hu, National Institute for Materials Science (Japan)

We propose a new quantum anomalous Hall effect characterized by simultaneous nonzero charge and spin Chern numbers. We show that this state can be realized through a full band engineering using a staggered electric potential, antiferromagnetic exchange field and intrinsic spin-orbit coupling to control the three degrees of freedom: spin, sublattice and valley. With first principles calculation we confirm that one can achieve this new state by inserting a [111] mono-atomic layer of gold (Au) into a Mott insulator LaCrO_3 of perovskite structure and applying an electric field along [111] direction. This material is ideal for spintronics applications, since a finite sample provides a spin-polarized quantized edge current, robust to both nonmagnetic and magnetic defects, with the spin polarization reversible by electric field. The total magnetization is compensated to zero, and thus the system can be considered as a topological half-metallic antiferromagnet.

9167-93, Session 17b

Unconventional superconductivity in topological insulators: in search for Majorana fermions *(Invited Paper)*

Ewelina Hankiewicz, Julius-Maximilians-Univ. Würzburg (Germany)

We consider superconductor(S) /surface state of topological insulator(TI)/ superconductor junctions (S) where the S regime describes the surface state of the TI in the proximity with the s-wave superconductor. The novelty of such S/TI/S junctions originates from the electron spin helicity (locking of the momentum and the spin for a surface of TIs) which leads to both the s-wave singlet and the p-wave triplet pairing on the surface underneath the superconductor. The existence of these two superconducting channels leads to interesting features in transport through these junctions.

In particular we show, within the Bogoliubov-de-Gennes approach, that the superconducting Klein tunneling (passing of helical Cooper's pairs through the barrier without a reflection) and formation of a topological Andreev bound state (ABS) (state of hybridized two Majorana fermions)) occur for the normal incidence where ABS is protected against backscattering. For transport channels different than for the normal incidence, the scattering from the junction barrier generates an energy gap in the spectrum supporting non-topological ABSs.

Due to mixed order parameter, the AC Josepson effect is fractional showing higher odd harmonics.

We conclude that favorable conditions for the observation of the topological ABS is to put a barrier in the normal part of the junction or consider narrow TI links with a small number of open channels close to one.

9167-94, Session 17b

A quantum dot coupled to a topological nanowire: a suitable structure to study Majorana bound states *(Invited Paper)*

Edson Vernek, Univ. de São Paulo (Brazil) and Univ. Federal de Uberlândia (Brazil); Poliana H. Penteado, Univ. de São Paulo (Brazil); Antonio C. Seridonio, Univ. Estadual Paulista (Brazil); José Carlos Egues, Univ. de São Paulo (Brazil)

The search for the so-called Majorana bound states (MBS) in topological superconductor systems [1] have attracted a great deal of effort in the recent years. Despite the recent experimental efforts, a clear-cut signature of the MBS is still lacking [2].

Here we discuss a distinctive geometry from those conventionally used in the experiments realized so far. We consider a system composed of a quantum dot coupled to a topological nanowire and to two normal leads [3]. We show that this system constitutes a suitable setup for the investigation of MBS as it provides unique and robust signatures for these bound states. Owing to the high tunability of quantum dot parameters, we discuss possibilities to tell apart features related to other phenomena such as Andreev bound states, the Kondo effect and disorder from those associated to MBS. By employing a simple spinless Kitaev model for the wire and a non-interacting dot we show that the MBS, predicted to appear at the end of the wire, "leaks" into the quantum dot. More interestingly, the "leaked" MBS remains pinned to the Fermi level of the leads ($varepsilon_F$) as the level of the dot is gated to below or above $varepsilon_F$. This pinning of the MBS has no analogue in other fermionic type of bound states.

To show the robustness of our results against interactions in the dot, we investigate a more complete model. In this case we include the Coulomb interaction in the dot and we model the topological wire as realized via a tight-binding chain that includes Rashba spin-orbit interaction, superconducting proximity affect and an external magnetic field. We show that the leaking of the MBS into the dot and its pinning described previously are preserved for $varepsilon_{dot} > varepsilon_F. Due to the Coulomb blockade phenomena, however, the pinning of the MBS may no longer be observed when the dot is singly occupied ($varepsilon_{dot} < varepsilon_F< varepsilon_{dot}+U$, where U is the Coulomb repulsion energy). The pinning of the MBS in the singly occupied regime can be recovered by increasing the Zeeman splitting in the quantum dot, as the Coulomb blockade phenomena is suppressed.

Direct electrical detection of spin-momentum locking in the topological insulator Bi_2Se_3 *(Invited Paper)*

Connie H. Li, Olaf M. J. van 't Erve, Jeremy T. Robinson, U.S. Naval Research Lab. (United States); Ying Liu, Lian Li, Univ. of Wisconsin-Milwaukee (United States); Berend T. Jonker, U.S. Naval Research Lab. (United States)

Topological insulators (TIs) are a new quantum state of matter characterized by metallic surface states populated by massless Dirac fermions. TIs are expected to exhibit new behaviors and open horizons for science previously inaccessible with "conventional" materials. One of the most striking properties is that of spin-momentum locking -- the spin of the TI surface state lies in-plane, and is locked at right angle to the carrier momentum. An unpolarized charge current should thus create a net spin polarization whose amplitude and orientation are controlled by the charge current. This remarkable property has been anticipated by theory, but never accessed in a simple transport structure. Here we show that a bias current indeed produces a net surface state spin polarization via spin-momentum locking in molecular beam epitaxially grown Bi2Se3 films, and this polarization is directly manifested as a voltage on a ferromagnetic metal contact. This voltage is proportional to the projection of the TI spin polarization onto the contact magnetization, is determined by the direction and magnitude of the bias current, scales inversely with Bi2Se3 film thickness, and its sign is that expected from spin-momentum locking rather than a Rashba effect. Similar data are obtained for structures with two different ferromagnet/tunnel barrier contacts, demonstrating that these behaviors are independent of the details of the detector contact. These results demonstrate direct electrical access to the TI surface state spin system and enable utilization of its remarkable properties for future technological applications.

9167-96, Session 18a

Experimental observation of a large ac-spin Hall effect *(Invited Paper)*

Georg Woltersdorf, Martin-Luther Univ. Halle-Wittenberg (Germany); Christian H. Back, Dahai H. Wei, Martin Obstbaum, Univ. Regensburg (Germany)

In spin electronics the spin degree of freedom is used to transmit and store information. Ideally this occurs without net charge currents in order to avoid energy dissipation due to Joule heating. To this end the ability to create pure spin currents i.e. without net charge transfer is essential. Spin pumping is the most popular approach to generate pure spin currents in metals, semiconductors, graphene, and even organic materials. When the magnetization vector in a ferromagnet (FM) - normal metal (NM) junction is excited the spin pumping effect leads to the injection of pure spin currents in the normal metal. The polarization of this spin current is time dependent and contains a very small dc component. However in contrast to the rather well understood dc component the two orders of magnitude larger ac component has escaped experimental detection so far. Here we show that the large ac component of the spin currents can be detected very efficiently using the inverse spin Hall effect (ISHE). The observed ac-ISHE voltages are one order of magnitude larger than the conventional dc-ISHE measured on the same device. The spectral shape, angular dependence, power scaling behavior, and absolute magnitude of the signals are in line with spin pumping and ISHE effects. Our results demonstrate that FM-NM junctions are very efficient sources of pure spin currents in the GHz frequency.

9167-97, Session 18a

Insight about spin Hall effects from spin pumping *(Invited Paper)*

Axel Hoffmann, Wei Zhang, Argonne National Lab. (United States); Vincent Vlaminck, Univ. San Francisco de Quito (Ecuador) and Argonne National Lab. (United States); John E. Pearson, Samuel D. Bader, Ralu Divan, Argonne National Lab. (United States); Lihui Bai, Paul Hyde, Yongsheng Gui, Can-Ming Hu, Univ. of Manitoba (Canada)

Spin Hall effects intermix spin and charge currents in non-magnetic materials and offer the possibility to generate and detect spin currents without ferromagnets [1]. In order to gain insight into spin Hall effects, spin pumping is especially useful, since it enables the generation of spin currents over large interfaces, and thereby generates spin Hall effect voltages up to mV, which can be used for quantifying the spin Hall angle, which is direct measure of the charge-to-spin (and vice versa) conversion efficiency [2,3]. Furthermore, analyzing the data as a function of normal layer thickness enables the determination of the spin diffusion length independent of possible variations of normal metal resistivity and yields 5.5±0.5 nm for Pd [4] and 1.2±0.5 nm for Pt [5]. Even shorter spin diffusion lengths have been determined for Ir and IrMn. Lastly, using the angular field dependence of the electric voltages allows us to show that the spin current from spin pumping scales as theoretically expected with precession angle even into the non-linear excitation regime [6].

This work was supported at Argonne by U.S. DOE-BES, MSE and at Manitoba by NSERC, CFI, and URGP.

Generation and detection of spin currents in magnetic hybrid structures *(Invited Paper)*

Antonio Azevedo, Obed Alves-Santos, Gabriel A. Fonseca-Guerra, Joaquim B. Mendes, Rafael O. Cunha, Univ. Federal de Pernambuco (Brazil); Roberto L. Rodriguez-Suarez, Pontificia Univ. Católica de Chile (Chile); Sergio M. Rezende, Univ. Federal de Pernambuco (Brazil)

The generation of spin current can be obtained by the spin pumping effect in which a time-varying magnetization pumps spins into a nearby material. It can also be accomplished by means of the spin Seebeck effect in which a heat flow within a ferromagnet can produces a flow of spins. In both effects, the flow of spin occurs with no flow of charge carrier. By taking advantage of the spin Hall effect and its reciprocal, the inverse spin Hall effect, the spin and charge currents can be mutually converted into each other in thin layers of materials with large spin-orbit interaction. In this talk we will briefly review the state of the art in this area as well as will show results in which Permalloy (Py), a ferromagnet, and Ir20Mn40, a high temperature antiferromagnetic metal, can also be used as spin current detectors. In both cases the measurements were carried out in bilayers of FM/Py and FM/IrMn, where FM is the insulator ferrimagnetic yttrium iron garnet (YIG). We also show that a self induced inverse spin Hall effect can be generated in single layers of Permalloy under ferromagnetic resonance condition. All of these results open up new possibilities of the detection of pure spin current.

Spin noise spectroscopy in semiconductors: from a billion down to single spins *(Invited Paper)*

Jens Hübner, Hendrik Kuhn, Ramin Dahbashi, J. Wiegand, Fabian Berski, Leibniz Univ. Hannover (Germany); J. G. Lonnemann, Leibniz University Hannover (Germany); Michael Oestreich, Leibniz Univ. Hannover (Germany)

Spin noise spectroscopy (SNS) in semiconductors has matured during the past nine years into a versatile and well developed technique being capable to unveil the intrinsic and unaltered spin dynamics in a wide range of semiconductor systems [1,2]. Originating from atom and quantum optics as a potential true quantum non-demolition (QND) measurement technique, SNS is capable of unearthing the intricate dynamics of free or localized electron and hole spins in semiconductors being eventually coupled to the nuclear spin bath as well. Here, I review the major steps which inspired the success of spin noise spectroscopy in semiconductors and present the most recent extensions into the low-invasive detection regime of the spin dynamics for the two extreme limits of very high and extremely low loss rates of spin decoherence, respectively. On the one hand, merging ultrafast laser spectroscopy with SNS enables the detection of spin noise with picosecond resolution, i.e., with THz bandwidths [3] yielding access to otherwise concealed microscopic electronic processes [4]. On the other hand, we present very

high sensitivity SNS [5] being capable to measure the extremely long spin coherence of single holes enclosed in individual quantum dots venturing a step forward towards true optical QND experiments in semiconductors [6]. In addition, I discuss how higher-order spin noise statistics of, e.g., single charges can give information beyond the linear response regime governed by the fundamental fluctuation-dissipation theorem and thereby possibly shed some light onto the nested coupling between electronic and nuclear spins.

Comparison of spin accumulation from FMR-driven spin pumping and DC spin injection within a single silicon-based MOS heterostructure *(Invited Paper)*

Ezekiel Johnson-Helperin, The Ohio State Univ. (United States)

The use of the spin Hall effect and its inverse to electrically detect and manipulate dynamic spin currents generated via ferromagnetic resonance (FMR) driven spin pumping has enabled the investigation of these dynamically injected currents across a wide variety of ferromagnetic materials. However, while this approach has proven to be an invaluable diagnostic for exploring the spin pumping process it requires strong spin-orbit coupling, thus substantially limiting the materials basis available for the detector/channel material (primarily Pt, W and Ta). As a result, comparison of spin pumping generated spin currents with the large body of work based on DC electrical spin injection in materials such as GaAs and Si is problematic. Here, we report FMR driven spin pumping into a weak spin-orbit channel through the measurement of a spin accumulation voltage in a Si-based metal-oxide-semiconductor (MOS) heterostructure. This alternate experimental approach enables the investigation of dynamic spin pumping in a device geometry that is also compatible with more established DC spin injection techniques, allowing for the first time a direct comparison between FMR and electrically driven spin injection mechanisms.

9167-101, Session 18b

Graphene spintronics: spin injection and proximity effects from first principles *(Invited Paper)*

Igor Zutic, Univ. at Buffalo (United States); Guilherme M. Sipahi, Univ. de São Paulo (Brazil); Predrag Lazic, Institut Ruder Boškovic (Croatia); Roland K. Kawakami, The Ohio State Univ. (United States)

We formulate a computationally-inexpensive model to study spin injection and proximity effects in graphene/ferromagnet junctions. By presenting spin polarization maps, we establish a versatile tool to tailor the desired spin-dependent properties for graphene spintronics which suggest a wealth of opportunities, not limited to magnetically storing and sensing information, but also including processing and transferring information.

9167-102, Session 18b

Valley polarization by optical pumping on MoS_2 monolayer *(Invited Paper)*

Baoli Liu, Gang Wang, Chuanrui Zhu, Institute of Physics (China); L. Bouet, Univ. de Toulouse (France); Bernhard Urbaszek, Institut National des Sciences Appliquées de Toulouse (France); Thierry Amand, Xavier Marie, Univ. de Toulouse (France)

Transition metal dichalcogenides are emerging as promising new materials for applications in electronics andoptoelectronics.In particular, monolayer molybdenum disulfide (MoS2) has recently received significant attention experimentally. In contrast to graphene, monolayer(ML) MoS2 has a direct band gap in the visible regionof the optical spectrum and a unique coupling of carrier spin andk-space valley physics due to combined effect of inversion symmetry breakingand the spin-orbitinteraction. The circular polarizationof the absorbed or emitted photon can be directly associatedwith selective carrier excitation in one of the two non-equivalent K valleys (K+ or K—, respectively).

In this presentation, we demonstrate experimentally that valley polarization can be created by circularly polarized light excitation on MoS2 monolayer.The circular polarization of photoluminescence (PL) reaches valus up to 50% polarization at room temperature[1,2]. The measurement of PL polarizationwith transverse magnetic fields up to 9 T shows that the valley-index excitation is robust [2]. Finally, we present the investigation of the effect of uniaxial tensile strain on the valley polarization of monolayer and bilayer MoS2 at room temperature [3]. The polarization decreases with increasing strain for both monolayer and bilayer MoS2.These results shed light on the band structure of MoS2 nanostructures.

Charge and spin transport across graphene-ferromagnet junctions *(Invited Paper)*

Enrique Cobas, Adam L. Friedman, Olaf M. J. van 't Erve, Jeremy T. Robinson, Berend T. Jonker, U.S. Naval Research Lab. (United States)

We present experimental measurements of vertical charge and spin transport at graphene/ferromagnetic metal (FM) junctions[1]. The combination of the spin-resolved band structure of certain ferromagnetic metal surfaces with the peculiar band structure of graphene has been predicted to make graphene a tunnel barrier for majority-spin carriers[2,3]. This spin-filtering phenomenon enables highly spin-polarized charge currents with low impedance, an effect that could be a boon to spintronics technology including novel spin-transfer torque (STT) non-volatile memory. Using scalable large-area synthesis and fabrication techniques, we fabricate arrays of FM/Graphene/FM junctions using 1-5 layers of graphene. We find low interface impedance and significant negative magnetoresistance even at room temperature, indicative of the predicted spin-filtering phenomenon. Charge and spin transport across these junctions is examined as a function of applied bias, applied magnetic field and temperature.

Gap opening in zigzag graphene nanoribbons: direct experimental determination of the onset of spin-spin interactions of edge states *(Invited Paper)*

Lian Li, Univ. of Wisconsin-Milwaukee (United States)

Graphene nanoribbons (GNR) have been explored extensively for bandgap engineering, arising from quantum confinement for ribbons with armchair edges, and spin-spin interactions for zigzag edges. In both cases, many-body e-e interactions have been predicted to increase the gap to well above 1 eV for NRs of a few nms, attractive for practical applications. However, its experimental realization remains elusive, particularly the key parameter of many-body effect correction is still untested experimentally. This is largely due to challenges synthesizing zigzag graphene nanoribbons (ZGNR) just a few nm in width. Here, we synthesize ZGNR using Fe nanoparticle-assisted H etching of epitaxial graphene/SiC(0001) in ultrahigh vacuum, which produces monolayer thick NR as narrow as 1 nm for the investigation of width-dependent bandgaps. Using in situ spatially resolved tunneling spectroscopy, we determine a critical threshold of 3 nm, above which width-independent gaps of up to 0.50 eV are found. Below which, however, we find a tunable gap that scales with ribbon width, with a gap of 1.64 eV found for a 1.1 nm ribbon, the largest measured to date for ZGNR. These results provide the first direct experimental confirmation of the spin-spin interactions in gap opening in ZGNR, and reveal a critical width of 3 nm for its onset, and demonstrate that a practical and tunable bandgap can indeed be realized in ZGNRs, albeit a very narrow width must first be achieved.

Conference 9168: Carbon Nanotubes, Graphene, and Associated Devices VII

9168-1, Session 1

Biomimetic multi-length scale manufacturing in carbon *(Invited Paper)*

Marc J. Madou, Univ. of California, Irvine (United States)

Carbon micro- and nanofabrication techniques (C-MEMS and C-NEMS) are based on the pyrolysis of patterned polymers at different temperatures and in different ambient atmospheres. Carbon, because it is brittle and hard, is a difficult material to machine, polymers on the other hand can be machined easily in a wide variety of machine tools and as a consequence shapes and sizes that are difficult to achieve directly in carbon can easily be made by patterning a polymer first and then converting it to carbon. The C-MEMS and C-NEMS applications we are highlighting in this presentation are ultrasensitive carbon interdigitated arrays (IDA) for nanoelectrochemistry and suspended carbon nano-wires for sensor application in the liquid and gas phase.

9168-2, Session 1

Characterization of plasmon propagation in graphene on PZT substrates via infrared nano-imaging

Michael D. Goldflam, Univ. of California, San Diego (United States); Guangxin Ni, Univ. of California, San Diego (United States) and National Univ. of Singapore (Singapore); Zhe Fei, Alexander S. McLeod, Univ. of California, San Diego (United States); Barbaros Özyilmaz, Antonio H. Castro Neto, National Univ. of Singapore (Singapore); Michael M. Fogler, Dmitri N. Basov, Univ. of California, San Diego (United States)

Using scattering-type scanning near-field optical microscopy (s-SNOM), we have characterized graphene plasmons on a graphene-lead zirconate titanate (PZT) back-gated structure. By applying modest back-gate voltages of ±1 V across the PZT, we have been able to induce variations in the graphene plasmon wavelength of more than ~200 nm. The change in plasmon wavelength we observe corresponds to a shift in carrier concentration in the graphene by more than one order of magnitude. Additionally, we describe the plasmonic losses originating from the presence of PZT in such a device. Our results also suggest that persistent tuning of the graphene plasmon may be achieved by utilizing the ferroelectric nature of PZT.

9168-3, Session 1

Optical impedance transformer for transparent conducting electrodes

Ken X. Wang, Stanford Univ. (United States); Jessica R. Piper, Stanford University (United States); Shanhui Fan, Stanford Univ. (United States)

A fundamental limitation in TCE is thought to be the trade-off between photonic and electrical performances. In this paper, we show that one can improve the photonic performance by optical engineering, without compromising the electrical performance. Specifically, broadband and omnidirectional absorption suppression can be achieved in a TCE embedded in high refractive index dielectric cladding layers with nanostructured antireflection coatings. The scheme acts effectively as an optical impedance transformer.

The first element of the strategy is to suppress the optical absorption in the graphene layers by high index cladding layers. We discuss two configurations. In the first configuration, the graphene layers are embedded in the high index background that fills the entire space. Due to the negligible thickness of the graphene layers, the electromagnetic field approaches its static limit, and the average electric field intensity in graphene is equal to that in the background. For the same incident intensity, the electric field is weaker in a higher-index material. As a result, the absorption coefficient in each graphene layer is $pi alpha / n$. Multiple graphene layers would absorb multiples of $pi alpha / n$. In the second configuration, only the half-space below the graphene layers is filled with the same dielectric material. The absorption coefficient in each graphene layer is $pi alpha [2/(1+n)^2]$.

The second element of the strategy is to achieve antireflection. In the first strategy, we sandwich the graphene layers between the substrate and superstrate layers. Since a higher refractive index of the substrate and superstrate materials is desirable for maximal suppression of absorption in graphene, there would be significant reflection at the superstrate-air interface. Tapering of nanostructures, which provides a graded index for optical impedance matching, has proven to be an effective antireflection strategy. For the antireflection to be optimal, the periodicity of the nanopyramid lattice needs to be smaller than the wavelength of incident light, and the height of the nanopyramid needs to large enough for a gradual index transition. Satisfying these two requirements should result in strong suppression of reflection over broad ranges of both wavelengths and incident angles.

Combining the physics of those two elements, we could construct structures with extraordinarily high transmission. We compare the performance of the optical impedance transformer structure to graphene layers suspended in air and on a substrate.

9168-4, Session 1

Microwave impedance microscopy (MIM) of aligned single walled carbon nanotubes: imaging electronic nanotube character at the nanoscale

Eric Seabron, Scott MacLaren, Univ. of Illinois (United States); Slava V. Rotkin, Lehigh Univ. (United States); William L. Wilson, Univ. of Illinois (United States)

For the last fifty years the electrical engineering community has driven integrated circuit technology to unimagined heights, shrinking silicon transistors, lowering the cost and power requirements of the building blocks for all computation. As transistor technology approach fundamental barriers, Single Walled Carbon Nanotubes (SWCNT) has emerged as one material option for producing the next generation high performance nanoscale transistors. For aligned SWCNT on quartz substrates, emergent device applications require arrays of purely semiconducting SWCNTs at high densities. Over the past three years there have been many breakthroughs in the processing of CNTs for electronic devices spanning densification, doping, and purification. However, in order to advance this process research a reliable inspection technique must be developed. We show that Microwave Impedance Microscopy (MIM) has the capability of mapping an individual nanotube's electrical properties with nanoscale (<50nm) resolution. We show that MIM images can be analyzed to give important quantitative and qualitative information about the aligned CNT arrays without any sample modification. We present a theoretical model of the nanoprobe – nanotube interaction which will allows us to qualitatively correlate tube electronic properties; this may give us insight into chirality driven growth dynamics and help us verify the effectiveness of various purification methods.

9168-5, Session 1

Mapping charge transport in chirality-selected carbon nanotube networks by electroluminescence and Raman microscopy

Florian Jakubka, Stefan B. Grimm, Stefan P. Schiessl, Florentina Gannott, Jana Zaumseil, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Field-effect transistors (FETs) based on networks of semiconducting single-walled carbon nanotubes (s-SWNT) are promising building blocks for flexible electronics. Within random and semi-aligned networks of s-SWNT the current paths are likely to be non-homogeneous depending on network density, diameter distribution and connectivity. Here we introduce two techniques to effectively map and visualize current paths and charge density distribution within the FET channel: 1) near-infrared electroluminescence (EL) from ambipolar s-SWNT network FETs and 2) in-situ confocal Raman microscopy on electrolyte-gated transistors,

We use networks of s-SWNT containing only certain chiralities, e.g., (7,5) or (10,5) nanotubes, which were extracted by dispersion with the conjugated polymer poly(9,9-dioctylfluorene) and other polyfluorene copolymers. Top-gate FETs produced with spincoated films of these s-SWNT show balanced ambipolar transport and efficient near-infrared electroluminescence. Mapping the emission from these networks during a gate voltage sweep allows us to visualize preferential current paths that depend on the source-drain electrode assignment and density of the nanotubes. Furthermore, it is possible to map the distribution of charges within an electrolyte-gated FET based on s-SWNT networks by confocal Raman microscopy. The G'-peak position of the nanotubes shifts linearly with applied gate voltage and thus charge carrier density. This allows us to map the carrier distribution in an operating FET with a spatial resolution of 300 nm. These maps reveal a strong dependence of carrier distribution on network density and source-drain bias.

9168-13, Session 1

Nonlinear optical and electrical conductivity properties of carbon nanotubes (CNT) doped in sol-gel matrices

Mariana Pokrass, Soreq Nuclear Research Ctr. (Israel) and Tel Aviv Univ. (Israel); Zeev Burshtein, Ben-Gurion Univ. of the Negev (Israel); Galit Bar, Applied Physics Division, Soreq (Israel); Raz Gvishi, Soreq Nuclear Research Ctr. (Israel)

Carbon-nanotubes (CNTs) are fascinating compounds, exhibiting exceptional electrical and thermal conductivities, mechanical strength, and non-linear optical (NLO) properties. Their unique structures create large Pi-Pi* electronic clouds. The energy level schemes thus created allow many electronic transitions between the ground and the excited states. In this work, we present a study of non-linear optical and electrical conductivity properties of CNT–doped hybrid organic-inorganic glass composites prepared by a Fast-Sol-Gel method. These composite glasses solidify without shrinkage or formation of cracks, and present promising properties as optical media.

The CNT composite glasses present enhanced absorption at 532 nm, and saturable absorption at 1064 nm. The enhanced absorption at 532 was attributed to 2-photon absorption; saturable absorption was attributed to depletion of the absorbing ground-state, and was analyzed using the modified Frantz-Nodvik equation. Absorption cross-sections were extracted for saturable absorption phenomenon. Such CNT composites glasses may be used as "optical limiting" filters near 532 nm, or as saturable absorbing filters for passive Q-switching of short-pulsed lasers near 1064 nm.

The CNT composites conductivity was studied as a function of the CNT concentration. The electrical properties were interpreted using percolation theory. The maximal measured conductivity was 0.001 (1/?cm) for the CNT composites, representing a conductivity increase of at least 12 orders of magnitude compared to that of pure silica. A low percolation threshold of 0.22 wt.% CNT was obtained. Electrostatic Force Microscopy (EFM) and Conductive mode Atomic Force Microscopy (C-AFM) studies exhibited conductivity at the micro-level, which was attributed to the CNTs dispersion mode inside the matrix.

9168-6, Session 2

Electronics and optoelectronics based on carbon nanomaterial heterostructures *(Invited Paper)*

Mark C. Hersam, Northwestern Univ. (United States)

Improvements in carbon nanomaterial monodispersity have yielded corresponding enhancements in the performance of electronic, optoelectronic, sensing, and energy technologies. However, in all of these cases, carbon nanomaterials are just one of many materials that are employed, suggesting that further device improvements can be achieved by focusing on the integration of disparate nanomaterials into heterostructures with well-defined interfaces. For example, organic self-assembled monolayers on graphene act as effective seeding layers for atomic layer deposited (ALD) dielectrics, resulting in metal-oxide-graphene capacitors with wafer-scale reliability and uniformity comparable to ALD dielectrics on silicon. Similarly, the traditional trade-off between on/off ratio and mobility in semiconducting carbon nanotube (CNT) thin-film transistors (TFTs) is overcome by replacing conventional inorganic gate dielectrics with hybrid organic-inorganic self-assembled nanodielectrics, yielding on/off ratios approaching 10^6 while concurrently achieving mobilities of ~150 cm^2/V-s. Finally, p-type semiconducting CNT thin films are integrated with n-type single-layer MoS2 to form p-n heterojunction diodes. The atomically thin nature of single-layer MoS2 implies that an applied gate bias can electrostatically modulate both sides of the p-n heterojunction concurrently, thereby providing 5 orders of magnitude gate-tunability over the diode rectification ratio in addition to unprecedented anti-ambipolar behavior when operated as a three-terminal device. Furthermore, these CNT/MoS2 p-n heterojunctions show a strong photocurrent response, whose spectral characteristics can be tuned by an applied gate potential. Overall, this work establishes that carbon nanomaterial applications can be substantially enhanced and diversified into new areas through precise integration into heterostructure devices.

9168-7, Session 2

Femtomolar molecular detection with CNT based SERS substrate *(Invited Paper)*

Ali Ozhan Altun, ETH Zürich (Switzerland); Tiziana C. Bond, Lawrence Livermore National Lab. (United States); Hyung Gyu Park, ETH Zürich (Switzerland)

A metal/dielectric/vertically aligned CNT sandwich structure is fabricated for chemical and biomolecular detection using the science of surface enhanced Raman spectroscopy (SERS). High sensitivity is accomplished with the insertion of a nanolayer in between plasmonic metal (gold) and the metallic wire template (multiwalled carbon nanotubes (CNT)). The rational design is twofold: (i) inserting of a screening material against electron transfer between gold and CNT to prevent otherwise quenched local surface plasmon resonance; and (ii) creating a "kissing nanowire" effect to the gold-hafnia-CNT nanowires to enahnce the SERS-based, chem-biodetection sensitivity. Experiments verified appropriateness of our nanoarchitecture design rules by demonstrating femtomolar detection of BPE (1,2 bis-(4-pyridyl)-ethylene) with the hafnium oxide insert layer. This outstanding results of ultrahigh sensitivity as well as CNT-surface plasmon coupling motivated us to pursue a systematic study to gain a deeper understanding on this optoelectronic phenomenon. There are two possible theories to explain the surface plasmon quenching: energy loss (i) through electron transfer and (ii) through dipole-dipole coupling of the fields. If electron transfer is the mechanism, insertion of a dielectric intermediary which provides a Schottky barrier higher than the surface plasmon energy level will eliminate this energy loss. If field coupling is the concern, increasing the dielectric constant of the intermediary will shield the electric fields associated with the surface plasmon dipoles. We have performed a set of experiments to answer these questions by observing the effects of Schottky barrier and dielectric constant on SERS signal by applying different material insertions between gold and CNT.

9168-8, Session 2

Atomically thin optoelectronics: the ideal semi-metal and the insurmountable insulator

Nathaniel M. Gabor, Univ. of California, Riverside (United States)

Graphene, an atomically thin sheet of hexagonally oriented carbon, is a zero band gap conductor (semi-metal) that exhibits extraordinary electronic behavior and broadband optical absorption. Hexagonal boron nitride, which shares a similar structure to that of graphene, is a highly insulating electronic material that does not absorb any light in the visible spectrum. By combining graphene and boron nitride into ultrathin vertical stacks, we can fabricate new optoelectronic devices that demonstrate highly sensitive optical response, yet are only as thick as the width of a DNA molecule. In this talk, I will discuss how stacking these atomically thin materials allows us to explore new types of optoelectronic devices: 1) lateral devices that reveal a novel hot carrier transport regime [Science 344, p.648 (2011)], and 2) interlayer devices which exhibit hot carrier photo-thermal up conversion [submitted Nature Nanotechnology], both of which may lead to more efficient energy harvesting technologies.

9168-9, Session 2

Graphene nanoobjects (GNOs) tailored by interference lithography

Alireza Kazemi, Xiang He, Javad Ghasemi, Seyed Hamidreza Alaie, Noel M. Dawson, Brianna Klein, Terefe Habteyes, Steven R. J. Brueck, Sanjay Krishna, The Univ. of New Mexico (United States)

Graphene nano-objects (GNOs) are nanometer-sized fragments of graphene that show unique optical and electronic properties (e.g. band gap opening and exiton confinement), which make them interesting candidates for a whole range of new applications. These small graphene fragments can have different forms such as graphene nanoribbons (GNRs), graphene nanomesh (GNM) and graphene quantum dots (GQDs).

In this work, we present a facile approach to fabricate GNOs using interference lithography (IL) which is a very low-cost, reliable and scalable technology for the fabrication of nanoscale periodic patterns over large areas. Periodic photoresist (PR) lines and hole arrays were patterned on a monolayer graphene by IL, and used as an etch mask for making GNRs and GNM, respectively.

First a monolayer CVD graphene (on 285 nm Sio2/silicon substrate) was patterned with a 100 nm photoresist (PR) lines with a period of 300 nm, and an O2 plasma was performed to reduce the PR linewidth to ~ 20 nm. After washing the PR lines, an array of uniform GNRs were left on the substrate.

To make GNM, photoresist hole arrays were patterned on a monolayer graphene with a period of 300 nm and diameter of 200 nm. After performing O2 plasma, the PR width was reduced to ~ 20 nm. Following the PR removal, a very uniform GNM was obtained.

The fabricated GNRs and GNM were then used as a channel for a field effect transistor (FET), and optical and electrical characterizations were performed.

9168-32, Session 2

Formation of Fabry-Perot cavity in one-dimensional and two-dimensional GaAs nanostructures

Shermin Arab, The Univ. of Southern California (United States); P. Duke Anderson, Univ. of California, Los Angeles (United States); Maoqing Yao, Chun-Yung Chi, Michelle L. Povinelli, P. Daniel Dapkus, Stephen B. Cronin, The Univ. of Southern California (United States)

We report formation of optical cavity and observation of Fabry-Perot resonance in GaAs nanowires and nanosheet grown by metal organic chemical vapor deposition (MOCVD) method with selective area growth (SAG). These nanostructures are grown on (111)B. The formation of cavity in nanowires and nanosheets are fundamentally different. While in nanowires optical cavity is formed along the wire with ends of the wire behaving as mirrors, the three non-parallel edges of GaAs nanosheets are involved in trapping the light. We show that through surface passivation and local field enhancement, both the PL intensity and hence Fabry-Perot peak intensity increases significantly. Transferring the GaAs nanowires and nanosheet on gold substrates (instead of Si/SiO2 substrate) leads to substantial enhancement in the PL intensity (5X) and 3.7X to infinite enhancement of FP peaks. In order to reduce the non-radiative recombination in these nanowires the surface states in the nanowires can be passivated by either an ionic liquid (EMIM-TFSI) or an AlGaAs surface layer. Both forms of passivations lead to enhancement of optical response up to 12X.

9168-10, Session PWed

Separation of the semiconducting and the metallic types of single-wall carbon nanotube by electrophoresis method

Hsi-Chao Chen, National Yunlin Univ. of Science and Technology (Taiwan); Chih-Feng Yen, Chang Gung Memorial Hospital (Taiwan); Guan-Jhen Chen, National Yunlin Univ. of Science and Technology (Taiwan); Tzu-Ti Hsiao, Chang Gung Memorial Hospital (Taiwan); Yang Zhou, Graduate School of Optoelectronics, National Yunlin University of Science and Technology (Taiwan); Kuo-Ting Huang, National Yunlin Univ. of Science and Technology (Taiwan); Hsin-Ta Lee, Graduate School of Optoelectronics, National Yunlin University of Science and Technology (Taiwan); Wan-Ting Yang, National Yunlin Univ. of Science and Technology (Taiwan)

This study was to separate the semiconducting and the metallic types of single-wall carbon nanotubes (SWNTs) by electrophoresis method with the different dispersants that are DNA, Triton X-100 and sodium dodecyl sulfate (SDS), respectively. The dispersants can modify the surface of SWNTs and disperse in the DNA free water or deionised water. As a result of the conductive electricity of m-SWNT (Metallic SWNT) is higher than s-SWNT (Semiconducting SWNT), m-SWNT is very suitable to apply on the flexible substrate coating of transparent conductive film. However, the different dispersants such as DNA, Triton X-100 and SDS coated on SWNTs have different polarity of electronic field. Hence, the different power of electrophoresis was applied to separate out s-SWNT and m-SWNT from the hybrid SWNT. In addition, the DNA nucleic acid fragments length and quantitative can be determine with electrophoresis method. The electrophoresis method is a low cost, low energy required and efficientibility for this fabrication. DNA's nonspecific binding to SWNT wall has been visualized by high resolution transmission electron microscopy. The results of Raman spectrum can verify the separation efficiency and determine the electrical of the samples with the radial breathing mode (RBM, 100-400cm-1) of SWNT. After the dispersion process with DNA, a new peak (~1450 cm-1) has been observed between D-band (~1350cm-1) and G-band (~1550cm-1) that also can identify s-SWNT and m-SWNT. At same time, Fourier transform infrared spectroscopy (FTIR) was used to identify function group for dispersant with SWNT.

9168-25, Session PWed

Fabrication and characterization of 3D gaphene composited metal oxide for energy storage device

Duyoung Choi, Cihan Kurua, Serdar Yavuz, Sungho Jin, Univ. of California, San Diego (United States)

Supercapacitors represent energy storage devices that have attracted increasing attention because of a number of important features including high power density, fast charging/discharging rate, and excellent cycle stability. Typically, carbon based materials are good electrodes for capacitors while transition metal oxides and electrically conducting polymers are good candidates for pseudocapacitors. Among the different electrode materials, graphene attracted a significant attention due to their good conductivity, mechanical flexibility, and stable electrochemical behavior. In comparison, MnO2 is one of the thoroughly investigated transition metal oxides for pseudocapacitors due to its high theoretical specific capacitance (1370 F/g), relatively low cost, and environmental friendliness. However, the theoretical capacitance of MnO2 has rarely been achieved in experiments, mainly due to its poor electrical conductivity (10-5~10-6 S/cm). In order to obtain a high specific capacitance from MnO2, many studies have been conducted, most of which are based on incorporating MnO2 with conductive materials and forming hybrid electrode structures. Such outstanding properties make them promising in a wide range of applications from hybrid vehicles and portable electronics to military devices, where high power density and long cycle-life are highly desirable. In this work, we demonstrate a successful fabrication of scalable 3D MnO2-graphene hybrid electrodes. The electrochemical performances of such 3D hybrid electrodes have been investigated for supercapacitors in a three-electrode system at room temperature, and their structures and properties are described.

9168-26, Session PWed

Ab-initio analysis of carbon nanotube based ammonia gas sensor

Anurag Srivastava, Vikash Sharma, Kamalpreet Kaur, Indian Institute of Information Technology and Management (India); Rajeev Ahuja, Uppsala Univ. (Sweden); Vepa K. Rao, Defence Research & Development Establishment (India)

An ab-initio study has been performed for the analysis of ammonia gas sensing of Carbon Nanotube. The computation has been performed using generalized gradient approximation (GGA) parameterized with Revised Perdew Burke Ernzerhoff (RPBE) type. The electronic property analyses shows that as the single ammonia molecule comes into the contact of the surface of CNT, the metallicity of CNT decreases substantially.The further increases in the number of ammonia molecules in the environment, the metallic nature of CNT changes to semiconducting. Thus, metallic to semiconducting transition confirms the presence of ammonia near to CNT surface.

9168-27, Session PWed

Solar powered UAV using graphene supercapacitors capable of 24/7 flight

Charles Welch, Daniel Roseguo, James Chavez, Daneilla Alvarez, Art Lomibao, Sean Matthews, California State Polytechnic Univ., Pomona (United States)

Solar planes have never been a practical concept due to the high weight and long charge time of batteries. Along with that, solar panels have not been able to effectively provide enough power to sustain long duration flight. Our project plans to provide an optimum integration of solar technology and graphene energy storage to meet the task of flying continuously throughout the night. Due to graphenes amazing physical characteristics, we can provide a low weight, low charge time, high storage supercapacitor, that can adequately use solar charging to the utmost efficiency. The supercapacitors used in this project were designed and invented by the team lead and are a unique and functional solution for energy storage. Using these newly designed supercapacitors, our team was able to cut the battery weight of our UAV in half, and still provide enough power storage to fly continuously through the night. Along with that, the complete design of this aircraft including the flight control system, solar panel integration, circuit design, and flight design is a benchmark for the integration of solar technology for flight. Overall we hope the research from our project can lead the way for integration of graphene supercapacitors in solar technology.

9168-28, Session PWed

Thermal dissipation of photonic crystal defect cavity by the single-layer graphene

Min-Hsiung Shih, Academia Sinica (Taiwan)

Graphene, a two-dimensional material composed of carbon atoms arranged in a hexagonal lattice, which exhibits excellent thermal conductivity, is a potential heat dissipation medium for compact optoelectronic devices. In the meanwhile, photonic crystal cavities have become a promising technology for creating compact and efficient light sources in dense chip-scale optical systems. Most photonic crystal cavities are implanted in suspended membrane structures (air-dielectric-air) to achieve improved vertical optical confinement in the minute cavity. However, thermal accumulation is a critical problem when optical energy is localized within a sub-micrometers region. In this study, single-layer graphene (SLG) grown by chemical vapor deposition (CVD) is used to cover the surface of a photonic crystal (PhC) cavity, where the heat flux produced by the PhC cavity can be efficiently dissipate along the in-plane direction of the SLG. The thermal properties of the graphene-capped PhC cavity were characterized by experiments and theoretical calculations. The simulation showed that SLG received the majority of the heat fluxes during the dissipative process, which resulted in a substantially lower temperature in the SLG-capped PhC cavity compared with that in the bare PhC cavity. The thermal resistance of the SLG-capped PhC cavity obtained from experiments is lower than half of that for a bare PhC cavity. The temperature of a SLG-capped PhC cavity is 45 K lower than that without SLG capping under an optical power of 100 μW. Both the experimental and simulation results indicate that the SLG is a promising material for the heat dissipation in the compact optoelectronic devices.

9168-11, Session 3

Large-scale characterization of graphene and 2D materials *(Invited Paper)*

Maziar Ghazinejad, California State Univ., Fresno (United States)

I will discuss the current state of large-scale metrology techniques for industrial characterization of 2D materials such as graphene and MoS2. A variety of high-throughput methods for metrology of 2D materials that characterize target properties against desired metrics will be reviewed. Next, I describe how fluorescence quenching metrology (FQM) provides a scalable characterization technique to visually evaluate the quality and identify complex patterns of 2D materials sheets. The method relies on how different 2D materials will photophysically respond when they are coated with proper fluorescence dye. Steady-state and time-resolved absorption and emission spectroscopy are used to characterize the photophysical behavior of 2D materials. It is demonstrated that with an appropriate choice of Fluorophores the interaction between fluorescence dyes and 2D materials can be used for identifying the chemical structure and quality of 2D materials such as graphene. The results show that an industrial characterization technique can be developed based on the fluorescence quenching phenomenon.

9168-12, Session 3

Ultrafast carrier dynamics in graphene quantum dots

Hyojung Kim, Jihee Kim, Sungkyunkwan Univ. (Korea, Republic of); Junichiro Kono, Pulickel M. Ajayan, Rice Univ. (United States); Mun Seok Jeong, Sungkyunkwan Univ. (Korea, Republic of)

Energy bandgap engineering of graphene is one of the main topics in the research community, and thus the size of graphene has been controlled to smaller and smaller, resulting in the bandgap opening. Recently, graphene quantum dots (GQDs) have been fabricated with the size smaller than 4 nm using acidic exfoliation and etching of pitch carbon fibers, leading to strong quantum confinement. For further optical and optoelectrical applications, it is essential to investigate the dynamics of photoexcited carriers in GQDs. Here, we firstly report the carrier dynamics in GQDs using femtosecond transient absorption (TA) spectroscopy to understand the photoexcited carrier distribution, and inhomogeneously broadened absorption spectra on GQDs.

We performed TA spectroscopy with excitation wavelengths at resonance (520 nm, 2.38 eV), and above resonance (350 nm, 3.54 eV), respectively. TA signal was probed by white light continuum (WLC), ranging from 450 to 750 nm (2.75 eV~1.65 eV). To generate WLC, an amplified Ti:sapphire laser with 1-kHz repetition rate and 800 nm (1.55 eV) center wavelength was focused on the CaF2 crystal.

The power-dependent TA signal in GQDs is measured with the pump pulse at 350nm (3.54eV), which is above resonant energy. We could observe snapshots of photoexcited carrier distribution in GQDs from different time delays. The carriers decay rapidly when the excitation power is higher due to strong Coulomb interaction. Furthermore, we observed the dynamic spectral hole-burning effects in GQDs at resonant energy, 520 nm (2.38 eV). We will analyze and discuss these ultrafast carrier dynamics results in GQDs.

9168-14, Session 3

Semiconducting 2D TMDCs: synthesis and characterization

Zafer Mutlu, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Layered transition metal dichalcogenide semiconductors such as WS2 and MoS2, with an indirect band gap in bulk form and a direct band gap in monolayer layer form, exhibits tunable electronic properties, allowing realization of advanced optoelectronic devices, transistors, valley polarization devices and spintronic components. To enable practical applications of large-area, high quality 2D materials at the centimeter and wafer scales, process control needs to be implemented for optimizing the morphology and electrical properties of grown layers. Herein, we have successfully synthesized large-scale single-and few-layered MoS2 and WS2 sheets by chemical vapor deposition technique. Raman-PL spectroscopy and ab-initio density-functional-theory computations are used to evaluate the optical properties and electronic band structures of grown layers. Surface morphology, thickness and quality of the layers are studied by SEM, AFM and OM. Furthermore, we have studied the electrical transport properties of the synthesized layers using back- and top-gated FETs.

9168-15, Session 3

Simulation of Maxwell-Dirac equations in graphene nanostructures

Xuecang Zhang, Huawei Technologies Co., Ltd.. (China)

Graphene, with many supreme properties such as the extremely high carrier mobility, is a highly attractive and promising material for numerous applications, particularly in high performance electronic and photonic devices. Simulation of the coupling transport of electromagnetic fields and carriers in graphene nanostructures is of great importance for the analysis and design of graphene optoelectronic nanodevices. According to the rigorous quantum electrodynamics, the most fundamental model for this coupling transport is the Maxwell-Dirac equations. In this paper, for the first time, we derive the appropriate form of Maxwell-Dirac equations for graphene nanostructures, and propose a time splitting spectral method for the numerical solution of this multiphysics problem.

In this time splitting spectral method, we split each time step into three substeps. In each substep, we split the linear and nonlinear parts of the complicated nonlinear coupling Maxwell-Dirac system, then iteratively solving each simple part by linearizing the nonlinear part. The time derivatives are discretized by finite difference method with second order accuracy schemes. The spatial differential operators are approximated by spectral differentiation matrices. The proposed numerical method is validated by numerical examples that simulate the propagation of electromagnetic wave in graphene nanowaveguides.

9168-16, Session 3

Electron dynamics in graphite studied by femtosecond two-color pump-probe spectroscopy

Seungwon Seo, Chungnam National Univ. (Korea, Republic of); Ho Jong Kim, Su Yong Jeong, Korea Research Institute of Standards and Science (Korea, Republic of); Kwang-Jun Ahn, Seoul National Univ. (Korea, Republic of); Ki-Ju Yee, Chungnam National Univ. (Korea, Republic of)

We measured time-resolved reflectance change in graphite by two-color pump-probe spectroscopy. Graphite samples were made by the scotch tape method on a Quartz substrate with 25 nm Titanium and 300 nm SiO2 layer. The pump beam was from an optical parametric oscillator(OPO) laser. The wavelength of the OPO laser was variable, we used 1200 nm ~ 2500 nm from the signal and idler part. The probe beam was obtained from supercontinuum source that had broad wavelength, we selected 500 nm ~ 1200 nm. The experiment results show that there are two characteristic times in the decay of the reflectance. After the electrons were excited, the electron temperature is very high, as time goes on, the temperature is decreased towards the lattice temperature through the intra band relaxation process. So, the faster decay factor is related with the change of the temperature because of the Fermi-Dirac distribution. The other slower decay factor is related with the change of refractive index through the carrier recombinations. Although the recombining carriers may have lower energies than the probe photons, this process can affect the probe reflectance because of the Kramers-Kronig relation. From the change of the reflectance, absorption change can be calculated in graphite for each probe wavelength. Then, the electron temperature and chemical potential are determined by the absorption change. Finally, we map the electron distribution as a function of time delay from the obtained electron temperature and chemical potential until the excited electrons return to the initial stage.

9168-30, Session 3

Titanium carbide coated graphite: a unique material combination

Vilupanur A. Ravi, Mehrdad Haghi, California State Polytechnic Univ., Pomona (United States)

Titanium carbide-coated graphite is a novel material that combines the hardness of a ceramic with that of a soft and easily machinable substrate. There are several other advantages to this coating/substrate combination, e.g., graphite is lightweight and has excellent chemical stability while titanium carbide is also quite stable in a broad range of corrosive media while also being wear resistant. One of the unique features of this material is the specular reflection from the as-coated surface that is akin to the reflection from a polished metallic surface. There are some issues with microcracking of the coatings due to the thermal coefficient of expansion mismatch between the carbide and the graphite substrate. In this presentation, we will discuss different aspects of this material including the coating microstructure, non-stoichiometry of the coating and consequences, thermomechanical modeling, corrosion and wear/erosion behavior of the coatings. Some potential applications will be discussed as well.

9168-17, Session 4

Graphene materials for advanced energy storage *(Invited Paper)*

Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Graphene is a one atom thick two-dimensional material that exhibits exceptional physical and electronic properties, and offers alternatives for applications in energy storage devices, nanoelectronics, spintronics, biosensors, and medicine. I will describe innovative approaches for the synthesis of hierarchical three dimensional graphene hybrid materials which possess characteristics including ultra large surface area, mechanical durability and high conductivity which are appealing to diverse energy storage systems. Rapid charging and discharging supercapacitors are promising alternative energy storage systems for applications such as portable electronics and electric vehicles. Integration of pseudocapacitive metal oxides with structured nanomaterials has received a lot of attention recently due to their superior electrochemical performance. In order to realize high energy density supercapacitors, we developed a simple and scalable method to fabricate graphene/MWNT/MnO2 nanowire hybrid systems. Excellent capacitance retention and high charge-discharge cycles have been demonstrated. Next, I will talk about three-dimensional cone-shape carbon nanotube clusters decorated with amorphous silicon for lithium ion battery anodes. The seamless connection between silicon decorated CNT cones and graphene facilitates the charge transfer in the system and provides a binder-free technique for fabricating lithium ion batteries. Very high reversible capacity and excellent cycling stability has been demonstrated. Such multi-scale engineered materials could have wide range implications to facilitate new technological innovations in energy storage.

9168-18, Session 4

Thermoelectric, electro-thermal, and opto-thermal characterization of thin film CNT devices consisting of dense, aligned, and macroscopically long SWCNTs

Kristopher J. Erickson, Sandia National Labs. (United States); Xiaowei He, Rice Univ. (United States); A. Alec Talin, Bernice Mills, Sandia National Labs. (United States); Robert H. Hauge, Junichiro Kono, Rice Univ. (United States); François Léonard, Sandia National Labs. (United States)

Understanding the thermoelectric, electro-thermal and opto-thermal properties of CNT devices is critical for their application as sensors, photo-detectors, power generators and for thermal management. We investigate these properties in devices consisting of dense, aligned, and macroscopically long SWCNTs, including those with p-n junctions. Results from Joule heating, focused laser illumination, direct heating, and electronic transport experiments, with accompanying models, are presented for the thorough analysis of device thermoelectric, electro-thermal and opto-thermal properties. As example applications, we determine the ZT factor of CNT devices, and demonstrate the photothermoelectric origin of photocurrent in novel CNT IR and THz detectors.

9168-19, Session 4

Intrinsic regime of exciton photophysics in ultra-clean carbon nanotubes bridging an air gap

Ibrahim Sarpkaya, Stevens Institute of Technology (United States); Zhengyi Zhang, Columbia Univ. (United States); William Walden-Newman, Stevens Institute of Technology (United States); James Hone, Chee Wei Wong, Columbia Univ. (United States); Stefan Strauf, Stevens Institute of Technology (United States)

Carbon nanotubes (CNTs) have recently gained tremendous interest as a nanomaterial for next generation optoelectronics and quantum photonic devices.

However, to date, the photophysics of excitons in carbon nanotubes is largely affected by extrinsic effects. This is very detrimental for optoelectronic device applications since low quantum efficiencies due to dominant non-radiative optical recombination processes leads to strongly reduced optical emission rates of nanoscale light sources as compared to, e.g., semiconductor quantum dots. To overcome these extrinsic effects we have combined sophisticated growth of ultra-clean SWCNTs bridging an air gap over pillar posts with time-resolved photoluminescence measurements of individual SWCNTs over 14 orders of magnitude. Our measurements demonstrate a new regime of intrinsic exciton photophysics with narrow spectral linewidth down to 200 μeV and prolonged spontaneous emission times up to T1=18 ns, about two orders of magnitude better than prior measurements and in agreement with values(10-100ns) hypothesized by theorists about a decade ago.

With these supposedly ultraclean air-bridged samples we also carried out first experiments on exciton dephasing times for individual SWCNTs in the time-domain. The interferometric measurements demonstrated exciton dephasing times up to 2 ps, about four-fold longer than in previous ensemble studies (500 fs).

The ultra-narrow linewidth and prolonged exciton dephasing times suggest that the acoustic phonon coupling giving rise to exciton dephasing is significantly weaker than previously believed, which is promising news for device applications, and raises the question about the ultimate limit for SE lifetimes and exciton dephasing in the intrinsic regime.

9168-20, Session 4

Pillared graphene nanostructure for ultrafast charge and discharge energy storage devices

Wei Wang, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

In this work, we report on an innovative of pillared graphene nanostructures (PGN) directly on conductive substrates by an ambient

pressure chemical vapor deposition (APCVD) process. The seamless connection between current collector and activae materials provides a relatively strong electrode integrity, which facilitates charge transfer in the system. Symmetrical supercapacitors (SCs) are fabricated based on this hybrid CNT and graphene nanostructure. SCs based on PGN show superior high-rate handability of up to 100 V sec-1. The electrochemical stability, excellent capacitive performance, and the ease of preparation suggest this PGN system is promising for future energy storage applications.

9168-33, Session 4

Cu surface morphology affects on self-limiting single layer growth of graphene films by chemical vapor deposition

Isaac Ruiz, Zafer Mutlu, Robert Ionescu, Mihrimah Ozkan, Lauro Zavala, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

The synthesis of graphene with large-area uniformity is an essential requirement for their application in electronic and optical devices. Here, we reported on fast synthesis of large-scale single layer graphene with no annealing and growth times of less than 1 minute by oversaturating Cu foils with a high precursor partial pressure via chemical vapor deposition (CVD). To understand the growth mechanisms involved, the effect of Cu foil properties (purity, manufacturer and surface morphology) and growth parameters (growth time, pressure, annealing pre-treatment time and precursor partial pressure) on fast synthesis of graphene films was systematically investigated using Raman spectroscopy, atomic force microcopy, scanning electron microcopy and optical microcopy. We showed that certain foils promote self-limited growth of graphene films without any pre-treatment, while other foils favor the growth of thick graphitic like films or single- and multi-layered graphene films by depending on the type and surface morphology of Cu foils. Furthermore, we examined changes in the surface morphology of Cu foils using electropolishing. Microscopic observations revealed that surface polishing of inexpensive low purity Cu foil, which previously yielded a thick graphitic film, could promote the single layer growth of graphene with large-area uniformity.

9168-21, Session 5

Cross-linked carbon nanotube thick films

Gregory A. Konesky, K-Plasma Ltd. (United States)

The use of heat spreaders allows the thermal footprint of a semiconductor device to be expanded, permitting laser diodes to operate at higher powers or computer processing chips to operate at higher clock speeds. The heat spreader must necessarily have high thermal conductivity and be thermally isotropic. Heat spreaders have been constructed of a copper and diamond powder composite and provide a thermal conductivity typically between 600 and 800 W/m K at moderate cost. CVD diamond heat spreaders can provide thermal conductivities of 1000 W/m K but have relatively high cost. We have experimented with the use of argon ion bombardment to join adjacent and overlapping CNTs in a thick film to form a continuously interconnected network whose thermal conductivity is isotropic. A 1 cm2 film of multi-wall CNT (MWCNT), 5 µm thick was subjected to a 4 keV argon ion bombardment with a total fluence of approximately 2.25 x 10^17 ions. A change in morphology was observed, from unprocessed MWCNT films that rather resemble a “bowl of spaghetti,” to individual nanotubes being joined at points of intersection. Thermal conductivity was measured using the 3? technique and indicated an isotropic thermal conductivity of 2150 W/m K. Upon closer examination under high magnification (800,000X), it becomes clear that overlapping MWCNTs were not just attached by their outer walls, but became fully interpenetrating. A mechanism is explored whereby overlapping MWCNTs, when struck by an argon ion of sufficient energy, have that area briefly disrupted, and then self-reassemble into an interpenetrating junction.

9168-22, Session 5

Nanoporous graphene sponge for supercapacitor electrodes

Hamed Hosseini Bay, Daisy Patino, Zafer Mutlu, Paige Romero, Mihrimah Ozkan, Cengiz S. Ozkan, Univ. of California, Riverside (United States)

Graphene is a unique two dimensional material with exceptional physical and chemical properties. The theoretical surface area of graphene is reported to be 2630 m2g-1, which is significantly higher than activated carbons, graphite and single-walled carbon nanotubes. As a result, graphene and graphene based composite materials have been of great interest for various applications in energy storage/production. Accordingly, owing to its high surface area, graphene is a decent candidate as an electrode in electrochemical supercapacitors. Recent studies indicate that graphene demonstrates the highest capacitance among all carbon-based electrodes for supercapacitors. Moreover the graphene sheets surface is readily accessible by electrolyte. Herein, to increase the capacitance of graphene as well as the power and energy density, a novel porous 3-dimensional graphene-based structure is synthesized by a modified CVD method. In this case, no chemical treatment or activation is necessary and the process is not subjective to particular catalyst substrates. To prepare precursor materials for such structure, a modified sol-gel process has been implemented. Nanostructure samples were characterized by Raman Spectroscopy, Optical Microscopy, Scanning Electron Microscopy, Transmission Electron Microscopy and BET technique. Cyclic voltammetry measurements were also carried out and the results suggest that the use of 3-dimensional nanoporous graphene sponge as electrodes for supercapacitors can be a potential way to achieve enhanced gravimetric capacitance as well as higher energy and power density.

9168-23, Session 5

Enhanced D- and G-band signals from silver-dressed carbon nanotubes

Paul Dawson, Queen’s Univ. Belfast (United Kingdom); Jose A. Duenas, Univ. de Huelva (Spain); William I. Milne, Univ. of Cambridge (United Kingdom); Olivier J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Carbon nanotubes have been used as a micro- to nano-scale scaffolding for forming general SERS substrates[1,2] where the key functionalization step has been the deposition of a (highly granular) noble metal film, sometimes directly on the CNTs[1] and sometimes with an intermediate dielectric spacer[2]. Here, however, we focus on the enhanced Raman signal from the CNTs themselves where the D- and G-band signals from a forest of vertically-aligned, multi-walled CNTs are enhanced by a factor of 10-20 when dressed (capped or coated) with silver. These plasmonic structures – supporting highly localised plasmons (silver-capped case) and/or more extended optical antenna-like modes (silver-coated case) – offer a novel and unusual instance of SERS in that the enhancement interaction takes place at the inner interface of the silver dressing. Nonetheless, the enhancement is greater than that reported for nanotubes deposited on rough silver or gold substrates. Moreover, spatially resolved mapping of the D- and G- band intensities reveals good uniformity of the signal enhancement, with very few hot- or dead- spots on the ~micron scale of the focused input beam. The Ag-dressing procedure thus offers a reliable Raman-scattering based means of characterizing CNTs, but with significantly increased sensitivity, extendable to the probing of individual CNTs. The results are analysed with reference to experimental comparator cases and to modelling of the electromagnetic response of the system.

9168-24, Session 5

Nano porous graphene room temperature field effect transistor fabricated using self-assembled mask technique

Duyoung Choi, Cihan Kurua, Sungho Jin, Univ. of California, San Diego (United States)

We have successfully fabricated and characterized nano-porous graphene (NPG) with neck width of sub-20 nm. Anodized aluminum oxide nano-mask was prepared by facile and simple self-assembly technique without using polymer buffer layer, which was utilized as a template for oxygen plasma etch to produce near periodic NPG. The NPG exhibits a homogeneous mesh structure with an average neck width of 10 nm ~ 19 nm. The sub-20 nm neck width creates a quantum confinement in NPG, which has led to a bandgap opening of ~ 0.2 eV in graphene. Electronic characterization of single layer NPG field effect transistors (FETs) were performed at room temperature. We found that the NPG allows for experimental confirmation of the relationship between electrical conductance and bandgap. Electrical characterization of NPG confirmed that the current on-off ratio is inversely proportional with neck width, indicating the formation of an effective gap due to the confinement effect. The electrical resistance of the graphene increases significantly by a factor of ~x15 by removal of substantial graphene regions via nano-patterning into hexagonal array pores. It is likely that the availability of large number of edges created in the NPG provides ideal sites for chemical attachment, leading to a significant reduction of the RS. We have shown that both electronic transport and Raman characteristics change in a concerted manner on graphene patterning. The availability of such NPG will provide an interesting system for fundamental investigation of transport behavior in the highly interconnected graphene network, and will enable exciting opportunities in sensitive biosensors and a new generation of devices.

9168-29, Session 5

A comparative study of thermal interface materials with graphene, carbon nanotube, and boron nitride fillers

Fariborz Kargar, Univ. of California, Riverside (United States); S. Legedza, Quantum Seed LLC (United States); R. Salgado, P. Goli, Univ. of California, Riverside (United States); J. Renteria, Quantum Seed LLC (United States); Alexander A. Balandin, Univ. of California, Riverside (United States) and Quantum Seed LLC (United States)

Rapidly increasing power densities in electronics make efficient heat removal a crucial issue. Development of the next generations of integrated circuits requires substantially improved thermal management. Thermal interface materials (TIMs), applied between heat sources and heat sinks, are essential ingredients of thermal management. Conventional TIMs filled with thermally conductive filler materials require high volume fractions of filler (f~50%) to achieve thermal conductivity of the composite in the range of ~0.5-5 W/mK at room temperature. The discovery of unique heat conduction properties of graphene [1-2] stimulated research work directed at the use of inexpensive liquid phase exfoliated graphene as fillers for TIMs [3-4]. The present study addresses an important question of comparing graphene performance as filler materials with that of carbon nanotubes (CNTs) and boron nitride (BN) flakes. The measurements have been conducted using the standard TIM tester. Our results show that adding a small fraction of graphene (f=4%) to a commercial TIM increases the resulting thermal conductivity much stronger than the addition of CNTs or BN. The obtained data suggest that graphene and few-layer graphene couple better to the matrix materials than the alternative fillers. [1] A.A. Balandin, et al., Nano Lett., 8, 902 (2008); [2] A.A. Balandin, Nature Mat., 10, 569 (2011); [3] K.M.F. Shahil and A.A. Balandin, Nano Lett., 12, 861 (2012); [4] V. Goyal and A.A. Balandin, Appl. Phys. Lett., 100, 073113 (2012).

9169-1, Session 1

Sub-Abbe resolution in STED lithography and bio-applications *(Invited Paper)*

Thomas A. Klar, Johannes Kepler Univ. Linz (Austria)

Similar to the further development of two-photon microscopy into two-photon lithography[1], it was proposed already in the early reports of STED microscopy that the confined excitation volume can be applied to spatially control chemical reactions on the nanometer scale[2].

In this contribution, we address the question of minimal structure size and minimal resolution in STED-lithography. We show that free standing lines can be written with a lateral[3] and axial width of only 55 nm. The structures show good biocompatibility and allow for bio-functionalization with proteins, down to the single protein level[4]. The ability to place individual proteins into nano-confined spaces plays a growing role in bioscience, from basic studies in biology to the development of nanoscopic sensors.

While STED-lithography cannot (yet) compete with UV or with electron beam lithography, there is justified hope that both, feature size and resolution can further be improved within the next years, similar to STED nanoscopy which started with a resolution above 100 nm and has reached sub-10 nm resolution meanwhile. Compared to UV and e-beam lithography, STED-lithography has two major advantages. First, it is capable of three dimensional structuring. Second, photons of visible light contain much less energy compared to UV photons or accelerated electrons and hence, photosensitive substrates such as polymers or even living tissue might be structured.

9169-2, Session 1

Nanoparticle-assisted STED, theory, and experimental demonstration *(Invited Paper)*

Yannick Sonnefraud, Institut NÉEL (France); Yonatan Sivan, Ben-Gurion Univ. of the Negev (Israel); Hugo G. Sinclair, Christopher W. Dunsby, Mark A. Neil, Paul M W. French, Stefan A. Maier, Imperial College London (United Kingdom)

We show that metal nanoparticles can be used to improve the performance of super-resolution fluorescence nanoscopes based on stimulated-emission-depletion (STED). Compared with a standard STED nanoscope, we show theoretically a resolution improvement by more than an order of magnitude, or equivalently, depletion intensity reductions by more than 2 orders of magnitude and an even stronger photostabilization.

Moreover, to demonstrate the effect, we compare the resolution attained imaging dye-doped silica nanoparticles with or without a shell of gold. To do so, at first confocal images of single NPs of the two sets are recorded, followed immediately by a STED image. The same process is repeated for varying STED beam power. The resolutions obtained in both images are compared and an improvement using STED calculated. We observe that an optimum resolution, limited by the particle sizes, can be reached for the hybrid NPs for a power of the STED beam one order of magnitude smaller than for the bare cores.

This demonstration opens the door to improvement of existing STED nanoscopes by assisting in the development of low-power, low-cost nanoscopes. This has the potential to increase the availability of STED nanoscopes and lead to a significant expansion of our understanding of biological and biochemical phenomena occurring on the nanoscale.

9169-3, Session 1

Breaking diffraction limit: integrated hybird-superlens hyperlens for diffraction limit *(Invited Paper)*

Din Ping Tsai, Academia Sinica (Taiwan)

We numerically propose an innovative device for magnifying far-field image by finite element method (FEM) simulation. It possesses ability to image a sub-wavelength object at far field and compensate the drawbacks of the proposed hyperlens so far. This device is integrated with two kinds of anisotropic metamaterial, including the upper planar superlens and the lower cylindrical hyperlens, in which the signs of permittivity tensors are opposite. Since the specific dispersion relations between these two components, such proposed device is named as the "Hybrid-Superlens Hyperlens", which is capable of deriving the high spatial-frequency components excited by the objects on one flat surface and transferring it to far field.

Basically, the polarization of light source is an important factor for plasmon based imaging devices because it may affect the integrity of resolution image which is resulting from the excited surface plasmon polarions (SPPs) near the patterned region. Therefore, we also theoretically investigated the imaging characteristics of hybrid-super-hyperlens with both linearly and radially polarized illumination. We further demonstrate that the whole magnifying far field images can be obtained at one scan procedure by using radially polarized light source, that is, superposition of the images under incident light with different polarized directions is unnecessary. This planar shape design has great potential for practical applications such as photolithography and planar integrated optical devices.

9169-4, Session 1

Conical diffraction as a versatile building block to implement new imaging modalities for superresolution in fluorescence microscopy

Clément Fallet, Julien Caron, Stephane Oddos, Bioaxial (France); Jean-Yves Tinevez, Institut Pasteur (France); Lionel Moisan, René Descartes Univ. (France); Gabriel Y. Sirat, Philippe O. Braitbart, Bioaxial (France); Spencer L. Shorte, Institut Pasteur (France)

We present a new technology for super-resolution fluorescence imaging, based on conical diffraction. Conical diffraction is a linear, singular phenomenon taking place when a polarized laser beam is diffracted through a biaxial crystal. The illumination patterns generated by conical diffraction in thin biaxial crystal that are sharper than the classical Gaussian beam, and we use them to generate a super-resolution imaging modality.

Whereas most of the current technologies in superresolution use non-linear processes and require high quality immersion objectives and dedicated sample preparation, Bioaxial SuperResolution (BSR) resolution enhancement can be achieved with any type of objective no matter the magnification, numerical aperture, working distance, or the absence or presence of immersion medium on any kind of sample preparation and standard fluorophores.

The system generates datasets made of thousands of images, one for each beam shape and beam position, similarly to some other Image Scanning techniques. Given the low light doses used in each image, the data formation derives from a linear model with limits predicted by Fourier analysis and recent superresolution theory developments. In the framework of Bayesian Inverse Methods, we developed two numerical solvers which exploit the data formation model and the noise distribution in modern low-light cameras.

This technique has been successfully used for live-cell super-resolution imaging over a long period, and shows that the light dose required for super-resolution imaging is far below the threshold likely to impact phototoxicity.

9169-5, Session 2

Correlation studies between localized surface plasmons and surface-enhanced Raman scattering of Gold-Silver NanoDumbbells (GSNDs) at the single-particle and single-molecule level *(Invited Paper)*

Haemi Lee, Korea Research Institute of Chemical Technology (Korea, Republic of); Yung Doug Suh, Korea Research Institute of Chemical Technology (Korea, Republic of) and Sungkyunkwan Univ. (Korea, Republic of)

Fabricated plasmonic nanostructures (especially structures with plasmonic nanogap) have been of major interest to scientific and engineering communities because of their interesting and useful optical properties. However, the exact relationships between their structure and various optical properties such as surface-enhanced Raman scattering (SERS) and localized surface plasmon (LSP) are not clearly known yet, and it still requires deeper understanding of their relationships between structure and optical properties for the reliable utilization of these structures in various applications. In particular, SERS originates from a highly localized region referred to as hot spot in a plasmonic gap typically with less than a few nanometers whereas Rayleigh scattering originates from the induced dipole moment occurred near a nanostructure. Such distinct physical origins thus invoke the intrinsic limitation in correlation of those optical signals.

In this talk, we present that there is a strong positive relationship between the coupled dipolar/quadrupolar LSPs and SERS intensity of dimeric Au-Ag core-shell nanodumbbell (GSND) structures with ~0.9-nm nanogap, using a multistep tip-matching-based high-precision correlation measurement. Our result can be particularly useful in probing the complicated interactions among the different modes of LSPs, thereby elucidating the relationship between the SERS activity and LSPs in which complex interactions of each LSP mode are involved (H. Lee et al. Nano Lett. 2013, 13, 6113). This observation thus suggests that our correlation approach using Rayleigh scattering and SERS is useful and could overcome the intrinsic limitation in correlating Rayleigh scattering with SERS caused by the difference in the far-field and near-field characteristics of Rayleigh scattering and SERS, respectively. Also, we present there is a specific interaction between longitudinal quadrupolar and transverse dipolar LSPs from a minor population of dimers and show that this interaction results in a strong SERS signal.

9169-6, Session 2

3D plasmonic nano imaging and spectroscopy of a living cell with a gold nanoparticle *(Invited Paper)*

Satoshi Kawata, Katsumasa Fujita, Nicholas I. Smith, Osaka Univ. (Japan); Jun Ando, RIKEN (Japan); Kazuki Bando, Osaka Univ. (Japan); Kai-Chih Huang, National Taiwan Univ. (Taiwan)

Raman scattering microscopy visualizes molecular distribution in a sample without any labeling or modification [1]. Tip-enhanced Raman scattering (TERS) microscope has been successfully used for visualizing molecular distribution at nanometer resolution, while its application is limited to surface imaging [2]. We have developed a SERS microscope with a gold nanoparticle as a probe, which is captured in a biological cell and works as a nano-light source [3]. The nanoparticle travels inside the cell, meeting local molecules. Raman signal scattered at a local molecule along the path is enhanced by the nanoparticle. As a result, molecular distribution along the cellular pathway is collected. The nanoparticle position in during motion was precisely tracked with high-resolution CCD in three dimensions through a dual-focus dark-field microscope, while Raman scattering is detected with spectrophotometer with the feedback system to control the particle image fixed at the slit [4]. We achieved a temporal resolution of 100ms for both particle tracking and Raman spectroscopy. In the presentation, we will show the result of molecular imaging in a living cell in three dimensions, which represents the cellular function of biomolecules associated with organelle transportation and lysosomal accumulation.

9169-7, Session 2

Residual pesticide detection on food with particle-enhanced Raman scattering

Bikas Ranjan, Huang LiChuan, Kyoko Masui, Yuika Saito, Prabhat Verma, Osaka Univ. (Japan)

Modern agriculture relies highly on pesticides to protect agricultural food items from insects for high yield and better quality. Increasing use of pesticides has raised concern about its harmful effects on human health and hence it has become very important to detect even small amount of pesticide residues. Raman spectroscopy is a suitable nondestructive method for pesticide detection, however, it is not very effective for low concentration of pesticide molecules. Here, we report an approach based on plasmonic enhancement, namely, particle enhanced Raman spectroscopy, which is rapid, nondestructive and sensitive. In this technique, Raman signals are enhanced via the resonant excitation of localized plasmons in metallic nanoparticles. As plasmonic resonance frequency highly depends on the shape, size and material of nanostructures, hence it is possible to grow nanoparticles of a chosen shape and size to tune its plasmonic resonance with the resonance of Raman signals of any desired pesticide for better enhancement. Gold is a promising material that has ability to tune surface plasmon resonance frequency in visible to near-IR, which depends on shape and size of nanostructures. We synthesized desired shape and size of gold nanoparticles by using seed mediated growth method, and successfully detected very tiny amount of two pesticides, named benomyl and polycarbamate. We also confirmed that the detection of these pesticides was not possible by usual Raman spectroscopy.

9169-8, Session 2

Multi-wavelength surface-enhanced Raman scattering metasurface with broadband absorption over large area

Nan Zhang, Kai Liu, Haomin Song, Xie Zeng, Dengxin Ji, Qiaoqiang Gan, Univ. at Buffalo (United States)

Surface-enhanced Raman spectroscopy (SERS) refers to a vibrational spectroscopy technique for the characterization of low concentration analytes bound to or near plasmonic surfaces. It has been widely used as a highly surface-sensitive and label-free analytical technique for chemical and biological sensing applications down to single molecule level. Therefore, substrates with localized enhanced electromagnetic field that can excite strong Raman scattering are heavily required. Current dominant substrate fabrication techniques include electron beam lithography, nanoimprint, self-assembled nanosphere, and hybrid nanoporous lithography, which are time-consuming and costly methods only suitable over small areas. In addition, most SERS substrates were designed for a particular excitation wavelength only, which limited measurements of different molecules excited by the optimal laser lines

with higher SERS signals. To overcome these limitations, we report a simple and cost-effective method to manufacture large-scale three-layered super absorptive SERS metasurfaces using direct sputtering deposition. By controlling the deposition and post thermal treatment conditions, random metallic nanoparticles can be formed simply on a diverse range of substrates to function as the nanoantennas supporting strongly enhanced localized plasmon modes. Due to the randomly distributed dimension of these nanoantennas, broadband plasmonic absorption over 80% ranging from 450 nm to 1000 nm can be obtained, which generates strong enhancement of the excitation and Raman scattered signal simultaneously. Using this substrate, we achieved a high area-average EF of 8.2 x 10^6 and excellent uniformity with only 14.5% variation simultaneously over the entire sample area, which is better than many commercial SERS substrates.

9169-9, Session 3

Superresolution microscopy through thick tissue using adaptive optics *(Invited Paper)*

Brian R. Patton, Robert Vrees, Daniel Burke, Univ. of Oxford (United Kingdom); Travis J. Gould, Joerg Bewersdorf, Yale School of Medicine (United States); Martin J. Booth, Univ. of Oxford (United Kingdom)

Superresolution microscopes have been able to resolve features on the scale of tens of nanometers and lower. These microscopes - including scanning methods (STED, RESOLFT, etc.) and stochastic wide field methods (PALM, STORM, GSDIM, etc.) - all suffer from the effects of aberrations that compromise resolution, signal and consequently image quality. Adaptive optics has been demonstrated in a range of diffraction-limited resolution microscope modalities to compensate for system and specimen-induced aberrations. However, the use of adaptive optics in superresolution microscopes presents new challenges. We investigate how aberrations affect the properties of superresolution microscopes and develop new adaptive optics schemes to measure and correct the aberrations. In particular we show how the commonly-used 2D STED configuration is robust to aberrations, whereas the 3D STED configuration is particularly sensitive. A new scheme is presented that permits the adaptive compensation of aberrations in the 3D STED microscope through optimization of a new application of the Fourier Ring Correlation image quality metric. This system is used to perform three-dimensionally resolved superresolution imaging through thick (~10 to 50 micrometre) specimens. Significant improvements in resolution and image intensity are achieved. The adaptive correction of specimen-induced aberrations in this manner will be an essential step to the wider use of superresolution methods in a wider range of biologically relevant specimens.

9169-10, Session 3

Adaptive optics STED microscopy in thick biological tissue *(Invited Paper)*

Mary Grace M. Velasco, Travis J. Gould, Edward Allgeyer, Emil Kromann, Yale Univ. (United States); Daniel Burke, Martin J. Booth, Univ. of Oxford (United Kingdom); Joerg Bewersdorf, Yale Univ. (United States)

Super-resolution microscopy techniques have realized sub-diffraction limit resolution on the order of tens of nanometers. For thick samples such as tissue sections, stimulated emission depletion (STED) microscopy is the preferred super-resolution method due to its basis on a confocal laser scanning geometry that provides optical sectioning. To achieve super-resolution, STED microscopy incorporates a high-intensity “donut-shaped” laser focus into a conventional confocal setup. If this focus is super-imposed onto the diffraction-limited focus of the excitation laser, fluorophores at the periphery of the excitation focus will be quenched via STED while those in the center can still fluoresce. In this way, the effective point-spread function is engineered to a sub-diffraction size.

The quality of the donut is critical to achieving super-resolution via STED. If the intensity in the donut center is non-negligible, fluorescence will be suppressed in that region as well, thus negating any resolution enhancement. This is of particular concern when attempting 3D STED in thick tissue sections since sample-induced aberrations compromise the quality of the donut shape and impose a practical limit on the maximum depth to which one can image. To overcome this constraint, we employ adaptive optics to correct specimen-induced aberrations. Using spatial light modulators and a novel image quality feedback metric, we demonstrate on-the-fly correction of the random aberrations introduced by a thick tissue sample. This implementation of adaptive optics can be modified for use in in vivo neuroimaging via STED, which has to date been limited to the superficial layers of the mouse cortex.

9169-11, Session 3

Size matters: STED imaging of functional neuroanatomy *(Invited Paper)*

Valentin Nägerl, Univ. Bordeaux Segalen (France) and CNRS (France)

Neurons span an incredibly complex and beautiful morphology, which is absolutely critical for their function and plasticity. Many key neuronal structures like dendritic spines, axons and glial processes are way too small to be properly resolved by conventional light microscopy, making it difficult to study how the functioning of synapses, neurons and circuits is influenced by dynamic nanoscale anatomical structures.

I will review our progress in developing STED microscopy, which provides optical resolution beyond the diffraction barrier, for nanoscale imaging in living brain slices and in vivo, and present several applications regarding synapse biology: 1) nanoscale imaging up to 100 µm below tissue surface in acute brain slices by a combination of two-photon excitation and STED microscopy; 2) regulation of synapse compartmentalization by spine neck plasticity based on a combination of STED imaging, FRAP, patch-clamp electrophysiology and 2P glutamate uncaging experiments; and 3) nanoscale morpho-functional plasticity of axons during LTP by time lapse STED imaging, electrophysiological recordings and computational modeling.

9169-12, Session 3

Three-dimensional optical nanoscopy with opposing lenses

Alexander Egner, Laser-Lab. Göttingen e.V. (Germany)

Far field optical microscopy is a well established method for the non-invasive 3D-investigation of cellular structures. However, the resolution of conventional light microscopy is limited by diffraction to ~200nm in the focal plane and ~600nm along the optic axis. In order to discern identical labels which are much closer than this, one has to overcome the diffraction barrier. The utilization of optical switching events allows one to circumvent Abbe’s diffraction limit: The switching of only markers within an area which is much smaller than the size of a diffraction limited spot to a visible “bright” state while all other markers are switched to a non-visible “dark” state defines a sub-diffraction area. By sequentially recording all areas within the diffraction spot, it is possible to assemble a sub-diffraction image. The first radical concept for improving the resolution of a far field microscope was Stimulated Emission Depletion (STED) microscopy. In this concept the saturated depletion of the excited state of the fluorescent molecule is used to generate a fluorescent spot that is narrower than the diffraction limit. isoSTED microscopy proved a resolution of up to 21 nm in the lateral and 30 nm in the axial direction, meaning that the resolution is higher by more than an order of magnitude as compared to confocal microscopy.

9169-13, Session 3

Using optical lattice for STED parallelization

Bin Yang, Institut d'Optique Graduate School (France); Frédéric Przybilla, Michael Mestre, LP2N,Institut d'Optique d'Aquitaine (France); Jean-Baptiste Trebbia, Brahim Lounis, Institut d'Optique Graduate School (France)

Recent developments in stimulated emission depletion (STED) nanoscopy achieved nanometer scale resolution and showed great potential in live cell imaging. However, STED nanoscopy is a scanning microscope, which constitutes a drawback for fast wide field imaging, since the gain in spatial resolution requires dense pixelation and hence long recording times. Thus STED needs parallelization for fast wide-field imaging. Using well-designed optical lattices for depletion together with wide-field excitation and a fast camera for detection, we achieve large parallelization of STED nanoscopy. Wide field of view super-resolved images are acquired by scanning over a single unit cell of the optical lattice, which can be as small as 290 nm * 290 nm. Optical Lattice STED imaging is demonstrated with a resolution down to 70 nm at 12.5 frames per second.

9169-14, Session 4

Plasmon-assisted chemical reactions revealed by high-vacuum tip-enhanced Raman spectroscopy *(Invited Paper)*

Shuaicheng Lu, Shaanxi Normal University (China); Shaoxiang Sheng, Institute of Physics (China); Zhenglong Zhang, Shaanxi Normal University (China); Hongxing Xu, Institute of Physics (China); Hairong Zheng, Shaanxi Normal University (China)

With strong surface plasmons excited at the metallic tip, tip-enhanced Raman spectroscopy (TERS) has both high spectroscopic sensitivity and high spatial resolution, and is becoming an essential tool for chemical analysis. It is a great challenge to combine TERS with a high vacuum system due to the poor optical collection efficiency. We used our innovatively designed home-built high vacuum TERS (HV-TERS) to investigate the plasmon-driven in-situ chemical reaction of 4-nitrobenzenethiol p-aminothiophenol (PATP) molecules dimerizing to dimercaptoazobenzene, respectively. The chemical reactions can be controlled by the plasmon intensity, which in turn can be controlled by the incident laser intensity, tunneling current and bias voltage. The different substrates of gold and silver films will influence not only the chemical reactions, but also the measured spectroscopic features. The temperature of such a chemical reaction can also be obtained by the clearly observed Stokes and Anti-Stokes HV-TERS peaks. Our findings offer a new way to design a highly efficient HV-TERS system and its applications to chemical catalysis and synthesis of molecules, and significantly extend the studies of chemical reactions.

9169-15, Session 4

Tip-enhanced Raman investigation of "x-shaped" carbon nanotube

Prabhat Verma, Yoshito Okuno, Yuika Saito, Satoshi Kawata, Osaka Univ. (Japan)

The electronic properties of SWNTs can change with deformation, which can be very interesting for devices where one would like to play around with the electronic properties. However, usual Raman microscopy cannot reveal the localization of such changes. In fact, the semiconducting SWNTs can locally show metallic characteristics even with a slight deformation, such as the one caused by the pressure of one SWNT crossing over the other in "X" shape. The effect, however, is extremely localized. We present TERS investigation of extremely localized semiconductor-to-metal transition of SWNTs in such a situation.

9169-16, Session 4

The origin of interferometric effect in scattering near-field scanning optical microscopy

Yan Li, Nan Zhou, Purdue Univ. (United States); Edward C. Kinzel, Missouri Univ. of Science and Technology (United States); Xifeng Ren, Univ. of Science and Technology of China (China); Xianfan Xu, Purdue Univ. (United States)

Scattering near-field scanning optical microscopy (s-NSOM) has been widely used to investigate optical interactions beyond the diffraction limit. With the use of heterodyne or pseudo-heterodyne method, the background noise in s-NSOM can be significantly suppressed, and both amplitude and phase of optical near field can be resolved. Meanwhile, interference patterns are still often observed in s-NSOM measurements. In this work, we investigate the formation of interference patterns appearing in s-NSOM results. We use a single nanoslit to demonstrate the mechanism of formation of these interference patterns: the interaction between the in-plane component of the incident light and SPP launched by the nanoslit. This is in contrast to some other explanations that the SPP is launched from the NSOM probe. In the experiment, we observe a change of periodicity in the interference patterns as the orientation of nanoslit changes. In addition, by changing the laser focusing position relative to the nanoslit, we also observe a variation in the strength of interference, demonstrating SPP launched by the nanoslit is involved in the process. We also use an analytical model and numerical simulations to compute the formation of interference patters. The calculation results reasonably agree with the measurement results, validating the mechanism we proposed. This study will help to understand s-NSOM results from plasmonic nanostructures.

9169-17, Session 4

Aperture-SNOM reveals plasmonic magnetic near-fields

Niels Verellen, Katholieke Univ. Leuven (Belgium) and IMEC (Belgium); Denitza Denkova, Katholieke Univ. Leuven (Belgium); Alejandro V. Silhanek, Univ. de Liège (Belgium); Ventsislav K. Valev, Univ. of Cambridge (United Kingdom); Pol Van Dorpe, IMEC (Belgium) and Katholieke Univ. Leuven (Belgium); Victor V. Moshchalkov, Katholieke Univ. Leuven (Belgium)

We report mapping of the lateral magnetic near-field distribution of plasmonic resonant modes in different nanostructure geometries by a hollow-pyramid probe aperture-SNOM. By means of full-field simulations we investigate how the near-field probe acts as a confined local light source and how it efficiently excites surface plasmons. This excitation occurs at lateral magnetic field maxima and affects the detected light intensity, enabling the visualization of the lateral magnetic near-field distribution of surface plasmon modes with subwavelength spatial resolution. Our approach complements the available methods for imaging the different field components of light.

9169-18, Session 4

Development of a plasmonic tip for the localized studies of magnetic materials

Joshua F. Einsle, Alexander Amy, Queen's Univ. Belfast (United Kingdom); Thomas H. J. Loughran, Euan Hendry, Robert J. Hicken, Univ. of Exeter (United Kingdom); Robert M. Bowman, Paul Dawson, Queen's Univ. Belfast (United Kingdom)

Coupling light into plasmonics excitations on metal dielectric nanostructures has been demonstrated to result in the ability to focus electromagnetic waves for sub-wavelength resolution. (Gramotnev & Bozhevolnyi, 2013) This focusing property has been incorporated into a variety of scanning probe tip systems for improved spatial resolution of nanostructures.(Bao et al., 2012; Johnson et al., 2012; Lindquist, Johnson, Nagpal, Norris, & Oh, 2013; Lindquist, Nagpal, Lesuffleur, Norris, & Oh, 2010; Weber-Bargioni & Schwartzberg, 2011) In all of these systems the response of the sample under study is assumed to have minimal to no impact on the polarization of the electromagnetic wave. Essentially the input and output polarization states are the same. However, for the nanoscale optical study of magnetic systems via the magneto optical Kerr effect, the probing structure needs be able to quantifiably discriminate changes in polarization. Further, in the context of heat-assisted magnetic recording it has been suggested that three-dimensional plasmonic devices offer the ability to both induce both an electromagnetic enhancement as well as sub-wavelength localization in the magnetic material. (Kryder et al., 2008) In this work we will present a variety of gold plasmonics antennas for integration into a Time-Resolved Scanning Kerr Microscope, which address these three key properties (localization, enhancement and polarization discrimination). These devices will allow for the possibility to optically explore the characteristic length scales over which a non-local spin transfer torque may act. This provides an interesting intersection of plasmonics and spintronics.

9169-19, Session 4

Effect of metal tip localized surface-plasmon mode on exciton transport in and radiation emission properties in carbon nanotubes

Andrei Piryatinski, Oleksiy Roslyak, Los Alamos National Lab. (United States); Charles Cherqui, Univ. of Washington (United States); David H. Dunlap, The Univ. of New Mexico (United States)

We report on a general theoretical approach to study exciton transport and emission in a Single-Walled Carbon Nanotube (SWNT) in the presence of a localized Surface-Plasmon (SP) mode within a metal tip interacting via near-field coupling. We derive a set of quantum mechanical equations of motion and approximate rate equations that account for the exciton, SP, and the environment degrees of freedom. The material equations are complemented by an expression for the radiated power that depends on the exciton and SP populations and coherences, allowing for an examination of the angular distribution of the emitted radiation that would be measured in experiment. Numerical simulations for a (6,5) SWNT and cone-shaped Ag metal tip (MT) have been performed using this methodology. Comparison with physical parameters shows that the near-field interaction between the exciton-SP occurs in a weak coupling regime, with the diffusion processes being much faster than the exciton-SP population exchange. In such a case, the effect of the exciton population transfer to the MT with its subsequent dissipation (i.e., the F"{o}rster energy transfer) is to modify the exciton steady state distribution while reducing the equilibration time for excitons to reach a steady sate distribution. We find that the radiation distribution is dominated by SP emission for a SWNT-MT separation of a few tens of nanometers due to the fast SP emission rate, while the exciton-SP coherences can cause its rotation.

9169-20, Session 4

Extending the functions of scanning near-field optical microscopy *(Invited Paper)*

Anke Horneber, Marius F. van den Berg, Jan Rogalski, Eberhard Karls Univ. Tübingen (Germany); Kathrin Swider, Eberhard Karls University (Germany); Kai Braun, Eberhard Karls Univ. Tübingen (Germany); Martin Meixner, Eberhard Karls University (Germany); Alfred J. Meixner, Dai Zhang, Eberhard Karls Univ. Tübingen (Germany)

Scanning near-field optical microscopes (SNOM) are able to correlate local optical properties with topography at the nanometer scale, ideal to investigate material properties. Introducing new microscope functions offer us insights into various aspects, such as morphology related photophysical and photochemical processes.

Using the "lightning rod" and plasmonic effects at an optically excited sharp gold tip apex, our parabolic mirror assisted SNOM has the capability to get below the diffraction limit, improving the optical resolution down to sub-30 nm [1-4]. In order to deal with materials with different optical and conductive properties or surface characteristics, our group further extended the present shear-force feedback based SNOM by introducing three new functions.

• Integrating a scanning tunneling microscope (STM) feedback function: Local structural property related Raman peak shifts and PL intensity variations in graphene will be demonstrated.

• Integrating a photocurrent microscopy function: Raman and photoluminescence spectroscopy combined with local photocurrent detection will be used to investigate the influences of local morphology on the photophysical and photochemical processes in ?-conjugated optoelectronic materials.

• Integrating an ultrafast laser system: Non-linear optical microscopy with signals, such as two-photon-luminescence and second-harmonic-generation, combined with hyperspectral SNOM imaging will be used to study the influences of plasmonic resonances on the non-linear optical properties of metallic nanostructures.

9169-21, Session 5

Sensitivity, resolution, and speed in detection and tracking of biomolecules *(Invited Paper)*

Jens Ehrig, Marek Piliarik, Susann Spindler, Siegfried Weisenburger, Vahid Sandoghdar, Max-Planck-Institut für die Physik des Lichts (Germany)

Some of the exciting challenges of modern biology and biophysics concern efforts to surpass the limits of conventional optical imaging. In particular, novel contrast mechanisms, sensitivity, signal acquisition rate and spatial resolution have been substantially improved over the past two decades.

In localization microscopy, photobleaching of fluorophores typically limits the localization precision to a few tens of nanometers in state of the art experiments at room temperature. We recently demonstrated Angstrom localization precision by substantially enhancing photostability at cryogenic temperatures [1]. We have now extended this technique to colocalization of two fluorophores on the backbone of a double-stranded DNA. By measuring the separations of fluorophore pairs placed at various design positions, we verify the feasibility of cryogenic distance measurement with sub-nanometer accuracy [2].

The second part of the talk will focus on optical imaging via interferometric scattering detection microscopy (iSCAT) which relies on measuring the interference of the Rayleigh scattering with a reference light beam. Thus, the signal is proportional to the amplitude rather than intensity of the scattered light and allows for the detection of very weak scattering. We demonstrate that using iSCAT it is possible to detect the scattering of individual proteins as small as 60 kDa [3].

Furthermore, using iSCAT we study the diffusion of very small gold nanoparticles (typically 20 nm) attached to GM1 or DOPE lipids in DOPC lipid bilayers at frame rates of up to 1 MHz with nanometer precision [4]. We thus present a very powerful single particle tracking approach that has the potential to resolve some of the longstanding questions of the temporal and spatial scales of heterogeneities in local lipid and protein composition in cell membranes.

9169-22, Session 5

Nanoscale imaging of neurotoxic proteins *(Invited Paper)*

Clemens Kaminski, Univ. of Cambridge (United Kingdom)

Nanoscale Imaging of Neurotoxic Proteins

Misfolding and aggregation of peptides and proteins is a characteristic of many neurodegenerative disorders, including Parkinson's Disease (PD) and Alzheimer's (AD). Their common feature is that normally unstructured and soluble proteins, misfold and aggregate into insoluble amyloid fibrils, which make up the deposits in the brains of patients suffering from these devastating illnesses. A key requirement to gain insight into molecular mechanisms of disease and to progress in the search for therapeutic intervention is a capability to image the aggregation process and structure of ensuing aggregates in situ.

In this talk I will give an overview of research to gain insight on the aggregation state of alpha synuclein (relevant to PD) beta-amyloid and Tau (relevant to AD) in vitro [1], in cells [2] and in live model organisms [3].

In particular we wish to understand how these and similar proteins nucleate to form toxic structures and to correlate such information with phenotypes of disease [3]. I will show how direct stochastic optical reconstruction microscopy, dSTORM, is capable of tracking amyloidogenesis in vivo and how we can correlate the appearance of certain aggregate species with toxic phenotypes [4].

Using multiparametric imaging methods we follow the trafficking of aggregates between cells and see how the misfolded state propagates from cell to cell. I will show how such information at the molecular level guides our understanding of disease pathology in humans.

9169-23, Session 5

Optimization of image acquisition parameters for high-speed single molecule switching nanoscopy

Yu Lin, Joerg Bewersdorf, Jane Long, Fang Huang, Whitney Duim, Yale Univ. (United States)

Single Molecule Switching Nanoscopy (SMSN) is a fluorescence microscopy technique that breaks the diffraction limit of resolution at the expense of an increased image recording time. The spatiotemporal resolution of SMSN strongly depends on localization precision, localization density and the photoswitching rate of the fluorophores. Recently, we have reported advances in improving temporal resolution down to 33 ms by combining new sCMOS camera technology, novel sCMOS-specific localization algorithms and high readout laser intensities to induce rapid fluorophore blinking for fast SMSN imaging.

Here we present a study systematically optimizing of excitation laser intensity and camera frame rate to achieve both high precision and high density localizations within a limited time. We performed SMSN on microtubules (MT) of COS7 cells (immuno-labeled for α-tubulin with Alexa 647) at varying laser intensities and frame rates and measured the number of photons detected per switching cycle, the localization uncertainty and density. Our data reveals that laser intensity or exposure time have only a small effect on photon output of Alexa 647. Furthermore, we also demonstrates that imaging at 800-1,600 frames per second (fps) at intensities up to 113 kW/cm2 provides nearly uncompromised localization precision and >3-fold higher localization density in a 10-second interval, than imaging at 50-100 fps at an intensity of 10 kW/cm2 (used traditionally in SMSN).

9169-24, Session 5

High speed fluorescence photoactivation localization microscopy imaging

Andrew J. Nelson, Mudalige S. Gunewardene, Samuel T. Hess, Univ. of Maine (United States)

Fluorescence Photoactivation Localization Microscopy requires the sample of interest to be tagged with a fluorescent label with at least one bright and at least one dark state. Imaging conditions need to be such that most of the label molecules are in the dark state. Typically, the sample is illuminated by two wavelengths of light, an activation wavelength which drives molecules from the dark state to the bright state, and a readout wavelength to excite fluorescence of the molecules in the bright state. At proper intensities, only a subset of the total number of fluorescent molecules will be visible; these molecules are imaged by a camera as a function of time. Eventually, the fluorophores will photobleach, allowing room for new molecules to become activated, fluoresce, and imaged. After many molecules have been imaged, a computer can localize the position of the detected molecules in each frame with uncertainty of a few tens of nanometers. The superresolution image is then constructed from all the localized points. Typically this process can require several seconds to acquire enough data to render an image, which yields a temporal resolution of a few seconds, which is in many cases not suitable for imaging the highly dynamic environment of a living sample. Recently, we have developed methods for imaging fluorescent proteins in living cells with a time resolution of 0.1 seconds, allowing for faster and more representative imaging of living samples. High speed imaging requires high laser intensities and particular attention to limiting sample exposure and optimizing signal to noise. Despite the limitations and challenges of high speed superresolution imaging, these techniques offer researchers the ability to explore an even larger variety of dynamic biological systems.

9169-25, Session 6

Plasmon enhanced spectroscopies *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Metallic nanostructures with their ability of confining and enhancing incident light offer unique possibilities for manipulating light at the nanoscale.[1] Plasmonic nanostructures can also exhibit coherence effects such as Fano resonances where the interference between superradiant and subradiant modes produces extinction features with characteristic narrow and asymmetric line shapes.[2] Due to their narrower spectral width compared to standard plasmon resonances, Fano resonances can provide very large field enhancements.[3] Using symmetry breaking it is possible to tune the Fano interference into specific regimes: a weak coupling regime suitable for LSPR sensing; and a critical coupling regime providing large field enhancements suitable for plasmon enhanced spectroscopies. Finally I will discuss several recent applications where plasmonic Fano resonances have been used to enhance surface enhanced spectroscopies such as SERS[4],four wave mixing,[5] and SECARS.[6]

Surface enhancement in UV with variety of nanostructures *(Invited Paper)*

Yuika Saito, Satoshi Kawata, Osaka Univ. (Japan); Atsushi Tagushi, Tokyo Univ. of Agriculture and Technology (Japan); Yasuaki Kumamoto, RIKEN (Japan); Mitsuhiro Honda, Prabhat Verma, Osaka Univ. (Japan)

Localized surface plasmon resonances (LSPRs) have formed the basis of a wide range of nanophotonics research and technologies, including surface-enhanced spectroscopy (SERS) and nano-imaging, ultratrace biochemical sensing, subwavelength optical waveguiding and light manipulation, and light emitters and photovoltaic cells with boosted efficiencies. Although technological developments in these applications have predominantly focused on the visible and near-infrared (NIR) spectral range over the years, there is increasing interest in extending the technology to UV wavelengths. A potential advantage of UV plasmons is the high photon energy that matches the electronic transition energy of many organic molecules and solids. The electronically resonant excitations of materials can be favorably combined with various spectroscopic techniques, such as Raman and fluorescence spectroscopy, which will broaden the scope of the spectroscopic applications of LSPR to include ultra-sensitive detection of DNA and proteins, UV material characterization, and UV nanoimaging.

We performed size-controlled fabrication of Al nanostructure arrays with the aim of providing direct control of the LSPR at UV wavelengths. In order to achieve ultrasmall Al nanostructures, nanosphere lithography (NSL) was used in combination with mask heating to modify the nanosphere mask morphology. By adjusting the fabrication condition, the size of the aperture was continuously reduced until it became infinitesimally small, which realized seamless size reduction of the fabricated aluminum nanostructure.

The fabricated metal nanostructures were actually utilized for surface enhancement in UV range. We will present the application of these nanostructures for SERS and photocatalytic reactions.

9169-27, Session 6

Control over plasmon enhanced Raman and fluorescence from quasi free-standing Au nanorod arrays

Signe Damm, Frances Lordan, Univ. College Dublin (Ireland); Antony P. Murphy, Queen's Univ. Belfast (United Kingdom); Mark McMillen, Queen's University Belfast (United Kingdom); Robert J. Pollard, Queen's Univ. Belfast (United Kingdom); James H. Rice, Univ. College Dublin (Ireland)

Nanoscale structures made from coinage metals such as gold or silver possess localized surface plasmon-polariton (LSP) excitations when the material interacts with light of the correct frequency and polarization. When LSPs are formed strongly enhanced electromagnetic near-fields are generated at the surface of the supporting nanostructure. This property has attracted considerable research interest due to its potential applications in sensors, photonic circuits and medical diagnostics and therapeutics. Metallic nanostructures that possess anisotropic symmetry, such as quasi free-standing Au nanorods and nanotubes, are reported to produce localized surface plasmon-polariton resonances (LSPRs) with high quality factors. LSPs generated from free-standing 2D nanorod and nanotube arrays have been applied to enable surface-enhanced Raman scattering (SERS) and surface enhanced fluorescence (SEF) spectra from Rhodamine 6G molecules adsorbed on the surface of the arrays. Measuring SERS and SEF simultaneously is potentially attractive for sensor applications. But at present, the challenge is to fabricate conditions that enable both SERS and SEF responsive from nanoprobes since the optimum distance between metal surface and probe molecule for enhancing fluorescence emission and Raman scattering is different. Here we study the conditions that optimize SERS and SEF from free-standing Au nanorod and nanotube arrays by studying the effect of changing the surrounding environment using dielectric spacer layers such as Al_2O_3, SiO_2 and solutions. We demonstrate that it is possible to obtain SERS and SEF simultaneously from Au nanorod and nanotube arrays.

Optical antennas for nanoscale materials characterization *(Invited Paper)*

Joanna Atkin, Univ. of Colorado at Boulder (United States)

Scattering-scanning near field optical microscopy (s-SNOM) consists of focusing light onto a sharp metal tip, which acts as an optical antenna to localize and enhance the optical field. This approach is compatible with a wide variety of excitation sources, including ultrafast and broadband, and optical modalities. This allows an unprecedented degree of specificity, sensitivity, and selectivity with respect to functional features of materials systems, with nanometer spatial resolution and femtosecond temporal resolution. I will discuss several specific molecular and solid state systems which display some form of spatial inhomogeneity that can be probed with s-SNOM.

In addition, I will discuss the combination of plasmonic and optical antenna concepts with ultrafast and shaped laser pulses, to provide the precise control of an optical excitation on femtosecond time and nanometer length scales. I will present a new concept extending tip-enhanced spectroscopy into the nonlinear and ultrafast regime for background-free nano-scale imaging and spectroscopy, based on adiabatic nano-focusing on a tip. I will discuss the potential of this approach for implementing radiative decay engineering and coherent control.

9169-29, Session 7

Super-resolution confocal micrsocopy using optical saturation *(Invited Paper)*

Katsumasa Fujita, Nicholas I. Smith, Osaka Univ. (Japan); Shi-Wei Chu, National Taiwan Univ. (Taiwan); Satoshi Kawata, Osaka Univ. (Japan)

The recent development in optical microscopy has successfully overcome the limitation of the spatial resolution caused by the diffraction effect of light. Stimulated emission depletion (STED) and localization microscopy (FPALM/PALM/STORM) utilize the optical switching effect of fluorescence molecules to achieve the spatial resolution beyond the diffraction limit. Recently, we have proposed the use of saturated excitation (SAX) of fluorescence molecules to improve the spatial resolution of confocal microscopy. Since the saturated excitation introduces the nonlinear relation between excitation and fluorescence emission, detection of the nonlinear fluorescence responds allows us to reconstruct a fluorescence image with the improved spatial resolution. The nonlinear fluorescence signal is localized within the focal volume, therefore SAX microscopy can effectively suppress the background fluorescence signal, allowing us to observe a thick specimen, such as 3D-cultured cells, with the improved spatial resolution and image contrast. Since saturation is a fundamental phenomenon seen in any optical effect, SAX microscopy can also be applied to imaging techniques based on other optical phenomena, such as two-photon excitation. We recenlty observed the saturation effect in plasmonic light scattering from a gold nanopaticle and applied it to the super resolution imaging in metal particle observation.

9169-30, Session 7

Optical nanoscopy of a living cell *(Invited Paper)*

Balpreet S. Ahluwalia, Univ. of Tromsø (Norway); Deanna L. Wolfson, Frank Y. S. Chuang, Univ. of California, Davis (United States); Thomas R. Huser, Univ. Bielefeld (Germany)

Optical nanoscopy allows to study biological and functional processes of sub-cellular organelles. In structured illumination microscopy (SIM) the sample is illuminated with a grid-like interference pattern to encode higher spatial frequency information into observable Moiré patterns. By acquiring multiple images and a computation trick a super-resolved image is obtained. SIM provides resolution enhancement of 2X in each axis as compared to conventional microscopes. For a visible light, SIM provides an optical resolution of 100 nm. The challenges associated with optical nanoscopy of a living cell are photo-toxicity, special dye requirements and artifacts due to cell movement. SIM works with conventional dyes and is a wide-field technique making it suitable for imaging living cells. In this work, we will discuss the opportunities and challenges of imaging living cells using SIM. Two applications of optical nanoscopy of living cells will be discussed; a) imaging of mitochondria in a keratinocyte cell and b) cell-to-cell HiV viral transfection. Selective binding of stains was used for imaging sub-mitochondrial regions. Mito-Tracker stain was trapped inside the mitochondria consequently imaging mitochondrial compartments, whereas GFP-BacMan stains the mitochondrial membrane. For HiV work, the transfection of viral protein was successfully imaged from an infected Jurkat cell (Gag-iGFP expressing) to the primary CD4+T cells. The entire process of HiV transfection was imaged i.e. formation of viral synapse and the accumulation of viral protein at the cell membrane followed by the transfection of viral protein to the target cell.

9169-31, Session 7

Localized plasmon assisted structured illumination microscopy

Joseph L. Ponsetto, Feifei Wei, Zhaowei Liu, Univ. of California, San Diego (United States)

A new super resolution imaging method, i.e. Localized Plasmon assisted Structured Illumination Microscopy (LPSIM), is presented. Using a periodic hexagonal array of silver nanodiscs as localized plasmonic antennas, we vary incident laser polarization over a wide angle range to create dynamically tunable near-field excitations. For fluorescent samples placed on top of the antenna array, these excitations result in robustly changeable, finely structured illumination patterns. Since localized plasmons are confined to the dielectric-metal interface of the antennas, the antenna geometry alone limits the illumination pattern feature sizes, which enables a dramatic resolution improvement in comparison with the standard Structured Illumination Microscopy (SIM). Standard SIM schemes are limited to a 2X resolution improvement over the diffraction limit, because the structured illumination itself is diffraction limited. By leveraging the properties of localized plasmons, we untether ourselves from any propagating light or propagating surface plasmon dispersion limitations. This highly parallelizable approach allows for a wide field of view. The low number of sub-images required for reconstruction maintains the capacity for a high frame-rate. In full-wave simulations, recovered images for distributions of quantum dots as well as other non-sparse objects are presented, demonstrating high image quality and significant resolution improvement over existing methods. Based on Rayleigh criteria and full-width half maximum characterization, resolution of 51 nm (3X the diffraction limit) is shown. This resolution shown at safe visible frequencies holds promise for examining living cell dynamics at the nano-scale. The theory, design, and applications of this method will be discussed in detail.

9169-32, Session 8

Polarization analysis of the liquor films autofluorescence images to diagnose the time of death

Taras M. Boychuk, Bukovinian State Medical Univ. (Ukraine); Artem O. Karachevtsev, Yuriy Fedkovych Chernivtsi National Univ (Ukraine)

This paper presents the research results for diagnostic efficiency of a new azimuthally stable Mueller-matrix method applied to analyze the laser autofluorescence coordinate distributions of liquor films of the deceased.

A new model of the generalized optical anisotropy of biological films is offered to define processes of the laser autofluorescence. It is important to mention that influence of the complex mechanisms of both phase anisotropy (linear birefringence and optical activity), linear (circular) dichroism is taken into account.

The interconnections between the azimuthally stable Mueller-matrix elements characterizing laser autofluorescence and different mechanisms of optical anisotropy are determined.

The statistic analysis of coordinate distributions of such Mueller-matrix rotation invariants is proposed. Thereupon the quantitative criteria (statistic moments of the 1st to the 4th order) of determine the time of death.

9169-33, Session 8

Tunable phonon polaritons in van der Waals crystal of boron nitride

Siyuan Dai, Zhe Fei, Univ. of California, San Diego (United States); Qiong Ma, Massachusetts Institute of Technology (United

States); Aleksandr S. Rodin, Boston Univ. (United States); Martin Wagner, Alexander S. McLeod, Mengkun Liu, Univ. of California, San Diego (United States); Will Gannett, Will Regan, Univ. of California, Berkeley (United States); Kenji Watanabe, Takashi Taniguchi, National Institute for Materials Science (Japan); Gerardo Dominguez, California State Univ., San Marcos (United States); Mark Thiemens, Univ. of California, San Diego (United States); Antonio H. Castro Neto, National Univ. of Singapore (Singapore); Alex Zettl, Univ. of California, Berkeley (United States); Fritz Keilmann, Ludwig-Maximilians-Univ. München (Germany); Pablo Jarillo-Herrero, Massachusetts Institute of Technology (United States); Michael M. Fogler, Dmitri N. Basov, Univ. of California, San Diego (United States)

Van der Waals heterostructures assembled from atomically thin crystalline layers of diverse two-dimensional solids are emerging as a new paradigm in the physics of materials. We use infrared (IR) nano-imaging to study the properties of surface phonon polaritons in a representative van der Waals crystal, hexagonal boron nitride (hBN). We launched, detected and imaged the polaritonic waves in real space and altered their wavelength by varying the number of crystal layers in our specimens. The measured dispersion of polaritonic waves was shown to be governed by the crystal thickness according to a scaling law that persists down to a few atomic layers. Our results are likely to hold true in other polar van der Waals crystals and may lead to their new functionalities.

9169-34, Session 8

Gas-metallic nanoparticle surface interaction characterized with in situ electron energy loss spectroscopy

John M. Kohoutek, Pin Ann Lin, National Institute of Standards and Technology (United States) and Univ. of Maryland, College Park (United States); Jonathan Winterstein, Henri Lezec, Renu Sharma, National Institute of Standards and Technology (United States)

We use an environmental scanning transmission electron microscope (ESTEM) equipped with electron loss spectroscopy (EELS), a monochromated electron source, and a custom-built gas flow cell to perform energy loss measurements on metallic nanoparticles (NPs) exposed to a local gaseous environment at varying pressures.

In particular, we characterize the effect of exposure to CO or H2 (at partial pressures of 10 Pa, 100 Pa, and HV) on the localized surface-plasmon-resonance (LSPR) of an Au NP. By addressing various sites around the perimeter of a triangular Au NP (edge length ~ 20 nm) with the electron beam in STEM mode, the energy loss spectrum resulting from site-specific excitation of LSPR is probed with a spatial resolution of ~ 1 nm and energy resolution of ~100 meV.

Local gas adsorption is evidenced by peak shifts in the energy loss spectrum, which are found to be positive for CO and negative for H2. Strong site selectivity is evident, with CO and H2 adsorbing preferentially at edge and corner sites, respectively.

To characterize the sign and magnitude of the energy shifts, finite-difference-time-domain (FDTD) simulations of electron-beam excitation of the NP are performed using a Drude model in which the local electron concentration is allowed to vary spatially over the particle volume. This is a result of both and the inhomogeneous spatial distribution of the adsorbate and its degree of electronegativity. An excellent match to experimental results is obtained for the respective cases of site-specific adsorption of CO, which is electropositive, and H2, which is electronegative.

9169-35, Session 8

Fourier-Stokes polarymetry of linear and circular birefringence of woman reproduction system tissues

Artem Karachevtsev, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

This paper presents the results of:

• Analytical reasoning of ability of spatial-frequency Stokes polarymetry method for mechanism phase anisotropy selection of structured fiber networks of histologic biological tissue sections .

• Experimental ability of linear and circular birefringence manifestation of fiber networks of benign and malignant tumors of womb side, on basis of spatial-frequency selection of azimuthally-stable Mueller-matrix images.

• Development abstract method of polarization reconstruction of phase anisotropy parameters of phase anisotropy in histological sections of biological tissues with spatial-frequency separation their visualization.

• Experimental realization present method in differentiation of anisotropy parameters of polycrystalline networks in case of oncological pathology severity –“pre-cancer- cancer” of women reproductive system parts.

• Generalization and approbation of Fourier methodology of azimuthally-stable polarization mapping of diffuse radiation field by human skin of laser radiation in distant diffraction zone.

Conference 9170: Nanoengineering: Fabrication, Properties, Optics, and Devices XI

Tuesday - Wednesday 19–20 August 2014

Part of Proceedings of SPIE Vol. 9170 Nanoengineering: Fabrication, Properties, Optics, and Devices XI

9170-1, Session 1

High-sensitivity silicon nanowire phototransistors *(Invited Paper)*

Siew Li Tan, Xingyan Zhao, Yaping Dan, Univ. of Michigan-Shanghai Jiao Tong Univ. Joint Institute (China)

Silicon nanowires (SiNWs) have emerged as a promising material for high-sensitivity photodetection in the UV, visible and near-infrared spectral ranges. The majority of SiNW photodetectors reported to date are mainly composed of either the photoconductor or PN junction photodiode structure. In this work, we demonstrate novel planar SiNW bipolar phototransistors on silicon-on-insulator (SOI) substrate using CMOS-compatible processes. The nanowires were patterned by electron beam (e-beam) lithography followed by metal contact evaporation, and subsequently etched by inductively coupled plasma reactive ion etching (ICP-RIE). The bipolar phototransistor consists of a PNP structure along the nanowire axis with an optically-injected base region. The doping densities of the active regions were defined by ion implantation using thick PMMA e-beam resist film as masks. The dopants were activated by rapid thermal annealing. We investigate the electronic and optical properties of the SiNW phototransistors by changing the active-region lengths and passivating the nanowire surfaces. Preliminary numerical device simulation shows that the optically-injected base photocurrent is amplified by over 2 orders of magnitude and that surface recombination velocity of the nanowire has a considerable effect on the gain. Compared with conventional bulk Si devices, the SiNW phototransistors are expected to offer the advantages of lower operating power and noise than avalanche photodiodes, higher sensitivity than Si photodiodes, as well as improved high-frequency response over bulk Si phototransistors.

9170-2, Session 1

Thermo-active behaviour of ethylene vinyl-acetate | MWCNT composites examined by in situ NEXAFS

Eva M. Campo, Bangor Univ. (United Kingdom)

Carbon nanotubes (CNTs) have garnered considerable interest in a wide range of academic fields, owing to their extraordinary mechanical, thermal, electronic and optical properties. CNTs are attractive candidates as fillers in composite materials, considerably improving the properties of the host. Recently, vast research has focused on the active properties of certain polymer-CNT composites. Development of this field is hindered by the absence of a unified actuation model explaining the molecular mechanics of these phenomena. Consequently, there is no method to predict whether specific materials exhibit this “smart behaviour”.

Near edge X-ray absorption fine structure (NEXAFS) spectroscopy is a valuable synchrotron technique for the study of nanocomposites, offering a wealth of information about local chemistry of the system, all with excellent energy resolution. Additionally, the use of a highly polarized beam allows for assessment of conformational arrangement of soft matter, which is of critical importance when the system is governed by non-covalent interactions.

In this study, temperature-dependence of thermally active ethylene-vinyl acetate (EVA) | MWCNT films are studied through in-situ NEXAFS spectroscopy. The effects of straining to promote CNT alignment and the role of dispersants are also addressed. Systematic variations in π^* C=C and π^* C=O were analysed and correlated with mechanical actuation at the macroscale. An actuation model based on CNT torsional effects is finally proposed, supporting our findings.

9170-3, Session 1

Light extraction enhancement of vertical LED by growing ZnO nano-rods on tips of n-GaN pyramids and polarization dependent measurement of nano-structure

Yen-Ju Wu, Cheng-Yi Liu, Chin-Han Liao, National Central Univ. (Taiwan)

Creating a textured pyramidal structure on the emitting n-GaN surface of the vertical GaN-based LED by wet-etching is considered to be the most effective approach for enhancing the light extraction efficiency of the vertical GaN-based light-emitting diodes (LEDs). The present study shows that the light extraction efficiency of the pyramidal n-GaN surface can be further enhanced by growing ZnO nano-rods on the n-GaN surface.

In addition, we find that the growth location of the ZnO nanorods on the n-GaN surface by hydrothermal method is highly correlated with the polarity of the n-GaN surface. By manipulating the polarity of the pyramidal n-GaN surface and water-dissolution process, ZnO nanorods can be specifically grown on the tips of the pyramids. With the tip-only ZnO NRs on the pyramidal n-GaN emitting surface, the light-output power of LED with a pyramidal n-GaN surface can be remarkably further enhanced by 49.6% at 250 mA. The correlation between the ZnO nanorods and polarity of the growing surface is studied by X-ray absorption spectroscopy (XAS). Thus, using the XAS analysis, we will demonstrate the correlation between the growth and the dissolution of nanostructure of the ZnO with the polarity of the ZnO c-plane surface, surface termination, and surface activity. The detail optical characterization of the vertical thin-GaN LEDs with ZnO NRs and its polarization dependent measurement would be present and discussed in this talk.

9170-4, Session 1

PbS quantum dot sensitized InGaZnO metal oxide hybrid phototransistor for near infrared detection

Do Kyung Hwang, Korea Institute of Science and Technology (Korea, Republic of); Hee Sung Lee, Yonsei Univ. (Korea, Republic of); Yun Jae Lee, Won Kook Choi, Korea Institute of Science and Technology (Korea, Republic of); Seongil Im, Yonsei Univ. (Korea, Republic of)

Colloidal quantum dots (QDs) are an important class of new materials due to their unique physical properties. In particular, PbS QD has great potential for optoelectronic applications because it is highly desirable as light absorber for near-infrared (NIR) detection. InGaZnO (IGZO) metal oxide is a promising alternative to amorphous or poly silicon technologies, which can facilitate the development of microelectronic or optoelectronic circuit systems on glass and flexible substrates. Here, we propose new hybrid approach of two emerging classes of PbS QD as light absorber and IGZO as the charges transport layer to create a bi-functional optoelectronic device application. The PbS QD can be functionalized directly onto the surface of IGZO TFT to produce a gate tunable, highly sensitive, and easily integrated PbS sensitized IGZO hybrid phototransistor for NIR detection. This hybrid phototransistor exhibits significant photo-induced threshold voltage shifts in the spectral range of 1400 - 700 nm, resulting in state-of-the art photoresponsivity over 103 A/W and specific detectivity on the order of 1014-1015 Jones. To further evaluate real potential towards optoelectronic circuit system, a photo gating resistive-load inverter is implemented by connecting a unit phototransistor to an external load resistor. The photo-induced

threshold voltage shifts of the hybrid phototransistor lead to a certain static or dynamic output voltage signal from our photo-gating inverter. We expect that this hybrid phototransistor can be simply integrated on glass or plastic substrates that can be applied to pixels on flat panel photo imaging applications or building blocks on complex photo gating logic circuits.

9170-5, Session 1

Heterojunction of nano-poly (O-toluidine) on silicon nanowires is investigated as a candidate heterojunction diode

Salah E. El-Zohary, Univ. of Tokushima (Japan) and Tanta Univ. (Egypt); Mohamed Shenashen, Akinori Tsuji, Toshihiro Okamoto, Masanobu Haraguchi, Univ. of Tokushima (Japan)

A heterojunction of Nanostructured conducting polymer poly O-toluidine (NPOT)/ silicon nanowires (SiNWs) is investigated as a candidate heterojunction diode. For this purpose, NPOT and NPOT/ SiNWs heterojunction is fabricated through economical cheap and simple techniques. I-V measurements of the device are made at room temperature under dark conditions. The heterojunction diode parameters such as turn on voltage, reverse saturation current (I0), ideality factor (ζ), barrier height (ϕB) and series resistance(Rs) are determined from I-V curves using Schottky equations. These values of these parameters are also extracted and verified by applying different methods of calculation. Compared to conducting polymers such like polyaniline or polyperrole on porous silicon heterojunctions mentioned in many research papers in literature, our proposed heterojunction expected to promise a novel heterojunction diode and hybrid solar cell. The reason may be understood as the aligned one-dimensional nanowire arrays offer a promising substrate providing a direct pathway for charge transport and high mobility for carriers. Also it was reported that SiNWs could play an important role in providing a large effective junction area which could help in light trapping helping in solar cell applications. In addition, we believe that in situ polymerization method, the chemical method used here is able to make a good coverage above and in interspaces of the fabricated SiNWs. This give good coverage compared the spin coating method which usually used. Good coverage is needed to fabricate a valuable and good heterojunction beween the conducting polymer and the Si nanostructures.

9170-6, Session 1

Transparent self-assembled InGaZnO thin film transistors with SiO_2-based solid electrolyte dielectric

Yuanjie Li, Xi'an Jiaotong Univ. (China); Yanghui Liu, Ningbo Institute of Materials Technology & Engineering (China); Wenci Sun, Xi'an Jiaotong Univ. (China)

Transparent amorphous oxide semiconductors (TAOS) have attracted considerable technological interests because of their high mobility (10-30 cm2/Vs), large-area uniformity and low temperature deposition capability. In particular, amorphous InGaZnO (a-IGZO) is regarded as a promising active channel material for flexible thin film transistors (TFTs)-driven display and sensors. In this work, TFT devices with the bottom gate structure have been fabricated with solid electrolyte nanocolumnar SiO2 film of ~800 nm by plasma-enhanced chemical vapor deposition (PECVD) as the gate dielectric layer on indium-tin-oxide (ITO) glass substrates. The ITO/SiO2/IZO capacitor structure was also fabricated to characterize the capacitance-frequency properties of SiO2 gate dielectric. A nickel shadow mask was placed directly above the SiO2 dielectric layer with a distance of ~50 μm. Subsequently, a 147 nm thick IGZO layer was sputtered on the SiO2/ITO/glass substrate using a commercial IGZO target (In:Ga:Zn=2:2:1 mol%) at room temperature by RF sputtering. During deposition, the IGZO layer diffracts into the shadow region of the nickel mask and a thin IGZO channel layer is self-assembled simultaneously. Optical transmission spectra of the TFT arrays on glass substrates were characterized using a UV/Visible spectrometer system. The electrical characteristics of the devices were measured by a Keithley semiconductor parameter analyzer and precision impedance analyzer in dark. Enhancement-mode IGZO/SiO2/ITO transparent TFT devices with field effect mobility of 10.5 cm^2/Vs, VT of 0.7 V, subthreshold swing (SS) of 70 mV/dec and Ion/off of 1.5x10^6 have been achieved in this work.

9170-7, Session 1

Characteristic temperature analysis for PbSe/ PbSrSe multiple quantum well structure

Majed Khodr, American Univ. of Ras Al Khaimah (United Arab Emirates)

The characteristic temperature calculations and dependency on cavity length was analyzed for Pb0.934Sr0.066 Se multiple Quantum well Structure at three temperature ranges 77< T<150 K, 150< T<300 K, and 77< T<300 K. In this work, we show the behavior of the characteristic temperature as a function of cavity length and were able to best fit the data to a second degree polynomial. Inclusion of theoretical values for the quantum efficiency due to Auger recombination reduces the characteristic temperature T0 in these ranges. It was found that inclusion of the quantum efficiency decreases the characteristic temperature by a factor of 0.6 for a wide range of cavity lengths. When results were compared to experimental data, it was concluded that there is a leakage current above the barrier due to thermionic emission. The leakage current density was estimated to be around 5423 A/cm2 at room temperature. With this high value more work is needed to understand the thermionic emission process to improve on the performance of this material system and similar ones.

9170-8, Session 2

Mechanical behavior of microelectromechanical microshutters

Devin E. Burns, Justin S. Jones, Mary J. Li, NASA Goddard Space Flight Ctr. (United States)

Microelectromechanical based microshutters are optically transmissive elements with high open/close contrast ratios (>10,000), high fill factors (>70%), and the ability to cover large optical fields of view, which can provide significant performance improvements for optical, IR, and UV instruments. Microshutters developed for the James Webb Space Telescope require magnetic actuation, which adds mass and increases complexity. Recently, electrostatically actuated microshutters have been developed and demonstrated under laboratory conditions. Electrostatic actuation eliminates the magnetic drawbacks, and may make microshutters more broadly available for space and ground based applications.

Successful electrostatic actuation is predicated on low drive voltages achieved by increasing capacitive forces or reducing microshutter stiffness. For microfabrication practicality and to maintain shutter sizing (resolution), shutter stiffness was lowered by reducing the structural layer thickness. In the current work, we present a micro-mechanical test system capable of measuring the microshutter stiffness and structural properties of related test structures. This system was validated using micro-cantilever beam test structures by comparing their deflection to beam theory predictions. Tests on microshutters consist of data from two design layups; one with 250 nm and one with 500 nm of Si3N4 as the primary structural layer (both also have 200 nm Al). The thicker microshutters were observed to be approximately 4 times as stiff; with a stiffness of 47 nN/micron versus 12 nN/micron. These results were found to be in good agreement with an analytical model and a finite element model which will be used to guide future design modifications.

9170-9, Session 2

Nanotube liquid crystal-elastomers: birefringence, flexible energy conversion, and photomechanical response

Balaji U. Panchapakesan, Xiaoming Fan, Univ. of Louisville (United States)

Rubber composites based on nanotube liquid crystals offer anisotropic physical properties and flexible energy conversion. Combining carbon nanotube liquid crystals with elastomers here in we demonstrate high optical anisotropy and photomechanical response of such composites to near infra-red excitation that is orders of magnitude larger than the pristine polymer. On NIR excitation, with application of small or large pre-strains significant expansion or contraction of the sample occurs respectively that is continuously reversible. Polarization microscopy revealed birefringence of transparent nanotube liquid crystal rubber composites with aligned domains turning light or dark through rotation of the polarization of linearly polarized light. Domains size was observed to exponentially decrease with increase in nanotube film concentration. The amount of carbon nanotubes used to fabricate the liquid crystal actuators was about ~300-700 times smaller than nanotube and graphene based photomechanical actuators reported till date. Extraordinary opto-mechanical response of ~10 MPa/W for ultra-small amounts of nanotube liquid crystals, high degree of transparency, anisotropic optical properties, and reversible stimuli responsivity of composites makes liquid crystals of nanotubes and elastomers as a new system that is important for soft actuation, energy conversion and photo-origami applications. Energy conversion efficiencies of ~1000 times greater than reported light driven piezoelectric polymer systems is reported for nanotube liquid crystal rubber composites.

9170-10, Session 2

Photothermal nanopositioners based on graphene composites

Balaji U. Panchapakesan, Univ. of Louisville (United States)

The addition of nanomaterials to polymers can result not only in significant material property improvements, but also assist in creating entirely new composite functionalities. By dispersing graphene nanoplatelets (GNPs) within a polydimethylsiloxane matrix, we show that efficient light absorption by GNPs and subsequent energy transduction to the polymeric chains can be used to controllably produce significant amounts of motion through entropic elasticity of the pre-strained composite. Using dual actuators, a two-axis sub-micron resolution stage was developed, and allowed for two-axis photo-thermal positioning (100 micro-meter per axis) with 120 nm resolution (feedback sensor limitation), and ~5 micro-meter/s actuation speeds. A PID control loop automatically stabilizes the stage against thermal drift, as well as random thermal-induced position fluctuations (up to the bandwidth of the feedback and position sensor).

Maximum actuator efficiency values of ~0.03% were measured, approximately 1000 times greater than recently reported for light-driven polymer systems.

9170-11, Session 2

Progress towards a MEMS tunable infrared filter using porous silicon

Dmitry A. Kozak, National Research Council (United States); Todd H. Stievater, Marcel W. Pruessner, William S. Rabinovich, U.S. Naval Research Lab. (United States)

Porous silicon is a very promising material for photonics and micromechanical applications. Etched from a silicon substrate, porous silicon can be adjusted to have an index of refraction from just below that of bulk silicon (nSi~3.5) to below that of silicon oxide (nSiO2~1.5). This property allows the formation of either well-defined discrete layers with controlled thicknesses and refractive indices, or films with a continuous variation of the index of refraction. The ability to control porosity, and therefore the index of refraction, allows for the creation of extremely highly reflective and wide bandwidth distributed Bragg reflectors (DBRs). In this work, we investigate porous-silicon distributed Bragg reflectors for spectroscopy in the mid-wave infrared (MWIR, 3-5 um) and long-wave infrared (LWIR, 7-12 um) wavelength ranges, and progress towards applying these reflectors in a tunable MEMS filter. Our design would provide wide tunability in the MWIR and LWIR regions. Utilization of porous silicon eliminates stress-related mechanical deformations unavoidable with deposited thin films. DBRs with reflectivity above 95% were etched, with reflectivity bandwidth covering either the entire MWIR or LWIR ranges. By spacing a thin cavity layer between two DBR's, an extremely narrow bandpass optical Fabry-Perot filter can be fabricated. With the addition of either thermal or mechanical tuning, these devices can be used for hyperspectral sensing and imaging, as well as for infrared molecular spectroscopy and chemical sensing.

9170-12, Session 2

Mid-infrared opto-nanofluidics for label-free on-chip sensing

Pao T. Lin, Massachusetts Institute of Technology (United States); Sen W. Kwok, Hao-Yu Lin, Harvard Univ. (United States); Vivek Singh, Lionel C. Kimerling, Massachusetts Institute of Technology (United States); George M. Whitesides, Harvard Univ. (United States); Anuradha Agarwal, Massachusetts Institute of Technology (United States)

A mid-infrared (mid-IR) label-free chemical sensor was developed using opto-nanofluidics consisting of a Si-liquid-Si slot-structure. A broadband mid-IR lightwave can be strongly confined within a nanofluidic capillary by utilizing the large refractive index contrast ($\Delta n \sim 2$) between the liquid core waveguide and the Si cladding. Through an optical-field enhancement together with a direct interaction between the probe light and the analyte, the sensitivity for chemical detection is increased by 50 times when compared to evanescent-wave sensing. This spectral characterization distinguished several common organic liquids (e.g., n-bromohexane, toluene, isopropanol) accurately, and could determine the ratio of chemical species (e.g., acetonitrile and ethanol) at low concentration (< 5 µL/mL) in a mixture through spectral scanning over their characteristic mid-IR absorption peaks. The combination of CMOS-compatible planar mid-IR microphotonics, and a high-throughput nanofluidic sensor system, provides a unique platform for chemical detection.

9170-13, Session 3

Keeping x-ray eyes on nanoparticles synthesis in the solution – in-situ diffraction and absorption studies *(Invited Paper)*

Malwina Staniuk, Markus Niederberger, Dorota Koziej, ETH Zürich (Switzerland)

Nowadays, materials utilized in energy-related application exhibit the hierarchical architecture.[1] However, their superior functionalities are related to the intrinsic properties of nanoparticles and effects induced by the interaction between the individual building blocks. Thus, a formidable challenge is the intimate mixing and assembling of the components into complex structures and a good deal of work is still required to optimize and extend them to practical usage. An attractive method is a direct synthesis of multicomponent/hybrid structures in the solution. Therefore, we are particularly interested in controlling and understanding complexity of the solution-based reactions. We follow the processes of transition

from inorganic molecule of precursor to crystalline nanoparticles by means of in-situ synchrotron based X-ray absorption spectroscopy and X-ray diffraction. We show different mechanisms leading to the crystal structure transition in the solution: (a) driven by increasing size of nanoparticles, (b) driven by time dependent kinetics and (c) driven by catalytic reactions of products.[2-3] Additionally, we shed light on ways to access the interdependence between the changes of the oxidation state of precursor and the several parallel reactions leading to nucleation and growth of nanoparticles. These results are fundamental on the way to control oxidation states in liquid-phase synthesis of nanoparticles.[3]

9170-14, Session 3

Optical characterization of CMOS compatible micro optics fabricated by mask-based and mask-less hybrid lithography

Sunglin Wang, Chris Summitt, Lee Johnson, Melissa A. Zaverton, Thomas D. Milster, Yuzuru Takashima, The Univ. of Arizona (United States)

Silicon photonics devices offer a promising solution for the integration of optical data transmission technology into local computer peripheral devices. However, the implementation has not yet been perfected due to the difficulty of coupling light across multiple levels. One possible implementation is through the fabrication of an optical via, or optical path perpendicular to the surface of the integrated photonics chip. In order to fabricate an optical via which will integrate multiple levels in a silicon photonics device, mask-less lithography can be used together with a familiar packaging material. As a crucial component for the optical via, an in-plane light coupler by which the direction of the light is bent in 90 degrees is needed. This coupler should be fabricated using a CMOS compatible material and process without wet or dry etching to avoid additional cleaning processes. For the purpose, buffer coat material can be used to fabricate a mirror-based coupler by using conventional mask-based lithography followed by mask-less hybrid lithography. The hybrid process allows fabrication of a well-defined structure with arbitral shape such as micro mirrors at designated location on the chip for example next to waveguides. We report fabrication and characterization of the optical property of the 45 degree micro mirror. Surface angle and roughness are evaluated by an interferometer. The result agrees with inspection by the other methods such as cross sectional scanning electron microscope. Experimental evaluation of optical efficiency of the system including the mirror for routing of the laser beam in 90 degree will be addressed.

9170-15, Session 3

High efficiency photonic hierarchical nanostructures self-assembled from the gas phase

Luca Passoni, Luigino Criante, Istituto Italiano di Tecnologia (Italy) and Politecnico di Milano (Italy); Francesco Fumagalli, Istituto Italiano di Tecnologia (Italy); Francesco Scotognella, Istituto Italiano di Tecnologia (Italy) and Politecnico di Milano (Italy); Guglielmo Lanzani, Fabio Di Fonzo, Istituto Italiano di Tecnologia (Italy)

The increasing awareness of industries in the commercial opportunities given by nanotechnology is driving the research and development of novel material designs with cutting edge functionalities. Nature, with several billion year of R&D, has often been taken as example to derive smart solution to engineering problems. In the field of optics the natural world molds the flow of light with wide variety of nanometer scale modulations of materials properties, like porosity and morphology (e.g. cuticle of the beetles, butterfly wings or mother of pearls). Being able to mimick these strategies with added high-tech functionalities would open up a broad array of applications. Existing fabrication techniques of porous photonic architectures severely limit their exploitation. Here we report on photonic hierarchical nanostructures obtained by self-assembly from the gas-phase at low temperature. Periodic refractive index modulation is achieved by stacking layers with different nano-architectures. Fine control over material density and porosity allows the fabrication of high efficiency ($R(\lambda) > 85\%$) single material photonic crystal with tuneable Bragg-diffraction peak. The fabrication of high efficiency broad band dielectric mirrors ($R \approx 1$ over the whole visible spectum) on glass and flexible substrates, opto-fluidic switches and matrix of photonic crystal pixels with feature size < 10 micron is demonstrated. Porous photonic crystals fabricated with conductive, semiconductor and insulating materials are shown to withstand temperature (>500°C) common in silicon platform. This new technique is demonstrated to be a promising route for filtering, optical-sensing, electro-optical modulation, light harvesting energy devices and photocatalysis applications.

9170-16, Session 3

Near-edge x-ray absorption fine structure studies of electrospun poly(dimethylsiloxane)/poly(methyl methacrylate)/multiwall carbon nanotube composites *(Invited Paper)*

Eva M. Campo, Bangor Univ. (United Kingdom)

Near-edge X-ray absorption fine structure (NEXAFS) spectroscopy provides a wealth of information about local bonding, chemical environment, and conformational configuration of a system, rendering the technique an attractive tool in the study of nanocomposites. In this work, NEXAFS spectroscopy is used to analyse electrospun Poly(dimethylsiloxane) (PDMS) /Poly(methyl methacrylate) (PMMA) / Multiwall Carbon Nanotube (MWCNT) nanocomposites.

Critical to electrospinning and general nanocomposite design and synthesis, this work addresses alignment of fibres and polymeric chains, as well as fillers. Spectra acquired with composite fibre direction parallel and perpendicular to the beam polarisation suggested a simple electrospinning setup was not sufficient to align polymeric chains uniaxially. Though polymer phase segregation was observed in SEM, NEXAFS spectra revealed good composite homogeneity. Strong conformational effects were observed, however, in angular resolved NEXAFS spectra.

Nanofiller size was observed to greatly influence composite spectra. Emissions attributed to C-H and C=O groups were most significantly altered on addition of filler, suggesting their importance in interfacial bonding. Finally, proposed bonding models of non-covalent CH-π interactions and hydrogen bonding are discussed.

9170-17, Session 3

Rate-dependent viscoelastic contact of polymeric materials in transfer printing

Seyoung Im, Jaeshin Park, KAIST (Korea, Republic of); Jae-Hyun Kim, Hak-Joo Lee, Korea Institute of Machinery & Materials (Korea, Republic of)

This work presents a multiscale computation of decohesion or debonding in transfer printing between silica and cross-linked poly-dimethlysiloxane (PDMS). We employed the interfacial cohesive zone law obtained from the atomic interactions at the interface between the PDMS and silica (Smith et al, 2004 and 2007) to analyze the macroscopic mechanical system of Jang et al (2011). The interfacial cohesive law is coarse-grained with the aid of the relaxation method (Nguyen and Ortiz, 2002), and utilized for a FE analysis of the transfer printing process. The PDMS is considered as a viscoelastic elastomer with its instantaneous deformation behavior being described as a hyperelastic material. Ogden's

hyperelasticity model is considered, and finite strain viscoelasticity is implemented consistent with the hyperelasticity.

Power delivery and self-heating in plasmonic nanoscale devices

Nan Zhou, Luis M. Traverso, Xianfan Xu, Purdue Univ. (United States)

Plasmonic devices, made of nanoapertures or nanoantennas, have played significant roles in advancing the fields of optics and opto-electronics by offering subwavelength manipulation of light in the visible and near infrared frequencies. For example, in optical near-field nanolithography, nanostructured plasmonic len has been chosen as the focusing element. The development of heat-assisted magnetic recording (HAMR) opens up a new application of plasmonic nanostructures, where they act as near field transducers (NFTs) to locally and temporally heat a sub-diffraction-limited region in the recording medium to reduce the magnetic coercivity. Generally, for these applications, plasmonic nanostructures should simultaneously deliver enough power to certain targets with as small as possible incident laser power to reduce the self-heating effect, which could lead to degradation of performance and failure of the device. In this work, we study the effect of material properties on the coupling efficiencies of different nanoaperture-based designs and the corresponding energy dissipation. We will show the limitations of common metallic materials as a result of self heating. The possibility of using alternative or ideal plasmonic materials for delivering higher power and/or reducing heating in these plasmonic nanostructures will be discussed.

9170-19, Session 4

Directly deposited plasmonic metasurface for omnidirectional visible super absorption

Kai Liu, Xie Zeng, Univ. at Buffalo (United States); Suhua Jiang, Fudan Univ. (China); Dengxin Ji, Haomin Song, Nan Zhang, Qiaoqiang Gan, Univ. at Buffalo (United States)

Plasmonic metamaterial super absorbers are emerging as attractive candidates for photo-harvesting, surface enhanced biosensing, photocatalysis, and thermal energy recycling. However, most of reported meta-absorbers with periodic nanopatterns were fabricated using expensive and low-throughput top-down nano-lithography techniques, therefore imposing a serious cost barrier for the development of practical applications. Additionally, other alternative methods such as chemical synthesis and nanostencil lithography are so complicated that technical barriers still exist to obtain high-quality and large-area metallic nanopatterns. We here report a simple, scalable and cost-effective method to manufacture uniform super absorptive metasurfaces in large areas using a direct tilted-sputtering technique. Using this technique, densely packed metallic nanopatterns with controllable size distributions can be easily formed on either rigid or flexible substrates. These metallic nanopatterns were then covered sequentially by an ultrathin dielectric film and optically-thick metallic ground plate to constitute designed three-layered meta-absorbers. A remarkable optical absorption peak over 96% in the visible regime was obtained successfully which is insensitive to polarization states and incident angles up to 70º. Moreover, the lateral dimension of these random nanopatterns can be tuned further by post thermal annealing processes, resulting in a wide spectral tunability of the super absorption resonances in the visible-to-near-infrared domain. This omnidirectional, polarization-insensitive super absorber structure is particularly promising for the development of novel thin-film energy harvesting devices, all-angle color filters and biomimetic photonic structures.

9170-20, Session 4

Effects of different wetting layers on the growth of smooth ultra-thin silver thin films

Chuan Ni, Piyush J. Shah, Andrew M. Sarangan, Univ. of Dayton (United States)

Ultrathin silver films (thickness below 10 nm) are of great interest as optical coatings in low-emissive windows and plasmonic devices. However, producing these films has been a continuing challenge because of their tendency to form clusters rather than smooth contiguous thin films. In this work we have studied the effect of Cu, Ge and ZnS as wetting layers (1.0 nm) to achieve ultrasmooth ultrathin silver films. The silver films (5 nm) were grown by RF sputter deposition on silicon and glass substrates using a few monolayers of the different wetting materials. SEM imaging was used to characterize the surface properties such as island formation and roughness. Also the optical properties were measured to identify the optical impact of the different wetting layers. Finally, a multi-layer silver based structure is designed and fabricated, and its performance is evaluated. The comparison between the samples with different wetting layers show that the designs with wetting layers which have similar optical properties to silver produce the best overall performance. In the absence of a wetting layer, the measured optical spectra show a significant departure from the model predictions, which we attribute primarily to the formation of film clusters.

9170-22, Session 4

Simulation of a film of random particulate medium containing aggregates of metal nanospheres

Saswatee Banerjee, Sumitomo Chemical Co., Ltd. (Japan)

We dispersed silver nanospheres of diameter 5nm in a homogeneous binder. Films were spin-coated on glass substrates. The transmission spectra of such films are measured as particle concentration is varied. The transmission spectra show deeper and wider minima in the shorter wavelength side as the concentration of nanoparticles increase. This might be explained by the formation of aggregates of nanoparticles and the coherent interaction among the constituent elements of the aggregates. The coherent interaction can include excitation of the modes due to coupling of localized surface plasmon resonance (LSPR) modes of individual particles. To explain the dependence of transmission spectra on the concentration of particles we computed the scattering properties of particle aggregates [1].

The scattering properties of a single spherical particle can be computed

analytically using Mie theory. No analytical computation method is available for aggregates of nanoparticles. Numerical methods, like finite-difference time-domain (FDTD) method can be used.

We computed the scattering properties of aggregates of silver nanospheres using a three dimensional monochromatic version of recursive convolution finite-difference time-domain (RC-FDTD) method [2]. In contrast with the conventional broadband RC-FDTD [3], the monochromatic version allows one to use the handbook values of permittivity of the material of the particles at every simulation wavelength. The algorithm employs the 1st order Drude model [3] to make it stable for metals with negative real part of permittivity. The particle-aggregates are generated using a random number generator that distributes nanospheres uniformly throughout a larger sphere made of the homogeneous binder medium.

9170-23, Session 4

Spin Hall effect of light reflected from an air-magnetic thin film interface

Jinli Ren, Yan Li, Jianbo Yang, Qihuang Gong, Peking Univ. (China)

The displacements for |P> polarization (electric field parallel to the plane-of-incidence) and |S> polarization (electric field perpendicular to the plane-of-incidence) induced by the spin Hall effect of light reflected from a magnetic cobalt thin film have been investigated. The significant differences from those of an air-glass interface are attributed to the special complex permittivity and refractive index of the cobalt film. The real part of the complex refractive index has more influence on displacements for |P> polarization than for |S> polarization. There also exists a particular incident angle corresponding to the zero displacement for |P> polarization. It shifts from 52 to 76 degree when the real part rises from 1.0 to 4.0. For both |P> and |S> polarizations, the maximal displacements rapidly rise with the decrease of the imaginary part. Our simulations further demonstrate that polarization-insensitive spin separations can be realized by choosing the medium with an optimal permeability.

9170-24, Session 5

Monolithic mode-locked lasers based on high finesse silicon ring resonators

Milad Akhlaghi Bouzan, William Hayenga, Peter J. Delfyett Jr., Mercedeh Khajavikhan, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Low noise mode-locked lasers and stabilized optical frequency combs are receiving considerable attention due to their broad spectrum of applications that ranges from signal processing and communications to metrology. Progress has been made in the realization of ultralow noise pulse trains that are used as sampling pulses for analog to digital converters from electrically efficient and compact semiconductor gain media. However, these realizations require ultralow expansion (ULE) quartz etalons for filtering the axial mode groups, making miniaturization difficult. Further advances are needed to reduce the size of these sources so that a chip-scale footprint can be achieved to enable new applications. One important step towards miniaturization is the integration of a high finesse optical filter that would serve to replace the ULE etalon.

In this talk, we report our experimental results towards the realization of a fully integrated mode-locked semiconductor laser. We present a high finesse and large FSR ring resonator capable of generating pulses at a repetition rate of ~32 GHz when is coupled to a semiconductor amplifier via a larger fiber loop. In addition, an intensity modulator incorporated in the fiber loop and modulated at the free spectral range of the ring resonator produces a stabilized mode-locked optical frequency comb. The performance specifications of this system will be presented and compared with state of the art etalon-based cavities for the realization of on-chip mode-locked lasers. We also present our recipe for fabricating large and low loss silicon ring resonators pertaining to this work.

9170-25, Session 5

Optimization of mode pattern and transmission analysis of GaN LED with ITO grating

Juliet Chico, Gabriela Aleman, Xiaomin Jin, California Polytechnic State Univ., San Luis Obispo (United States)

We study nano-ITO grating surface GaN LED to improve light extraction efficiency by optimizing the device parameters. We propose new study method which is optimization of mode pattern and transmission analysis of an LED. Modal and transmission analyses are performed on a gallium nitride (GaN) based light emitting diode to achieve maximum light extraction. Optimization is achieved when the cavity and waveguide modes are in their best condition, emitting waves that interfere constructively with the nano-grated LED, produced by the best grating case. The various structural effects of the nano-gratings on light transmission are investigated, thus concluding that the transmission efficiency has a strong dependence upon these structural effects brought forth by the parameters of the nano-grated structure. By varying the period, height, and width of the ITO grating, we generated a 69.42% efficiency increase in the light extracted compared to the non-grating case of 54.74%, which is a 27% improvement. The grating location is also investigated through modal analysis, which shows that the optical confinement factor (OFC) is greatly dependent on this parameter, reaching a maximum of 13.21%. With the improved grating location, a transmission analysis is performed, producing the light transmission of 81.88%, compared to the non-grating case of 55.89%, achieving a 47% improvement.

9170-27, Session 5

Construction of germanium nanowire and nanotube arrays by electrodeposition from an ionic liquid

Jiupeng Zhao, Xusong Liu, Yao Li, Harbin Institute of Technology (China)

Germanium have gained much attention as a promising semiconductor material and one-dimensional gemanium nanostructures both in the form of nanowire (NW) and nanotube(NT), are proven to be the most interesting structures due to their unique shapes and microstructures. Therefore it has significance and scientific value to explore a new method for construction 1D germanium arrays and to study their properties. Electrodeposition of semiconductors in ionic liquids shows its unique advantages. The arrays of germanium nanowires and nanotubes are constructed by using template assisted electrodeposition in ionic liquids for the first time. The composition and microstructures of 1D germanium arrays are studied in detail. The relationship of process parameters, compostion and microstructure are discussed in order to improve performances of the materials. The growth process and the mechnism of germanium NW and NT are also discussed.

9170-28, Session 5

Multi-cell design for III-N avalanche photodiodes

Puneet Suvarna, Jack Bulmer, Jeffrey M. Leathersich, Jonathan Marini, Fatemah S. Shahedipour-Sandvik, SUNY College of Nanoscale Science and Engineering (United States); L. Douglas Bell, John Hennessy, Shouleh Nikzad, Jet Propulsion Lab.

(United States) and California Institute of Technology (United States)

GaN and AlGaN (III-N) avalanche photodiodes (APDs) are emerging as an alternative to current ultraviolet(UV) photodetector technologies based on UV enhanced Silicon, micro-channel plates, and photo multipliers. They promise high quantum efficiency, tunable cutoff wavelength, visible and solar blind detection without the use of filters , high operating temperature and high-energy radiation tolerance. These properties are highly sought after, for applications in missile warning systems, corona detectors, space imaging, spectroscopy and other advanced applications.

Current work in III-N APDs is based on the p-i-n and p-i-n-i-n Separate Absorption and Multiplication (SAM) design. This work describes a new design for III-N based APDs based on a parallel array of micron sized III-N mesas. The multicell architecture creates a non-uniform electric field across the device resulting in localized avalanches at a lower voltage compared to a single cell photodiode of equivalent area. The APD structures are grown on sapphire substrates using optimized III-N metalorganic chemical vapor deposition (MOCVD) processes, followed by patterning using a BCl3/Cl2 Inductively coupled plasma etch and regrowth of the p-layer. Devices with diameters ranging from 20 to 120?m are fabricated and characterized for dark current, gain, spectral responsivity and other APD performance metrics. The measurement results are compared with physics based simulations done using Synopsys TCAD.

9170-29, Session 5

Enhancement of laser damage resistance of high- and anti-reflective optical multilayers by tailoring the electric field distribution and post annealing

Gülgün H. Aydogdu, Haci Batman, Alp Eren Sinan Özhan, ASELSAN Inc. (Turkey)

High performance reflectors are well known in the literature, however it is difficult to manufacture in the broad band and uv region with metal deposition due to adhesion and protection problems. In our approach we developed different design with PVD method and discussed the way to solve problems. Additionally, results tested by MIL standards are presented.

9170-30, Session 5

VLSI photonics for lidar sensors

Louay A. Eldada, Quanergy Systems, Inc. (United States)

We report on advanced VLSI photonic integrated circuits used for the production of light detection and ranging (LiDAR) sensors that enable real-time high-accuracy 3D mapping and object detection, tracking, identification and classification.

9170-31, Session 6

Ultra-high aspect ratio nanostructure fabrication using vertical directionality controlled metal assisted chemical etching *(Invited Paper)*

Anne Sakdinawat, Chieh Chang, SLAC National Accelerator Lab. (United States); Richard C. Tiberio, Stanford Univ. (United States); Michael J. Rooks, Yale Univ. (United States); Raymond Leung, Carl Zeiss X-ray Microscopy, Inc. (United States); Johanna L. Nelson Weker, SLAC National Accelerator Lab. (United States)

Vertical, directionality controlled metal assisted chemical etching (V-MACE), a method that can be used to fabricate ultrahigh aspect ratio, dense, nanoscale features, will be presented. Using V-MACE, we have fabricated high efficiency x-ray diffractive optics for the hard x-ray region for applications in x-ray microscopy, x-ray diffraction, and astronomy. Structures include x-ray Fresnel zone plates and spiral zone plates with aspect ratios ranging from 20:1 to greater than 100:1 aspect ratio with feature sizes currently ranging from 30 - 100 nm.

9170-32, Session 6

Nano fabrication of compound bifocal zone plate for x-ray optics

Armen V. Kuyumchyan, American Nanoscience and Advanced Medical Equipment, Inc. (United States); Alexey Y. Suvorov, Japan Synchrotron Radiation Research Institute (Japan)

The development of nanotechnology gives new possibilities for fabrication of different X-ray optical elements. The compound silicon crystal Zone Plate (ZP) is fabricated by an electron beam lithography and lift-off technology. ZPs structures have been etched by ion-plasma up to 6 µm deep. A linear ZP of the first and second orders fabricated for X-ray radiation 10 kev energy, the focal distance is 57sm. The experiment was performed at the beam line BL29XU Spring-8 of the Japan Synchrotron Radiation Facility. The experimentally and theoretically investigations were done for x-ray energy at the 10 KeV and 12.4 keV (0.1nm wavelength). Depending on the absorption of ZP; it can be: a) amplitude ZP, b) phase ZP, c) amplitude-phase ZP. The radial distribution of intensity is determined as a convolution of the zone plate transmission function and the Kirchhoff propagator in par-axial approximation. The algorithm is based on the FFT procedure and studied by means of computer programming simulation.

9170-33, Session 6

A spiral focusing vortex lens: shaping scalable orbital angular momentum of light

Hong Liu, A*STAR Institute of Materials Research and Engineering (Singapore); Muhammad Q. Mehmood, Kun Huang, National Univ. of Singapore (Singapore); Karen L. Ke, A*STAR Institute of Materials Research and Engineering (Singapore); Huapeng Ye, National Univ. of Singapore (Singapore); Patrice Genevet, Harvard School of Engineering and Applied Sciences (United States); Mingsheng Zhang, A*STAR - Data Storage Institute (Singapore); Cheng-Wei Qiu, National Univ. of Singapore (Singapore); Jinghua Teng, A*STAR Institute of Materials Research and Engineering (Singapore)

Recent developments have shown that light's orbital angular momentum (OAM) can be harnessed for a diversity of applications including optical manipulation, microscopy imaging, astronomy, quantum information, optical communication and remote sensing. The traditional vortex phase plate and recently-proposed metasurfaces are all discrete devices to generate Laguerre-Gaussian (LG) and higher-order Bessel beams of an intrinsic limitation—increasing the topological charge will lead to a dispersion of annular intensity followed by a lower photon density. To harness OAM in practice, for example, quantum entanglement, optical trapping and atom-level optical manipulation, optical vortex beam simultaneously carrying highly concentrated photons as well as substantial amount of OAM are in great demand. In this study, we demonstrate a spiral vortex lens to generate as well as focus optical vortex beam twisting around its beam-axis to follow a conical trajectory with the unique feature of a crescent-shaped intensity cross section, which is microscopically-confined and projected to as far as ~ 50? away in free space. Scalable OAM can be achieved simply by manipulating its radial and azimuthal factors. Due to the aperiodic and continuously variant nanostructure, it provides a compact solution to produce scalable OAM concurrently with highly concentrated photons through continuously modulating the amplitude and phase in the diffraction field. Comprehensive theoretical studies reveal that this fantastic property comes from the anisotropic inhomogeneity in the nanostructures, which governs the interaction of the spiral vortex lens with light over a broadband range. Acting as in-principle an inexhaustible-OAM turbine, this spiral focusing vortex lens has great potentials in optical manipulation, 3D light shaping, laser processing and photonics miniaturization.

9170-34, Session 6

Omnidirectional wavelength selective emitters/absorbers based on dielectric-filled anti-reflection coated two-dimensional metallic photonic crystals

Yi Xiang Yeng, Jeffrey B. Chou, Massachusetts Institute of Technology (United States); Veronika Rinnerbauer, Johannes Kepler Univ. Linz (Austria); Veronika Stelmakh, Yichen Shen, Sang-Gook Kim, Massachusetts Institute of Technology (United States); John D. Joannopoulos, MIT Institute for Soldier Nanotechnologies (United States); Marin Soljacic, Ivan Celanovic, Massachusetts Institute of Technology (United States)

We demonstrate designs of dielectric-filled anti-reflection coated (ARC) two-dimensional (2D) metallic photonic crystals (MPhCs) capable of omnidirectional, polarization insensitive, wavelength selective emission/absorption. Up to 26% improvement in hemispherical emittance/absorptance below the cutoff wavelength is observed for optimized hafnium oxide filled 2D Tantalum (Ta) PhCs over the unfilled 2D Ta PhCs. The optimized designs possess high hemispherical emittance/absorptance of 0.86 at wavelengths below the cutoff and low hemispherical emittance/absorptance of 0.12 at wavelengths above the cutoff, which is extremely promising for applications such as thermophotovoltaic energy conversion, solar absorption, and infrared spectroscopy.

9170-35, Session 7

A versatile platform for sp2-carbon substrate non-covalent functionalization by supramolecular self-assembly: towards applications in nanophotonics *(Invited Paper)*

André-Jean Attias, Ping Du, David Kreher, Fabrice Mathevet, Univ. Pierre et Marie Curie (France); Fabrice Charra, Commissariat à l'Énergie Atomique (France)

In view of the demanding forthcoming applications in nanotechnology, it is of prime interest to create functions out-off the plane and fully exploit the room above the substrate. Accessing the third dimension is so a mandatory step for nanooptics/electronics. Previously we introduced the Janus-like 3D tecton concept. It consists of a dual-functionalized unit presenting two faces linked by a rigid spacer: one face (A) is designed for steering 2D self-assembly, the other one (B) is a functional molecule. The objective is to take advantage of the in-plane self assembling of building blocks lying on face A to control the positioning of out-off plane active unit B, linked to the base by a rigid pillar. Here we present a series of Janus tectons incorporating chromophores ranging from fluorescent dyes to photoswitchable molecules. We will present the optical properties in solution as well as the properties of the self-assembled functional monolayers on sp2-hybridized carbon supports investigated by STM. The successful self-assembly on graphene, together with the possibility to transfer the graphene monolayer onto various substrates, considerably expends the domains of application of our functionalization strategy

9170-36, Session 7

Laser-assisted biosynthesis for noble nanoparticles production

Nickolai V. Kukhtarev, Tatiana V. Kukhtareva, Vernessa M. Edwards, Sherita Moses, Alabama A&M Univ. (United States)

Extracellular Biosynthesis technique (EBS) for nanoparticles production attracted a lot attention as environmentally friendly and not expansive methodology. Our recent research was focused on rapid approach of the green synthesis method and achievement of reduction and homogeneous size distribution of nanoparticles by pulse laser application. Noble nanoparticles (NNPs) were produced using various ethanol and water plant extracts. The choice of plants in the present paper has been made based on their biomedical applications. In this paper, leaved plants such as Magnolia Grandiflora, Geranium, Aloe 'Tingtinkie', Aloe Barbadensis (aloe vera), Eucalyptus Angophoroides, Sansevieria Trifasciata, Impatiens Scapiflora, with water and ethanol extract, were used as reducing agents to produce nanoparticles. The reaction process was monitored using UV-Visible spectroscopy. NNPs were characterized by Fourier Transfer Infrared Spectroscopy (FTIR), Transmission Electron Microscopy (TEM), Dynamic Light Scattering technique (DLS). During the pulse laser Nd-YAG illumination (λ=1064nm, 532nm, PE= 450mJ, 200mJ, 10 min) the blue shift of surface plasmon resonance absorption peak was observed from ~424nm to 403nm for silver NP; and from ~530nm to 520 nm for gold NPs. In addition, NNPs solution after Nd-YAG illumination was characterized by narrowing of the surface plasmon absorption resonance band, which corresponds to monodispersed NNPS distribution.
FTIR, TEM, DLS, Zeta potential results demonstrated that NNPs were surrounded by biological molecules, which naturally stabilized nanosolutions for months. Cytotoxicity investigation of biosynthesized NNPs is in progress.

9170-37, Session 7

Nanoimpriont fabrication of wiregrids micro-polarizers in near infrared spectra using SU-8 as an intermediate film

Junxin Wang, Andrew M. Sarangan, Univ. of Dayton (United States)

Polarization imaging in the visible spectrum is an area of growing interest, but the technology to integrate pixel-level polarizers has proven to be difficult. A number of different techniques have been used in the past, but the least obtrusive method is to fabricate the wiregrids on a transparent substrate and hybridize it to the image sensor. Wire grids are most easily fabricated by lift-off lithography, but this comes at the expense of reduced aspect ratios and reduced optical extinction ratio. An attractive alternative is the damascene process, where grooves are first etched into a dielectric and then planarized with the desired metal. Although silica glass is the most desired substrate for visible applications, compared to silicon it is more difficult to process because of its poor photoresist etch contrast and adhesion. In this paper, we demonstrate a different technique for the damascene process where a polymer film on glass is used as the substrate for imprinting the grooves, followed by metallization and planarization. A high resolution 150nm periodic stamp is fabricated on silicon using deep UV (266nm) interference lithography and deep silicon etching. This nanostructure pattern is transferred onto a patternable epoxy (SU-8) using vacuum thermo-compression and in-situ UV exposure and thermal curing. SU-8 was chosen because it is optically clear and easily imprinted. Because of its mechanical properties, it is also durable and can withstand the planarization step. In this paper we will show the results from this process, including process details, SEM images and performance data.

9170-38, Session 7

Breaking the diffraction limit with photoinhibited superresolution lithography

Darren L. Forman, Robert R. McLeod, Univ. of Colorado at Boulder (United States)

Photoinhibited superresolution (PInSR) lithography is a two-color, one-photon technique promising fast sub-diffraction limit patterning in the far-field. While previous work has shown that the method is susceptible to blurring from reactive species diffusion, we have recently successfully addressed the issue with a low-mobility methacrylate resist. Here we demonstrate superresolved patterns, with feature spacing 3x better than the 0.2 NA diffraction limit. To better understand the photocrosslinking resist used to generate these results, we propose new methods for probing reactive species concentration and polymerization dynamics at submicron scales. Experimental results help to guide the development and calibration of a coupled PDE kinetic model, which is also presented. Numerical simulations using the model are then used to further explore the system dynamics and inform efforts to improve resolution, photospeed and pattern fidelity.

9170-40, Session 8

Computational analysis of noble ZnO/MgO branched nanorod structure on V-LED with finite-difference time-domain method

Jae Yong Park, HyungWon Cho, Pohang Univ. of Science and Technology (Korea, Republic of); Byeong-Uk Ye, Jeong Min Baik, Ulsan National Institute of Science and Technology (Korea, Republic of); Jong-Lam Lee, Pohang Univ. of Science and Technology (Korea, Republic of)

GaN based light emitting diode (LED) is one of the most promising solid-state lighting due to high efficiency and long life time. However, most of the generated photons are confined in the device due to its total internal reflection (TIR) and only 4.1% of photons can contribute to the efficiency. Many attempts are being made to improve the light extraction efficiency of GaN LEDs such as surface texturing, photonic crystals and nanostructures. However, these methods are expensive and show limits in increasing the light extraction efficiency. Another promising method is using ZnO nanorod structures on GaN LED as a light extraction layer. This showed enhancing up to 79% than flat LED in the light extraction, but this effect originating from size reduction (<100nm) of nanorod was not practical to make. Waveguide from the TIR also can be generated in ZnO nanorod so that makes limitation on enhancing light extraction. In this report, a ZnO nanorod on which MgO branches were grown on the side walls are designed to maximize the extraction of photons. The light extraction mechanism is analyzed by Finite-difference time-domain (FDTD) method which the far-field and electric-field distribution shows further extraction of the light wave-guided inside ZnO nanorod through MgO branches. Compared to ZnO nanorod, the optimized ZnO/MgO branched nanorod structure (radius 25nm, height 500nm MgO branches) enhanced extraction efficiency up to 68%.

9170-41, Session 8

Polarized light emission by deposition of aligned semiconductor nano rods

Mohammad Mohammadimasoudi, Lieven Penninck, Univ. Gent (Belgium); Tangi Aubert, Raquel Gomes, Zeger Hens, Univ. Gent (Belgium); Filip Strubbe, Kristiaan Neyts, Univ. Gent (Belgium)

The ability to control the position and orientation of nanorods (NRs) in a device is interesting both from a scientific and a technological point of view. Because NRs exhibit anisotropic absorption, and spontaneous and stimulated emission, aligning individual NRs to a preferred axis is attractive for many applications in photonics such as solar cells, light-emitting devices, optical sensors, switches, etc.

Electric-field-driven deposition from colloidal suspensions have proven to be an efficient method for the controlled positioning and alignment of anisotropic particles. In literature strong AC fields are combined with casting of single drops and subsequent drying of the solvent, which is not compatible with reproducible and homogeneous deposition on large substrates as required for large size applications such as solar cells or OLEDs. In this work, we present a novel technique for the homogeneous deposition and alignment of CdSe/CdS NRs on a glass substrate patterned with transparent indium tin oxide (ITO) interdigitated electrodes, with a spacing of a few micrometers. This method is based on applying a strong AC electric field over the ITO electrodes during the dip-coating procedure and subsequent evaporation of the solvent. The accumulation, alignment, and polarized fluorescence of the NRs as a function of the electrical field during deposition are investigated. An alignment with order parameter of 0.67 and a polarization ratio of 0.60 has been obtained.

9170-42, Session 8

Design of single-polarisation single-mode photonic nanowire

Amira Baili, Rim Cherif, Amine Ben Salem, SUP'COM (Tunisia); Than Singh Saini, Ajeet Kumar, Ravindra K. Sinha, Delhi Technological Univ. (India); Mourad Zghal, SUP'COM (Tunisia)

Waveguides with sub-wavelength dimensions known as photonic nanowires have the potential in realizing single-polarization single mode (SPSM) fibers, which guide only one polarization state of fundamental modes, have greater advantages in polarization sensitive applications, such as fiber optic gyroscopes, fiber optic current sensors, high-power fiber lasers, and coherent optical communications.

In this paper, we have presented a novel design approach for realizing photonic nanowires that can deliver SPSM performance. By producing high anisotropies in the core and the cladding structure through the elimination of lines of air holes in the cladding while two air holes are removed as the core, a high birefringence which accounts for a broadband of SPSM transmission is obtained. Therefore, aiming to have a low confinement loss, eight air holes are enlarged surrounding the silica core region.

By applying the full-vector finite element method with an anisotropic perfectly matched layer as boundary conditions (PML), the optical properties of the proposed design including the birefringence, the effective mode area, nonlinearity, the confinement loss and the chromatic dispersion are investigated in detail. The simulation results demonstrate that the proposed nanowire characterizes an ultra-wideband range of 620 nm for SPSM operation which typically includes all the transmission telecom windows. We have found that the designed SPSM-nanowire exhibits low loss through the slow axis fundamental mode within the wavelengths ranging from 1.28 to 1.9 µm. The confinement loss of the slow axis mode is less than 0.15 dB/km while the fast-axis mode is unguided. Moreover, the dispersion profile can be highly tailored to achieve flat or zero dispersion around the 1.55 µm telecommunication wavelength.

9170-43, Session 8

Generation of ZnSSe and CdZnS nanoparticles by laser ablation in liquids

Maarif A. Jafarov, Baku State Univ. (Azerbaijan)

Here, we report the synthesis of ZnSSe and CdZnS nanoparticles by laser ablation of the bulk material in different solvents and their characterization by absorption spectroscopy and transmission electron microscopy (TEM). The properties of the resulting particle, which are not stabilized by binding groups other than the solvent, will be discussed.

The laser light used for the ablation was the second harmonic wave (532 nm) of a high frequency Nd:YAG laser.

The pulses were focussed onto a piece of bulk semiconductor, which was held inside a quartz cell with 1 cm pathlength containing 3.5 ml of a solvent. The position of the sample cell with respect to the incident laser beam could be accurately adjusted in three directions by means of micrometer screws. For all experiments a lens with a focal length of 5 cm was used. The laser pulses had a duration of ≈600 ns and pulse energies between ≈5 and 10 mJ. The repetition rate of the laser was generally 50 Hz and the total ablation time per measurement was typically several minutes. The estimated photon fluencies varied between ≈5 and ≈30MWcm-2. Since nonlinear refraction and thermal heating can significantly affect the focussing conditions, the photon fluence at the surface of the semiconductor can vary from solvent to solvent and it depends on the particle yield. The fluence also changes during the ablation process. At the start of an ablation experiment before nanoparticles are formed at a significant number density, the focus is usually tighter, as particle shielding, and refractive and thermal effects are less pronounced. Generally laser ablations were executed in air-saturated solvents which were not stirred during the ablation.

Before each ablation reference spectra of the pure solvents were measured in order to ensure that no traces of impurities remained in the ablation cell. When after the initial laser ablation the particle suspensions were additionally exposed to focussed laser pulses, the colour of the suspensions changed from light grey to almost transparent.

As opposed to the ablation experiment we chose a much higher laser repetition rate for the irradiation experiment since the rate of change of the sample absorption was small. The fact that the laser energy per pulse is smaller at the high repetition rate did not seem to affect the outcome of these experiments. In some samples agglomeration of particles in the form of tiny flakes appearing in the suspension was observed upon prolonged exposure to laser pulses. At first inspection, the change of the spectra could therefore be based on gravitational precipitation of larger particles, which would explain the absorbance decreasing over the entire wavelength range of the spectrum with increasing exposure time.

The semiconductor nanoparticles exhibited different stability in the different solvents. Suspensions of ZnSSe and CdZnS in acetonitrile appeared to be most stable with precipitation times of many weeks. Acetone also stabilized both semiconductor nanoparticles rather well. In alcohols (methanol and also in triethyleneglycol) the particles fell out of suspension more rapidly, typically within days (in the case of ZnSSe in methanol even within a few hours).

We demonstrated that approximately spherical ZnSSe and CdZnS nanoparticles can be produced by laser ablation of the bulk material in solution. The particles are not highly monodispersed with radii of (10±3) nm as shown by TEM. The radii were estimated on basis of a pseudo-potential calculation in the weak and strong confinement regime. The size distribution could be shifted by prolonged laser irradiation of suspensions after the initial ablation; two mechanisms for the size reduction were suggested. The absorption behaviour of nanoparticle suspension is not strongly dependent upon the presence of oxygen during and after ablation. The ablation is not strongly solvent dependent, with the exception of water. A reproducible photoluminescence from laser-ablated ZnSSe and CdZnS particles in suspensions was not observed.

9170-44, Session 8

Deep UV microsphere nanolithography to achieve sub-100 nm feature size

Alireza Bonakdar, Hooman Mohseni, Northwestern Univ. (United States)

Fabrication of nanostructures for bio-sensing and light trapping/extracting applications is typically accompanied by slow production and limited area due to the required sub-micron feature size. In these applications, periodic array of metal/dielectric features can produce important optical resonance responses such as Fano response, chiral response, and negative refractive index. Here, we propose a deep ultra-violet (DUV) photolithography technique that can produce a variety of periodic nanostructure clusters with a sub-100 nm feature size. The method is based on microsphere nanolithography, which focuses DUV field into the so-called photonic nano-jet – a propagative intensive field underneath the sphere. The position of photonic nano-jet can be moved by changing the angle of exposure. The DUV microsphere nanolithography is inherently self-aligned, mask-less and optics-less (the optical element such as lens is not required), which makes this method attractive for low-cost and high-throughput nano-manufacturing schemes, such as roll-to-roll production. Here, we present fabricated arrays of nanoscale complex structures to demonstrate the capabilities of this nanolithography method.

9170-45, Session 8

Optimizing computer control ball polishing of spherical surfaces

Rasool Koosha, Peiman Mosaddegh, Hosein Hashemi, Isfahan Univ. of Technology (Iran, Islamic Republic of)

About half a century ago, computer controlled-polishing (CCP) was represented as a respond to great demand for precision glass manufacturing. Since then, CCP is developed to challenge the difficulties of manufacturing of more complex optical components. Simulation of polishing process and optimization of dwell time are the most prominent key factors of CCP in which numerous papers are published. In this paper, a new model based on discretizing tool path with sub-millimeter distances in length is presented to simulate polishing process. As a result, complex polishing tool path as spiral or epicyclical tool path can be easily and precisely modeled with 50-100 micron accuracy. Converting continuous tool path to discrete points with small steps would improve surface quality in an optimum time and it also reduces fluctuation in tool feed rate. This smooth gradient in feed rate can improve final quality and prevent any damage to polishing machine. Then, a fuzzy algorithm is programmed to optimize the dwell time of polishing process. Considering initial surface error under tool positions and tool influence removal rate, the method calculates optimum dwell time distribution to reduce surface roughness in a short period of time. Both polishing simulation and dwell time fuzzy optimization algorithms are easy to program and could be conducted to operate the CCP on a 3 axis CNC machine. The methodology developed in this study is used for ball polishing of spherical lenses. To establish the authenticity of represented method, a BK7 flat lens with 130 mm in diameter and 320 mm radius in curvature was selected to perform CCP process. The result of initial surface measurement shows 1.114µm of surface roughness for PV (Peak to Valley) and 175 nm for rms (Root Mean Square). The represented method was applied to calculate the optimum dwell time distribution over a spiral tool path with 1 mm in step over. Based on the simulation results, the 3axis CNC machine was programmed to operate polishing process. Based on the final surface measurement, the surface roughness was reduced to 394 nm for PV and 74 nm for RMS. The experimental results show that surface error declined by 64% in PV and 57% in rms which are in good agreement with the modeling.

9170-47, Session PWed

Fabrication of high aspect ratio silicon gratings by interference lithography and potassium hydroxide anisotropic etch technique

Yanchang Zheng, Keqiang Qiu, Univ. of Science and Technology of China (China); Xiaolong Jiang, Qingbo Wang, Lixiang Wu, Lali Bi, Yilin Hong, University of Science and Technology of China (China)

The authors report a new process for the fabrication of 320nm period gratings with ultrahigh aspect ratio on (110) oriented silicon-on-insulator (SOI) wafers. This new fabrication process combines Lloyd-mirror interference lithography with aqueous potassium hydroxide (KOH)

anisotropic etch technique. An alignment method with small error (within ±0.062°) was developed to align grating patterns to the vertical (111) planes of (110) SOI wafers. In addition, a room temperature etch process using 50wt%KOH was chosen to finally get an etch anisotropy of 231. Better etch uniformity was achieved by adding a surfactant to the aqueous KOH to promote the release of hydrogen bubbles. To increase latitude in KOH etching process, evaporation of aluminum under a sloped angle with respect to the grating structures was utilized to obtain a high duty cycle nitride mask. To prevent the collapse of ultrahigh aspect ratio grating structures caused by surface tension, a liquid carbon dioxide supercritical point dryer was used in the drying process. The authors successfully fabricated 320nm period gratings with aspect ratio up to 100 on a 5-um-thick silicon membranes on (110) SOI wafers. This nanofabrication process could also be widely applied in the fabrication of other periods and more complicated silicon gratings.

9170-48, Session PWed

Fabrication and microscopic analysis of sheath-core structured TiO_2 nanofibers

Dong-Gue Kang, Dae-Yoon Kim, Min-Wook Park, Soon-Chun Park, Won-Jin Yoon, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

Fabricated nanofibers containing epitaxially grown single crystalline TiO2 nanowires with anatase structure were successfully fabricated by electrospinning method of poly(vinylpyrrolidone) solutions mixed with single crystalline titanium dioxide nanowires and titanium (IV) isopropoxide Ti(OiPr)4 precursor. Utilizing SEM and TEM, morphological examination was conducted. Structure and orientation of the epitaxially grown TiO2 single crystalline nanofibers were also identified by the combined techniques of WAXD and SAED. Improved optoelectronic properties of TiO2 nanofibers were also identified by UV-Vis spectroscopy experiments. This work was mainly supported by Converging Research Center Program (2013K000404), Basic science Research Program (2013R1A1A2007238), Global Ph.D Fellowship Program (2013H1A2A1033907), and BK21 PLUS Program, Korea.

9170-49, Session PWed

Transparent conducting ZnO nanorods for nanoelectrodes as a reverse tunnel junction of GaN light emitting diode applications

Sung Jin An, Kumoh National Institute of Technology (Korea, Republic of)

Homogeneous and heterogeneous semiconductor nanostructures have already been employed for fabricating light emitting devices (LEDs). Despite a remarkable advance in the nanodevice fabrications, the practical use of the nanodevices has still remained out of reach. Meanwhile, well-developed device fabrications in top-down approach have yielded high brightness GaN-based LEDs in a market. Nevertheless, the LED efficiency should be increased for general illumination. Since the internal quantum efficiency is quite high enough, recent efforts on increasing LED efficiency has been focused on enhancing light extraction efficiency by reducing total internal reflection. In addition to the low light extraction efficiency, a highly resistive p-contact layer on nitride semiconductors has been another big obstacle in fabricating high efficiency LEDs. Here we demonstrate that reverse tunnel junction (TJ) LEDs fabricated with a hybrid structure of vertical ZnO nanorod arrays grown on GaN can improve the LED efficiency, size, and structure significantly. The I–V curve of the GaN LEDs with TJ-ZnO NRs exhibits Schottky performance. Also, GaN LEDs with TJ-ZnO NRs demonstrated four times enhanced light output power compared with that of TJ-ZnO thin film, resulting from increased light extraction efficiency. TJ-ZnO NRs offers both high transparent current spreading layer for uniform current injection and easy method for high extraction efficiency. Also, this technique can expand the design flexibility of optoelectronic devices, allowing LEDs without semi-transparent p-contacts and p-GaN etching. More generally, we believe that the simple bottom up heteroepitaxial approach may readily be expanded to fabricate many other heteroepitaxial semiconductor nanorod optoelectrical devices.

9170-50, Session PWed

Nonlinear ultrasound formation in semiconductor structures under its pulse laser irradiation

Mykola Melnichenko, Mykola Isaiev, Oleg V. Lyashenko, National Taras Shevchenko Univ. of Kyiv (Ukraine); Oleksandr I. Vlasenko, V.E. Lashkaryov Institute of Semiconductor Physics (Ukraine); Andrey Kuzmich, National Taras Shevchenko Univ. of Kyiv (Ukraine); Vitaliy P. Veleshchuk, V.E. Lashkaryov Institute of Semiconductor Physics (Ukraine); Roman Burbelo, National Taras Shevchenko Univ. of Kyiv (Ukraine)

Laser irradiation is successfully applied in various areas of modern material research. Such powerful pulse laser irradiation is often used in the processes of nanomaterials fabrication, e.g. when rapid annealing is needed.

Moreover, pulse laser based techniques are essential tools for nanomaterials and nanocomposite structures study. In particularly, laser ultrasound (LU) techniques are perspective for simultaneous investigation of thermal and elastic properties of such materials at different scales. These techniques are based on photoacoustic effect - transformation of absorbed electromagnetic radiation into ultrasonic waves. It should be mentioned that the efficiency of such transformation strongly increased with density of excitation radiation, so the nonlinear phenomena (such as dependence of thermal physical and elastic parameters on temperature) play a crucial role for processes of LU formation.

In this paper the results of theoretical and experimental investigation of ultrasound generated in semiconductors structures under its irradiation by pulse laser irradiation with different wavelengths. It was shown that nonlinear behave of LU amplitude dependence on excitation radiation intensity mainly caused by temperature dependence of thermal conductivity of investigated media. The obtained results could be applied to ensure perfect control for in-situ nanomaterials fabrication processes study.

Surface potential and field effect in structures with Ge-nanoclusters grown on Si(100) surface

Yurii Hyrka, Sergiy V. Kondratenko, National Taras Shevchenko Univ. of Kyiv (Ukraine)

The structures consisting of Ge-nanoclusters grown on silicon oxide layer are promising candidates for optoelectronic devices as well as for nonvolatile memory circuits, nanotransistros and solar cells. This is due to their optical and photoconductive properties.

Crystalline germanium nanoclusters (NCs) are grown by a molecular-beam epitaxy technique on chemically oxidized Si(100) surface at 700ºC.

Lateral transport and Kelvin force microscopy measurements have shown that structures with Ge-nanoclusters, grown on oxidized silicon surface characterized by fluctuations of the electrostatic potential caused by spatial distribution of holes trapped by quantum confinement states of Ge-nanoclusters or/and interface traps of Ge-nanoclusters/SiO2 and SiO2/Si interfaces. Field effect on lateral conductivity and surface photovoltage spectra were investigated.

9170-52, Session PWed

Comparison of triangular and squared ITO nano-grating of GaN LEDs

Ashli Behill, Tattiana K. C. Davenport, Xiaomin Jin, California Polytechnic State Univ., San Luis Obispo (United States)

We study nano-scale ITO top transmission gratings to improve light extraction efficiency by optimizing the device parameters. Our study is based on finite difference time domain (FDTD) method to measure light extraction from a device with various grating structures and layer thickness. We simulate our device using a two-dimensional model with top-gratings in a crystal lattice arrangement described by grating cell period (A), grating cell height (d), and grating cell width (w). We also define ITO layer thickness (L), as the layer between the p-type GaN and the ITO surface layers. Simulation models vary in grating period, grating width, and ITO layer thickness. Our simulations monitor the amount of light emitted from the top, bottom, and side of the LED model. These results are used to determine the total light extraction. Our study deals with a LED model with triangular-gratings. We achieve a 165.67% improvement for triangular ITO grating, which has an ITO layer thickness of 230nm, a 230nm grating width and 50 % duty cycle. Our study for square-gratings shows that it also can improve the total light extraction efficiency. Thus far, we have only achieved a 7.16% improvement with an ITO layer thickness of 230nm, a 230nm grating width and 10% duty cycle. We will present our comparison in further detail which will include various ITO layer thicknesses, grating widths and duty cycles.

9170-53, Session PWed

Large strain lead-free ceramics for piezoelectric actuators with nanoscale ceramic-ceramic composite structures

Jae-Shin Lee, Hyun-Young Lee, Jin-Kyu Kang, Univ. of Ulsan (Korea, Republic of); Soon-Jong Jeong, Korea Electrotechnology Research Institute (Korea, Republic of)

Increasing demand for environmentally friendly materials in both electronic and automotive industries promotes extensive studies on lead-free piezoelectric materials in order to replace Pb-based ones that contain over 60 wt% Pb. In this work, we studied the dielectric, ferroelectric, field-induced strain properties of Bi-based lead-free perovskite ceramics with A- or B-site dopants or other ABO3 compounds. Many Bi-based ceramics were found to show large normalized strains in the range of Smax/Emax = 500 – 700 pm/V at RT near ferroelectric-relaxor phase transition region. However, there still remain several challenges to be overcome for field applications; large strain-field hysteresis, high electric-field to trigger large strain, and strain stability in a limited temperature range. In order to overcome such barriers, we attempted to prepare ceramic-ceramic composites by embedding ferroelectric particles in a relaxor matrix, resulting in lowering the triggering field even though the maximum strain was almost unchanged. The ceramic-ceramic composites are believed to enlighten a new road to large strain lead-free alternatives of Pb-based actuator materials.

9170-54, Session PWed

Lightfast optical current in dielectric by plasmonically induced local field

Seungchul Kim, Pohang Univ. of Science and Technology (Korea, Republic of) and Max Planck Ctr. for Attosecond Science (Korea, Republic of); Ojoon Kwon, Pohang Univ. of Science and Technology (Korea, Republic of)

Recently, ultrafast strong field induced optical current in SiO2 dielectric medium has demonstrated. By inducing laser intensity more than 10^13 W•cm-2, the optical current was generated in a dielectric gap without any DC bias. This phenomena is affected by the magnitude electric field of incident laser field and the generated current follows the speed of optical frequency enabling lightfast electronics in the future. In this study, we especially applied nanoplasmonic field to trigger and control current flow in a nanometer spatial resolution. Nanoplasmonic field enables to manipulate light field in nanoscale domain. By using nanoplasmonic field, optically induced current flow can be selectively controlled by characteristic of nanoplasmonic nanostructure.

For that, saw tooth like 2D nano Au pattern was numerically and experimentally investigated to boost up the intensity of incident 3.5 fs few cycle laser with minimum field distortion and broadening. The intensity enhancement factor of plasmonic field at the saw tooth tip was ~40 enabling Wannier–Stark effect at incidence intensity level of only 10^11W•cm-2. This will be useful for developing practical lightfast optical electronics in the future.

9170-55, Session PWed

Preparation of Bi-based lead-free ceramic multilayer actuators

Jae-Shin Lee, Jin-Kyu Kang, Young Hwan Hong, Dae-Jun Heo, Dong-Wook Lee, Univ. of Ulsan (Korea, Republic of)

Piezoelectric materials that can interchangeably convert mechanical to electrical energy are widely used as sensors and actuators for electronic, automotive, and medical applications. Increasing demand for environmentally friendly materials in both electronic and automotive industries promotes extensive studies on lead-free piezoelectric materials in order to replace Pb-based ones that contain over 60 wt% Pb.

In this work, Pb-free multilayer ceramic actuators (MLAs) including Nb-doped Bi1/2(Na,K)1/2TiO3 (BNKT:Nb) ceramic layers with electrically conducting AgPd-ABO3 thick films were prepared using tape-casting and screen-printing. The co-firing induced defects in the MLAs were analyzed by examining co-firing induced deflections and microcracks as a function of sintering temperature as well as the composition of the inner electrode. It was found that co-firing induced deflections were significantly relieved by employing AgPd-ABO3 composite layers as inner electrodes instead of pure AgPd via reducing thermal mismatch between the electromechanical and electrode layers. We have successfully fabricated lead-free electrostrictive multilayer actuators with normalized strain Smax/Emax of 350 pm/V, which seems very promising for lead-free actuator applications.

9170-56, Session PWed

Graphene based multi-cavity terahertz absorbers

Jeong Min Woo, Hyunwoong Kim, Sungbae J. Lee, Jae-Hyung Jang, Gwangju Institute of Science and Technology (Korea, Republic of)

Terahertz (THz) frequency band has promising applications in the areas of security imaging, cancer diagnosis, and bio-sensors because THz wave has non-ionizing bio-innocuous property, transparent characteristics against cardboard or textile, and highly selective absorption spectral lines that can be used as “fingerprint” of various bio-materials.

For the construction of more application agile THz systems, devices, which emit, detect, absorb, and control THz waves efficiently, are required. THz absorbers are also interesting to selectively or totally reject background THz radiation in THz sensor systems.

In this study, graphene layers were utilized as thin resistive films to construct Salisbury screen absorbers and Jaumann absorbers in THz frequency range. The sheet resistance of graphene layer can be easily controlled by chemical modification of graphene surface to achieve optimum absorbance in both types of the absorbers. Salisbury screen

consists of a graphene layer, dielectric spacer layer, and backside reflector. The fabricated Salisbury screen based absorber exhibited multiband spectral responses with periodic absorption frequencies. Jaumann absorber consisting of periodically arranged multiple dielectric spacer layers sandwiched by multiple graphene layers and backside reflector provides wider bandwidth compared with Salisbury screen absorbers.

A Salisbury screen based absorber with chemically doped graphene layer having sheet resistance of 689 □/Ω exhibited absorbance values of 0.95 and 0.97 at 0.5 and 1.5 THz, respectively, and 3-dB bandwidth of 0.6 THz. Jaumann absorbers with double and triple stacked structures exhibited absorbance values of 0.72 and 0.92 at 0.5 THz, and much wider 3-dB bandwidths of 0.84 THz and 0.86 THz, respectively.

9170-57, Session PWed

Formation of sub-wavelength pitch regular structures employing a motorized multiple exposure Lloyd's mirror holographic lithography setup

Dainius Virganavicius, Linas Simatonis, Ausrine Jurkeviciute, Tomas Tamulevicius, Sigitas Tamulevicius, Kaunas Univ. of Technology (Lithuania)

Today technology is moving towards a direction of scaling down things to ever smaller dimensions. The trend since started by IC industry is expanding now into other areas, e.g. photonics, MEMS, microfluidics, sensors, etc. For that reason, there is an immense demand for techniques capable of producing nanoscale structures. Holographic lithography (HL) is emerging as a very promising, powerful and cost effective technique for surface patterning, among them. The biggest limitation of HL is that only periodic patterns can be produced. Despite this drawback, HL has been shown to be applicable for structuring photonic crystals, nanowires, porous membranes, magnetic dots, etc.

In this work 1D and 2D periodic nano structures in thin positive and negative tone photoresist, spin coated on float glass and crystalline silicon substrates were fabricated employing advanced, fully automated Lloyd mirror HL setup. The exposures were performed employing 15 mW power and 375 nm wavelength solid state laser with a coherence length extending over few meters. The laser beam was expanded employing microscope objective with 99 % transmission at the laser wavelength. 2D patterns were obtained applying sequential exposures with the sample rotation in between. Regular structures with different point lattice symmetries with half pitches reaching 100 nm were fabricated and investigated employing scanning electron and atomic force microscopes. The produced regular structures were used in the technology of refractive index sensors based on diffractive leaky wave mode as well as templates for capillary assisted particle deposition.

InP nanowires with axial/radial junctions for applications as light emitting diodes and photodetectors

Ali Nowzari, Lund Univ. (Sweden); Vishal Jain, Lund Univ. (Sweden) and Halmstad Univ. (Sweden); Magnus Heurlin, Kristian Storm, Magnus T. Borgstrôm, Lund Univ. (Sweden); Håkan Pettersson, Lund Univ. (Sweden) and Halmstad Univ. (Sweden); Lars Samuelson, Lund Univ. (Sweden)

Semiconductor nanowires with their sub-wavelength dimensions have opened a new era in semiconductor optics. Today nanowires can be fabricated with different compositions and structures, suitable for applications as light sources, detectors, light propagation media, solar cells and other optical devices. The nanometric dimensions of nanowires allows heteroepitaxy of III-V materials on Si, a major trend in realizing optoelectronic devices. InP nanowire-based Light emitting diodes (LEDs) and Photodetectors(PDs), monolithically integrated on Si, and operating at suitable wavelengths, can potentially be configured as transmitters/receivers for on-chip optical interconnects. In this work vertical arrays of InP nanowires, grown by MOCVD method on Nanoimprint Lithography (NIL) patterns are used to fabricate LEDs and PDs. p-i-n Junctions are formed axially throughout the length of the Nanowires as well as radially in the Core-MultiShell(CMS) configuration. Infrared LEDs has been fabricated and tested for electroluminescence as well as Infrared PDs tested for light response.

Conference 9171: Nanobiosystems: Processing, Characterization, and Applications VII

Monday - Wednesday 18–20 August 2014

Part of Proceedings of SPIE Vol. 9171 Nanobiosystems: Processing, Characterization, and Applications VII

9171-1, Session 1

Natural and nature-inspired semiconductors for biocompatible electronics *(Keynote Presentation)*

Eric D. Glowacki, Niyazi Serdar Sariciftci, Johannes Kepler Univ. Linz (Austria)

Many natural chromophores have recently emerged as suitable semiconducting materials for (opto)electronic applications. The motivation for exploring such molecules is the realization of biodegradable and biocompatible electronics fabricated from cheap and nontoxic materials. We find that natural pigment-forming dye molecules, such as those from the indigo family, form highly-ordered thin films with excellent ?-stacking. Using such films, we have demonstrated field-effect transistors (FETs) and complementary-like circuit elements utilizing exclusively natural materials operating at the state-of-the-art level with respect to mobility and operational stability in ambient conditions. These dyes show air-stable ambipolar charge transport with balanced hole and electron mobilities in the range of 1x10-2 – 2 cm2/Vs. Hydrogen-bonding causes strong intermolecular electronic coupling, resulting in optical properties dominated by excimeric and charge-transfer effects. A very important property is that these molecules form high crystal lattice energy solids with exceptional operational, thermal, and chemical stability. FETs with indigos can be operated without any passivation in highly-demanding aqueous environments, within a pH range from 3-11 and with a variety of different ions. We report on the results of stressing tests in such underwater environments. The –NH and =O functional groups lend themselves to easy functionalizing, which we have exploited to two ends: 1) creation of stable colloidal nanocrystals with controllable morphology and optical properties, and 2) biofunctionalization. We discuss also preliminary experiments concerning field-effect transistor biodetectors based on these materials. Hydrogen-bonded natural and nature-inspired materials are an interesting and previously unexplored class of organic semiconductors with inherent potential for biointegrated applications.

Organic semiconductor biophotonics *(Invited Paper)*

Ashu K. Bansal, Shuoben Hou, Olena Kulyk, Andrew McNeill, Eric Bowman, Univ. of St. Andrews (United Kingdom); James Ferguson, Ninewells Hospital and Medical School (United Kingdom); Ifor D. W. Samuel, Univ. of St. Andrews (United Kingdom)

There is a growing trend in medicine towards compact devices for monitoring and treatment. Such devices would ideally be flexible and wearable , thereby enabling ambulatory monitoring and treatment in which the patient can move around. Organic semiconductors have attractive properties for realizing this vision as they enable thin and flexible devices to be made. In this talk I will show three examples of such applications. The first is the development of a wearable light sources for skin cancer treatment. The second is a sensor using polymer LEDs and photodiodes to measure changes in tissue oxygenation. The third application is a muscle contraction sensor in which anisotropic scattering of light from a polymer LED is detected by polymer photodiodes, giving an optoelectronic device that could control a prosthetic limb. These results provide interesting directions for polymer optoelectronics, and the possibility of measuring a range of important biomedical processes.

9171-5, Session 2

The synthesis and bio/nano applications of DNA brushes *(Invited Paper)*

Kuniharu Ijiro, Hokkaido Univ. (Japan)

Polymer brushes are polymers in which individual polymer chains stand side by side on a surface, causing the chains to stick out like bristles on a brush. A DNA brush is a kind of polymer brushes. We newly prepared DNA brushes through the immobilization of biotinylated oligo-DNA on the streptavidin substrate and polymerization by DNA polymerase (Klenow Fragment exo-) as a surface initiated polymerization. To confirm the appearance and feature of the DNA brush, we determined the length and density of the grafted DNA and evaluated surface physical property. The DNA brushes were applied for the substrates of cell culture, functional interfaces and advanced lithography technology.

Metal array structures on the stimuli-responsive gel *(Invited Paper)*

Hideyuki Mitomo, Naonobu Shimamoto, Kenta Horie, Yasutaka Matsuo, Kenichi Niikura, Kuniharu Ijiro, Hokkaido Univ. (Japan)

Now technologies to fabricate nano-structures have been established well. And hydrogels are well known as the stimuli responsive materials. A large volume change can be induced by absorbing or exuding water, namely swelling or deswelling, on the hydrogel. In this work, we have developed the fabrication method of nano- or micro-patterned metal thin film on hydro-gels. We prepared gold (Au) thin film pattern on Si substrate by using top-down or bottom-up fabrication method. Molds for the gels were made up from the Si substrate with Au thin film pattern, transparent slide glass and silicone rubber spacer. We poured the monomer solution

into the mold and carried out the polymerization by UV irradiation for several hours. After that, hydro-gels with thin film patterns were released from the mold. Au thin film patterns were transferred on the PAA gel due to their interaction and the gel showed structural colors depending on the dot spacings or the plasmon absorption. These structural colors or plasmon absorption were changed when the gel was immersed in various NaCl solutions because the distance between each Au dot had been changed by swelling and shrinking of the hydrogel. This shows that we created a new type of tunable photonic devices based on soft and wet matters.

9171-8, Session 2

A thylakoid layer-by-layer assembly for stable cell-free photosynthesis devices

Bong Sup Shim, Yuran Shon, Hongsup Hwang, Hyun Kim, Inha Univ. (Korea, Republic of)

Spinach chloroplast thylakoids, on which complete sets of photosynthetic membrane proteins are preserved and which behaved as nanoparticles, were densely organized by molecularly controlled layer-by-layer (LBL) assembly. The resulting nanostructured composite films showed photoelectrochemical activities with thylakoids whose stabilities were much improved on the LBL multilayers compared to one on a randomly structured film or in solution. The thylakoids LBL films could generate photochemical electrons continuously with the 2,6-dichlorophenolindophenol (DCPIP) mediated photosynthetic energy conversion cycle for more than a week. The PC12 neural cells were also proliferated and differentiated on this nanostructured photosynthesis film. Because the photofunctional groups of the films originated from a purely biotic system, the reported thylakoid LBL film have biocompatibility, biosafety, and biodegradability, essential qualities of eco-friendly electronic applications, such as in disposable electronics and implantable meditronics, as well as cell-free fuel production.

Investigation of a DNA nucleobase as a gate dielectric for potential application in a graphene-based field effect transistor

Adrienne Williams, Fahima Ouchen, Steve S. N. Kim, Yen H. Ngo, Air Force Research Lab. (United States); Said Elhamri, Univ. of Dayton (United States); Shin Mou, Air Force Research Lab. (United States); Henry D. Young, Wright State Univ. (United States); Rajesh R. Naik, James G. Grote, Air Force Research Lab. (United States)

In this study, we investigated use of various substrates-silicon carbide, glass, kapton, photo print paper, polydimethlysiloxane, and willow glass in the transfer of graphene. Four monolayers of graphene were transferred onto these substrates in which bulk charge carrier mobilities were determined. Guanine was physically vapor deposited at ~60 nm onto the substrates that showed consistency in the transport measurements. Room temperature transport measurements were obtained with the Guanine on these substrates for 3 and 6 days. For the first time, we observed room temperature stability measurements with Guanine as the dielectric material physically vapor deposited onto transferred graphene. Specifically, these transport measurements were significantly more stable with the Guanine, but with a significant decrease in bulk carrier mobility with PMMA.

9171-12, Session 3

Nonlinear optical properties of chromophore functionalized DNA-surfactant complexes *(Invited Paper)*

François Kajzar, Ana-Maria Manea, Univ. Politehnica of Bucharest (Romania); Valentin I. Vlad, National Institute for Lasers, Plasma and Radiation Physics (Romania); Adrian Petris, National Institute for Laser, Plasma and Radiation Physics, Department of Lasers, (Romania); Tatiana Bazaru Rujoiu, National Institute for Lasers, Plasma and Radiation Physics (Romania); Alexandrina Tane, Ileana Rau, Univ. Politehnica of Bucharest (Romania)

Recent results on DNA functionalization, thin film processing and characterization of their nonlinear optical (NLO) by optical third-harmonic generation will be reported and discussed. In particular the results concerning influence on the matrix on chromophore electronic structure and resulting NLO response will be presented. The results of photothermal and chemical stability of thin films studies will be also reviewed.

The authors acknowledge the financial support of Romanian Ministry of Education, Research, Youth and Sports, through the UEFISCDI organism, under Contract Number 3/2012, Code Project PN-II-PT-PCCA-2011-3.1-0316.

Hyper Rayleigh scattering of biomolecules: the case of thymine and adenine *(Invited Paper)*

Anthony Maurice, Univ. Claude Bernard Lyon 1 (France); Franck Bertorelle, Univ de Claude Bernard Lyon I (France); Emmanuel Benichou, Pierre-François Brevet, Univ. Claude Bernard Lyon 1 (France)

The measurement of the hyperpolarizability of biomolecules is essential to develop a quantitative analysis of the Second Harmonic Generation (SHG) from biological tissue. Beyond this measurement, generally hampered by the weakness of the hyperpolarizability measured, the underlying question of the development of models to rationalize the hyperpolarizability of peptides and proteins is addressed. We discuss this point of view for aromatic and non aromatic amino acids.

Light amplification and lasing from dyes doped in DNA-complex thin films prepared by soaking method *(Invited Paper)*

Yutaka Kawabe, Takemasa Suzuki, You Iisaka, Chitose Institute of Science and Technology (Japan)

An alternative fabrication method for dye-doped DNA-surfactant complex films was developed and amplified spontaneous emission (ASE) and lasing under low energy optical pumping were demonstrated.

In this new preparation technique, thin DNA-cethyltrimethylammonium (CTMA) complex films were made by a conventional spin coating method, and were applied to the process of staining with a hemicyanine dye by soaking films in acetone solution of the dye for one day. Molar ratio of the dye to DNA for the final products was estimated to be 1/5, the value was much higher than those achieved via usual mixing method. ASE threshold under the pumping of a pulsed frequency-doubled YAG laser was about 0.3 mJ/cm2. Laser emission was also available under the pumping with two interfering beams forming a dynamic grating of gain coefficient. Durability test indicated that 70% of their initial performance was maintained after 1 hour of continuous optical pumping.

This technique was applied to water soluble dyes because the DNA complex was insoluble to water as well as acetone. We employed anionic Eosin Y dye, succeeding in sample formation and ASE emission. Different types of surfactants were also complexed with DNA, showing dependence of emission peak wavelength.

These results give a clue about the structure or interaction modes between DNA and surfactants, suggesting strongly that dye molecules are not intercalated into nor bound to DNA double strand directly, but are incorporated in the DNA system via ion-exchange process or aggregating with cationic surfactants.

9171-15, Session 4

Random lasing in dye doped bio-organic based systems: experimental and stochastic approach *(Invited Paper)*

Antoni C. Mitus, Grzegorz Pawlik, Jaroslaw Mysliwiec, Lech Sznitko, Konrad Cyprych, Adam Szukalski, Andrzej Miniewicz, Wroclaw Univ. of Technology (Poland); François Kajzar, Ileana Rau, Univ. Politehnica of Bucharest (Romania)

We present results of detailed experimental studies on random lasing phenomenon achieved in biopolymeric matrices based on modified deoxyribonucleic acid loaded with different luminescent dyes. The random lasing originates due to the light scattering induced by formation of microcrystals or clusters in the bulk of biosystem. The mechanism of diffusive transport of light, its amplification and randomization in biopolymeric matrices is studied theoretically in terms of non-standard diffusion approach, including sub/super diffusion, continuous time random walk and Levy flights.

DNA film on the surface and inside the capillary for optoelectronic and photonic applications *(Invited Paper)*

Kyunghwan K. Oh, Seongil Im, Yeonjin Yi, Jae Hoon Kim, Yonsei Univ. (Korea, Republic of); Juhiuk Son, The Univ. of Seoul (Korea, Republic of); Sung Ha Park, Sungkyunkwan Univ. (Korea, Republic of); Dong Ki Yoon, Yoon Sung Nam, KAIST (Korea, Republic of); Woohyun Jung, Bjorn Paulson, Inchul Shin, Ji-Hyung Hwang, Yonsei Univ. (Korea, Republic of)

DNA has been recently modified to be dissolved in organic solvents, which enabled thin film fabrication. DNA thin films have initiated a new area of research DNA optoelectronics, to investigate optoelectronic properties of the most abundant organic substance. In our research group formed by Yonsei, SKKU, KAIST, and KIST have focused on fabrication of DNA material from the nanoscopic to microscopic scale. We present optical properties of DNA solid, liquid, from UV to tera Hertz range. Transmission, refractive index, and absorption were measured. Waveguides fabrication based on various DNA films are also reported. In terms of electronic transport, we also present the unique capability of Guanine base in thin film transistors. Linear and nonlinear properties of DNA films, solutions were also characterized.

Photobleaching for DNA-based photonic devices *(Invited Paper)*

Bjorn Paulson, Inchul Shin, Reza Khazaeinezhad, Sahar Hosseinzadeh Kassani, Woohyun Jung, Kyunghwan K. Oh, Yonsei Univ. (Korea, Republic of)

One of the major unsolved challenges in the field of DNA-based photonics involves the scarcity of methods for the controlled, repeatable, and efficient fabrication of all-DNA biopolymer waveguides. We investigate the efficacy of photobleaching bulk DNA and DNA-CTMA thin films to cause permanent refractive index change, with the goal of forming waveguides and more complex structures. Both continuous and pulsed lasers in the UV and visible have been tested for bleaching effect on bulk DNA films formed by drop casting and on DNA-CTMA films formed by a mix of drop casting and spin coating. Due to concerns about

the accuracy of ellipsometric data on DNA thin films, bleaching efficacy is being tested by attempted device fabrication, as well as by ellipsometry. At present an aluminum mask is used to physically shadow a region of the thin film into a patterned channel waveguide structure. Waveguiding by the channel waveguides is tested by coupling light from a fiber taper into the edge of the thin film, and looking for a diffraction pattern in the far-field light emitted at the opposing edge. Additional work may involve the use of lanthanide ion- or transition metal ion-doped DNA films.

Micro and nanostructuration of polymer materials and applications *(Invited Paper)*

Thi Thanh Ngan Nguyen, Mai Hoang Luong, Mai Trang Do, Duy Manh Kieu, Qinggele Li, Dam Thuy Trang Nguyen, Quang Cong Tong, Isabelle Ledoux-Rak, Ngoc Diep Lai, Ecole Normale Supérieure de Cachan (France)

Polymer materials offer unique opportunities in nanophotonics and nanobiosystem since both top-down and bottom-up strategies can be pursued and combined towards the nanoscale. Besides, polymer materials can be, with simple methods, functionalized with nonlinear optical or fluorescent materials (organic, inorganic, or metal). The ensemble can be optically structured in a flexible way to obtain a polymer-based photonic nanostructure ("host") containing active materials ("guest"), which may provide an enhancement of the guest optical response, leading to attractive applications. For example, the fabricated polymer structures may find easily applications in the domain of the detection and analysis of chemical or biological species for environmental monitoring, protection against hazardous agents, and for various issues related to health. In this talk, I will explain two important fabrication techniques, namely interference and one-photon absorption direct laser writing, which present different advantages and allow both to obtain desired micro and nanometric 2D and 3D structures. I also discuss about some potential applications of these polymer-based structures, for example, for laser, nonlinear optics, and plasmonics.

Diatom frustule photonic crystal geometric and optical characterization

Jonathan Mishler, Phillip Blake, Andrew J. Alverson, Donald K. Roper, Joseph B. Herzog, Univ. of Arkansas (United States)

Diatom algae are single-celled, photosynthetic organisms, with an exoskeleton called a frustule; a periodically patterned structure made of silica. Over the last decade, diatom frustules have been researched as possible candidates for photonic crystals. A MATLAB program characterizing the periodic structures of diatom frustules from an SEM image was developed to determine how their periodic structures determine their optical properties. This program outputs the physical distance of each pore edge to the pore centroid as a function of angle for each pore. SEM images from a variety of centric diatoms were input into the program, and their pore geometries were characterized. Correlations between their respective pore geometries and optical properties were then established, giving insight as to how artificially manufactured photonic crystals should be designed for specific optical properties. Furthermore, numerical methods were used to computationally model the optical properties of diatom frustules. By artificially varying the pore geometry of the frustules, new optical nanostructures were designed for use as biomimetic plasmonic crystals.

Novel pH-sensitive probes with a ratiometric detection for intracellular pH

Ipuy Martin, Ecole Normale Supérieure de Lyon (France); Cyrielle Billon, Univ. de Lyon (France); Guillaume Micouin, Ecole Normale Supérieure de Lyon (France); Jacques Samarut, Univ. de Lyon (France); Chantal Andraud, Ecole Normale Supérieure de Lyon (France); Bretonniere Yann, Ecole Normale Supérieure de Lyon (France)

Phenolic compounds are amongst the most important class of dyes. The main characteristic property of phenols is the acidity of the OH group. This unique property has been intensively exploited in the design of fluorescent indicator for intracellular pH.

We will present here the design, the synthesis and the study of the physical and optical properties of a new series of simple push-pull dipolar phenol derivatives containing the 2-dicyanomethylene-3-cyano-4,5,5-trimethyl-2,5-dihydrofurane (DCDHF) ring. Spectrophotometric procedures enabled determining the pKa values by a non linear regression of the sigmoidal response of absorption value vs pH. The fluorescence properties of all compounds were also studied in water and the most promising ones were incubated in cells to monitor intracellular pH variations.

This large family can be obtained in a simple synthesis through a Knoevenagel condensation performed by controlled microwave irradiation. The pKa values vary from 4.2 to 8.9, which span the intracellular pH range. As expected, installation of electro-withdrawing group ortho to the hydroxy group induces a decrease of the pKa value. The different dyes present a ratiometric fluorescence with maxima around 550 nm (phenol) and 620 nm (phenolate). The overall brillance of these objects reach 500 to 4000 L.mol-1.cm-1.

Moreover, study of the variation of fluorescence or fluorescence intensity ratios as a function of pH show a good response around physiological pH. Those fluorophores also present a very fast cellular uptake and are easily visualized by fluorescence microscopy making them very good candidates for intracellular pH probes.

Hyper Rayleigh and hyper Raman from neat water

Anthony Maurice, Univ. Claude Bernard Lyon 1 (France); Qianli Ma, CEA, Direction de l'Energie Nucléaire, Département de Radiochimie des Procédés (France); Emmanuel Benichou, Univ. Claude Bernard Lyon 1 (France); Fabrice Canto, Laurent Couston, CEA, Direction de l'Energie Nucléaire, Département de Radiochimie des Procédés (France); Pierre-François Brevet, Univ. Claude Bernard Lyon 1 (France)

The observation of hyper Rayleigh Scattering from aqueous solutions is in effect an adequate configuration to observe hyper Raman Scattering too. Even though neat water is not a strong Raman scattering medium, bands located near 670 cm-1 and 3450 cm-1 for instance are easily observed. In the past, two geometrical configurations have been used to observe both hyper Rayleigh and hyper Raman Scattering, namely right angle and backward collection. We re-investigate here this problem and discuss the effect of the collection configuration on the measured intensities.

9171-26, Session PWed

Energy transfer within sub-nanoscale arrangements of DNA-templated chromophores and lipid-DNA nanocomplexes

Ho Yeon Son, KAIST (Korea, Republic of)

Light-harvesting antenna in natural photosystem are precisely designed through self-assembly of functional molecules with large protein complexes in a thylakoid lipid bilayer. The exquisite antenna in biological systems absorb the light, transfer the resulting excitation energy in a long distance, and finally direct it to a reaction center for charge separation and catalysis. However, sub-nanometer arrangement of chromophores into a stable macro-scale structure for a long-range, directed transfer of excitation energy has not yet been achieved in artificial light-harvesting systems. Here we introduce a multi-scale assembly approach of chromophores for a long-range Förster-type resonance energy transfer (FRET) by arranging chromophores on a nanoscale using DNA templates and incorporating the DNA-templated chromophores into larger lipid structures. Single strand DNA molecules containing a terminal residue linked with three different chromophores (JOE, TAMRA, and TexasRed) are hybridized with their complementary matrix DNA strand. The FRET efficiencies and antenna effects of the single and double-step energy transfers dramatically increase by the incorporation of DNA-templated chromophores into DNA-lipid complexes, which enable the secondary assembly of DNA between the inter-lipid spaces of multi-lamellar lipid structures. We expect that the supramolecular alignment of DNA-templated chromophores, which has never been explored previously, can be a very promising route toward directed, long-range light-harvesting for a wide range of applications in photocatalysis, sensing, and optoelectronics.

9171-27, Session PWed

Viral-templated nanocrystalline Pd nanowires for chemiresistive hydrogen (H2) sensors

Chung Hee Moon, Yiran Yan, Miluo Zhang, Nosang V. Myung, Elaine D. Haberer, Univ. of California, Riverside (United States)

A palladium (Pd) nanowire-based hydrogen (H2) sensor has been fabricated with a novel viral-templated assembly route. H2 is a promising zero-emission fuel that has the potential to replace fossil fuels in many applications. It is odorless and non-toxic, yet extremely flammable above 4% in air due to its low ignition energy. In development of H2 fuel cells, a H2 sensor that can rapidly detect low concentrations of H2 gas is required to ensure safety. Palladium has been reported as a suitable material for H2 sensing due to its catalytic property and its increasing electrical resistance when reacted with H2 to form alpha-palladium hydride (?-PdHx). In this report, we have fabricated a viral-templated Pd nanowire-based sensor for sensitive, room temperature detection of H2. A filamentous M13 bacteriophage has been used as the viral-template for assembly of Pd nanowires at ambient conditions. The nanowires provide large surface area for effective and rapid H2 gas-Pd surface interaction, which in return, enhances sensor performance. Seed-mediated synthesis of Pd nanowires was performed on a genetically-modified gold-binding virus decorated with gold nanoparticles. The morphology and nanowire distribution of the device were observed under the scanning electron microscope and transmission electron microscope. The electrical resistances of the devices were controlled by modifying material deposition on the viral-template. Sensor performance was analyzed by exposing the devices to H2 concentrations from 100 to 2000 ppm. The M13 bacteriophage template enabled facile, ambient condition fabrication of Pd nanowires for rapid, sensitive H2 sensing at room temperature.

9171-28, Session PWed

Physicochemical characterization of silver nanoparticles synthesize using Aloe Vera (Aloe Barbadensis)

Abiola J. Kuponiyi, Lamin Kassama, Tatiana V. Kukhtareva, Alabama A&M Univ. (United States)

Production of silver nanoparticles (AgNPs) using different biological methods is gaining recognition due to their multiple applications. Although, several physical and chemical methods have been used for the synthesis and stabilizing of AgNPs, yet, a green chemistry method is preferable because it is cost effective and environmentally friendly. The synthesis was done using Aloe Vera (AV) extract because it has chemical compounds such as "Antrokinon" that are known for its antibacterial, antivirus and anticancer properties. We hypothesize that AV extract can produce a stable nanoparticles within the 100 nm range and be biologically active. The biological compounds were extracted from AV skin with water and ethanol which was used as the reduction agent for the synthesis of nanoparticles. The biological extract and AgNO3 were blended and heated to synthesize AgNPs. The reaction process was monitored using UV-Visible spectroscopy. Fourier Transfer Infrared spectroscopy (FTIR) was used for the characterization of biological compounds and their substituent groups before and after the reaction process. Dynamic Light scattering (DLS) method was used to characterize particle size of AgNPs and their bio-molecular stability. Results showed that biological compounds such as aliphatic amines, alkenes (=C-H), alkanes (C-H), alcohol (O-H) and unsaturated esters(C-O) which has an average particle size of 109 and 215.8 nm and polydispersity index of 0.451 and 0.375 for ethanol and water extract, respectively. The results suggested that ethanol derived AgNPs contained higher yield of organic compounds, thus has better solubility power than water. Ag NPs can be used to control salmonella in poultry industry.

9171-29, Session PWed

Toward a chemiresistive ammonia (NH_3) gas sensor based on viral-templated gold nanoparticles embedded in polypyrrole nanowires

Yiran Yan, Univ. of California, Riverside (United States); MILUO ZHANG, University of California (United States); Heng Chia Su, Nosang V. Myung, Elaine D. Haberer, Univ. of California, Riverside (United States)

Ammonia (NH3) is used in many industries such as agriculture, fermentation, and refrigeration. Yet, it is a highly toxic and corrosive gas. For this reason, sensitive, selective and fast NH3 detection is important. Polypyrrole (Ppy), a p-type semiconducting polymer, exhibits a reversible, yet sluggish increase in resistance when exposed to NH3 gas due to slow analyte diffusion within bulk material. The large surface-to-volume ratio of nanostructured Ppy can overcome these kinetic limitations by facilitating analyte diffusion, thus enabling rapid sensing response and recovery. In this work, a M13 viral template was utilized to assemble chemiresistive Ppy-based, nanowire NH3 gas sensors. The high aspect ratio of this filamentous virus, which is approximately 6-7 in diameter and 880 nm in length, assisted nanowire formation. A genetically-modified M13 bacteriophage which displayed an 8-mer gold-binding peptide along its length was used to direct the assembly of linear chains of gold nanoparticles on which Ppy was subsequently electrodeposited. To fabricate NH3 gas sensors, gold nanoparticle-embedded Ppy nanowires were assembled on Si/SiO2 substrate pre-patterned with gold electrodes. The morphology, surface density, and connectivity of the nanowires between the electrodes were examined by scanning electron microscopy. The viral template surface density and Ppy electrodeposition time were used to control electrical resistance of the sensor. Finally, sensor performance was evaluated for NH3 gas concentrations from 40-300 ppm, as a function of resistance. In conclusion, we have developed a unique method of assembly for nanowire Ppy-based NH3 sensors.

9171-30, Session PWed

Morphology manipulation of M13 bacteriophage template for nanostructure assembly

Tam-Triet Ngo-Duc, Mohammed S. Zaman, Univ. of California, Riverside (United States); Chung-Hee Moon, University of California, Riverside (United States); Elaine D. Haberer, Univ. of California, Riverside (United States)

With the rapid advance of nanotechnology, the demand for versatile techniques capable of arranging molecular and nanoscale objects with nanometer precision has grown. Biomolecules have nanoscale characteristic lengths and molecular recognition capabilities which are extremely valuable in designing and building nanomaterials. Specifically, viral capsids have proven particularly useful for in vitro assembly in which hierarchical structure is critical. Through genetic engineering, the properties and functionalities of viral proteins can be controlled, creating a programmable scaffold for inorganic material assembly and/or synthesis. Yet, a significant disadvantage exists for this approach. The overall structure or architecture of a specific virus cannot be drastically modified. A different virus must be engineered and characterized for each geometry-specialized (i.e. sphere, rod, filament) application. The M13 filamentous phage, which can be converted from its initial wire-like form to a rod to a spheroid through simple exposure to chloroform, poses a unique solution to this challenge. Here, we demonstrate the utility of the shape-shifting M13 phage template for nanomaterial morphological modification through the assembly of both gold nanowires and nanospheroids. Both peptide affinity and chemical-conjugation strategies are explored. The size and dispersity of the spheroid template were characterized with dynamic light scattering and transmission electron microscopy (TEM). In addition, TEM, energy dispersive spectroscopy and selected area electron diffraction were used to study the morphology, composition and crystallinity of the synthesized nanostructures. We have established the ability to shapeshift the M13 phage as a template for inorganic nanomaterials.

9171-31, Session PWed

Second harmonic generation from silver nanoparticles in aqueous solution with different protective agents

Minh Hoang Ngo, Isabelle Ledoux-Rak, Ecole Normale Supérieure de Cachan (France)

Nanometer-sized metallic colloidal particles with plasmonic resonances in the visible range display interesting and useful optical properties. Second harmonic generation (SHG) has emerged over the last decade as a powerful technique to measure the first hyperpolarizability tensor (?) of metallic nanoparticles [1]. Silver nanoparticles have showed potential applications in various fields such as environment, biomedicine, catalysis, optics and electronics etc. In this work, silver colloidal solutions have been synthesized rapidly in aqueous solution with different protective agent (PVP, PVA). By changing several parameters like the type and concentration of protective agent and the ratio of silver nitrate to NaBH4, we can control the particle size and morphology in these solutions. The ? values of Ag per atom and per particle for nanospheres at 1064 nm have been measured. Silver nanoparticles, which possess intense visible region surface plasmon absorption bands, prove to be excellent nonlinear scatterers.

Investigations of molecular nonlinear optical polarizabilities of azobenzenes substituted with strong acceptor groups

Valentin Victor Jerca, "Costin D. Nenitescu" Institute of Organic Chemistry (Romania) and Univ. Politehnica of Bucharest (Romania); Florica Adriana Jerca, "Costin D. Nenitescu" Institute of Organic Chemistry (Romania); Ileana Rau, Univ. Politehnica of Bucharest (Romania); François Kajzar, Univ. Politehnica of Bucharest (Romania) and Institut des Sciences et Technologies Moléculaires d'Angers, CNRS, Univ. d' Angers (France); Dan Sorin Vasilescu, Univ. Politehnica of Bucharest (Romania); Dumitru Mircea Vuluga, "Costin D. Nenitescu" Institute of Organic Chemistry (Romania)

Nonlinear optical (NLO) polymeric materials have attracted much attention due to their potential applications in the fields of optical information processing, optical sensing, and telecommunications [1]. Fundamentals for obtaining an efficient polymeric NLO material are: i) incorporation of highly polarizable chromophore; (ii) covalent bonding between chromophore and polymeric matrix in order to avoid phase separation and iii) high glass transition temperature to prevent chromophore relaxation [2]. In order to obtain better results optimization of the molecular hyperpolarizability should be done preliminary. Theoretical and experimental studies pointed out that hyperpolarizability value increase with the donor and/or acceptor strength [3]. Also, another key factor is the conjugation length of the molecule. The stronger the conjugation, the higher values for hyperpolarizability can be obtained.

Herein, azo-dyes with various substituents (cyano, nitro, methyl) and different substitution pattern were synthesized and characterized. The hyperpolarizability was determined using the solvatochromic method. A

correlation between donor/acceptor strength, substitution pattern and molecular hyperpolarizability was established, in order to maximize the NLO response of the final material.

Low dimensional optics *(Keynote Presentation)*

François R. Flory, Ludovic Escoubas, Institut Matériaux Microélectronique Nanosciences de Provence (France); Gerard Berginc, Thales Optronique S.A.S. (France); Cheng-Chung Lee, National Central Univ. (Taiwan)

Thanks to progresses in material science and nanotechnologies, surfaces and thin films can now be structured at different scales. Photonics components take benefit of this possibility to fulfill still more and more complex functions. They are composed as well of organic as inorganic materials, dielectric, semiconductor, and metallic materials, or a mixture of them. Multiscale and chiral structures can be used to control both spectral, spatial distribution of light together with its polarization state. The optical mode density in the near field and in the far field can then be designed in particular by combining more or less resonant structures for the optical waves, associating diffraction, interferences and anisotropy like Fabry-Perot, waveguides, plasmons, photonic crystals, ... With the development of nanometer size structures another step is overtaken allowing the control of the intimate interaction of optical waves with materials to tune their basic electronic properties and permittivity.
Both optical and electronic properties are also strongly dependent on coupling effects needing a global approach. Artificially nanostructured materials often called metamaterials then exhibit new properties. Different phenomena recently considered, including optical topological insulator and structures for vortex waves transporting angular momentum of photons, will be also discussed and illustrated.

9172-2, Session 1

Collective resonant modes at a metasurface

Didier Felbacq, Univ. Montpellier 2 (France); Emmanuel Kling, Sagem (France); Emmanuel Rousseau, Richard Razafindrakoto, Univ. Montpellier 2 (France)

This work deals with the scattering of an electromagnetic wave by a structure that is made of a collection of wires that are very small in diameter with respect to the wavelength. All the wires are identical and have a resonant response to the electromagnetic field at specific frequencies. When they are organized periodically they show a collective electromagnetic behavior that can be tuned to control the scattering of light. The work gives an accurate description of this collective behavior. The method is essentially based on multiple scattering and asymptotic analysis. By using Bloch conditions, the expression of the diffracted field can be obtained as a function of the Bloch vector. The wavelength is not assumed to be small with respect to the period but only with respect to the diameter of the rods. Therefore the limit analysis is more general than a direct homogenization of the same medium. This allows us to describe the collection of rods as a surface, electromagnetically characterized by an impedance operator whose explicit form is given. For wavelength shorter than twice the period, the structure behaves as a grating and several diffracted orders appear. These orders carry electromagnetic energy characterized by the efficiency coefficient. Because of the resonances, these efficiencies possess a pole-and-zero structure than allows to tune the structure from perfectly reflective to perfectly transparent. A numerical study is carried, showing the various regimes that can be reached with this kind of metasurfaces. In particuliar, the Bloch diagrams are given for both resonant and non-resonant rods.

9172-3, Session 1

Design a symmetrical film stack as a negative index metamaterial

Yi-Jun Jen, Wei-Chih Liu, Ci-Yao Jheng, National Taipei Univ. of Technology (Taiwan)

In this work, the equivalent Herpin index and phase thickness of a symmetrical film stack (SFS) that comprises anisotropic dielectric film D and metal film M are analyzed using film matrix method. Three layered SFS DMD and five layered SFS DMDMD are investigated by setting the thickness of each film is 1/10 of wavelength. The positive real part of equivalent Herpin index and the negative real part of phase thickness lead to a negative real part of equivalent refractive index. The range of refractive indexes of D and M that would lead to negative index material is indicated here. When a polarized light wave propagates into the negative index material, the negative refraction and backward wave propagation occur. Since the structure is an anisotropic, the equivalent Herpin index and phase thickness are also polarization-dependent.
At certain wavelengths, the phase thickness is positive for one linear polarization but negative for the other orthogonal linear polarization. Therefore, large phase retardation due to large birefringence over unity is observed. The polarization-dependent passband and stopband of the SFS are also calculated to identify the possible wavelengths at which the SFS works as a polarization beam splitter.

9172-4, Session 1

Lateral patterned ion beam modification of vanadium dioxide for optical applications

Jura Rensberg, Sebastian Vatterodt, Friedrich-Schiller-Univ. Jena (Germany); Mikhail A. Kats, Shuyan Zhang, You Zhou, Harvard School of Engineering and Applied Sciences (United States); Ronny Nawrodt, Christian Schwartz, Marcel Hopfe, Tim Barth, Friedrich-Schiller-Univ. Jena (Germany); Shriram Ramanathan, Federico Capasso, Harvard School of Engineering and Applied Sciences (United States); Carsten Ronning, Friedrich-Schiller-Univ. Jena (Germany)

Vanadium dioxide (VO2) undergoes a reversible, ultrafast metal insulator transition (MIT) at a critical temperature TC of ~ 68°C. Associated with this transition are abrupt changes in resistivity, optical transmittance or reflectance covering a broad spectral range from visible to infrared. It is well known that the TC can be modified by the incorporation of dopants into the VO2 lattice. However, doping thin films during growth is limited to vertical incorporation of dopant profiles. In contrast, ion beam doping also allows for lateral doping using suitable masking techniques. Here, we report on the implantation of noble gas as well as light dopants into thin VO2 films. In any case, ion irradiation leads to a high concentration of defects created by the implantation process. This on one hand downgrades the MIT properties, but we will show in this presentation on the other hand that the induced strain also shifts the critical temperature to lower temperatures. Furthermore, thermal annealing at various temperatures and under different vacuum conditions, respectively, was applied resulting in a recovery of the crystal lattice and the incorporation of the doping species. The MIT characteristics of the films were investigated by resistivity measurements and optical spectrometry. Finally, lateral patterned ion beam doping profiles have been realized, which show new possibilities for designing detection devices, optical modulators, thermal emitters and absorbers.

9172-5, Session 2

Nanostructured thin films and their macrobehaviors *(Invited Paper)*

Cheng-Chung Lee, Mei-Ling Lo, National Central Univ. (Taiwan); Shih-Fang Liao, National Central Univ (Taiwan)

There are abounds of nanostructured thin films in nature and show fascinating features such as self-cleaning waterproof and attractive iridescence. The waterproof is due to hydrophobic microstructure, called as lotus effect and the low surface energy so that the surface is wax-

like. The iridescent color comes from a combination of interference of structural multilayers and the intrinsic properties of the layers. Among them, the wing of papilio blumei butterfly is of particular interesting. There are three key periodic structures. The micro-structures surface of the butterfly wing was mimicked by a nanoimprint process to get the hydrophobic characteristic. The iridescence green band and cyan tail of the wing on papilio blumei butterfly were investigated. The spectral change with thickness of chitin-air layers was simulated. 2D photonic-crystal model was applied to explain the change of reflectance spectra and color with angle. The structure of papilio blumei butterflies was fabricated successfully by three main techniques, PS spheres bedding, electron-beam gun evaporation and ICP etching.

9172-7, Session 2

Nano-structures for high intensity fiber laser applications

Andrew C. Y. Ngo, A*STAR Institute of Materials Research and Engineering (Singapore); Liying Hong, DSO National Labs. (Singapore); Z. Liu, A*STAR Institute of High Performance Computing (Singapore); R. F. Wu, DSO National Laboratories (Singapore); E. H. Khoo, A*STAR Institute of High Performance Computing (Singapore); J. H. Teng, A*STAR Institute of Materials Research and Engineering (Singapore)

High power fiber lasers are proposed to be a better candidate than conventional solid-state lasers for industries such as precision engineering since they are more compact and easier to operate. However, the beam quality generally degrades when one scales up the output power of the fiber laser.

One can improve the output beam quality by altering the phase of the laser beam at the exit surface, and a promising method to do so is by integrating specially designed nano-structures at the laser facets. In fact, this method was recently demonstrated – by integrating gold concentric ring grating structures to the facet of a quantum cascade laser, one observes significant improvement in the beam quality. Nevertheless, to improve the beam quality of high power fiber lasers using the method mentioned above, the material of the nano-structures must be able to withstand high laser fluence in the range of J/cm2.

In this work, we investigated the laser-induced damage threshold (LIDT) values of various materials for high power fiber laser applications. Consequently, we demonstrated that the shortlisted material and the fabricated nano-structures can withstand laser fluence exceeding 1.0 J/cm2.

9172-8, Session 2

Optically transparent, mechanically durable, nanostructured superhydrophobic/omniphobic/anti-fogging glass thin films

Tolga Aytug, Liu Tao, Andrew R. Lupini, Ilia N. Ivanov, Parans M. Paranthaman, David K. Christen, Oak Ridge National Lab. (United States)

It is difficult to obtain a transparent medium with a superhydrophobic coating that has high optical quality, mechanical durability, and can be fabricated at large scale with good uniformity. Traditional superhydrophobic coatings are soft in nature, with a Teflon-like surface chemistry, which results in reduced adhesion and durability. By combining vapor phase deposition together with methods to produce differentially-etched, nanostructured glass materials, we have overcome many of these common problems. Here we describe the formation of atomically bonded, optical-quality, nano-textured porous thin glass film coatings on glass plates, utilizing metastable spinodal phase separation in a low-alkali borosilicate glass system. As formed, these coatings are structurally superhydrophilic (i.e., display anti-fogging functionality) and demonstrate robust mechanical properties. After appropriate chemical surface modification, they exhibit exceptional superhydrophobic performance with water droplet contact angles reaching as high as 172o. As an added benefit, in both superhydrophobic and superhydrophilic states these nanostructured porous surfaces can block ultraviolet (UV) radiation and can be engineered to be anti-reflective with broadband and omnidirectional transparency. Moreover, by changing the chemical affinity of the surface, anti-smudge and omniphobic functionality of these films (i.e., repellency against various liquids) is also demonstrated.The approach offers a facile route to creation of commercially viable leading edge coated optical quality products for industrial applications.

9172-43, Session 2

PbS sculptured thin film and their effect on liquid crystals alignment

Ashok Chaudhary, Matvei Klebanov, Ibrahim Abdulhalim, Ben-Gurion Univ. of the Negev (Israel)

Lead Sulphide (PbS) thin films are prepared using glancing angle deposition (GLAD) by thermal evaporation and compared to the films prepared at zero angle. The morphology of the GLAD films clearly shows that anisotropic structure is obtained and composed of micro-sheets having sharp top edges (few tens of nm tip width). The structure of the zero degree deposited samples consist of a random network of connected nanowires with porosity as high as 80%. The Raman spectra of the zero degree films exhibit sharp peaks representative of vibrations in nano-crystalline PbS while these sharp peaks are absent in the spectra of the GLAD films.

Due to the orientational order of the GLAD PbS we decided to check its effect on the alignment of liquid crystals (LC) as one might expect strong effect to occur [1,2]. A nematic LC (BL036) device was prepared with one substrate covered by lead sulphide STF and the other substrate is covered with polyimide on indium tin oxide (ITO). The dark and bright states of the device have been observed between two crossed polarizers and found the alignment of the LC to be along the STF sheets orientation with good contrast. A lower threshold voltage was noticed in the device. Such type of composite devices may lead to new optical and photonics applications.

9172-9, Session 3

New physics and applications of apertures in thin metal films *(Invited Paper)*

Reuven Gordon, Ahmed A Al Balushi, Abhay Kotnala, Ryan Gelfand, Skylar Wheaton, Univ. of Victoria (Canada); Shuwen Chen, Shilong Jin, National University of Defense Technology (China)

The nanoplasmonic properties of apertures in metal films have been studied extensively; however, we have recently discovered surprising new features of this simple system with applications to super-focusing and superscattering. Furthermore, apertures allow for optical tweezers that can hold onto particles ~1 nm; I will briefly highlight our work using these apertures to study protein - small molecule interactions and protein - DNA binding.

9172-10, Session 3

Nanostructured refractory thin films for solar applications

Emmanuel Ollier, Nicolas Dunoyer, Olivier Dellea, Helga Szambolics, CEA-LITEN (France)

The solar thermal sector needs very efficient thin film materials for solar radiation absorption. They are implemented on solar collectors included in solar receivers and are called selective materials because the required optical function depends on the wavelength range considered. Their reflectivity has to be minimized in the solar spectrum visible range to maximize the energy absorption. In the infrared range, their reflectivity must be maximized in order to reduce the infrared emissivity and the associated heat loss. The state of the art is mostly related to interferential multilayer films. Previous simulation work had shown that structured metallic surfaces could also allow a very good optical performance, opening the possibility to make them with refractory metals. But no process was available to realize the corresponding metamaterials. This work provides an original thin film, structured at both micro and nano scales. This double structuration provides a new and very efficient selective surface (absorption higher than 95% with less than 25% emissivity) based on a molybdenum refractory metamaterial. The electromagnetic simulations of the optical performances will be presented as well as the process flow based on thin film deposition, micromasking by a self-assembled layer and etching. The impact of the film deposition process and morphology in combination with an optimized etching step will be detailed. The optical characterizations in the visible and infrared ranges will be presented and compared to simulations at the nanoscale. The approach used opens prospects to realize micro-nanostructured films for various applications like optical management and superhydrophobic surfaces.

9172-11, Session 3

Ni/NiCrOx nanocomposite cermet as ideal candidate for solar thermal applications

Lucie Gaouyat, Univ. of Namur (Belgium); Zambing He, Univ. Antwerpen (Belgium); Jean-François Colomer, Philippe Lambin, Univ. of Namur (Belgium); Frederic Mirabella, CRM Group - AC&CS (Belgium); Dominique Schryvers, Univ. Antwerpen (Belgium); Olivier Deparis, Univ. of Namur (Belgium)

Solar absorbers are classified into six types [1]. Most commonly, the generic "tandem" absorber type is used, which consists of cermet (CERamic-METal) layers topped with anti-reflective (AR) layers. The cermet layer contains nanosized metallic particles embedded in a dielectric/transparent matrix. Concerning cermet layers deposited by magnetron sputtering, no evidence of this nanostructure was provided so far, although promising properties were previously established.

In this study, we first focus on the determining the nanostructure of NiCrOx layers. X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD) are used to get evidences of phase heterogeneity, crystallinity and grain size. For further assessment, transmission electronic microscopy (TEM) and high-resolution transmission electronic microscopy (HRTEM) are used to actually observe the nanostructure. Ni and NiO nanoparticles are found to be embedded in a NiCrOx matrix. This specific nanostructure is at the origin of remarkable optical properties of Ni/NiCrOx cermet material. As a demonstration of the potentialities of such a layer for solar absorbers applications, a layer of NiCrOx cermet was used in a tandem solar absorber stack, leading to solar absorptance as high as α=96.1% while keeping thermal emissivity as low as ε=2.2%. These results are compared with optical simulations, using refractive indexes determined by UV-visible and IR-ellipsometry. The above performances show that Ni/NiCrOx nanocomposite cermets are indeed ideal candidates for solar thermal applications.

9172-12, Session 3

Stretchable conducting materials with multi-scale hierarchical structures for biomedical applications

Hyun Kim, Bong Sup Shim, Inha Univ. (Korea, Republic of)

All of the conductive systems in human body such as central and peripheral neural networks, muscular and cardiomuscular systems are consisted with soft and stretchable materials. However, most of the artificial materials interfacing with those conductive systems such as neural electrodes, cardiac pacemakers have stiff mechanical properties. The rather contradictory properties between natural and artificial materials usually cause critical incompatibility problems in implanting body-machine interfaces for wide ranges of biomedical devices. Thus, we developed a stretchable and electrically conductive material with complex hierarchical structures; multi-scale microstructures and nanostructual electrical pathways. For biomedical purposes, an implantable polycaprolactone (PCL) membrane was coated by molecularly controlled layer-by-layer (LBL) assembly of single-walled carbon nanotubes (SWNTs). The soft PCL membrane with asymmetric micropores provides reversible stretching properties, while nano-thin SWNT coating preserves stable electrical conductivity even in a fully stretched state. This electrical conductivity enhanced ionic cell transmission and cell-to-cell interactions as well as electrical cellular stimulation on the membrane. Our novel stretchable conducting materials will overcome long-lasting challenges for bioelectronics applications by significantly reducing mechanical property gaps between artificial and natural body systems.

9172-13, Session 4

Engineering wavefront with Huygens, Fermat, Bragg, Friedel, and Fresnel laws *(Invited Paper)*

Zeno Gaburro, Univ. degli Studi di Trento (Italy)

We propose a metasurface that generalizes classical Snell and Fresnel laws, based on phase discontinuities. I provide an outlook on this structure, from different and complementary points of view, referred to classical Huygens, Fermat, Bragg, Friedel and Fresnel laws. The structure shows a generalization of the concept of crystallographic systematic absence. As a result, the Friedel law of crystals completely breaks down. A novel concept of "metacrystal" can be introduced, where systematic absences can be originated from form factors of meta-atoms, in contrast with natural absences, which are based on structure factors only. Applications will be also presented.

9172-14, Session 4

Computer-based numerical simulations of adsorption in nanostructures

Diana Khashimova, Technische Univ. Hamburg-Harburg (Germany)

Zeolites are crystalline oxides with uniform, molecular-pore diameters of 3-14Å. Significant developments since 1950 made production of synthetic zeolites with high purity and controlled chemical composition possible. In powder-form, zeolites are major role-players in high-tech, industrial catalysis, adsorption, and ion exchange applications.

Understanding properties of thin-film zeolites has been a focus of recent research. The ability to fine-tune desired macroscopic properties by controlled alteration at the molecular level is paramount. The relationships between macroscopic and molecular-level properties are established by experimental research. Because generating macroscopic, experimental data in a controlled laboratory can be prohibitively costly

and time-consuming, reliable numerical simulations, which remove such difficulties, are an attractive alternative.

Using a Configurational Biased Monte Carlo (CBMC) approach in grand canonical ensemble, numerical models for pure component and multicomponent adsorption processes were developed. Theoretical models such as ideal (IAST) and real adsorbed solution theory (RAST) to predict mixture adsorption in nanopores were used for comparison.

Investigative testing of the method on known materials, represented by all-silica zeolites such as MFI (channel type) and DDR (cage type), proved successful in replicating experimental data on adsorption of light hydrocarbons - alkanes, such as methane, ethane and butane. Additionally, adsorption of binary and ternary mixtures was simulated.

The given numerical approach developed can be a powerful, cost and time saving tool to predict process characteristics for different molecular-structure configurations. The approach used here for simulating adsorption properties of nanopore materials including process characteristics, may have great potential for other properties of interest.

9172-15, Session 4

Waves in tape helix loaded liquid crystal optical fiber

Masih Ghasemi, Pankaj K. Choudhury, Univ. Kebangsaan Malaysia (Malaysia)

Liquid crystals are non-homogeneous in nature, and also, these are optically anisotropic. Fibers made of liquid crystals have been greatly attracting owing to the interesting features that liquid crystals do exhibit. The investigation reported in this communication describes a rather new type of optical fiber structure composed of three layers with the outermost region being radially anisotropic liquid crystal, and the inner dielectric core-clad interface is loaded with conducting tape helix structure. Similarly to the case of sheath helix, the introduction of tape helix too would also throw the impact of alteration of the dispersion features of the guide. However, the situation becomes more complex in the sense that, apart from the helix pitch angle, the width of the tape helix structure becomes the additional factor to affect the dispersion characteristics. Further, to avoid computational complexities, the thickness of the introduced tape-like structure is considered to be nearly zero. We consider the core and the inner clad sections as made of linear, homogeneous and isotropic dielectrics, and the anisotropy remains in the outermost section due to the presence of nematic liquid crystal material. Taking into account a few low-order guided modes in the fiber structure, and considering the inclination of tape helix to be parallel as well as perpendicular to the optical axis (of the fiber), propagation characteristics are determined in terms of the relative power distributions. It is expected that the fiber structure would acquire a controlled dispersion characteristics, which would be of great use in many optical applications.

9172-16, Session 4

Shift happens: Optical sensing with Dyakonov--Tamm waves

Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States); Muhammad Faryad, Lahore University of Management Sciences (Pakistan)

Now that the Dyakonov-Tamm surface wave has been experimentally detected, my aim is to show theoretically that this surface wave can be exploited for the optical detection of analytes in fluids. A Bruggeman formalism is harnessed for that purpose and two relevant boundary-value problems are solved.

9172-17, Session 4

Voigt waves in electro-optic homogenized composite materials

Tom G. Mackay, The Univ. of Edinburgh (United Kingdom)

In the usual case of optical propagation in a linear, homogeneous, anisotropic, dielectric material, two independent plane waves, with orthogonal polarizations and different phase speeds, can propagate in a given direction. However, in certain anisotropic materials, such as dissipative biaxial materials, there are particular directions along which these two plane waves coalesce to form a single plane wave. This coalescent wave is called a Voigt wave. Most conspicuously, the amplitude of a Voigt wave is linearly dependent upon propagation direction. In the present study, a homogenized composite material (HCM), which arises from an assembly two (or more) particulate component materials, is considered. By judicious choice of the component materials and their particulate shapes, it can be arranged for the HCM to support Voigt wave propagation whereas its component materials may not. If one of the component materials is an electro-optic material then an externally-applied DC electric field may be used to control Voigt wave propagation in the HCM. The extent to which Voigt wave propagation can be controlled via a DC electric field is explored theoretically here, using an approach based on the strong-property-fluctuation theory. This study has possible implications for applications in telecommunications, sensing and actuation.

9172-35, Session PWed

Direct light-induced surface patterning on thin films of amorphous chalcogenide

Ugis Gertners, Zanda Gertnere, Univ. of Latvia (Latvia)

The demand of lower cost surface-relief based optical instruments such as grating-based resonators or filters for waveguides, diffractometers, spectrometers, etc. is one of the main driving forces for the investigation of direct light-induced relief formation. The most common techniques for fabricating and investigating these surface-relief gratings involve an interferometric or holographic recording setup.

We have investigated that the light-induced mass transfer process strongly depends on the material itself and polarization of the light. The behavior of mass transfer and thus the resulting recording could be related to interaction between the polar photo-induced defects and the polarized electric field of recording beam. It has been shown that the mass transfer can be directed both ways – towards or away from the electric field intensity gradient. The evolution of surface relief in dependence from the recording time and polarization has been investigated in detail. The mechanism of the direct recording of surface relief on amorphous chalcogenide films based on the photo-induced plasticity has been discussed.

9172-36, Session PWed

Deposition condition influence on optical properties of indium tin oxide

Taras Ganulia, Olga Lopatynska, Vasyl Lendel, Leonid Poperenko, National Taras Shevchenko Univ. of Kyiv (Ukraine)

Indium tin oxide (ITO) is a solid solution of indium(III) oxid and tin(IV) oxide. It is applied for the production of transparent electrodes of liquid crystal screens, Organic Light-Emitting Diodes, touch screens.

We investigated the optical properties of thin films of indium oxide, produced by reactive magnetron sputtering with different deposition time. The unoxidized silicon was used as a substrate. Time of the films deposition was equal to 10-60 seconds.

Ellipsometric parameters were determined in a wide range of incidence angles by standard laser ellipsometer. The model of non-absorbing homogeneous layer on the absorption substrate (Si) was proposed to calculate the refractive index and ITO films thickness.

9172-37, Session PWed

Construction of 3D ordered macroporous thin films and their applications

Yao Li, Jiupeng Zhao, Harbin Institute of Technology (China)

We present the recent experimental investigation of 3D ordered structures, or photonic crystals (PCs) based on the functional materials, which are inhomogeneous materials whose dielectric properties vary periodically in space on a macroscopic scale. These ordered materials have novel and interesting properties concerning both basic physics and technological applications. For three dimensional photonic crystals, various techniques have been used including photolithography and etching techniques. Some of these techniques are already commercially available. To circumvent nanotechnological methods with their complex machinery, alternate approaches have been followed to grow photonic crystals as self-assembled structures from colloidal crystal. After a brief description of the main properties of photonic crystals, we present the self-assembly methods for the construction of photonic crystals with inverse opal structures by using colloidal cystal templates. The 3D PCs can be built with different building blocks and different materials, including semiconductors, alloys, metals, metal oxides and polymers. All these materials are very attractive for practical applications because it is possible to govern of their optical properties with the unique structure.

9172-38, Session PWed

Self-cleaning antireflective film for solar module glass

Wen Ding, Feng Yun, Deyang Xia, Jin Wang, Zhongxiao Song, Jinhai Si, Xi'an Jiaotong Univ. (China)

Solar cells technology has been developed quickly in recent years. There are a lot of factors affecting the solar cell's conversion efficiency, among which is solar radiation absorption. As we all know, most of the energy in solar radiation is concentrated in the wavelength range of 0.17~4 µm, in which there is 50% visible light, 43% infrared radiation, and 7% ultraviolet radiation. Silicon based solar cell has an optical light band gap of 1.1~1.7 eV, matching the visible light spectra. Due to the fact that silicon surface reflects visible light, it lead to a large loss of solar energy, limiting silicon based solar cell conversion efficiency no more than 30%. Many researches have been done to enlarge the silicon solar absorption spectra. In this paper, work has been conducted to introduce a nano antireflective (AR) solar glass with anti-reflective self-cleaning property, which is made up of nano SiO2 and TiO2.The TiO2-SiO2 anti-reflective self-cleaning composite film was prepared by sol-gel method using the network structure and low refractive index of SiO2 and self-cleaning effect of TiO2. Compared with the traditional SiO2 antireflective (AR), the film's hardness and weather resistance of the films was promoted significantly. The degradation of transmittance of the film after damp-heat test only 0.23%. The visible light transmittance of the film can be obtained at 98.81%. The average peak power output of solar module using antireflective glass was improved by 3.0% than that of uncoated ones.

9172-39, Session PWed

Effect of aging with partial discharges on the remnant breakdown strength of polypropylene films with natural and synthetic nanofillers

Md. A. Rab, Rohitha Dhara, Prathap Basappa, Norfolk State Univ. (United States); Anil Poda, Georgia Institute of Technology (United States)

Abstract: Literature indicates that electrical, thermal, mechanical or other characteristics of dielectric insulation can be improved significantly by homogeneously dispersing nanofillers into the polymer matrix. In this research work, comparative analyses of remnant breakdown strength (BDS) of natural and synthetic nano filled polypropylene (PP) films will be investigated. Two factors affect the breakdown characteristics of nano filled polypropylene films. These factors are changes in polymeric morphology and changes in carrier density and mobility due to the inclusion of nanofillers into the polymer matrix. Changes in these physical properties depend on nanofiller concentrations and type .In this experiment; continuous eight hours of ageing of every synthetic or natural nanofilled PP sample under a constant high AC voltage are being performed. Various nanofiller concentrations (e.g. PP-0%, PP-2% and PP-6% etc.) are being used in current experiment. During ageing; surface partial discharge parameters are being recorded after every five minutes. These data can be analyzed statistically. Next, for all aged and unaged samples a "Short Time" test will be performed with the application of a 60 Hz voltage cycle across the electrodes. Voltage will be applied starting from 0 V and increased at a rate of 667 v/s until a sample failure. Then, using a two parameters (scale factor, α and shape factor, β) Weibull distribution, breakdown strength analyses will be performed. In this case, scale factor indicates 63.2% cumulative probability of failure of the sample and Shape factor refers to the scattering of breakdown strength values. High β value means smaller spread in BDS and more reliability of dielectric behavior of the sample. Finally, a comparison between remnant breakdown strength of PP films with natural and synthetic nanofillers will be done.

9172-40, Session PWed

Ion beam sputtered Y_2O_3 anti-reflection coatings for far-infrared optics

Hongxiang Liu, Institute of Optics and Electronics (China); Ruzhen Liu, Institute of Optics and Electronics (China)

It was investigated that transition metal oxide anti-reflection(AR) coatings were prepared by ion beam sputter for far-infrared optics. Relative to other oxide films, yttria and ytterbia coatings have a good optical performance in far-infrared band. The ion beam sputtered Y2O3 thin films with a relatively thick single layer are amorphous, and extremely adherent to the ZnS and ZnSe substrates. The average transmission of Y2O3 double-side AR coatings on the ZnSe optics was about 93% in the 8-10 µm band. These AR coatings passed adhesion, abrasion,T/RH and salt fog tests, and meet the requirements of highly durable ZnS windows for infrared cameras.

9172-41, Session PWed

Gas sensing properties of ZnO nanoparticles decorated reduced graphene oxide composites synthesized by hydrothermal method

Gwiy-Sang Chung, Univ. of Ulsan (Korea, Republic of)

In this paper, reduced graphene oxide (rGO)/ZnO composites are synthesized using a simple precipitation method with GO and Zn(NO3)2.6H2O as precursors at 120 oC. The composites are characterized by Fourier transform infrared spectroscopy, X-ray diffraction patterns and scanning electron microscopy, and exhibited reduced GO layers decorated with tiny ZnO nanoparticles. Physical properties of the composites proved that the dispersion of rGO sheets within composites is key for achieving an excellent electrical and optical performance of the samples. Investigation of opto-electronic properties revealed near UV to blue photoluminescence (PL) and semiconducting behavior of bare ZnO and ZnO/rGO sheets. The electrical properties of the pure material to composition also showed increased conductivity markedly upon reduction due to partial restoration of graphitic structure. Gas sensing properties also investigated and results showed preferred selectivity to H2, CO gases with good response, good repeatability and reversibility within room temperature to 150 oC.

9172-42, Session PWed

Quantum mechanical investigation of Fermi energy under dimension quantization with thin films in nanostructured materials

Subhamoy Singha Roy, JIS College of Engineering (India)

In this paper, an effort is made to study the Fermi-Dirac distribution function in degenerate semiconductors forming band tails ( ) on the basis of a newly formulated electron dispersion law (is the well Fermi-Dirac function) and also it will be of much more interest, to investigate the Fermi-Dirac distribution function under the condition of carrier degeneracy, since it will help my revise in transport coefficients and electron dynamics in electronic devices made of degenerate semiconductors (n-GaAs as an example).

9172-18, Session 5

Local field enhancement effects for dielectric coatings on silver nanorod arrays *(Invited Paper)*

Yi-Jun Jen, Meng-Jie Lin, Ci-Yao Jheng, Wei-Chih Liu, National Taipei Univ. of Technology (Taiwan)

Oblique angle deposition has been applied to fabricate various anisotropic thin films to reach novel optical applications such as achromatic waveplate. It is easy to fabrication a dielectric anisotropic multi-layer according to the polarization-dependent optical filter design. A slanted silver nanorod array (NRA) could be deposited with glancing angle of deposition around 89°. It is interesting to investigate the optical performance by depositing dielectric materials upon silver NRA with tilt angle of 70° respect to the surface normal. By controlling the deposition angle, SiO2 and Ta2O5 grow on sliver rods in different morphologies. The first kind is to have dielectric rods stand on the tops of silver rods. The second one is form a multilayer partially or wholly upon the lateral side of each rod. The multilayer designed as high reflection filter (HRF) by arranging SiO2 and Ta2O5 alternatively on a cylindrical silver rod with diameter of 80nm and a length of 300nm would enhance the local field intensity when the rod is illuminated by s-polarized and p-polarized light waves. In this work, the effects of number and thicknesses of layers on the local field intensity are analyzed. The enhanced local field intensity increases as the number of HRF increasing. The associated optical properties including transmittance, reflectance, and extinctance of the capped NRA are also investigated theoretically. It is demonstrated experimentally that the intensity of light scattering from the capped NRA is also enhanced due to the local field confinement around silver rod.

9172-19, Session 5

Study of partial discharge characteristics of nano filled polypropylene films according to the variation in electric field distribution on the sample

Md. A. Rab, Rohitha Dhara, Prathap Basappa, Norfolk State Univ. (United States); Anil Poda, Norfolk State University (United States)

Literature indicates that incorporation of small amount of nano fillers into the polymer matrix of polypropylene (PP) film can improve its partial discharge endurance and breakdown strength .Partial discharge (PD) can occur due to the localized breakdown of a small portion inside the dielectric insulation or due to the electrical discharges which bridge the insulation partially. In this research, the effect of variation in applied electric field distribution on partials discharge characteristics of nanofilled PP films will be investigated. Also, how nano filler concentrations in polymer matrix influence the electric field endurance of PP film will be explored. Electric field distribution can be varied by changing the gap spacing between rod and plane electrodes using different gap spacers (1-3 mm).Samples will be attached with the plane electrode. High AC voltage will be applied on each sample during experiment and corresponding partial discharge parameters will be recorded. These data can be analyzed statistically and physically .PP films with various nano filler concentrations (0%, 2%, and 6%) will be used in these experiments. Gap spacing between rod and plane electrodes affects partial discharge parameters significantly. Partial discharge inception voltage, average discharge magnitudes and maximum discharge magnitude etc. will be varying due to the variation in gap spacing. Detail analyses of effect of variation in gap spacing and filler concentrations on PD characteristics will be performed.

9172-20, Session 5

Ultra-thin metal oxide based light controlled converter for sensing surface chemicals

Arunas Šetkus, Virginijus Bukauskas, Audruzis Mironas, Šarunas Vaškelis, Ctr. for Physical Sciences and Technology (Lithuania)

The thin film technology offers very attractive possibility to create a converter of the surface chemical changes into detectable signal at the ambient temperatures in the real time scale. The work mechanism makes the converter acceptable for a combination with the organic modifiers. In this study an ultra thin construction of metal oxide layers is sandwiched between the metal contacts and a system with the gas sensitivity that can be varied by the light is made and characterised. We analyse the possibilities to combine an influence of the surfaces and interfaces on the band structure and the electrical properties of the complete construction. The results demonstrate that the changes of the characteristics induced by the gas-surface interaction can be intentionally tuned by the modifications of the construction at the nanoscale. Due to the built in potential differences, the multilayered construction combines the photovoltaic effect and the conversion of the gas-surface interaction into electrical response. Our report describes some aspects of the response to gas of the multilayered structure at the ambient temperature without an external power source but with an adapted illumination. The response controlled by the light is associated with the arrangement of the multilayered construction in which the tunnelling current is assisted by the impurity electron states in the barrier area with the nanoscale width. The density of the states is dependent on the potential difference between the contacts and the parameters of the ambient temperature gas sensor can be intentionally determined by the thin film technology.

9172-21, Session 5

Magnetic, magnetooptical, and magnetotransport properties of Ti-substituted Co_2FeGa thin films

Vladimir Khovaylo, National Univ. of Science and Technology “MISiS” (Russian Federation); Valeria Rodionova, Immanuel Kant State Univ. of Russia (Russian Federation); Maria Lyange, National University of Science and Technology (Russian Federation); Ksenia Chichay, Immanuel Kant Baltic Federal University (Russian Federation); Elena Gan’shina, Lomonosov Moscow State Univ. (Russian Federation); Alexei Bozhko, A. M. Prokhorov General Physics Institute (Russian Federation);

Makoto Ohtsuka, Rie Umetsu, Akinari Okubo, Department of Materials Science, Graduate School of Engineering, Tohoku University (Japan); Ryosuke Kainuma, Tohoku Univ. (Japan)

Recently, much attention has been paid to the study of thin films of the Co-based Co2YX Heusler alloys which are of considerable practical interest due to a huge tunneling magnetoresistance and specific magnetotransport properties. Since most of the studies have been devoted to Co2MnX systems, it is of interest to explore properties of other Co2YX systems. Here we report on experimental study of magnetic, magnetooptical and magnetotransport of Co2(Fe,Ti)Ga thin films.

The Co2Fe1-xTixGa thin films were deposited on MgO substrate by a dual magnetron sputtering apparatus. Chemical composition of the films was controlled by the changing of the spattering power of the targets. Determined by inductively coupled plasma spectroscopy chemical composition of the films studied is (in at.%) Co50.3Fe20.3Ti5.6Ga23.8.

Magnetic, magnetooptical and magnetotransport properties of Co50.3Fe20.3Ti5.6Ga23.8 thin films were studied for the as-prepared as well as annealed samples. Measurements of transverse magnetooptical Kerr effect revealed that the spectral response of the films strongly depends on the structural ordering which can be manipulated by annealing conditions. Peculiarities in the magnetic properties of the films were attributed to the coexisting phases with different degree of structural disorder. Resistivity of the as-prepared thin films was found to be large, rho ~ 170 mu Ohm cm (at room temperature). Such a high resistivity is related to the structural disorder of the as-deposited thin films and, as a rule, rho significantly decreases after annealing due to structural ordering. Magnetoresistance of Co50.3Fe20.3Ti5.6Ga23.8 thin films was found to be linear in the fields above 1 T which is typical for half-Heusler systems as well as for Heusler-based ferromagnetic shape memory alloys.

9172-22, Session 6

Plasmonic and nanophotonic enhanced organic photovoltaics: breaking the power conversion efficiency barrier *(Invited Paper)*

Qiaoqiang Gan, Univ. at Buffalo (United States); Filbert J. Bartoli, Zakya H. Kafafi, Lehigh Univ. (United States)

Present photovoltaic technology offers a promising source of clean and sustainable renewable energy, but suffers from relatively high fabrication cost. Solar cell technologies are being actively pursued based on solution-processable organic photovoltaic (OPV) materials that can be sprayed like inexpensive paint or printed over large areas on rigid or flexible substrates. However, due to the poor electrical conductivity of most organic materials, OPVs are inherently very thin leading to poor solar light absorption, and low power conversion efficiency (PCE). Researchers have been working hard to develop new approaches to increase solar light absorption without altering the thicknesses of the OPV devices. In this talk, we will provide an overview of recent progress on plasmonic and nanophotonic enhanced OPVs, one of the most promising solutions for enhancing the PCE of an OPV device [1]. Focus will be on surface dispersion engineering and ultra-thin-film interference mechanisms which are compatible with thin-film devices [2]. A renewed focus on the science and technology of nanophotonics for light management and trapping in OPVs will lead to PCEs surpassing currently achieved performance levels.

9172-23, Session 6

Investigation into the effect of space charge on the surface erosion of synthetic and natural organoclay nanofilled PP films

Rohitha Dhara, Md. A. Rab, Norfolk State Univ. (United States); Prtahp Basappa, Norfolk State University (United States)

Due to the differences in dielectric constant and conductivities between nanofilled PP in comparison to base PP, it is postulated that the space charge formation and distribution in nanofilled samples is significantly reduced when compared to that of the base PP. However, the formation of space charge is reported to be different in PP with natural and synthetic organoclay nanocomposites. Abou Dakka and et.al investigated on the space charge formation in natural and synthetic organoclay nanocomposite filled PP when aged under constant electric field. It was observed that the space charge formed at the center of the electrodes reduced by half in nanofilled PP to that of base PP. It was also observed that when synthetic nanofilled samples and natural nanofilled samples are aged under similar conditions, the accumulated space charge in synthetic samples was more than in natural samples. Due to the accumulated space charge at the center of the electrodes, the occurrence of PDs is minimized leading to reduced surface degradation of samples. The focus of this paper is to study the PD behavior and defect volume through surface study of synthetic and natural organoclay nanofilled PP samples. This is studied by aging of natural and synthetic nanofilled filled samples with same percentage of filler content and for same duration of time. The results will be analyzed by performing surface study of aged samples under surface Profilometer and 3-D microscope.

9172-24, Session 6

Optical properties of porphyrin - graphene oxide composites

Harsha Vardhan Reddy Maraka, Rusul M. Al-Shammari, Nebras Al-Attar, Univ. College Dublin (Ireland); Sergio Lopez, Tia E. Keyes, Dublin City Univ. (Ireland); James H. Rice, Univ. College Dublin (Ireland)

A large amount of research effort has been applied to understand, control and apply the properties of graphene. One area that graphene has attracted interest is in optical materials. For example graphene and derivatives such as graphene oxide are known to be plasmonicly active making them attractive as materials in optically active composites for a range of different applications such as solar cells or optical emitters for cost effective displays.

In this work we aim to (via a non-invasive functionalization approach) tune and alter the intrinsic features of optically “transparent” graphene, by integrating water-soluble porphyrin aggregates. Porphyrin aggregates are well known to be optically active and have been applied to a range of optical applications. In our studies we explore the potential to combine porphyrin aggregates and graphene oxide to assess the advantages of such as a composite compared to the individual systems.

We apply a range of optical spectroscopy methods including photo-absorption, fluorescence and Raman spectroscopy to assess ground-state and excited state interactions. It is known that in the excited state, radical ion pair states are formed including the radical cation of the electron donating porphyrins and electrons that are delocalized within the basal plane of grapheme forming functional nanographene based charge-transfer hybrids. however no studies on porphyrin aggragates and graphene oxide composites have been reported. Our studies show that comparing resonant Raman scattering with optical transmission and fluorescence microscopy that the presence of influences the microscopic structures of the resulting composites.

9172-25, Session 6

High angular tolerant color filters based on subwavelength grating structures

Chenying Yang, Weidong Shen, Yueguang Zhang, Xu Fang, Beishi Chen, Xu Liu, Zhejiang Univ. (China)

We propose three color filters (cyan, magenta, yellow) based on a two-dimensional (2D) grating using a plasmonic metamaterial, which maintain the same perceived specular colors for a broad range of incident angles with the average polarization. Particle swarm optimization (PSO) method is employed to design these filters during the optimization procedure as described in the previous article. The transmission curves at different incident angles are coincident and the color difference calculated by CIE DE2000 is less than 2 for the incident angle up to 45°, within the threshold value of the human visual sense. That is to say, as the incident angle increases gradually, the reflected specular color changes much less than the multilayer filter in CIE1931 chromaticity diagram. Besides, the filters shows a stable optical property with the varying azimuth angle of the incident light. The electric field distribution of the structure is finally studied to analyze the principle of operation, which is attributed to the surface plasmonic resonance of the periodic metal surface topography. Angle-insensitive color filters with such excellent performance have an enormous potential applications in fields of special illumination, display and spectral analysis and so on.

9172-26, Session 7

Nanocrystalline cellulose thin films for optical encryption *(Invited Paper)*

Yu Ping Zhang, Blu-O Technologies (Canada); Karen Allahverdyan, Laval University (Canada); Timothy Morse, McGill Univ (Canada); Vamsy P. Chodavarapu, McGill Univ. (Canada); Andrew Kirk, McGill Univ (Canada); Tigran Galstian, Laval University (Canada); Mark P. Andrews, McGill Univ. (Canada)

Nanocrystalline cellulose (NCC) exhibits unusual optical properties that make it of interest for hierarchical optical encryption in nanostructured films. The color-travel phenomenon of iridescence is exhibited by NCC when cast as a film from chiral nematic aqueous phase suspensions of the nanocrystals. In this presentation we discuss how this “iridescence by self-assembly” has potential for overt encryption as an anti-counterfeiting measure; and how it also offers an intrinsic level of covert encryption by reflecting left-circularly polarized light. We show that addition of a UV sensitive dye adds a third level of (covert) encryption, and that specially prepared films manifest a rare form of optical non-reciprocity that does not require the application of an applied field. Chirality parameters and stokes vector analyses suggest a simple authentication scheme. The method uses a UV light source and a circular polarizer in conjunction with an iridescent feature that can be verified by the eye or by chiral spectrometry.

9172-27, Session 7

Optical elaboration of nanostructure porous silica layer

Nicolas Desboeufs, Theirry Gacoin, Jacques Peretti, Jean-Pierre Boilot, Khalid Lahlil, Anh-Duc Vu, Lucio Martinelli, Yves Lassailly, Ecole Polytechnique (France)

Several spectacular photomechanical processes directly driven by the photo-isomerization transition of azobenzene type molecules have been investigated . These systems can be used in various technological applications, including photo-mechanics, diffractive optics, and micro- or nano-patterning. The cis-trans transition of the azobenzene is indeed accompanied by various changes of the material properties. An impressive example is the significant light induced surface mass transport. This phenomenon allows one-step inscription of high quality, photo-induced 1D and 2D surface patterns. Size and shape of this pattern can be easily tailored over a large scale ranging from a few tens of nanometers up to several microns by controlling the projected optical pattern. The originality of the process is that it’s an uncontacted and non-destructive reversible lithographic technique.

However, applications are limited by the strong azobenzene chromophores absorption in the visible range. Starting from our previous work on azobenzene doped sol-gel films , we report here a new and original method to remove all the organic chromophores while preserving the structuration. This method provides a new way to obtain uncolored and transparent pattern silica porous layer. Experimental results are supported by RCWA simulation to characterize the evolution of the pattern optical properties. Using this photoactive material it’s also possible to elaborate metal/dielectric hybrid 1D or 2D structures whose optical and mechanical properties can be controlled by light. Such hybrid system exhibits specific and interesting optical and plasmonic properties. Our results demonstrated a promising technique to reversibly elaborate hybrid nanostructured surface

9172-28, Session 7

Optical, electrical, and structural study of metallic nano-structured thin films fabricated by oblique angle deposition

Sung Jun Jang, Alireza Bonakdar, Hooman Mohseni, Northwestern Univ. (United States)

During last decade, there has been a long patient effort to find applications of oblique angle deposition. Many materials and structures have been explored to investigate their properties and potentials. Unless metallic nano-structures have an infinite amount of potential, still the metallic nano-structures formed by angle deposition are not sufficiently studied due to their structural limitation. Basically the angle deposition is based on directionality of vapor of physical vapor deposition so that the obtained structures from this technique should have also directional geometry. However, angle deposition is easy, fast and reliable process to fabricate nano-scale structures and there are some attractive applications to be investigated. One is highly transparent metallic thin films, which should be highly porous metallic films or metallic nano-rods but still connected each other. There are growing demands to have transparent but conductive film at level of metal film, which can be applicable to light harvesting and emitting devices as a low loss electrode. The other is superhydrophobic surfaces for ships’ hull coating. It can yield reduction of skin fraction drag for ships’ hull, thus increasing fuel efficiency. However, it is clear that the optical, electrical and structural investigation metallic nano-structure formed by angle deposition should precede for both applications.

In this report, we report metallic nano-structures fabricated by oblique angle evaporation. The optical, electrical and structural properties of metallic nano-structure were investigated. Dependency of various parameters governing metal evaporation was also explored. This report gives not only thoughtful understanding on metallic nano-structures formed angle deposition but also provides some ideas to engineer the properties of metal films for optoelectronic applications.

9172-29, Session 7

A solution to adhesion problem of oxide thin films on zinc selenide optical substrates

Mustafa B. Cosar, Bašak Yazgan, Gülgün H. Aydogdu, ASELSAN Inc. (Turkey)

This study was performed to bring a solution to the adherence problem between oxide thin film coatings and ZnSe substrates. ZnSe can be grown by Chemical Vapour Deposition (CVD) processes at high purity for optical applications. It can be easily shaped into the final form using

conventional grinding and polishing operations. Moreover, ZnSe has a high transparency (about 70%) within the 0.5 to 14 µm wavelength range which makes it an attractive candidate for dual band and laser applications. However, high refractive index of ZnSe (2.67) causes almost 30% of the incoming beam to be lost at the front and back surfaces due to reflection. In order to minimize these reflection losses, ZnSe is typically coated with multi-layered oxide thin films. During this study alternating high and low index layers were applied on the ZnSe substrates obtained from different vendors. Two different thin film deposition methods were utilize for this purpose, namely electron beam deposition and sputtering. All the samples were subjected to humidity and adhesion tests according to MIL-M-13508. We observed that prior to applying any heat treatment; oxide films exhibit a poor adhesion to the ZnSe substrates. In order to increase adhesion of these films, ZnSe samples were treated at 300C for varying amounts of time. Treated samples were examined in terms of their roughness, contact angle, morphology, refractive index, transparency, crystallography and chemical composition. We found that it is possible to manufacture durable thin film coatings on ZnSe, suitable for optical applications, utilizing well designed pre-treatment processes.

9172-30, Session 7

Mimumes for SUBTLE applications

Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

Inspired by natural multifunctionality, mimumes are microfibrous multifunctional metamaterials.

Their microfibrosity engenders multifunctionality. The chief vehicle for initial research would be the poly(p-xylylene) polymers that are currently used in bulk non-fibrous forms for packaging and tribological applications in electronic and biomedical arenas. In microfibrous forms, these materials are expected to display simultaneous ultrasonic, biomedical, terahertz, light, and energy functionalities, thereby enabling the paradigm of design for system performance.

9172-31, Session 8

Bottom-up fabrication of non-close packed nanopillar arrays for photonic applications

Motofumi Suzuki, Shinta Suganuma, Yasuyuki Kaneko, Kyoto Univ. (Japan)

In order to control optical absorption and radiation, periodic nanostructures are required in the wide variety of technical fields. However, it is not easy to fabricate the periodic structures over a large area at low cost by using conventional top-down processes. Although self-assembly of polystyrene (PS) nanospheres is one of possible candidates to fabricate the periodic nanostructures, tunability of shapes and dielectric constants are quite limited. In this study, we report a novel bottom-up process to fabricate the periodic arrays of nanopillars, which can be applied to omnidirectional absorption in the VIS range and highly directive thermal radiation emission.

The periodic arrays of nanopillars were created by taking advantages of the oblique deposition technique. Monodispersed PS nanospheres of 0.2, 0.5 and 0.75 µm in diameter were self-assembled into a close packed monolayer by floating-transferring technique. On the PS nanosphere array, SiO_2 was evaporated up to 50 nm at a deposition angle α=70°, while the substrate was rotated inplane during deposition. Then, the samples were annealed in air of 600 °C for 1 h. As the result, the periodic array of SiO_2 nanospherical crowns was remained on the substrate surface. Using the array of the nanospherical crowns as the template, SiO_2, Ta_2O_5, Si or Ge were evaporated at α=80°. Well-isolated nanopillars of those materials grow just on the nanospherical crowns. Consequently, we have succeeded to develop the completely bottom-up process to fabricate well-isolated ordered nanopillars, which is robust in selection of composed materials.

9172-32, Session 8

Nanosculptured thin films of tungsten oxide

Tomas Tolenis, Ramutis Drazdys, Ctr. for Physical Sciences and Technology (Lithuania)

Sculptured thin films are anisotropic optical coatings. By varying the conditions and geometry of deposition, columnar, chiral and even more complex films can be made. By changing the structure of the coating, optical properties differ too. Columnar films have different refractive index in different directions, when chiral films are known for their selectivity for circular polarisation. Combination of those properties with the photochromism can open a new area for optical elements.

In this work, tungsten oxide (WO_3) is chosen as photochromic material. Sculptured thin films were formed using electron beam evaporation machine. Columnar thin films of this oxide were evaporated and anisotropy of refractive index measured by ellipsometer and spectrophotometer. Chiral sculptured thin films of WO_3 were also produced by rotating the substrate about its axis. Bragg phenomena was investigated of the films and showed the selectivity of circular polarisation. All the samples were also measured with SEM and XRD techniques. SEM photos showed the structures of films, when XRD measurements revealed the crystallinity and the grain sizes of material. Photochromism effect of tungsten oxide material was studied using Nd:YAG laser. The laser radiated UV light and the changes in the visible spectra were observed.

9172-33, Session 8

The effect of the substrate temperature and the acceleration potential drop on the structural and physical properties of SiC thin films deposed by TVA method

Victor Ciupina, Univ. Ovidius Constanta (Romania) and Univ. of Bucharest (Romania) and Romanian Academy of Science (Romania); Cristian P. Lungu, National Institute for Lasers, Plasma and Radiation Physics (Romania); Rodica Vladoiu, Univ. Ovidius Constanta (Romania); Gabriel Prodan, Univ. Ovidius Constanta (Romania) and Institute for Nanotechnology and Alternative Energy Sources (Romania); Stefan Antohe, Univ. of Bucharest (Romania); Eugeniu Vasile, Univ. Politehnica of Bucharest (Romania); Marius Belc, Corneliu Porosnicu, National Institute for Lasers, Plasma and Radiation Physics (Romania); Iuliana M. Stanescu, Univ. Ovidius Constanta (Romania); Ionut Jepu, National Institute for Lasers, Plasma and Radiation Physics (Romania); Sorina Iftimie, Univ. of Bucharest (Romania); Virginia Nicolescu, Ceronav (Romania); Valer N. Zarovski, National Institute for Lasers, Plasma and Radiation Physics (Romania); Madalina D. Prodan, Aurelia Mandes, Virginia Dinca, Univ. Ovidius Constanta (Romania)

Crystalline silicon carbide (SiC) thin films was prepared at substrate temperature between 200C and 600C using Thermionic Vacuum Arc (TVA) method. To increase the acceleration potential drop a negative bias voltage up to -1200V was applied on the substrate. The 200nm thickness carbon thin films was deposed on glass and Si substrate and then 200-500 nm thickness SiC layer on carbon thin films was deposed. The structure and physical characteristics of as-prepared SiC coating were characterized by Transmission Electron Microscopy (TEM, STEM) Energy Dispersive X-Ray Spectroscopy (EDS), Electron Scattering Chemical Analysis (ESCA), tribological technique, optical absorption technique and electrical conductivity measurement technique.

At a constant acceleration potential drop, the electrical conductivity of the SiC films deposed on C, increase with increasing of substrate temperature. On the other part, a significant increase in the acceleration

potential drop at constant substrate temperature lead to a variation of the crystallinity and electrical conductivity of the SiC coatings. In the region below the optical band gap the optical absorption increase with increasing of the crystallinity of the SiC. The optical absorption spectra of the structures was measured with a spectrometer Perkin Elmer Lambda 35 UV-VIS.

The tribological behavior of SiC coating was evaluated with a tribometer with ball-on-disk configuration from CSM device with 6 mm diameter sapphire ball, speed in dry conditions being 0.2 m/s, with normal contact loads of 0.5N, 1.0N, 1.5N, 2.0N, under unlubricated conditions. The friction coefficient on SiC was compared with the friction coefficient on uncoated carbon layer.

Electrical conductivity of the silicon carbide coating on carbon at different temperatures was measured comparing the potential drop on the sample with the potential drop on a series resistance in constant mode.

9172-34, Session 8

Tunable stoichiometry of SiOx-BaTiOy-BOz fabricated by multi-target PLD

John G. Jones, Jonathan T. Goldstein, Air Force Research Lab. (United States); Lirong Sun, General Dynamics Information Technology (United States); Jason C. Anders, Wright State Univ. (United States); Steven R. Smith, Gerald R. Landis, Univ. of Dayton Research Institute (United States); Chad M. Holbrook, Neil R. Murphy, Air Force Research Lab. (United States); Gregory Kozlowski, Wright State Univ. (United States); Rachel Jakubiak, C. E. Stutz, Air Force Research Lab. (United States)

Nanostructured thin-films of multiple oxide materials were obtained by using pulsed laser deposition (PLD) with independent targets consisting of Si, BaTiO3, and B. The novelty of this technique is that typically one would have to make a different target material (i.e. densify a ceramic mixture of powder having the correct mixture) for each different desired stoichiometry, but with independent targets and a synchronized high speed mirror system the stoichiometry can be tuned or graded as desired. Using an excimer laser, 248 nm, at a power of 300 mJ per pulse, island growth occurred on a per pulse basis with some 150 pulses required to deposit 1 nm of material. Programmable stoichiometry of multi-component or nanostructured thin-films was achieved by using a 248 nm KrF excimer laser, a galvanometer mirror system, and three independent target materials. The number of pulses on each target can be programmed with a high degree of precision. Trends in material properties were identified by systematically varying the stoichiometries of multiple nanostructured thin-films and comparing the resulting properties measured using in-situ spectroscopic ellipsometry, x-ray diffraction (XRD), and energy dispersive spectroscopy (EDS) (reliable with ~ 1 um of material thickness). Typically thin-films deposited by PLD at temperatures below 300 C are amorphous, however, crystallinity was obtained with post growth heat treatment and verified with XRD. Ideally trends in dielectric measurements and breakdown potential will be shown for different stoichiometries.

Conference 9173: Instrumentation, Metrology, and Standards for Nanomanufacturing VIII

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Wednesday 20–20 August 2014

Part of Proceedings of SPIE Vol. 9173 Instrumentation, Metrology, and Standards for Nanomanufacturing, Optics, and Semiconductors VIII

9173-1, Session 1

Metrology for cellulose nanomaterials: update *(Invited Paper)*

Michael T. Postek, National Institute of Standards and Technology (United States)

Development of the metrology for advanced manufacturing of cellulosic nanomaterials (or basically, wood-based nanotechnology) is imperative to the success of this rising economic sector. Wood-based nanotechnology is a revolutionary technology that will create new jobs and strengthen America's forest-based economy through industrial development and expansion. It allows this, previously perceived, low-tech industry to leap-frog directly into high-tech products and processes and thus improves its current economic slump. Recent global investments in nanotechnology programs have led to a deeper appreciation of the high performance nature of cellulose nanomaterials. Cellulose, manufactured to the smallest possible-size (~2 nm x ~100 nm), is a high-value material that enables products to be lighter and stronger; have less embodied energy; utilize no catalysts, are biologically compatible and, come from a readily renewable resource. In addition to the potential for a dramatic impact on the national economy – estimated to be as much as $250 billion worldwide by 2020 – cellulose-based nanotechnology creates a pathway for expanded and new markets utilizing these renewable materials. The installed capacity associated with the US pulp and paper industry represents an opportunity, with investment, to rapidly move to large scale production of nano-based materials. It is conservatively estimated that a wood-based nanotechnology program would have a benefit to cost ratio of 25:1. However, effective imaging, characterization and fundamental measurement science for process control and characterization are lacking at the present time. This talk will discuss some of these needed measurements and potential solutions.

9173-2, Session 1

Development of a comprehensive metrology platform dedicated to dimensional measurements of CD atomic force microscopy tips

Johann Foucher, POLLEN Technology S.A.S. (France); Sebastian W. Schmidt, nanotools GmbH (Germany); Jérome Hazart, Aurelien Labrosse, Axel Largent, POLLEN Technology S.A.S. (France); Sandra Bos, CEA-LETI (France); Sebastian Schade, Bernd Irmer, nanotools GmbH (Germany)

Ever-shrinking feature dimensions in the semiconductor industry strongly drive the demands on CD metrology techniques and their measurement uncertainties. With the introduction of hybrid metrology, i.e. the approach to control process steps and parameters on the basis of complementary CD metrology systems, atomic force microscopy (AFM) has become more and more relevant as reference monitoring tool.

Over the last years, extensive improvements have been made on AFM tool stability and its abilities to serve as advanced 3D monitoring system. However, its applicability for CD features is still crucially determined by the AFM tip shape and dimensions.

The vital need for AFM tips applicable to critical device features thus requires highly accurate and precisely fabricated tip dimensions. With electron beam induced processing (EBIP) the current dimensional limitations given by state-of-the-art silicon etch technologies can be overcome. The reduction in tip dimensions, however, is accompanied by challenging demands on process control, quality inspection, and data extraction. With the ability to best meet these requirements, measurements are usually performed with dedicated CD-SEM tools allowing for optimized imaging at minimized contamination. However, whatever improvement is made on the CD-SEM regarding precision, real dimensions on the nanometer level extracted from free-standing 3D structures are hardly to obtain directly since its pretended accuracy remains ambiguous. As a consequence, only reference measurements, e.g. CD-AFM measurements, are able to fill the gap in order to reach the accuracy needed for an acceptable measurement uncertainty.

In this paper, we will present our most recent approach on the extraction of reliable tip dimensions from CD-SEM in order to answer future requirements on AFM tips. We demonstrate the capabilities of a newly developed, fully automatic analysis software based on advanced SEM image modelling and user a-priori knowledge integration in SEM image analysis algorithm. The impact of such breakthrough technology will be shown as a function of its stability and robustness by varying tip shape, imaging settings, and CD-SEM setup parameters. The extracted values are compared to data yielded from commonly used analysis approaches, and directly related to reference CD-AFM measurements. We will discuss the prospective challenges accompanied with shrinking tip dimensions and the potential of a comprehensive data fusion approach.

9173-3, Session 1

Recent advances of the metrological AFM at INRIM

Gian Bartolo Picotto, Roberto Bellotti, Istituto Nazionale di Ricerca Metrologica (Italy)

Quantitative measurements of nanostructured surfaces and particles are always frequently performed by metrological Atomic Force Microscopes (mAFMs). Several laboratories and manufacturers have developed their own design of mAFMs, all these characterized by their on-board metrology system and by the adopted opto-mechanical set-up. The non-linear motions, unwanted rotations, hysteresis and drifts of the moving elements are largely corrected by the on-board position sensors, mostly based on capacitive sensors, piezo-resistive elements and interferometers. In addition, the overall noise of the closed-loop system as well as the finite size and shape of the tip represents the other main sources of error in the reconstruction of the surface topography, namely when imaging high-aspect ratio structures at the nanoscale.

Some recent improvements of the instrument in use at INRIM for nanoparticles and surface metrology are discussed in this contribution. A new differential-type interferometric set-up has been developed to monitor and control the relative tip-sample z-displacements. The results of an internal comparison with step-height standards and reference artefacts are reported. Further, the characterization of the tip shape and size has been tested by using either reference nanoparticles and high-aspect ratio structures. Preliminary results including aspect ratio and curvature radius are outlined together with an upgrade of the own overall budget of uncertainty of the calibration of line-width standards.

9173-4, Session 1

Techniques for AFM tip characterization *(Invited Paper)*

Ndubuisi G. Orji, Ronald G. Dixson, National Institute of Standards and Technology (United States); Hiroshi Itoh, Chunmei Wang, National Institute of Advanced Industrial Science and Technology (Japan)

In atomic force microscopy (AFM) metrology, the tip is a major source of uncertainty. Images taken with an AFM show an apparent broadening

of feature dimensions. The resulting apparent feature in an image is a combination of the actual feature shape and the tip geometry. Parameters such as linewidth produce measurement results that include the added influence of the tip, and can be corrected if the tip width is known. Over the years, various methods and samples have been developed to extract the tip width and shape, and sometimes reconstruct the sample. We have a new tip characterizer for use with conventional and critical dimension AFM tips designed for size and shape evaluation. We model the characterization process with respect to CD-AFM tips, outline the type of evaluations that could be done and the types of uncertainty involved. We compared the measurement procedure and results with those obtained from a conventional tip characterizer. The comb characterizer when used in combination with current method provides more information about the quality of the tip.

9173-5, Session 2

Nanomanufacturing concerns about measurements made in the SEM Part III: vibration and drift *(Invited Paper)*

Michael T. Postek, András E. Vladár, National Institute of Standards and Technology (United States); Petr Cizmar, Physikalisch-Technische Bundesanstalt (Germany)

This is the third of a series of presentations discussing various contributions to the measurement uncertainty in scanned particle beam instruments and some solutions researched at NIST. The scanning electron microscope (SEM) has gone through tremendous evolution to become a critical tool for many and diverse scientific and industrial applications. These improvements have significantly improved the overall SEM performance and have made the instrument far easier to operate. But, ease of operation has also fostered operator complacency. In addition, the user friendliness has reduced the “apparent” need for more thorough operator training for using of these instruments. Therefore, this overall attitude has fostered the concept that the SEM is just another expensive digital camera or another peripheral device for a computer and that all of the issues related to obtaining quality data have been eliminated. Hence, a person using these instruments might be lulled into thinking that all of the potential pitfalls have been fully eliminated and they believe everything they see on the micrograph is always correct. But, as described in this and the earlier presentations this may not be the case. The first paper in this series, discussed some of the issues related to signal generation in the SEM, including instrument calibration, electron beam interactions and the need for physics-based modelling to accurately understand the actual image formation mechanisms. All these were summed together in a discussion of how these issues effect measurements made with the instrument. The second paper, discussed another major issue confronting the microscopist: specimen contamination and methods of contamination elimination. This third presentation discusses vibration and drift and some possible solutions. Over the years, workers at NIST have done a great deal of research into these issues in order to improve the fundamental metrology and some of this work is reviewed and discussed here.

Developing detection efficiency standards for atom probe tomography

Ty J. Prosa, Brian P. Geiser, Dan Lawrence, David Olson, David J. Larson, CAMECA Instruments, Inc. (United States)

Atom Probe Tomography, (APT) is a near-atomic-scale analytical technique, and due to recent advances in instrumentation and sample preparation techniques, APT is being used on a variety of increasingly challenging 3D applications [1].

Total system detector efficiency is a key parameter for 1) estimating system performance, 2) understanding the detection of low concentration species and small clusters of atoms, and 3) accurate reconstruction of atomic coordinates from detected ions; however, its experimental determination can be complicated. The techniques used to date provide limited precision and unknown accuracy because alternative means have not been reported [2]. These methods utilize the atomic periodicities observed in data and require significant data manipulation where each step may be prone to biasing the end result.

This work explores new practical ways to measure total system detector efficiency as well as the necessary specimen characteristics. By utilizing APT analysis of known volumes of material, a high quality measurement of the volume dimensions allows for estimation of the number of atoms within the volume. Adequately encapsulating these volumes ensures that all the field evaporated ions are incident on the detector. The simple ratio of the expected number of atoms to the detected number of atoms then provides a direct measurement of efficiency. We present efficiency measurements based on NIST SRM 2135c encapsulated in silver and nickel as well as progress on alternate materials and encapsulations.

9173-7, Session 2

Recent advances in scanning microwave impedance microscopy (sMIM) for nano-scale measurements and industrial applications

Stuart Friedman, Oskar Amster, PrimeNano, Inc. (United States)

The development and manufacturing of commercially viable nano-materials and nano-devices requires detailed knowledge not only of topography, but increasingly also of electrical properties. Measurement of permittivity and conductivity is well established at modest dimensions, but characterization of local electrical properties, for sub-micron and/or inhomogeneous samples, remains challenging. Scanning probe microscopies, such as AFM, have found significant research and industrial use for imaging and quantifying morphology and mechanical properties at the nano-scale. Electrical measurement modes such as conductive AFM, Kelvin probe force microscopy, and scanning capacitance microscopy have had some success in measuring electrical properties at the nano-scale; however, each technique is often limited to a subset of materials or samples.

Scanning Microwave Impedance Microscopy (sMIM), a new electrical measurement mode for AFM, has shown significant success in the imaging and characterization of electrical properties at 10’s of nm length scales. In this talk we will introduce the principles of operation for sMIM and review the state of the art, including imaging studies revealing electrical characteristics of novel materials and nanostructures, such as composites, graphene, patterned optical crystals and ferro-electrics. In addition to imaging, the technique is suited for a variety of metrology applications where specific physical properties are determined quantitatively. Examples include the measurement of dielectric constant (permittivity) and conductivity (e.g. dopant concentration). These capabilities will be presented, illustrating sensitivity and resolution for dielectric constant, doping levels and capacitance. For samples where properties such as dielectric constant are known the technique can be used to measure film thickness.

9173-8, Session 3

Standardization of methods for extracting statistics from surface profile measurements *(Invited Paper)*

Peter Z. Takacs, Brookhaven National Lab. (United States)

Surface profilers and optical interferometers produce 2D maps of surface and wavefront topography. The Power Spectral Density (PSD) function of the surface height distribution is a powerful tool to assess the quality and performance of the surface in question. In order to extract useful information about the spectral distribution of surface roughness or

mid-spatial frequency error over a particular spatial frequency band, it is necessary to first detrend the raw data and apply a window function before computing the PSD. This process eliminates discontinuities at the borders of the profile that would otherwise produce large amounts of spurious power that would mask the true nature of the surface roughness. This procedure is now part of a new draft standard that is being adopted by the US OEOSC for statistical analysis of optical surface data, OP1.005. Illustrations of the usefulness of this procedure will be presented.

9173-9, Session 3

Improved quality control of silicon wafers using novel off-line air pocket image analysis *(Invited Paper)*

John F. Valley, SunEdison (United States); M. Cristina Sanna, SunEdison Italy (Italy)

Air pockets (APK) occur randomly in Cz grown crystals and may become included in wafers after slicing and polishing. Previously the only APK of interest were those that intersected the front surface of the wafer and therefore directly impacted device yield. Mobile electronics have placed new demands on wafers to be internally APK-free for reasons of thermal management and packaging yield. We present a novel, recently patented, APK image processing technique and demonstrate the use of that technique, off-line, to improve quality control during wafer manufacturing. The APK, which occur only rarely within a finished wafer, are detected using in-line automated inspection equipment. The in-line equipment currently sorts for APK using metrics derived from camera images. First, the APK-suspect blob is found in the image based on a threshold image intensity. From then on the APK-suspect image data is treated as black and white (B&W) blob data. Metrics are extracted from the B&W image to quantify the circular nature of the blob's area. Other than thresholding, the image intensity information is not used directly in determining the APK metrics, therefore image judgment may occasionally be adversely impacted. However, the images are saved as monochrome 8-bit image files and are available for post-processing off-line. We present here a new set of APK image metrics based on image symmetry using the in-line saved images. Using automated off-line analysis these new metrics are shown to improve sort accuracy and purity when compared to human image judgment. The new metrics are shown to be particularly useful as the APK-suspect blob size gets smaller and pixelation effects make the B&W derived metrics less robust.

9173-10, Session 3

Interferometric measurement of dimensional and thermal stability of joints

Hagen Lorenz, René Schödel, Physikalisch-Technische Bundesanstalt (Germany)

At PTB, the most precise interferometric length measurements with sub-nanometre precision are carried out under vacuum conditions, using an instrumentation similar to regular gauge block (GB) interferometers. Repeated length measurements provide information about the intrinsic stability of the GB which can be affected by internal structural changes of the material. Such processes can also be triggered by external events like thermal or mechanical loading. Due to growing demands in precision engineering, there is a need to investigate not only the stability of materials but also of joints. The dimensional and thermal stability of joints, produced with techniques like gluing and screwing, has been investigated for the fist time over a long-term period in the range of months to years and with a precision as available for GBs.

We describe representative joints made of GBs and appropriate techniques that we have developed to exploit the parallelism of GB surfaces in order to achieve sub-nanometer accuracy of interferometric measurements. Dependent on the measurement task, the stability was measured longitudinally or laterally to the connection interface, i.e. the GBs had been joined at the front faces or at the side faces, respectively. Additional to the length, also the surface orientations of the joints were detected by analysis of the phase topographies.

With the use of the sample joints, elements frequently used in precision engineering can be examined carefully. It should be possible also to adapt the specimens with respect to specialized joining techniques applied in ultra precision instruments.

9173-12, Session 4

Refractometry of turbid nanoparticle suspensions and applications

Augusto García-Valenzuela, Humberto Contreras-Tello, Univ. Nacional Autónoma de México (Mexico)

To date only the measurement of the refractive index of homogeneous materials is well established. However, many materials of technological and scientific significance are not homogeneous at a scale comparable to visible wavelengths. In such cases, light traveling within the material gets scattered and some portion of it, or all of it, becomes diffuse. In these cases the medium is turbid and has an effective refractive index that is a complex quantity even if there is no absorption of light. There is a great potential of novel applications of a robust refractometry of turbid nano- and micro-particle suspensions. It has been recently shown that measurements of the complex effective refractive index can be used advantageously to determine particles' size, refractive index and concentration.

In this work we propose an improved device to obtain angular-intensity profiles around the critical angle of diffuse light transmitted from a turbid sample into a transparent prism. The sample is illuminated by a laser beam incident to the sample at a variable angle of incidence from the prism side. The refractometer enables us measuring the refractive index of particles suspensions of higher turbidity than in previous works. We use the refractometer to test a recently developed theoretical model and find very good agreement with experimental data. Overall, our objective is to establish on firm grounds a methodology for measuring the refractive index of turbid particle suspensions using the refraction of diffuse light around the critical angle and use it to characterize nano- and micro-particles in suspension.

9173-13, Session 4

Study of internal energy flows of a coma affected singular beam by Helmholtz Hodge decomposition

Monika Bahl, P. Senthilkumaran, Indian Institute of Technology Delhi (India)

We introduce an efficient and simple technique to determine the topology of singular optical beams. It is based on the Helmholtz Hodge Decomposition (HHD) of the focused structure of coma infused singular beams. The HHD segregates the phase gradient structure of an optical field into explicit solenoidal and irrotational components. A study of the Poynting vector or optical currents in the segmented divergence free component reveals the points of singularities formed along with their helicity, at the focal plane. A study of this power flow or energy circulation is important when one deals with set ups as in optical tweezers, optical micro-motors and spanners where the beams are focused by an optical lens. Minor perturbations like aberrations affect the energy flow in the focal volume. Our analysis segments the focal volume field structure into an explicit curl and a divergence component. The Poynting vector analysis in these parts reveals the topology of the input singular beam along with the energy flows at the focal plane. In this work, we concern ourselves with the former results. Fresnel-Kirchoff diffraction integral is numerically evaluated to determine the focal plane structure of the beam after it has been infected with coma aberration at the exit pupil of the lens. Results indicate a flattening of the dark core in the intensity patterns and the effect seems to be more pronounced as the charge

of the singular beam increases. The extracted information from the decomposed structures reveals the charge and the helicity of the input beam.

9173-14, Session 4

Mass sensing AlN sensors for waste water monitoring

Ryan Porrazzo, Graham Potter, Leigh K. Lydecker IV, Z. Foraida, Suhasini Gattu, Natalya Tokranova, James Castracane, SUNY College of Nanoscale Science and Engineering (United States)

Monitoring the presence of nanomaterials in waste water from semiconductor facilities becomes an important task for public health organizations. Advanced semiconductor technology allows fabrication of sensitive mass piezoelectric sensors which are able to detect less than 10 µg/L of nanomaterials such as nanoparticles of alumina, amorphous silica, ceria, etc. The interactions between acoustic waves generated by the piezoelectric sensor and nanomaterial mass attached to its surface define the sensing response as a shift in the resonant frequency. In this article the AlN film bulk acoustic resonator (FBAR) development and characterization are presented. Tilted c-axis oriented AlN films were deposited by a DC reactive magnetron sputtering to generate shear waves which don't propagate in water and thus the acoustic loses are reduced. The high acoustic velocity of AlN over quartz allows the increase in resonance frequency in comparison with a quartz crystal microbalance (QCM) and results in a higher frequency shift per mass change, or greater sensitivity. The membrane and electrodes were fabricated using a standard semiconductor technology. The surface device functionalization was performed to obtain selectivity towards a specific nanomaterial. As a result, the devices were covered with a "docking" layer that allows the nanomaterials to be selectively attached onto the surface. The different functionalization techniques were used and analyzed, such as electro-polymerization, layer-by-layer deposition, etc. The influence of the coating thickness on the sensitivity for mass detection was studied. The observed frequency shift for a certain mass load increases proportional to the resonance frequency squared.

9173-16, Session 4

Shack-Hartmann waveffront sensor non-null testing off-axis aspheric mirror on axis

Jinping Zhang, Shanghai Institute of Technical Physics (China); Zhongyu Zhang, Xue-jun Zhang, Changchun Institute of Optics, Fine Mechanics and Physics (China)

At the end stage of the grinding and rough polishing a reflection mirror, the shape of the surface usually deviates from the target one. Especially when the mirror has a steep aspheric surface, contact profilometer may not be possible or correct. The Hartmann test has a great advantage in larger dynamic range compared with interferometer. It means that the mirror can be tested with a Hartmann wave-front sensor without null compensator. This paper presents a new method that using Shack-Hartmann wave-front sensor to non-null test off-axis aspheric surface on axis, and analyzes the impact on test results by error source and misalignment. Using a simulated wave-front, testing an off-axis aspheric reflection mirror is carried out. This mirror is also tested by contact profilometer and interferometer. Comparing the three testing results, the Shack-Hartmann testing is not only more accurate than profilometer, but also has a larger dynamic range than interferometer. It also shows that the theory of testing system and separation of errors are correct.

9173-15, Session PWed

High-resolution optical measurement technique for diffraction gratings by using a variable angle phase modulation ellipsometer

Kyongseok Kim, Bo Ram Kim, Sung-Ho Lee, Seung-Han Park, Yonsei Univ. (Korea, Republic of)

In semiconductor industry, optical metrology is becoming a promising technique, replacing conventional measurement methods such as SEM and AFM. For instance, ellipsometric spectra obtained at a fixed angle of incidence (AOI) have been frequently used to extract geometric parameters of the nano-patterned structures. In this presentation, a variable angle ellipsometer to determine the geometrical parameters of diffraction gratings with good AOI precision is demonstrated. Our technique is based on the configuration of reversing the independent variable, i.e., varying AOI's at a fixed wavelength, which utilizes the sensitive dependence of the sidewall angle on AOI's.

A phase modulation ellipsometer (PME) with a monochromatic light source (He-Ne laser) is constructed and automatized by motorized stages with high precision. After optimizing the alignment, AOI can be controlled within 0.01°. The diffraction gratings with slightly varying geometrical parameters (height, width, and sidewall angle) are prepared and their ellipsometric angles (EAs) with scanning AOI are measured. The best fit to the measured EAs is acquired via parameterized nonlinear regression in rigorous coupled-wave analysis algorithm. The results show that the geometric parameters of the diffraction gratings can be successfully obtainable, indicating potential application of PME to analyze the independent variables of the optical metrology.

9173-17, Session PWed

Quantifying ellipsometric data uncertainties for multichannel rotating-element ellipsometers

Yong Jai Cho, Won Chegal, Hyun Mo Cho, Korea Research Institute of Standards and Science (Korea, Republic of)

The multichannel spectroscopic ellipsometers are well known as a real-time diagnostic tool in science and industry of surfaces, thin films, and nano patterns. The rotating-element ellipsometric configurations have been adopted widely for the multichannel spectroscopic ellipsometers. The requirements for enhancing ellipsometric accuracy become more stringent especially in the semiconductor industries but there is no generally accepted method for characterizing or quantifying ellipsometric data accuracy [1]. In the real spectroscopic ellipsometers, there are temporal random noises due to stochastic fluctuation in the exposures measured during a given integration time by a pixel or binning pixel group in the CCD arrays. Using a novel ellipsometric data acquisition method [2], we analyzed experimentally the error propagation from the measured Fourier coefficients of the irradiance waveform to the ellipsometric sample parameters [3]. In this presentation, we show that the closed-form expressions of ellipsometric sample parameters can be evaluated from the Fourier coefficients using the method of least squares. To quantify the ellipsometric data uncertainties due to the random noises, we obtain the standard deviations and correlation coefficients of the unnormalized Fourier coefficients formulated analytically for the novel data acquisition method and then analyze the error propagation from the measured exposures to the ellipsometric sample parameters.

9173-18, Session PWed

Scatterometric characterization of diffractive optical elements

Toni Saastamoinen, Univ. of Eastern Finland (Finland); Hannu Husu, MIKES Mittatekniikan keskus (Finland); Janne Laukkanen, Univ. of Eastern Finland (Finland); Samuli Siitonen, Nanocomp Oy Ltd. (Finland); Jari Turunen, Univ. of Eastern Finland (Finland); Antti Lassila, MIKES Mittatekniikan keskus (Finland)

Characterization of diffractive optical elements using invasive methods such as scanning electron microscope (SEM) or atomic force microscope (AFM) is slow and potentially destructive to the element. However, applying scatterometric method the measurements are not only fast but also the sample remains intact. Because of these advantages, scatterometer would be also be an ideal tool for online quality control of the fabrication processes. The scatterometric method, on the other hand, introduces an inverse problem which can be time consuming to solve at least for complex structures.

In this work we have analyzed a binary grating and a binary 1-to-5 beamsplitter which were measured using a laser diffractometer modified for high angular resolution detection of the intensities of diffraction orders. The binary samples were measured using several wavelengths and incidence angles in both TE and TM polarizations to ensure that the amount of data is sufficient to for the inverse problem. The inverse calculations were performed by applying Fourier modal method together with conventional optimization algorithms. After the solution of the inverse problem, the obtained dimensional parameters of the gratings were compared with the parameters determined from AFM measurements.

The correlation of the results was very good for the binary structure which confirms that the scatterometric method is capable of determining the parameters of the gratings. The results for the beamsplitter were also very promising which shows that the method also works for more complex structures.

9173-19, Session PWed

Precision analysis of three polarizer spectroscopic ellipsometer

Won Chegal, Yong Jai Cho, Hyun Mo Cho, Korea Research Institute of Standards and Science (Korea, Republic of)

We developed a spectroscopic ellipsometer based on a three polarizer configuration composed of a white light source, a fixed polarizer, a rotating polarizer, a sample, a fixed analyzer, and a multichannel spectrometer in order to investigate the precision optimization of real-time rotating-element spectroscopic ellipsometers. A novel Fourier analysis algorithm, i.e., the discrete Fourier transform of the measured exposures, was adopted to obtain the Fourier coefficients accurately and precisely, in contrast with the only data acquisition method used previously. From the spectra of the normalized Fourier coefficients experimentally obtained using the novel Fourier analysis, the offset angles of the fixed polarizer, rotating polarizer, and fixed analyzer were determined by regression calibration, and their values were almost constant, independent of the wavelengths used. The excellent fits to the experimental spectra of the ellipsometric sample parameters strongly suggest that the real-time spectroscopic ellipsometer based on the three-polarizer design is very reliable and that the precision of the data reduction functions represented in terms of the three Fourier coefficients was considerably enhanced compared with the commonly used data reduction functions. This approach will be helpful for analyzing the optimization of the precision of other types of rotating-element ellipsometers.

Van der Waals epitaxy of InAs nanostructures on graphene *(Invited Paper)*

Young Joon Hong, Sejong Univ. (Korea, Republic of); Takashi Fukui, Hokkaido Univ. (Japan)

Unconventional, noncovalent heteroepitaxy of inorganic semiconductors is of importance for making use of graphene as epitaxial substrates. The van der Waals (vdW) heteroepitaxy has been developed firstly by Koma since 1984. In this talk, the vdW InAs/graphene heterostructures, fabricated by metal–organic vapor-phase epitaxy, are presented. The critical factors leading to nucleation and growth for the vdW heteroepitaxy of inorganic semiconductor nanostructures on honeycomb carbon surface are presented in terms of lattice misfit and surface potentials. Importantly, the vdW heteroepitaxy enabled to grow InAs nanowires vertically aligned on single-layer graphene, implying that the vdW attraction is strong enough to grow vertical nanostructures with high aspect ratio. We also demonstrate the world thinnest substrate material, that is single-layer graphene. Moreover, suspended single-layer graphene was utilized for verifying the role of monoatomic layer as substrates for vdW epitaxy, yielding vdW epitaxial double heterostructures. We also present the controlled vdW epitaxy method for high-yield and uniform InAs nanowire arrays on graphene by utilizing substrate surface etching and patterning techniques. Our work provides a new important methodology and principles of fabricating the graphene-based epitaxial semiconductors for new functional electronic and optoelectronic device applications.

9174-4, Session 1

Direct band gap wurtzite GaP nanowires for LEDs and quantum devices *(Invited Paper)*

Simone Assali, Technische Univ. Eindhoven (Netherlands); Dominik Kriegner, Institute of Semiconductor and Solid State Physics, Johannes Kepler University (Austria); Ilaria Zardo, TU/e Eindhoven (Netherlands); Sebastien Plissard, CNRS, LAAS (France); Marcel M. A. Verheijen, Philips Innovation Services Eindhoven, High Tech Campus (Netherlands); Julian Stangl, Institute of Semiconductor and Solid State Physics, Johannes Kepler University (Austria); Erik P Bakkers, Technische Univ. Delft (Netherlands); Jos J.E.M. Haverkort, TU/e Eindhoven (Netherlands)

Theoretical band structure calculations for Gallium Phosphide (GaP) predict a direct band gap when this material is grown with the wurtzite (WZ) crystal structure [1-2]. Here, we discuss the growth of GaP nanowires with high-purity WZ crystal phase. Photoluminescence (PL) measurements will be shown to demonstrate the direct nature of the band gap [3]. In order to provide a deeper understanding of the band structure of the WZ GaP nanowires, polarization-dependent PL and Photoluminescence-excitation (PLE) measurements on transferred nanowires will be discussed. This allows us to address the nature of the optical transitions with respect to the theoretical predicted values [1-2] and the expected selection rules for the WZ phase [4]. Temperature-dependent PL-PLE scans reveal the excitonic nature of the optical transitions, together with room-temperature emission. Thus, WZ GaP nanowires are a promising candidate to solve the problem of the green gap in white LEDs technology [5]. Furthermore, WZ GaP nanowires could be used as building blocks for the solid state quantum systems. The control of the switch between the WZ and the zinc-blende (ZB) crystal structure over an atomic scale will be discussed, resulting in the formation of atomically sharp crystal phase quantum dot (CPQD) structures[1-2] along the nanowire length.

Silicon epitaxy in nanoscale for photovoltaic applications *(Invited Paper)*

Jinkyoung Yoo, Los Alamos National Lab. (United States); Shadi A. Dayeh, Univ. of California, San Diego (United States); Wei Tang, Univ. of California, Los Angeles (United States); Norman C. Bartelt, Sandia National Labs. (United States); Alp T. Findikoglu, Samuel T. Picraux, Los Alamos National Lab. (United States)

Epitaxial growth of silicon (Si) radial shell on Si nanowire will be presented. Single crystalline Si radial shell growths were conducted on core Si NWs. The dimensions of the core Si NWs were precisely controlled by lithographic techniques and Si deep reactive ion etching followed Crystalline 3D Si growth was performed by low-pressure chemical vapor deposition (CVD) growth. Atomically smooth Si template surfaces of NWs for 3D epitaxy were prepared by multi-step thermal oxidation and wet oxide etching. The single crystalline doped and undoped Si layers were grown in the range of 670 to 800oC to avoid autodoping issues at high growth temperatures. The growth rate and crystallinity of grown Si layers were investigated by scanning and transmission electron microscopy. Through a series of characterizations we observe an unprecedented dependence of growth rate of the single crystalline Si layers along the radial direction on initial diameter, which cannot be explained by the Gibbs-Thomson effect. We also discuss the effect of dopants on the epitaxial growth rate and discuss the growth mechanism of single crystalline Si radial shells at nanoscale dimensions.

Additionally, morphological evolution of 3D Si and critical thickness behavior will be discussed. Comprehensive studies reveal that judicious control of shell layer thickness enables us to get advantages of enhanced optical absorption and carrier generation under sun illumination in Si radial p-i-n junction. The epitaxial approach for radial shell formation will be useful for high performance photovoltaic device applications.

Vertical type GaN nanowire/thin film p-n junction light-emitting diodes *(Invited Paper)*

Young Joon Hong, Sejong Univ. (Korea, Republic of); Sung Jin An, Kumoh National Institute of Technology (Korea, Republic of)

For semiconductor nanowire-based optoelectronics, epitaxial nanowire arrays integrated on thin film offer ideal geometry for standard manufacturing and three-dimensional architectural devices. Meanwhile, the metal catalyst-assisted vapor–liquid–solid (VLS) process has produced well-controlled nanowire heterostructures promising for optoelectronic device applications. However, under some nanowire growth conditions, the method produces not only the desired nanowires but also nanocrystallites or film on substrates. In nanowire–thin film junction devices, such nanoislands and films can critically affect the junction device fabrication and performance.

The effect of nanoislands on nanowire–thin film junction light-emitting devices (LEDs) was examined by employing Ni-catalyzed VLS process that yields epitaxial GaN nanowire arrays and unnecessary nanoislands. Two different nanowire-based LED structures are prepared: n-nanowire/p-film (TYPE I); insulating layer-embedded coaxial p–n junction nanowires on n-film (TYPE II). TYPE I devices exhibited poor electrical rectifying features with a small on/off current and unclear turn-on threshold. The blue–green–yellow mixture electroluminescence resulted presumably from nanoislands. In contrast, TYPE II LEDs exhibited clear rectifying diode characteristics with typical EL turn-on voltage of ~3–4 V and enhanced on/off current ratio because the nanoisland layers were electrically isolated from p–n junctions by coating the crystallite layers with insulators. The EL color was pure blue from the depletion region of p-GaN shell layer. The LEDs were improved by suppressing the parasitic resistance and leakage current caused by the inevitable formation of nanoislands on the substrates during VLS nanowire growth.

9174-11, Session 3

Nanomaterials and nanostructures for LEDs: advanced nano-scale correlation of structural and optical properties of GaN nanorods *(Invited Paper)*

Frank Bertram, Otto-von-Guericke-Univ. Magdeburg (Germany)

In the past few years, tremendous progress has been achieved on epitaxial growth and processing of group III nitride nano- and microrods. Furthermore, these growth improvements have allowed the fabrication of optoelectronic devices based nanorods as active elements, i.e. light emitting diodes (LEDs). However, their efficiency is still far behind the performance of conventional GaN-based light emitting diodes.

The controlled growth of GaN nanorods offers a potential benefit for achieving higher efficiencies of III-Nitride based optoelectronic devices due to a high surface to volume ratio. Nanorods have a very large active area compared to their footprint. Since the active region is wrapped around the three-dimensional core (for core shell structures), the active layer scales with the rod's aspect ratio (i.e. the ratio of height and diameter). Therefore, by controlling their density, diameter and height, a tremendous increase of active surface can be achieved. Additionally, the low defect density in nanorods allows the characterization of single extended defects which is of high interest for a clear understanding of the formation of these defects.

In this study we present a direct nano-scale correlation of the optical properties with the actual real crystalline structure of single GaN nanorods using low temperature CL spectroscopy in a scanning transmission electron microscope (STEM). We concentrate on the crystalline quality, local In incorporation, n- and p-layer quality and defects of the complete structures.

Top-down III-nitride nanowires: from LEDs to lasers *(Invited Paper)*

George T. Wang, Qiming Li, Jeremy B. Wright, Sandia National Labs. (United States); Huiwen Xu, The Univ. of New Mexico (United States); Jonathan J. Wierer Jr., Daniel D. Koleske, Jeffrey J. Figiel, Sandia National Labs. (United States); Antonio Hurtado, Luke F. Lester, Changyi Li, Steven R. J. Brueck, The Univ. of

New Mexico (United States); Ting-Shan Luk, Igal Brener, Sandia National Labs. (United States)

Compared to conventional planar heterostructures, which dominate current optoelectronic architectures, III-nitride nanowires have several potential advantages including: reduced defect densities; reduced strain, which enables growth on arbitrary substrates as well as allowing for a greater range of alloy compositions and hence bandgap energies; access to nonpolar crystal faces; increased device area; and the ability to create 2-dimensional arrangements. I will discuss a "top-down" approach for fabricating ordered arrays of high quality III-nitride-based nanowires with controllable height, pitch and diameter. The process combines a lithographic dry etch followed by a selective, wet chemical etch of the nanowire sidewalls, leading to hexagonally-shaped nanowires with straight and smooth nonpolar m-plane sidewalls. Precisely engineered axial nanowire heterostructures can be formed from planar heterostructures, while radial nanowire heterostructures can be formed via regrowth. Using this top-down approach, both axial and radial type III-nitride InGaN/GaN nanowire LEDs were realized. The fabrication, structural characterization, and luminescence of these two different structures will be presented and their relative merits, weaknesses, and prospects discussed. III-nitride nanowires are also gaining interest as ultracompact and low-power nanoscale lasers in the UV-visible wavelengths. While GaN nanowire lasers typically operate in a multimode state, single-mode lasing is desired for applications needing high beam quality and spectral purity. Here we introduce multiple schemes for single optical mode selection and polarization control in GaN nanowire lasers, and demonstrate a photonic crystal nanowire laser design exhibiting a wide 60 nm of wavelength tuning.

Aluminum titanium oxide films for optical encapsulation and broadband optical coupling

Juan J. Diaz Leon, Univ. of California, Santa Cruz (United States) and Nanostructured Energy Conversion Technology and Research (United States); Ernest Demaray, Demaray, LLC (United States) and Antropy, Inc. (United States); David M. Fryauf, Junce Zhang, Kate J. Norris, Univ. of California, Santa Cruz (United States) and Nanostructured Energy Conversion Technology and Research (United States); Mark Johnson, Tango Systems, Inc. (United States); Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States) and Nanostructured Energy Conversion Technology and Research (United States)

Efficient optical coupling for in-coming and out-going light is critical for optoelectronic devices such as solar cells and light emitting diodes. We developed a material system that acts both as a moisture barrier and as a broadband antireflective coating with very low optical absorption. We used pulsed DC reactive magnetron sputtering with AC substrate bias to deposit aluminum titanium oxide (AlTiOx) binary alloy thin films with different compositions. We studied physical properties of the films that underwent a high pressure moisture endurance test. Results suggest that there is a specific range of aluminum-titanium ratio where AlTiOx films withstand the endurance test while films with one type of cation or films with compositions out of the range fails. The ability to continuously change refractive index of pinhole-free AlTiOx films could ensure effective encapsulation and efficient optical in- and out- coupling will significantly benefit the design of optoelectronic devices.

9174-19, Session 5

Insights into enhanced MOF growth mechanisms on fibrous mats *(Invited Paper)*

Sarah D. Shepherd, RTI International (United States); Junjie Zhao, Mark D. Losego, Paul C. Lemaire, Philip S. Williams, Christopher J. Oldham, North Carolina State Univ. (United States); Howard

J. Walls, RTI International (United States); Gregory W. Peterson, U.S. Army Edgewood Chemical Biological Ctr. (United States); Gregory N. Parsons, North Carolina State Univ. (United States)

Metal-organic frameworks (MOFs) have significant potential for applications such as gas sorption, sensors, separation processes, catalysis, and storage. Our research is focused on controlling growth and attachment of MOFs on fibrous scaffolds to generate multifunctional materials utilizing ALD (atomic layer deposition) and other novel synthesis techniques. Integrated systems of MOFs on fibers should offer advantages in handling, safety, and development of new applications for these promising materials.

ALD as a nanoscale seeding layer for MOF growth greatly influences crystal structures achieved, growth mechanisms, and attachment. Employing Al2O3 and TiO2 ALD layers of varying thicknesses onto micro and nanofiber mats also has a significant impact on the properties of the MOF being formed. Uncoated mats were shown to have poorer attachment of MOF crystals, lower mass loading overall, and less uniform coverage of the fibers than ALD seeded mats. We will present results for synthesis of HKUST-1 MOF [Cu3(BTC)2] on fibers using solvothermal and layer-by-layer (LBL) techniques. MOFs produced on fibers can achieve dynamic loadings comparable to those of traditionally prepared MOF powders, significantly increasing the application potential for MOF-enabled devices. Insights into the dependence of crystal formation on synthesis technique, fiber size, and ALD layer will be discussed. Results given consider MOF crystal size, quality, attachment, and coverage of the fibrous substrate.

9174-20, Session 5

Molecule meets MOF: bridging the gap between organic and inorganic electronic materials *(Invited Paper)*

Mark D. Allendorf, A. Alec Talin, Michael E. Foster, Vitalie Stavila, François Léonard, Sandia National Labs. (United States)

Conventional inorganic electronic materials such as silicon achieve their outstanding electro-optical properties as a result of long-range crystalline order. However, these properties can only be tuned over a very limited range. In contrast, the properties of conducting organic polymers are readily modified, but the high degree of disorder in these materials leads to poor mobility. Metal-Organic Frameworks (MOFs) are a recently created class of supramolecular materials in which metal ions are coordinated to rigid organic “linker” molecules, creating a nanoporous structure with an exceptional degree of synthetic versatility. However, virtually all known MOFs are insulators as a result of the largely ionic nature of the metal-linker bonds. Recently, we discovered that infiltrating the pores of the copper-containing MOF HKUST-1 with redox-active guest molecules, such as TCNQ (7,7,8,8-tetracyanoquinododimethane), increases the electrical conductivity of thin film devices by as much as seven orders of magnitude. This emergent property results from a novel donor-bridge-acceptor geometry, in which TCNQ binds to two Cu(II) dimer units within the MOF pore. In this presentation we will describe the synthesis and characterization of Molecule@MOF materials. Coupling these results with first-principles electronic structure calculations demonstrates that conductivity occurs via a hopping mechanism facilitated by the bridging TCNQ. From these results it will be clear that Molecule@MOF represents a novel class of electronic materials with the potential to bridge the properties gap between inorganic and organic conductors, providing a high degree of electronic tailorability combined with long-range order for high charge mobility.

Fluctuations of the surface potential and photoconductivity in nanoheterostructures Si/Ge with SiGe nanoislands *(Invited Paper)*

Darina P. Storozhuk, Sergey V. Kondratenko, National Taras Shevchenko Univ. of Kyiv (Ukraine); Yuriy N. Kozyrev, Chuiko Institute of Surface Chemistry (Ukraine)

The electrical and optical properties of the Ge/Si heterostructures with Ge nanoislands grown by a molecular beam epitaxy (MBE) technique were investigated. To research the recombination processes spectral and time dependencies of lateral photoconductivity were studied. Photoconductivity at $T<190$ K, in the spectral region where c-Si is transparent, is attributed to interband optical transitions involving the states in the nanoislands. It is shown that when the temperature was decreased then the most significant is the decrease in the

photoconductivity of the fundamental absorption of the nanoislands. In the study of the kinetics of photoconductivity nanoheterostructure Si/Ge at T <120 K observed long-term relaxation of the photocurrent. Relaxation was more quick in case when only nanoislands were photoexcitatied. The obtained results has shown the high efficiency of recombination centers of electron-hole pairs in SiGe nanoislands. Spatial distribution of the surface potential of the heterostructure Ge-Si with nanoscale islands using the Kelvin probe method (KFM) were investigated. To study the local contact potential difference (CPD) of the system tip-surface atomic force microscopy with Sb-doped Au-coated conductive probes were used. The maximum value of CPD was observed at the location at the Ge nanoislands regions whereas the Si-surrounding exhibited the lowest value. The observed changes in the local surface potential due to the charge localized states in nanoislands and Ge-Si interface.

Investigation on resistive switching characteristics of ZnO thin film *(Invited Paper)*

Min Wei, Univ. of California, Santa Cruz (United States); Chunfu Li, Fan Yang, Hong Deng, Univ. of Electronic Science and Technology of China (China)

Recently resistive switching (RS) based on ZnO thin film has attracted considerable attention since ZnO with doping can improve the switching ratio and device performance. In this work, Cu/ZnO/AZO (Al-doped ZnO) and Cu/ZnCuO (Cu-doped ZnO) /AZO structures were fabricated for RS, using AZO as bottom electrodes due to its lattice matching with ZnO, and metal Cu was deposited as the top electrodes. The current–voltage (I–V) characteristics of these two structures are analyzed and compared. The results demonstrated that ZnCuO RS had a higher switching ratio and a larger range of setup and reset voltage than ZnO RS. In addition, we also found that the high resistance state (HRS) and the low resistance state (LRS) were accordance with space charge limited current effect (SCLC) and Ohm's law respectively.

High-precision transfer-printing of vertically oriented 1D semiconductor arrays and integration into flexible devices

Mark Triplett, Univ. of California, Davis (United States); François Léonard, Sandia National Labs. (United States); M. Saif Islam, Univ. of California, Davis (United States)

Flexible electronics incorporating single crystalline semiconductors typically require post-growth processes to assemble the crystalline materials onto flexible substrates prior to device fabrication. We have developed a high precision transfer printing method for vertical arrays of single crystalline semiconductor materials which is adaptable to arrays with widely varying aspect ratios and densities enabling the assembly of arrays on flexible substrates in a vertical fashion. Subsequent fabrication processes for integrating transferred vertical arrays into flexible devices have also been developed and characterized. Flexible devices consisting of vertical silicon nano- and micro-wire arrays with robust top and bottom contacts have been fabricated and shown to be stable under bending stress, capable of reaching bending radii of 20mm. A thermionic-field emission current mechanism, due to the semiconductor-metal interfaces and doping levels present, was shown to be dominant for these devices. This mechanism is confirmed by device modeling and is consistent with standard semiconductor device physics principles, showing the consistency of our methods with current microelectronic fabrication techniques. The devices also act as flexible, deformable, nonpiezoelectric, and silicon based tactile sensors as they exhibit a reversible increase in conductivity with applied vertical stress. Our presented system provides a way forward for high-throughput, manufacturable, and scalable fabrication of flexible devices.

9174-33, Session 8

Carbon nanotube terahertz detector *(Invited Paper)*

Francois Leonard, Sandia National Labs. (United States)

We present a macroscopic terahertz detector based on optically thick films of dense and aligned carbon nanotubes. This p-n junction detector responds to a broad range of frequencies, shows a response at zero bias,

good linearity with THz power, and is intrinsically sensitive to polarization. A combination of electrical, thermal, opto-thermal, and thermoelectric experiments establishes the photothermoelectric mechanism of the response.

9174-34, Session 8

Acid-leached ?-MnO2 nanowires for electrochemical energy storage *(Invited Paper)*

Bryan Byles, Drexel Univ. (United States); Arunkumar Subramanian, Virginia Commonwealth Univ. (United States); Ekaterina Pomerantseva, Drexel Univ. (United States)

Nanowires of manganese oxides with tunnel crystal structures form a wide family of non-toxic and low cost materials with the general formula AxMnO2 (A = K, Na, Mg, etc.). These materials display a controlled variation in tunnel size and shape which can be used for a tunable ions intercalation. In addition, acid leaching of these phases opens ways to modify composition, morphology, electronic conductivity and surface properties of these materials, which are all crucial for the electrochemical intercalation-based energy storage. In this work we present electrochemical cycling of lithium ions in the original and acid-leached ?-MnO2 nanowires. We discuss the importance of the post-synthesis material treatment for the improvement of the functional properties. In addition, we demonstrate single nanowire electrochemical cells for the study of electrochemically-correlated mechanical properties of the nanowires.

9174-35, Session 8

Analyzing the evolution of microstructural disorder in thermally annealed bismuth telluride nanowires using a combined STEM/CBED approach *(Invited Paper)*

Kristopher J. Erickson, Steven J. Limmer, William G. Yelton, Caitlin Rochford, Michael P. Siegal, Douglas L. Medlin, Sandia National Labs. (United States)

Understanding microstructural disorder is critical for optimizing nanomaterials but poses a difficult challenge for characterization. The evolution of microstructural disorder within electrodeposited (ECD) Bi2Te3 nanowires, having thermoelectric applications, was studied following sequential ex situ thermal annealing steps using Convergent Beam Electron Diffraction and Scanning Transmission Electron Microscopy. This approach allowed changes in both intra-granular structural disorder and the grain structure to be quantified. These observations are put in context of the current understanding of ECD nanomaterial defect structures and ECD nanomaterial microstructure evolution during thermal annealing. This general approach is also applied towards quantifying structural changes in other nanomaterials.

9174-36, Session 8

SAD-GLAD core-shell nanorod arrays for fuel cell, photodetector, and solar cell electrode applications

Hilal Cansizoglu, Mehmet F. Cansizoglu, Mesut Yurukcu, Univ. of Arkansas at Little Rock (United States); Wisam J. Khudhayer, University of Babylon (Iraq); Nancy Kariuki, Deborah J. Myers, Argonne National Laboratory (United States); Ali U. Shaikh, Tansel Karabacak, Univ. of Arkansas at Little Rock (United States)

Shadowing effect in thin film growth originates from preferential deposition of obliquely incident atoms on higher surface points, which can lead to the formation of columnar thin films or isolated nanostructures. In a physical vapor deposition (PVD) technique, such as sputtering, one can control shadowing effect simply through substrate tilt angle. Glancing angle deposition (GLAD) technique, different than a conventional PVD process, incorporates a flux of atoms that are obliquely incident on a tilted and rotating substrate. Instead of a continuous thin film coating, these atoms can form arrays of three-dimensional nanostructures due to the shadowing effect. By simply controlling the deposition angle and substrate rotation speed, nanostructures of large variety of materials in the shapes of rods, screws, or springs can be obtained easily that are otherwise difficult to produce by conventional lithographical techniques. In this talk, a brief overview of the growth mechanisms and physical and optical properties of GLAD nanostructures will be presented. In addition, a new small angle deposition (SAD) technique as a simple means of conformally coating nanorod or nanowire arrays will be described. SAD utilizes a small tilt angle during PVD on nanostructured substrates, which allows the effective exposure of nanorod sidewalls to the incoming flux and leads to enhanced thin film conformality. In this talk, some recent results on core-shell nanorod arrays obtained by coating GLAD nanorods with a SAD shell will be presented. It will be shown that core-shell nanostructured geometries obtained by the simple SAD-GLAD method can significantly enhance catalyst activity for fuel cell electrodes, and charge carrier collection efficiency in photodetectors and photovoltaic solar cells.

Compound and alloyed contacts to Ge/Si and InGaAs nanowires and FinFETs *(Invited Paper)*

Shadi A. Dayeh, Univ. of California, San Diego (United States); Binh-Minh Nguyen, Los Alamos National Lab. (United States); Renjie Chen, Univ. of California, San Diego (United States); Wei Tang, Univ. of California, Los Angeles (United States)

The recent explosion of interest in alternative channel materials for sub-10 nm technology nodes urged studies of self-aligned ohmic compound and alloyed contacts to heterostructured Ge/Si core/shell nanowires and III-V semiconductor channels, similar to that of silicide contacts in the Si technology mainstream. We utilize in-situ transmission electron microscopy to unveil new observations on the detailed formation of such alloys and interfaces at an atomic scale by capturing single nucleation events during the reaction of Ni with Si, Ge and Ge/Si core/shell nanowires (NWs) and InGaAs FinFETs. The reaction between Ni and Ge/Si core/shell NWs is characterized with a single dominant Ni2Ge phase, in contrast to that of graded Ni fraction composition from Ni reservoir in a silicide/Si NW contact, and a Ni2Ge (111) //Ge (111) interface. We observe that the NiSix nucleates first and leads the reaction along the axis of the NW compared to Ni2Ge. Without appropriate management of this problem, it establishes a limit over which ultra-short channel devices in Ge/Si core/shell NWs could be realized. By removing the Si shell locally under the Ni contact to promote Ni2Ge formation, simultaneous propagation of the Ni2Ge and the NiSix was accomplished as demonstrated and was also demonstrated for a 2 nm Ge/Si gap in the heterostructured NW.

To study metal/III-V contact alloy formation, we utilized a novel wafer bonding technique to transfer thin (50 nm) InGaAs films onto SiO2/Si substrates and Si transmission electron microscopy (TEM) frames. InGaAs Fins with variable widths, lengths, and orientations were fabricated through a combination of electron-beam lithography and top-down dry etching steps, followed by Ni contact deposition. Rapid thermal annealing and in-situ TEM thermal heating cycles were conducted to react Ni with the InGaAs channel and deduce the reaction kinetics, dynamics, and resultant nickelide and interface structures. We observed sharp and abrupt nickelide-InGaAs interfaces for Fin channels narrower than 250 nm whereas multiple interfaces evolve for wider Fins. A faster reaction rate for [100] oriented Fins was observed when compared with [110] oriented ones. When a simple analytical treatment is applied to the Fin geometry, the nickelide length was found to have a square root dependence of inverse channel width and inverse channel height, in excellent agreement with experimental data. From this dependency, we extracted a surface diffusion coefficient of at a reaction temperature of 250 °C, which is 4-5 times larger than the extracted Fin 'body' diffusion coefficient. These results will be contrasted with those obtained for silicide/germanide reaction with Si/Ge nanowires, and the detailed structure, interface and reaction dynamics will be reported.

9174-40, Session 9

On-chip integrated 3D lithium ion batteries

Dmitry Ruzmetov, Andrei A. Kolmakov, Paul M. Haney, National Institute of Standards and Technology (United States); A. Alec Talin, Sandia National Labs. (United States)

All-solid-state Li-ion batteries are compatible with MEMS fabrication, exhibit extremely long lifetimes, negligible self-discharge rates, and offer enhanced safety. However, the low areal energy density of commercial thin film batteries limits both the performance and the miniaturization of autonomous MEMS. Simply increasing the thickness of the battery electrodes to store more energy reduces the power capability due to longer diffusion distances. In my presentation I will describe fabrication and performance of 3D Li ion batteries fabricated on Si and consisting of an array of cathode nanorods embedded in an anode matrix and separated by an ultra-thin solid electrolyte.

9174-41, Session 9

3D gate-all-around field effect transistors enabled by bridging nanowires

Jin Yong Oh, Univ. of California, Davis (United States); Hyun-June Jang, Won-Ju Cho, Kwangwoon Univ. (Korea, Republic of); Jong-Tae Park, Univ. of Incheon (Korea, Republic of); M. Saif Islam, Univ. of California, Davis (United States)

Transistors enabled by one-dimensional nanowires have attracted attention because they are expected to present a pathway to overcome the roadblocks to Moore's law and can enable gate-all-around transistors. However, lack of reproducibility in their growth, alignment into arrays, and contact formation to enable scalable fabrication of transistors is challenging. In this presentation, we demonstrate the integration of gate-all-around field-effect-transistors based on horizontally aligned silicon nano-bridges without experiencing tedious post-growth processes. These nano-bridge gate-all-around transistors exhibited a high on/off-current ratio, low sub-threshold swing and very low off-currents. In addition to designing low-voltage non-volatile memory cells, the photosensitivity of the 3D FETs is employed to demonstrate several analog and digital applications such as electro-optical OR gate circuit elements and frequency doublers.

9175-301, Session Plen

CPV: Lessons from the First 100MW and the Explosion of Next Generation Technologies

Adam P. Plesniak, Arzon Solar, LLC (United States)

The past decade has seen concentrator photovoltaics (CPV) technology transition from a few backyard experiments to an installed global capacity of well over 100 MW. With several utility scale power plants in commercial operation, the presentation will first focus on history and quality of performance since commissioning and overall customer satisfaction. Critical lessons learned from the process of designing, manufacturing and installing product for the utility scale renewable generation market are discussed. The presentation will reflect on how lessons thus far will guide CPV innovators through the flowering of Next Generation CPV technologies, from spectrum splitting optics to five junction solar cells, currently underway throughout the industry. Overall, CPV continues to serve as a robust platform for the new ideas and research needed to mature the higher performance and lower cost technologies critical for continued competitiveness of CPV in the renewable generation marketplace.

9175-2, Session 1

300 sun light engine for high concentrator application studies

John H. Park, Richard Jarzebiak, John Degroff, Katy Zadrovicz, Anderson Chen, Oriel® Instruments, a Newport Corp. Brand (United States)

As renewable energy generation is gaining momentum, it is clear that high powered turnkey sources specifically designed to simulate solar concentrator conditions will be needed to assist in evaluating receiver performances in a controlled environment. To fulfill this need, a solar simulator capable of producing 300 suns over a 1cm square area was demonstrated. For this task, an Oriel Instruments Solar Simulator chassis was selected using a 1.6kW Xe bulb. A concentrator tube was designed concentrate the collected Xe emission into a 1cm by 1cm beam spot at a working distance of 44mm. A proprietary filter was used to spectrally match the system to IEC and ASTM AM1.5D specifications. A spectrally flat Newport thermopile detector 818P-100-55 coupled with various apertures was used in a time transient metrology to empirically determine the unit is producing 300 suns with 12% beam uniformity at the 44mm working distance. With this light engine, large area high powered concentrator research can be used to easily and rapidly simulate concentrated applications.

9175-3, Session 1

Rugate fibers for solar concentration

Esmaeil Hooman Banaei, Apurva Jain, Hesam E. Arabi, Flex Optronix Technologies, LLC (United States); Amador Menéndez-Velázquez, ITMA Materials Technology (Spain)

Rugate filters, having smooth periodic refractive index variation across the thickness, have been used for several types of solar concentrator systems. Most commonly employed in spectrum-splitting solar concentrator systems, these filters efficiently split the solar spectrum into multiple wavelength ranges for conversion with an optimized bandgap-matched photovoltaic cell. Rugate filters have been also suggested as a top layer for luminescent solar concentrators (LSCs) to minimize waveguide surface losses of fluoresced light while allowing the incident solar spectrum to efficiently enter the waveguide. With current fabrication technology, rugate filters are expensive, and limited to small sizes and flat geometry.

We have developed an innovative and low-cost manufacturing process for fabrication of large-area rugate filters that can conform to any shape. Here, we will present simulation results on two solar concentration applications using our novel rugate filters in fiber geometry (i.e., rugate fibers): 1) Circularly symmetric polymer fiber luminescent solar concentrators (LSC) with rugate filter structures optimized for its fluorescence spectrum fabricated around its outer surface. This approach approximately doubles the concentration efficiency of fiber LSCs compared to the state-of-the-art. 2) Hollow-core fibers with rugate filter structures fabricated around the core with ultra-broadband reflection spectrum that essentially covers the entire solar spectrum. We introduce the use of such hollow-core rugate fiber bundles as a highly efficient light-guide medium for delivering broadband concentrated sunlight for internal lighting, direct heating and hydrogen generation applications.

Finally, we will present our progress towards experimental realization of both classes of rugate fibers.

9175-4, Session 1

Freeform solar concentrator with a highly asymmetric acceptance cone

Brian M. Wheelwright, College of Optical Sciences, The Univ. of Arizona (United States); J. Roger P. Angel, The Univ. of Arizona (United States); Blake M. Coughenour, Kimberly N. Hammer, College of Optical Sciences, The Univ. of Arizona (United States)

A solar concentrator with a highly asymmetric acceptance cone is investigated. Concentrating photovoltaic systems require dual-axis sun tracking to maintain nominal concentration throughout the day. In addition to collecting direct rays from the solar disk, which subtends ~0.5°, concentrating optics must allow for in-field tracking errors due to mechanical misalignment of the module, wind loading, and control loop biases. The angular range over which the module maintains 90% of nominal output is defined as the acceptance angle. Concentrators with substantial rotational symmetry likewise exhibit rotationally symmetric acceptance angles. In the field, this is a poor match with azimuth-elevation trackers, which have inherently asymmetric tracking performance. Pedestal-mounted trackers with low torsional stiffness about the vertical axis have better elevation tracking than azimuthal tracking. Conversely, trackers which rotate on large-footprint circular tracks are limited by elevation tracking performance. Guaranteeing symmetric tracking performance increases tracker costs.

We show that a line-focus concentrator, composed of a parabolic trough primary reflector and freeform refractive secondary, can be tailored to have a highly asymmetric acceptance angle. When mounted on a tracker with poor performance in the direction of largest acceptance angle, the combination performs better than a rotationally-symmetric system of the same geometric concentration. In the design given, the azimuthal acceptance angle is +/-1.15°, while the elevation acceptance angle is only +/-0.35°. This is well-suited for a pedestal alt-azimuth tracker with a low cost slew bearing (without anti-backlash features).

9175-6, Session 2

A small-scale concentrating solar thermal system

Christi K. Madsen, Texas A&M Univ. (United States); Alan Schulz, Wei Wu, aldo sosa, Texas A&M University (United States); Ran Huang, Texas A&M Univ. (United States); Tasnim Mohamed, Robert Atkins, John Simcik, Texas A&M University (United States)

The design, fabrication and characterization of a small-scale concentrating solar thermal system will be presented. The first application is to address residential hot water needs; however, additional applications can be enabled with the system's greater efficiency and temperature range compared to evacuated tube and flat plate systems. A large Fresnel lens, with an area on the order of one square meter on a two-axis tracking mount, is used to concentrate the solar energy and focus it to an area of a few square centimeters. A new solar receiver design will be discussed which leverages the thermal loss management properties of evacuated tubes in addition to efficient heat transfer to a fluid. Optical testing of the Fresnel lens and tracking mount concentration and efficiency as well as thermal stagnation and dynamic test results will be presented, demonstrating the overall efficiency of the system. The system is unique compared to currently available commercial domestic hot water systems, by leveraging concentration to achieve the maximum solar-to-thermal energy efficiency and low cost.

9175-7, Session 2

Design and laboratory tests of a prototype molten salt receiver for linear Fresnel CSP

Philip Gleckman, AREVA Solar, Inc. (United States)

AREVA Solar has constructed a prototype linear Fresnel power plant module that uses molten salt as the heat transfer fluid. This prototype represents a new technology option that joins parabolic troughs and towers that use molten salt for heat transfer and storage. The prototype dimensions are full commercial scale except for the length which is limited by available land and cooling equipment at Sandia National Laboratory's Molten Salt Test Loop facility.

The demonstration uses the same reflector field components as those deployed at AREVA Solar's 125 MWe commercial plant in India. The novel component is the receiver which has been designed for compatibility with the same reflector field. This receiver uses an array of heat collector elements rated for operation with 550°C salt. Light is collected from the field to the absorbing surfaces by mirrors in the receiver.

The demonstration was built mainly to validate the modeled thermal efficiency of the receiver, defined as the fluid enthalpy rise relative to the heat input. We will describe the experimental design, which includes an accurate measurement of optical flux on an unprecedented scale (1x100m). An axially nonuniform flux is expected, which is an artifact of the relatively short (50 m) length of the test reflector field compared to the receiver height (30 m). We describe how the experiment takes this artifact into account so that the results faithfully represent what one would expect at commercial length. We present optical and thermal models of the demonstration, and laboratory test results of critical components.

9175-8, Session 2

Reduction of radiative heat losses for solar thermal receivers

Clifford K. Ho, Joshua M. Christian, Jesus Ortega, Julius Yellowhair, Sandia National Labs. (United States); Matthew J. Mosquera, Charles E. Andraka, Sandia National Laboratories (United States)

Conventional receivers for concentrating solar power consist of panels of tubes with heat transfer fluid that absorb concentrated sunlight. The panels are arranged facing the incoming solar irradiance, but traditional cylindrical or cubical designs also maximize radiative and convective heat losses to the environment. This paper presents novel STAR (Solar Thermal Advanced Receiver) designs employing radial and finned tube configurations at multiple scales that reduce the radiative view factors and heat loss. In addition, the STAR designs have a trapping effect on the incident solar radiation, increasing the absorbed solar energy and receiver efficiency.

Parametric studies using computational fluid dynamics models coupled to optical ray tracing tools have been performed to evaluate the view factor, radiative and convective heat loss, and thermal efficiency of different STAR patterns relative to conventional designs. Both meso- (millimeters to centimeters) and macro-scale (meters) simulations have been performed to evaluate the impact of these features and processes at multiple scales, from individual tubes to the entire receiver. Results show that the new STAR designs can reduce radiative view factors by 70% and overall heat loss by 50% with an increase in thermal efficiency of 10% relative to conventional designs. This paper presents a summary of the designs, modeling results, issues, and proposed testing.

9175-9, Session 3

Plasmonic nanoparticle based spectral fluid filters for concentrating PV/T collectors

Drew DeJarnette, Todd Otanicar, Nick Brekke, Parameswar Hari, Kenneth Roberts, The Univ. of Tulsa (United States); Aaron E. Saunders, nanoComposix, Inc. (United States); Ratson Morad, Cogenra Solar, Inc. (United States)

Advanced solar conversion systems will require technologies that are capable of efficiently converting solar energy across the whole spectrum in an affordable manner while efficiently providing electricity and dispatchable thermal energy. An attractive method for this is by coupling photovoltaic cells to a thermal energy collector. These systems are often limited by the degradation of PV at high temperatures or the low conversion efficiency of thermal energy to electricity at low temperatures. A potential way to overcome this limitation and operate at higher temperatures is through the use of spectral filtering. Here we propose a design for a new type of concentrating PV/T collector to utilize plasmonic nanoparticles directly suspended in the working fluid of the thermal engine to filter the incoming solar flux. This liquid filter serves two purposes: the direct capture of thermal energy as well as filtering off of key portions of the spectrum before transmission to the PV cell. Our device builds upon the current Cogenra T14 system with a two-pass architecture: the first pass on the back side of the PV cell pre-heating the fluid from any thermalization losses, and the second pass in front of the PV cell to achieve the spectral filtering. Of primary interest here are the design choices surrounding the proper suite of nanoparticles to achieve high levels of sub-gap absorption while maximizing facile synthesis and minimizing cost. Additionally some preliminary modeling on the necessary thermal management of the two pass configuration is reported.

9175-10, Session 3

Sun to fibers (S2F): massively scalable collection and transmission of concentrated solar light for efficient energy conversion and storage

Juan Jose Diaz Leon, Univ. of California, Santa Cruz (United States) and Nanostructured Energy Conversion Technology and Research (United States); Matthew P Garrett, Junce Zhang, Baskin School of Engineering (United States) and Nanostructured Energy Conversion Technology And Research (NECTAR) (United States); Katherine Han, Antropy Inc. & Demaray LLC (United States); Ernest Demaray, Antropy Inc. (United States) and Demaray, LLC (United States); Roger W. Anderson, Univ. of California, Santa Cruz (United States); Allan Lewandowski, Allan Lewandowski Solar Consulting, LLC (United States); William Bottenberg, Bottenberg Associates (United States); Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States) and Nanostructured Energy Conversion Technology and Research (United States)

Concentrated solar energy has proven to be an efficient approach for both solar thermal energy applications and photovoltaics. Here, we propose a passive optical device, the adiabatic optical coupler (AOC), that efficiently couples concentrated solar light from a primary solar concentrator into an optical fiber, enabling light collection and energy conversion/storage to be at two different locations connected via low loss transmission, maximizing the overall system efficiency. The AOC offers secondary concentration of concentrated solar light through an adiabatic optical mode conversion process. Solar light highly concentrated by the two stage concentrator is delivered with very high exergy at the end of the optical fiber to be subsequently energy-converted or thermally stored. The ability to transport this high energy flux as light eliminates the need for high temperature working fluids replacing them with an optical fiber. In order to design the AOC and related peripherals, we used various modeling tools to cover different optical regimes at macroscopic and microscopic scales. We demonstrated a set of optical thin films with spatially varied refractive index up to 3 and negligible optical absorption by using a proprietary sputtering technique to fabricate the AOC. We further studied the films using experimental measurements and theoretical analysis to optimize their optical properties. Preliminary cost analysis suggests that solar thermal power generation systems that employ our S2F concept could offer cost and efficiency required for us to achieve the 2020 SunShot initiative levelized cost of electricity (LCOE) target. Success of this endeavor could change the energy conversion paradigm, and allow massively scalable concentrated solar energy utilization.

9175-11, Session 3

Shaping solar concentrator mirrors by radiative heating

J. Roger P. Angel, Thomas E. Stalcup Jr., The Univ. of Arizona (United States) and REhnu, Inc. (United States); Brian M. Wheelwright, Stephen H. Warner, Kimberly N. Hammer, The Univ. of Arizona (United States)

The University of Arizona has built and tested a process to rapidly mold glass reflectors by radiative heating. The new shaping method allows for production of reflectors with both line-focus, as widely used CSP plants, and point-focus. The shaped glass is coated with silver to obtain self-supporting, second surface glass mirrors, proven in in trough plants to have 20-year longevity. In the manufacturing process, a float glass square 1.65 m on a side is softened and slumps under gravity into a full-body mold. To preserve the original high polish of the float glass on both front and back surfaces, as required for a second surface mirror, the mold surface is machined to the required shape as grooves which intersect at cusps, reducing the mold contact area fraction to << 1%. The mold surface is gold-plated so as not to absorb thermal radiation. The shaping cycle starts with rigid glass at 500C. Rapid heating is provided by nichrome ribbon elements heated to 900C, in a 350 kW power burst. After two minutes, the slumped glass conforms accurately to the mold shape. It is then cooled back to the rigid state by a combination of radiation and forced convection, with a targeted time for the full cycle of 200 seconds. The shape of the replicas is measured by reflection of parallel laser beams on a one-inch square grid. Slope values are measured at 4000 points on a one inch grid, with a targeted replica accuracy of 1 mrad rms.

9175-12, Session 3

Self-tracking phase change concentrator device demonstrator

Volker Zagolla, Eric J. Tremblay, Christophe Moser, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Concentration photovoltaic systems uses free-space optics to concentrate sunlight onto photovoltaic cells, using mechanical trackers to accurately track the sun's position and keep the focal spot on the PV cell. We recently proposed and demonstrated a proof-of concept of a self-tracking mechanism using a phase-change material to greatly extend the acceptance angle of the concentration device. The light responsive mechanism allows for efficient waveguide coupling and light concentration independent of the angle of incidence inside its angular range of acceptance. The system uses a lens pair to achieve a flat Petzval field curvature over the acceptance angle range. A waveguide slab acts as the concentrating device. The use of a dichroic prism membrane separates the solar spectrum into two parts, lower wavelengths (<750nm) are coupled into the waveguide, while the energy of higher wavelengths (>750nm) is used to power the self-tracking mechanism. The energy in this part of the spectrum is absorbed by a carbon black paraffin wax mixture that undergoes a phase change and subsequently creates a coupling feature due to thermal expansion which allows the lower wavelength part to be coupled into the waveguide.
We show the extension of our proof-of concept to a device-like demonstrator, featuring the extension to a lens array and much larger dimensions. The demonstration device has a 50x concentration factor and an acceptance angle of +/- 16 degrees. We present experimental and simulation results of the demonstration device, fully characterizing its components and performance. A roadmap to higher concentration factors outlines future work.

9175-13, Session 4

Ray trace optimization of light trapping filtered concentrator

John Lloyd, Emily D. Kosten, Emily C. Warmann, Harry A. Atwater Jr., California Institute of Technology (United States)

Decades of research and development of monolithic multijunction solar cells has achieved high efficiencies, but despite continuing development, the obstacles of current and lattice matching still present challenges. Spectrum splitting is an alternative approach where optical components, rather than the semiconductor devices themselves, direct different energy light to the appropriate bandgap photovoltaic device.

Our approach is a type of cavity concentrator, where a textured dielectric slab with angle restricting elements randomizes and traps incident light while aperiodic dielectric multilayer filters designed for omnidirectionality selectively admit light into photovoltaic devices with appropriately tuned bandgaps. Previous work on this design involved a statistical ray optics multipass model coupled with modified detailed balance calculations. Here, we extend the analysis to include a full ray trace model of the design. The scripted model allowed for rapid optimization of the geometric design parameters as well as incorporation of non-idealities that were absent from the multipass model. Furthermore, this approach allowed for evaluation of multiple candidate filter sets, with the design optimized in the ray trace for each set of filters. We achieve module efficiencies in the range of 35-40% for attainable materials and filters.

9175-14, Session 4

Diffractive spectrum splitting module using high-contrast gratings *(Invited Paper)*

Sunita Darbe, Emily C. Warmann, Harry A. Atwater Jr., California Institute of Technology (United States)

Traditional multijunction solar cells have complexities and limitations due to series electrical connection, lattice-matching requirements and the need for tunnel junctions. Alternate multijunctions geometries employing spectrum-splitting optics to orient each frequency band of light toward a solar absorber that can best convert it are an attractive option to address some of these limits. Such devices can incorporate many independently connected cells with more freely optimized bandgaps.

We explore high-contrast gratings (HCG) as spectrum-splitting optics. In these gratings, constructive or destructive interference between incident light and the guided-mode within the high refractive-index planar diffractive structure result in very high reflectivity or transmissivity,

respectively. Appropriately designed HCG can be broadband and polarization insensitive. GaP and TiO2 structures embedded in glass, polymer or other low-index material are modeled using rigorous coupled-wave analysis (RCWA). Design rules-of-thumb are developed. RCWA and modified detailed balance calculations are used in conjunction to give an estimate of system efficiency accounting for realistic losses. HCG performance is compared with dielectric multilayer stacks and holograms as alternative methods for spectral splitting.

Mid-to-high concentration and six to eight III-V materials as absorbers for subcells lattice-matched to GaAs or InP substrates give the potential for module efficiencies well in excess of current world records.

9175-15, Session 4

Positional irradiance measurement: characterization of spectrum-splitting and concentrating optics for photovoltaics

Cristofer A. Flowers, Sunita Darbe, Carissa N. Eisler, California Institute of Technology (United States); Junwen He, Univ. of Illinois at Urbana-Champaign (United States); Harry A. Atwater Jr., California Institute of Technology (United States)

Multijunction photovoltaics enable significantly improved efficiency over their single junction analogues by mitigating unabsorbed sub-bandgap photons and voltage loss to carrier thermalization. Lateral spectrum-splitting configurations promise further increased efficiency through relaxation of the lattice- and current-matching requirements of monolithic stacks, albeit at the cost of increased optical complexity. Consequently, in order to achieve an effective spectrum-splitting photovoltaic configuration it is essential that all optical losses and photon misallocation be characterized and subsequently minimized.

We have developed a characterization system that enables us to map the spatial, spectral, and angular distribution of illumination incident on the subcell reception plane or emerging from any subset of the concentrating and splitting optics. This positional irradiance measurement system (PIMS) comprises four motorized stages assembled in a Z-X-R-Y configuration with three linear degrees of freedom and one rotational degree of freedom, on which we mount an optical fiber connected to a set of spectrometers covering the solar spectrum from 280-1700 nm. In combination with a xenon arc lamp solar simulator with a divergence half angle of 1.3 degrees, we are able to characterize our optics across the full spectrum of our photovoltaic subcells with close agreement to outdoor conditions. We have used this tool to spectrally characterize holographic diffraction efficiency versus diffraction angle; multilayer dielectric filter transmission and reflection efficiency versus filter incidence angle; and aspheric lens chromatic aberration versus optic-to-receiver separation distance. These examples illustrate the versatility of the PIMS in characterizing optical performance relevant to both spectrum-splitting and traditional multijunction photovoltaics.

9175-16, Session 5

Design of folded holographic spectrum-splitting photovoltaic systems for direct and diffused illumination conditions

Yuechen Wu, Juan M. Russo, The Univ. of Arizona (United States); Shelby D. Vorndran, College of Optical Sciences, The Univ. of Arizona (United States); Raymond K. Kostuk, The Univ. of Arizona (United States) and College of Optical Sciences, The Univ. of Arizona (United States)

Spectrum-splitting is a beneficial technique to increase the efficiency and reduce the cost of photovoltaic systems. This technique divides the incident solar spectrum into spectral components that are spatially separated and directed to PV cells with matching spectral responsivity characteristics. This approach eliminates problems associated with current and lattice matching that must be maintained in tandem multi-junction systems. In this paper, a two-junction holographic spectrum-splitting photovoltaic system is demonstrated with a folded PV geometry. The system is designed to make better use of both direct and diffused solar irradiation. It consists of holographic elements, a wedge-shaped optical guide, and PV substrates with back reflectors. The holographic elements associated with back reflectors spatially split the solar spectrum into corresponding PV substrates, and the wedge-shaped optical guide traps the diffuse rays inside the system until they are absorbed by the cells. In this paper, the system is analyzed under direct illumination for an InGaP2/GaAs combination, and an experiment is set up to measure the optical efficiency of holographic elements combined with the wedge substrate for the PV cells. A system efficiency of 34.46% is computed with data from an experimental reflection hologram. Also, a non-sequential ray tracing model is used to simulate the optical performance under direct, diffuse and global irradiation conditions. The optical and system efficiency, as well as the improvement over best bandgap (IoBB) PV cell also evaluated based on the simulation results.

9175-17, Session 5

Analysis of dispersive spectrum splitting systems

Juan M. Russo, The Univ. of Arizona (United States); Shelby D. Vorndran, College of Optical Sciences, The Univ. of Arizona (United States); Yuechen Wu, Raymond K. Kostuk, The Univ. of Arizona (United States)

Shockley and Queisser have shown that systems based on single junction PV cells are limited to a system efficiency of 33%. This restriction results from the mismatch between the photon energy of the incident sunlight and the inability of a single junction device to optimally convert the broad incident spectrum. One approach to overcome this difficulty is to incorporate multiple PV cells with different bandgaps that are optimized to convert different parts of the incident spectrum to electrical power. Spectrum splitting configurations distribute incident photons onto several single bandgap PV cells that are spatially separated. Although, systems with different methods and geometries have been proposed, optical systems relying on reflective filters have not been compared to transmissive ones. Since reflection-type films are primarily based on the interference of reflected waves from optical interfaces, systems based on these filters do not have dispersion losses. Dispersive spectrum splitting systems rely on optical elements that use diffraction or refraction for spectral separation. The dispersion from a single broad band optical element can be used for spectral separation. The geometrical relationship between focusing power, the degree of dispersion, the system aperture, and the PV cell aperture and position can be used to tailor the spectral shape of the incident spectrum into each of the PV cells comprising the system. In this paper, the effects of dispersion introduced by transmission type filters are presented compared to reflective filters.

9175-18, Session 5

Two-axis spectral splitting optical concentrator based on single injection molded plastic element

Marco Stefancich, Carlo Maragliano, Harry Apostoleris, Matteo Chiesa, Masdar Institute of Science & Technology (United Arab Emirates)

High efficiency concentrator photovoltaic systems are currently based on III/V cells and, to offset the high cell capital cost, elevated optical concentrations are used, with consequent reduction in acceptance angles and tight tolerance optics.

While this allows for spectacular conversion efficiencies, it does not provide cost effectiveness in a market dominated by low efficiency/low cost technologies.

An alternative approach, well known in literature, is based on the combined use of an optical concentrator and a spectral splitting element allowing for the use of separate cells with different spectral responses and, thus, opening the way to a much wider range of possible materials and technologies.

While many configurations have been presented during the years, optical efficiency has often been an issue due to the separate action of the concentrating and splitting element.

We propose here, as substantial evolution of a previous design [1], a single injection molded plastic non-imaging optical element embodying both two axis concentration and spectral splitting functions. Based on the specific dispersion characteristics of polycarbonate and on a constructive analytical design procedure, this element allows for optical efficiencies exceeding 80%. Theory, simulations and preliminary experimental results will be presented.

9175-19, Session 6

Low cost anti-soiling coatings for CSP collector mirrors and heliostats

Scott R. Hunter, D. Barton Smith, Georgios Polizos, Daniel Schaeffer, Dominic F. Lee, Panos G. Datskos, Oak Ridge National Lab. (United States)

Most concentrating solar power (CSP) facilities in the USA are located in the desert southwest of the country where land and sunshine are abundant. But one of the significant maintenance problems and cost associated with operating CSP facilities in this region is the accumulation of dust, sand and other pollutants on the collector mirrors and heliostats. The optical performance of the CSP collectors is key to achieving low electricity costs, where a 1% decrease in reflectance directly leads to a 1% increase in the levelized cost of electricity (LCOE) generated by these facilities.

In this paper we describe the development of low cost, easy to apply anti-soiling coatings based on superhydrophobic (SH) functionalized nano silica materials and polymer binders that posses the key requirements necessary to inhibit particulate deposition on and sticking to CSP mirror surfaces, and thereby significantly reducing mirror cleaning costs and facility downtime. These requirements are excellent optical clarity with minimal diffuse reflectance, coating mechanical and exposure durability in harsh desert environments while maintaining SH and dirt shedding properties. The coatings developed to date have excellent SH properties with water contact angles > 1650 and rolling angles < 50. The solar weighted optical transmission of the anti-soiling coating over the 250 nm to 3?m is >99% of uncoated mirror surfaces with coating diffuse reflectance being <1% over this wavelength range. Ongoing mechanical and accelerated solar UVA exposures also indicate these coatings will meet the required durability goals.

9175-20, Session 6

Optical and adhesive properties of dust deposits on solar mirrors and their effects on specular reflectivity and electrodynamic cleaning of solar collectors for mitigating energy-yield loss

Malay Mazumder, Boston Univ. (United States); Julius Yellowhair, Sandia National Labs. (United States); Jeremy Stark, Calvin Heiling, John N. Hudelson, Zhonkai Xu, Hannah Gibson, Mark N. Horenstein, Boston Univ. (United States)

Operating CSP plants with high specular reflection efficiency with minimum thermal losses determines the overall system performance in $/kWh. Utility-scale solar power plants are mostly installed in deserts and semi-arid zones of the world where large areas having highest direct normal irradiance with minimal interruption by rain or clouds are available. In these areas, dust layer buildup on solar collectors becomes a major cause for energy yield loss. Development of transparent electrodynamic screens (EDS) and their applications for self-cleaning operation of solar collectors are presented. An EDS consists of thin rectangular, transparent conducting parallel electrodes deposited on a dielectric surface. The electrodes are insulated from each other and are embedded within a thin transparent dielectric layer. The electrodes are activated using three-phase high-voltage pulses at low current (< 1 mA/m2). The three-phase electric field lifts the dust particles form the substrate by the electrodynamic forces and a traveling wave that propels the dust layer off of the collector's surface. The cleaning process takes less than 2 minutes; requires less than 1 Wh/m2 energy without any water or manual labor. The reflection efficiency can be restored > 95% of the original clean-mirror efficiency. We briefly review (1) loss of specular reflection efficiency as a function of particle size distribution and dust composition, (2) degradation of mirrors caused by dust deposits at high RH, and (3) the effects of the electrode design and materials used on the EDS-integrated solar mirrors. The electrode geometry and material selection are researched in order to produce the best optical and electrical performance including the cost-effective deposition techniques. Finally, the essential features of levelized cost of mirror cleaning (LCOMC) by EDS are presented.

9175-21, Session 6

Anti-oxidation, high-performance solution-processed Ni plasmonic nanochain-SiOx selective solar thermal absorbers

Xiaobai Yu, Xiaoxin Wang, Thayer School of Engineering at Dartmouth (United States); Qinglin Zhang, Univ. of Kentucky (United States); Jifeng Liu, Thayer School of Engineering at Dartmouth (United States)

In order to address the metal oxidation issue in cermet solar thermal absorbers at high working temperatures, we developed solution-processed plasmonic Ni nanochain-SiOx ($x \leq 2$) selective solar thermal absorbers that exhibit high solar absorption, low thermal emittance, and strong anti-oxidation behavior up to 600 ºC in air. The thermal stability is far superior to more conventional Ni nanoparticle-Al2O3 selective solar thermal absorbers, which readily oxidize at 450 ºC. Ni nanochains were embedded in SiOx and SiO2 matrices which are derived from hydrogen silsesquioxane (HSQ) and tetraethyl orthosilicate (TEOS) precursors, respectively. Fourier transform infrared spectroscopy (FTIR) shows that the dissociation of Si-O cage-like structures into Si-O networks helped to retard the oxidation process of Ni, possibly by facilitating the formation of chemical bonding between Si in the matrix and the Ni nanochains. X-ray photoelectron spectroscopy (XPS) further shows that the excess Si from the dissociation of HSQ formed silicide-like chemical bonds with Ni that are robust to high temperature oxidation and protect the Ni nanostructures. Moreover, the Ni-SiOx system showed 90% solar absorptance and a low thermal emissivity of 15% at 300 ºC in air, compared to ~30% emittance of conventional coatings at this temperature. This technology helps to eliminate the problem of vacuum breaching and further reduces the fabrication cost of the solar selective coating. With a high solar absorptance, a low thermal emittance, and excellent anti-oxidation property, this type of selective solar thermal absorber can potentially lead to transformative technologies such as vacuum-free CSP receivers.

9175-22, Session 6

The end of the road for carbon-based metal oxide matrices for selective solar absorbers?

Patricia B. Forbes, Musa Kunene, Univ. of Pretoria (South Africa); Kittessa T. Roro, Andrew Forbes, CSIR National Laser Ctr. (South Africa)

A novel solar absorber coating based on a nanocomposite of carbon in nickel oxide on an aluminium substrate was developed. The material was found to have the optical properties required of an ideal solar absorber: high absorbance in the solar wavelength range and low emittance at infrared wavelengths. However, lifetime testing of the material gave poor results. The reason for this was therefore investigated. TGA-FTIR analyses showed mass loss of the solar absorber material during extended heating thereof in air, and further proved that carbon dioxide was released leading to loss of carbon. The SEM EDS analyses of the thin film on the aluminium substrate showed that carbon was not confined to the pores of the material, but appeared to rather be evenly distributed throughout it. The carbon signal which had been evident when an area EDS analysis was performed on a pre-lifetime test sample was not present in a similar analysis of a post-lifetime sample, which again indicated loss of carbon from the material upon heating in air. The stability of the solar absorber material, specifically with respect to the carbon content, needs to be enhanced in order for it to find use as a solar absorber, although the improvements achieved may not be sufficient to allow the material to pass the required lifetime tests.

9175-23, Session 7

First demonstration of a novel 2D-waveguiding solar concentrator

Ran Huang, Yuxiao Liu, Christi K. Madsen, Texas A&M Univ. (United States)

The first experimental demonstration results will be presented for a novel, two-dimensional waveguiding solar concentrator consisting of a primary concentrator (a microlens array) and a secondary concentrator (tapered multimode waveguides) coupled to photovoltaic cells. The microlens array collects the incident sun light and focuses it onto a turning mirror. The turning mirror couples the light into a tapered multimode waveguide, which alleviates connection, cooling and uniformity issues associated with conventional solar concentrating systems. Therefore, a large area of light can be efficiently concentrated to a small waveguide cross-section and guided to an array of co-located photovoltaic cells with high optical efficiency. To achieve the maximum coupling efficiency of the light to the waveguide, the design of the turning mirror and waveguides are optimized to avoid any inherent decoupling loss in the subsequent waveguide propagation. Simulations indicate that the structure, using only total internal reflection surfaces, can achieve 800x concentration with 89% optical efficiency under ±0.7 ? incidence angle. We will present details on the experimental device characterization. A critical requirement for this design is maintaining low waveguide propagation losses, which we demonstrate can be less than 0.2 dB/cm.

9175-24, Session 7

Field performance of CPV systems using different Fresnel lenses

Mingguo Liu, William Bagienski, Robert B. Gordon, Adam P. Plesniak, Vahan Garboushian, Arzon Solar, LLC (United States)

Concentrator photovoltaic (CPV) arrays utilize mirrors or refractive lenses to concentrate sunlight (typically >500 suns) onto high-efficiency multijunction solar cells. In the last several years, refractive Fresnel lenses have become dominant among CPV companies as the method of light collection. Two types of Fresnel lenses are currently used in the industry: PMMA (polymethyl methacrylate) and SOG (silicone on glass). There are currently several vendors for each type of lens. Differences in fabrication and tooling can cause the same type of lens from different vendors to exhibit different performance characteristics. In order to optimize the energy output of a CPV system, it is important to understand lens performance in the field. However, there is very limited data on the comparison of lenses from different vendors in real world conditions. Due to the wide variation of weather with location and time, it is necessary to do such a comparison in the same location using the exact same configurations. The 30MW CPV plant in Alamosa, CO has 504 Amonix 7700 systems equipped with PMMA lenses from three vendors. This provides a good platform for a side-by-side comparison of these vendors. The plant has been in operation since March 1st, 2012. Since then, a large amount of data has been collected from these systems as well as three meterological stations. In addition, Amonix implemented a system in Pomona, CA to compare SOG lenses and PMMA lenses side-by-side. Seven months of data has been collected on this system. In this paper, we present the comparison of the PMMA lenses from three vendors as well as SOG lenses from one vendor in real world conditions.

9175-25, Session 7

Electroluminescence imaging of Morgan Solar's 4th generation CPV technology for in-line quality control and optical efficiency estimation

Michael Sinclair, Pascal Dufour, Kristine M. C. Drew, Morgan Solar, Inc. (Canada); Stefan Myrskog, Morgan Solar Inc (Canada); John Paul Morgan, Morgan Solar, Inc. (Canada)

Electroluminescence imaging is widely used in photovoltaic (PV) module manufacturing to identify defects in silicon PV cells. When a PV cell is illuminated under forward bias comparatively dark areas indicate defects such as cracks, poor soldering connections, discontinuities in the metallization, etc. An analogous test on a Concentrated PV system can be used to capture high resolution pseudo-efficiency maps that highlight optical defects in the concentrator system. Electroluminescence from a triple-junction cell under forward bias in a concentration optic results in a collimated beam of light. By imaging the output beam, one can estimate local and overall optical efficiency by analysing the intensity distribution of the emitted light. The experimental setup as well as key parameters of the imaging system are presented. Image processing is discussed, including comparison of experimental to nominal results and the quantitative estimation of optical efficiency. Efficiency estimates are validated using measurements under a collimated solar simulator and ray-tracing software. Further validation is performed by comparison of the electroluminescence technique to direct mapping of the optical efficiency. Initial prototype benchtop results indicate an estimation accuracy of better than 5% (3?) at the module level can be achieved, with a combined measurement and analysis time of less than 5 seconds per optic. An extension of this approach to in-line quality control is discussed.

9175-26, Session 7

On-sun performance of a commercial dish-based HCPV system

Blake M. Coughenour, The Univ. of Arizona (United States); Thomas E. Stalcup Jr., REhnu, Inc. (United States); Brian M. Wheelwright, Andrew Geary, Kimberly N. Hammer, The Univ. of Arizona (United States); J. Roger P. Angel, REhnu, Inc. (United States) and The Univ. of Arizona (United States)

REhnu Inc., with the University of Arizona, has developed a commercial dish-based High Concentration Photovoltaic (HCPV) system. The basic unit uses a paraboloidal glass reflector 1.65 m x 1.65 m square to bring sunlight to a high power point focus. A unique XRX-Köhler optical system

reformats the concentrated sunlight so as to uniformly illuminate 36 triple junction cells at 920x geometric concentration. The secondary optics and MJ cells are integrated with active cooling into a central, self-contained Power Conversion Unit (PCU) suspended above the dish reflector, which generates 800W of power for 1000W/m2 DNI at 32% DC net system efficiency.

Our 2nd generation prototype utilized a larger, 3.1 m x 3.1 m square mirror and consistently generated 2.7 kW of power normalized to 1kW/m2 DNI and has logged over 500 hours of on-sun testing. The 2nd generation unit operates at 28% DC net system efficiency with an operating cell temperature of only 20°C above ambient.

Having proven this system concept and cell cooling technology with low parasitic loss, our 3rd generation prototype was redesigned with a focus on manufacturability, lower cost, higher efficiency, and smaller size. This new 8lb handheld unit utilizes injection-molded plastic parts and minimal fasteners. Electrical connections and cooling connections are made to the PCU and the closed loop active cooling system is placed behind the mirrors on the two-axis tracking structure. Eight of these reflector/PCU units can be mounted on a single tracking structure.

9175-27, Session PWed

Analysis of a hybrid solar combined cycle in Algeria

Mohammed Laissaoui, Ctr. de Développement des Energies Renouvelables (Algeria)

The present work has for objective the simulation of a hybrid solar combined cycle power plant, compared with combined cycle conventional (gas turbine and steam turbine), this type of power plants disposed an solar tour (heliostat field and volumetric receiver) insurant a part of the thermal energy necessary for the functioning of the gas turbine

This solar energy serves to feed with heat the combustion air of the gas turbine when heout of the compressor and the front entered the combustion chamber.

The simulation of even central and made for three zones deferential to know the zone of Hassi R' mel, Bechare, and the zone of Messaad wilaya of El djelfa. The radiometric and meteorological data arise directly from the software meteonorme 7. The simulation of the energy performances is made by the software TRNSYS 16.1 chamber.

9175-28, Session PWed

Luminescent optical epoxies for solar concentrators

Anni Partanen, Aapo Harju, Jarkko Mutanen, Hanna Lajunen, Tuula Pakkanen, Markku Kuittinen, Univ. of Eastern Finland (Finland)

Luminescent solar concentrators were discovered in 1970s to lower the cost of solar cells by reducing the area of solar cell. These concentrators consisted of polymer containing luminescent dye. Afterwards quantum dots have also been used in a similar way in solar concentrators. The matrix material used in solar concentrator should have high transmittance in the visible region, and the dye should have low self-absorbance and high quantum efficiency.

We have fabricated luminescent optical epoxies and studied their luminescence properties. Fluorescein, Rhodamine B, 2,5-diphenyloxazole, trans-stilbene and Erythrosin B were separately mixed with Bisphenole A epoxy resin (Bisphenol A diglycidyl ether) which was cured with with Isophorone diamine hardener. Two different micropatterns were transferred to the epoxy samples during the hardening using cyclo-olefin polymer mold with an efficient and straightforward method.

The micropatterns were copied adequately in the epoxy surface, which would also suggest that nanopatterning would also be possible. Furthermore, the ability to pattern the surface allows fabrication of for example anti-reflective, hydrophobic and self-cleaning structures. Transmission measurement's show high transmittance (approx. 90%) of the epoxy matrix in visible region (350–800 nm), which is requirement for a good luminescent solar concentrator. Autoluminescence of the epoxy enables the use of UV radiation from sun. In addition the epoxy matrix should also protect the luminescent material from, e.g., oxidation and wear.

9175-29, Session PWed

High temperature concentrator solar cells for hybrid energy convertors

Jonathan Grandidier, Bill J. Nesmith, Subbarao Surampudi, Jet Propulsion Lab. (United States)

We are considering a high efficiency concentrator solar cell operating at high temperature. The advantage of high temperature photovoltaics (PV) is the possibility to integrate it with thermal energy convertor. High temperature PV could also be used in extreme environment such as planet from the inner solar system. Understanding optical and electrical performance of solar cells as a function of time and under various operating conditions including temperatures and thermal fluxes is critical to being able to predict the long term lifetime, reliability, life cycle cost and performance of concentrator PV systems. Our baseline photovoltaic energy conversion device is a high efficiency triple junction solar cell made of Indium Gallium Arsenide (InGaAs) for the top junction, Gallium Arsenide (GaAs) for the middle junction and (Ge) for the bottom junction. Ge is also used as a wafer for solar cell growing. In our proposed system, the solar spectrum is concentrated onto the solar cell and a fraction of the light depending on the PV temperature is converted into electricity. Measurements for these types of cells to at least 250C show that the conversion efficiency drops linearly by .04%/ C. The particularity of the proposed system is that all the heat resulting from non-converted light is used as the input for a thermal energy conversion engine. For a reasonably efficient engine the total electrical output optimizes at a value greater than the PV alone somewhere in the 250C to 400C range.

9176-1, Session 1

Surface science investigations of hematite-based photoelectrocatalysts *(Keynote Presentation)*

Bruce E. Koel, Peng Zhao, Coleman X. Kronawitter, Princeton Univ. (United States)

We report on fundamental studies of surface structure and reaction chemistry associated with the heterogeneous oxidation of water on hematite (?-Fe2O3)-based photoanodes that are promising materials for photoelectrochemical hydrogen generation. Applying a classical surface science approach, we have utilized a range of techniques for surface analysis to characterize the structure and properties of Ni-doped and mixed-oxide hematite surfaces formed by vapor deposition under controlled conditions. The structure of Ni-modified thin films of ?-Fe2O3 model catalysts with different morphology and geometry was characterized by LEED and STM. Then, water adsorption and reaction were studied by TPD, XPS, UPS, and vibrational spectroscopy by HREELS, characterizing the influence of Ni-modification on thermal and photochemical reaction mechanisms. Ni doping is found to be associated with a new termination for the ?-Fe2O3(0001) film. Water TPD shows that Ni doping induces new surface chemistry, as revealed by a new, higher temperature OH recombination desorption peak, which is due to more stable surface-bound OH groups as identified by UPS. These surface-science type experiments were combined with photoelectrochemical water oxidation measurements on photoanodes prepared by thin-film and nano-materials synthesis to elucidate new information on the surface phases of hematite-based photoanodes and about their specific stability and reactivity toward photoelectrochemical water splitting.

9176-2, Session 1

The role of fast charge dynamics in the water oxidation reaction *(Invited Paper)*

Tanja Cuk, Univ. of California, Berkeley (United States)

The early steps of water oxidation are investigated during catalysis with transient optical spectroscopy. Experiments on n-SrTiO3 with high quantum efficiency for O2 evolution under laser excitation (~80%) record how the interfacial kinetics change dramatically with the potential at which holes sit at the interface. The potential of holes at the interface is tuned continuously in a unique manner: by a carrier inversion process that unpins the valence band edge under applied voltage and light excitation. This continuous tuning enables us to determine spectroscopically the activation barrier for interfacial charge transfer during the early steps of water oxidation. For n-SrTiO3, this barrier is determined in a regime of high over-potential. In parallel, experiments on a photodiode activated Co3O4 catalyst aim to understand this charge transfer barrier in a regime of low over-potential.

9176-3, Session 1

Interfacial electronic structure and confinement effects for low-cost solar water splitting *(Keynote Presentation)*

Lionel Vayssieres, Xi'an Jiaotong Univ. (China)

The development of low cost metal oxide semiconductor heteronanostructures consisting of highly pure quantum dots/rods entirely fabricated from metal salts and aqueous chemistry without surfactant and at low temperature with controlled surface chemistry and intermediate bands for efficient visible-light conversion and highly quantized band structure for band/bandgap engineering is demonstrated. Such unique characteristics, combined with in-depth investigation of their electronic structure at synchrotron radiation facilities, optical, structural and transport properties provide comprehensive fundamental understanding of the energetics and structure-property relationships as well as key trends for efficiency optimization. Quantum dot-sensitized oriented iron oxide quantum rods showing full visible light absorption and stability against photo-corrosion for efficient and low cost hydrogen generation by direct solar (sea)water splitting at neutral pH is presented. Finally, the latest advances in size effects on electronic structure, surface chemistry and electrical properties of large bandgap oxide semiconductor will be presented and discussed for solar hydrogen generation improvement.

9176-4, Session 1

The chemistry of adsorbed water on semiconductor surfaces for aqueous photoelectrochemistry *(Invited Paper)*

Coleman X. Kronawitter, Bruce E. Koel, Princeton Univ. (United States)

The surface chemistry of water molecules adsorbed on single crystals, model structures relevant to photoelectrode-water interfaces in solar photoelectrochemical systems, is discussed. In heterogeneous processes relevant to photoelectrochemistry, the interaction of water with semiconductor and metal oxide surfaces is often a critical event whose character influences subsequent chemical pathways that ultimately dictate the reactions' efficiencies and selectivities. For reactions where water is neither reactant nor product, the presence of water at the interface can nonetheless influence both the selectivity and efficiency of interfacial charge transfer. An experimental surface science approach is used to characterize adsorbed water molecules on copper oxide and other semiconductor surfaces known to actively facilitate solar energy conversion in photoelectrochemical fuel synthesis devices. In this approach, ultra-high vacuum conditions are used to facilitate the fabrication of highly characterizable adsorbate systems, and the use of single crystal substrates permits analysis of surface chemistry independent of sample grain boundaries and morphology. An understanding of the surface chemistry of adsorbed water is developed through core-level spectroscopies, scanning probe microscopy, as well as analysis of desorption products from thermal reactions.

9176-5, Session 1

Development of a low cost, portable solar hydrogen generation device

Kyle D. Rose, Manmohan D. Aggarwal, Ashok K. Batra, Alabama A&M Univ. (United States); Dennis Wingo, Skycorp Inc. (United States)

Hydrogen is a clean energy source that is environmentally friendly and safe. It is well known that electrolysis is a common method used to produce hydrogen. Other high cost methods for hydrogen production can be countered by the development of this low cost pulse width modulated circuit, using direct current provided by naturally existing solar energy as a power source. Efforts are being made in the scientific community to produce a low cost, portable, solar hydrogen generating device for a number of clean energy applications such as fuel cells and energy storage. Proof of concept has already been tested in the laboratory and a small prototype system is being designed and fabricated in the workshop at Alabama A&M University. Our results of this study and details of the electronic circuit and the prototype shall be presented.

9176-6, Session 2

Visible light active materials for efficient photoelectrochemical hydrogen production *(Keynote Presentation)*

Sanjay Mathur, Univ. zu Köln (Germany); Leonhard Mayrhofer, Fraunhofer-Institut für Werkstoffmechanik (Germany); Markus Niederberger, ETH Zürich (Switzerland); Jan Augustynski, Univ. of Warsaw (Poland); Joan Ramon Moranted, Institut de Recerca en Energia de Catalunya (Spain); Helge J. Lemmetyinen, Tampere Univ. of Technology (Finland); Davide Barreca, Univ. degli Studi di Padova (Italy); Volkmar Lüthen, Siemens AG (Germany); Bernd Proft, Sachtleben Pigment GmbH (Germany)

The photoelectrochemical (PEC) water splitting is an alternative to transform abundant solar energy directly to eco friendly hydrogen as a storable fuel without carbon footprint. The aim of this single step transformation is to produce hydrogen directly from sea water only by using sun light and a suitable semiconductor as photoactive material. In order to drive these reactions, such semiconductor materials should provide a sufficient band gap (1.8-2.2 eV) with band edges well aligned to the redox potentials of water enable them to efficiently harvest sun light and provide charge carries for the electrochemical water splitting surface reactions. Furthermore those materials should be stable in aqueous environment, non toxic, abunded and cheap for industrial production. Transition metal oxides like TiO2, WO3 or Fe2O3 are interesting candidates for such applications. Even so this systems has been intensely investigated they still suffer from some drawbacks, like an inefficient light harvesting or fast recombination of generated charge carries, hindering there industrial applications. In order to overcome those drawbacks material modifications are needed.

We here present our recent results from the SOLAROGENIX project (EC-FP7 Grant No. 310333) starting from theoretical modeling to the synthesis and device integration of new photoelectrochemical material systems. We demonstrate the development of novel multi-functional nano crystalline photo active materials by different synthesis and post synthetic material modification strategies, which can be either wet chemical or gas phase approaches.

9176-7, Session 2

Homogeneous and heterogenized iridium water oxidation catalysts *(Invited Paper)*

Alceo Macchioni, Univ. degli Studi di Perugia (Italy)

Water oxidation is supposed to be the critical step of an artificial photosynthetic process aimed at producing solar fuels [1]. Although several materials and molecular species capable of catalyzing water oxidation have been reported, the performances are far to be of practical interest. Among molecular catalysts, iridium pre-catalysts have been attracting much attention over the last few years [2] because they exhibit remarkable TOF and TON values. We contributed to this field by synthesizing the iridium catalysts with the highest TOF reported so far [3] and developing robust iridium catalysts with dandling functionalities suitable to be anchored on photoactive materials [4]. At the same time, we started a systematic investigation on the transformation of the catalysts when subjected to “oxidative stress” [5] and on the reaction mechanism [6]. Our recent results are illustrated in this contribution.

9176-8, Session 2

N-doped ZnO nanorod arrays with gradient band structure for photoelectrochemical water splitting *(Invited Paper)*

Shaohua Shen, Liang Zhao, Xi’an Jiaotong Univ. (China)

Solution based ZnO nanorod arrays were modified with controlled N doping by an advanced ion implantation method, and then utilized as photoanodes for PEC water splitting under visible light irradiation. An obvious N dopant concentration of 3.5 wt% was acquired by varying the implantation doses up to 1?1015 ions/cm2. N doped ZnO nanorod photoanodes displayed markedly enhanced PEC performance, a photocurrent of 150 ?A/cm2 was achieved under visible light illumination, which was about 2 orders of magnitude higher than that of pure ZnO. A comprehensive characterization was performed to explore how N dopant influences the physicochemical properties of ZnO nanorod arrays acting as water-splitting photoanodes. The relationship between optical properties, band structure, photoluminescence intensity and PEC performance indicated that gradient N ion doping can extend optical absorption ability, introduce internal driving force for photo-induced charge transfer and hence increase the PEC performance of ZnO nanorod arrays. These results proposed the potential application of ion implantation method for exploiting novel water splitting materials with improved visible light response.

9176-9, Session 2

Investigation of solar hydrogen generation from the GaN and InGaN thin films

Peifen Zhu, Takahiro Toma, Chee-Keong Tan, Nelson Tansu, Lehigh Univ. (United States)

Generation of hydrogen with low cost method is important for providing the clean energy in various energy consuming applications. One of the methods is to use TiO2 material in photoelectrochemical cell (PEC), however, the solar-to-hydrogen conversion efficiency is low due to the low solar energy absorption. Finding the suitable catalyst materials with the nonhazardous feature is necessary to provide high efficiency in the clean hydrogen generation. GaN-based material has been demonstrated for successful clean hydrogen generation, proving to be a suitable material for PEC application. Therefore it is important to systematically study the different material system for further enhancement solar-to-hydrogen conversion efficiency.

In this work, we systematically investigated GaN-based material in PEC with the comparison of various types of GaN-based thin films. The types of GaN-based thin films are categorized into n-GaN, u-GaN, p-GaN, and p-InGaN thin films. Hydrogen evolution was observed for n-GaN, u-GaN and p-GaN, p-InGaN thin films as working electrode under one sun AM 1.5 illumination. Current density of 1.73 mA/cm2 and 0.80mA/cm2 were achieved for n-GaN and u-GaN, respectively, at applied voltage of 1.2 V. The solar-to-hydrogen conversion efficiency of different thin films are described through measured current density as a function of applied voltage. The n-type thin film is shown to have higher efficiency of 0.7% in converting solar energy into hydrogen as compared to un-doped (0.3%) and p-type thin film, due to the lower resistivity in the n-type material, which is 0.008 Ohm?cm compared to the u-GaN (0.161 Ohm?cm) and p-GaN (4.73 Ohm?cm). Further details of the mechanisms behind the chemical reactions in these thin films will be discussed through various experimental measurements, and comparison of the results with ternary samples will be discussed.

9176-10, Session 3

Charge transfer dynamics at semiconductor quantum dot interface for solar energy conversion *(Keynote Presentation)*

Yasuhiro Tachibana, RMIT Univ. (Australia)

Semiconductor quantum dot (QD) is one of the most attractive nanomaterials for solar energy conversion devices. With their relatively large extinction coefficients and a wide light absorption range over visible wavelengths, QDs can be effective light absorbers. QDs are generally synthesized and handled in solution phase, facilitating solution processed device assembly. However, despite these attractive properties, controlling exciton states and charge separation and recombination dynamics has been challenging. For example, the excited electron and hole can readily be trapped by the surface states, losing initial excited energy. Charge separation of QD-TiO2 interface is relatively slow compared to dye sensitized system, which may compete with charge trapping process or exciton state decays. In this presentation, we will show quantitative analysis of charge trapping in QDs and demonstrate relationship of the QD nanostructures with the interfacial electron transfer reactions.

Several types of QDs with a narrow size distribution are synthesized to control the potential energy levels of the conduction and valence bands. We then analysed influence of QD surface states on the interfacial charge transfer dynamics. The interfacial structure is modified to control the dynamics. The relationship between the QD surface/interfacial structure and solar cell performance will be discussed.

This work was financially supported by JST PRESTO program, Japan. The Office for University-Industry Collaboration, Osaka University, is also acknowledged for the financial support.

9176-11, Session 3

A novel Co-Pi capped pyramidal BiVO4 nanorod arrays with enhanced solar water oxidation *(Invited Paper)*

Jinzhan Su, Yankuan Wei, Liejin Guo, Xi'an Jiaotong Univ. (China) and International Research Ctr. for Renewable Energy (China)

Photoelectrochemical (PEC) water splitting is a promising strategy for the capture and storage of the abundant solar energy. In which, development of effective OER catalysts is a major challenge in energy conversion and storage. A simple but effective cobalt–phosphate water oxidation catalyst (Co-Pi) was reported by Nocera. Co-Pi has previously been deposited on the flatten BiVO4 thin film and showed a superior performance for water oxidation. In the present work, we report a Co-Pi capped BiVO4 nanowire arrays with Co-Pi selectively photodeposited on the tips of BiVO4 nanowires. The pyramidal-shaped BiVO4 nanowire arrays are synthesized in aqueous solution by the seed-layer mediated growth on FTO and then Co-Pi was photochemical deposited on the tips of BiVO4 nanowires. The comparison of the photocurrent-voltage characteristics of the BiVO4 electrodes with and without the presence of Co-based catalyst demonstrated that the catalyst generally enhanced the anodic photocurrent of the BiVO4 electrode and this enhancement showed more pronounced at lower potential. The mechanism of selectively photodeposition of Co-Pi on the tips of BiVO4 nanowires was discussed and was attributed to hole aggregation on the pyramidal shape of BiVO4 nanowires. This study may provide important new understanding of the enhancement and limitations of the Co-Pi catalyst coupled with semiconductor electrodes for water-splitting applications.

9176-13, Session 4

Solution synthesis of advanced materials for solar hydrogen *(Keynote Presentation)*

Gunnar Westin, Uppsala Univ. (Sweden)

The development of catalysts for solar fuels, solar cells and photo-assisted water and air cleaning require robust, routes capable of producing advanced complex materials. These multi-functional devices should both be effective in absorbing photons to generation of holes and electrons, charge transport and catalysis of surface reactions. Quantum confinement in typically less than 3-4 nm sized oxide systems may also be utilized for improved charge separation and transport properties which puts high demands on the precision of the processing routes. For such tough demands solution based routes are the best suited, but there is a need for further development of well understood, flexible routes to high quality, complex nano-structures. Here solution based processing routes to doped and non-doped oxide nano-particles, thin- and ultra thin films are presented. The oxide systems involve doped and non-doped Fe2O3, TiO2, ZnO, spinel and perovskite nano-particles, films and ultra-thin films, as well as metal nano-particles and ultra-thin films. The synthesis and prodcts were studied by a wide array of techniques including; SEM, TEM, XRD, TGA, DSC/DTA, IR-, Raman and UV-Vis-NIR spectroscopy.

9176-14, Session 4

The effect of temperature in flux-assisted synthesis of SnNb2O6

Dalal A. Noureldine, Kazuhiro Takanabe, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Water splitting using photocatalysis is a promising approach to provide the world's increasing energy demands from renewable and sustainable sources. A flux-assisted method was used to synthesize SnNb2O6 as a visible-light-responsive metal oxide photocatalyst. The role of flux was investigated in detail using different flux to reactant molar ratios (1:1, 3:1, 6:1, 10:1, 14:1) and different reaction temperatures (300, 500, 600 °C). The obtained products were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), Diffuse Reflectance UV-Vis Spectroscopy, X-ray photoelectron spectroscopy (XPS), the Brunauer-Emmett-Teller method (BET), and High Resolution Scanning Transmission Electron microscopy (HR-STEM). We successfully tuned the particle morphology by increasing the flux to reactant molar ratio, which afforded defined particles with non-aggregated surfaces. The XRD patterns and SEM analyses confirmed a 2D anisotropic growth along the bc plane, providing a plate-like morphology as the flux ratio increased. The DR.UV-Vis spectra of the obtained samples were consistent with the formation of SnNb2O6 in a single phase. The photocatalytic activity for hydrogen evolution was enhanced as the flux ratio was increased, reaching the highest value at a 1:10-F ratio. This result was explained by the beneficial role of increased flux in allowing the formation of tin niobate at a lower reaction temperature than with solid-state synthesis. This heightened activity coincides with the minimized amount of Sn4+ on the surface boundaries, which may act as trap states. The HR-STEM observation revealed that no preferential deposition of Ag, Pt and PbOx nanoparticles was observed depending on the surface facets of SnNb2O6.

9176-15, Session 5

High efficiency and highly stable water splitting on InGaN nanowire arrays under visible light irradiation *(Keynote Presentation)*

Zetian Mi, Md. G. Kibria, Bandar M. Alotaibi, McGill Univ. (Canada)

Recently, metal-nitrides (GaN and InGaN) have emerged as a viable photocatalyst for solar water splitting under ultraviolet, visible and potentially infrared light irradiation. By engineering the surface charge properties of InGaN nanowire arrays using Mg-dopant, we have demonstrated the absorbed photon conversion efficiency for InGaN nanowire photocatalyst can reach above 50%. Moreover, we have developed multi-band InGaN nanowire photocatalysts and photoelectrodes that can exhibit efficient and stable water splitting and hydrogen generation under ultraviolet, blue, and green light irradiation.

The realization of spontaneous water splitting under red and infrared light irradiation is being investigated and will be reported.

9176-16, Session 5

Electronic structure and interfacial phenomena in the generation of solar fuel characterized by In situ x-ray spectroscopy *(Invited Paper)*

Chung-Li Dong, National Synchrotron Radiation Research Ctr. (Taiwan); Jinghua Guo, Lawrence Berkeley National Lab. (United States)

In relation to the energy crisis and the global extreme climate, much attention is currently being paid to renewable energy resources. The search for new sources of clean energy is rapidly becoming one of the most pressing technological challenges that we are facing today. Enormous progress has been made in developing new materials that are tailored by nanostructuring, and other advanced synthesis methods. In many important energy systems such as solar energy conversion, electronic structure and fundamental interfacial phenomena play crucial roles in material performance. Without knowledge of the fundamental electronic and atomic structures of the materials and the changes of those structures upon reaction, better engineering the material for more practical purposes is impossible. To understand and ultimately control the interfaces in solar fuel generation calls for in-situ/operando characterization tools in which x-ray spectroscopy offers many unique features. X-ray absorption probes the local unoccupied electronic structure and x-ray emission probes the occupied electronic structure. The addition of resonant inelastic soft-x-ray scattering can tell the energy levels that reflect the chemical and physical properties. This presentation reports the development of in-situ reaction cells for x-ray spectroscopy towards the recent studies of photosynthesis, electrochemical and catalytic reactions. The challenge to monitor the electronic structure under operando condition has been that x-rays cannot easily peek into a high-pressure catalytic cell or a liquid photoelectrochemical cell. The successful development of the in-situ cell has overcome the barrier. A number of experimental studies are presented and suggest that in-situ/operando x-ray spectroscopy becomes a useful tool for investigating renewable energy materials in working conditions.

9176-17, Session 5

Hierarchical TiO2/In2S3 nano-heterostructures for high efficiency photoelectrochemical hydrogen generation

Mehrdad Balandeh, Alessandro Mezzetti, Fabio Di Fonzo, Istituto Italiano di Tecnologia (Italy)

In this study we report synthesis and characterization of quasi-1D hyperbranched TiO2 nanostructures sensitized with In2S3 quantum dots (QDs) in order to broad the light absorption spectra to the visible region as a photoanode for hydrogen production. The hierarchical nanorostructures have better electron mobility and charge transport than nanoparticles also has very large surface area even larger than branched nanorods (B-NRs). TiO2 has low efficiency for photoelectrochemical hydrogen production due to its large bandgap but it can provide the large surface area, high charge mobility, light harvesting/scattering. In the other hand the In2S3 has lower bandgap and can absorb light in the visible region. The TiO2 hierarchical nanostructure film was deposited by Pulsed Laser Deposition (PLD) technique. The PLD technique is well known as a technique that can grow wide range of metal oxides with a complex morphology and high surface area. The as deposited films were amorphous so the 2 hours annealing at 500 ˚C in air was performed to obtain the anatase crystalline phase. The hierarchical nanostructure TiO2 synthesis by PLD was sensitized by In2S3 quantum dots. The sensitization was performed by successive ionic layer absorption and reaction (SILAR) technique which is able to deposit a very uniform and thin layer all over this complex structure. The In2S3/TiO2 photoelectrochemical performance was characterized by using an electrochemical workstation coupled with a solar simulator.resulting in 1 mA.cm-2 current density under solar simulator illumination (solar spectrum matched to AM 1.5G, 100 mW/cm2 total power density).

9176-18, Session 6

Functionalization of Ag nanoparticles using local hydrophilic pool segment designed on their particle surface *(Invited Paper)*

Motoyuki Iijima, Yokohama National Univ. (Japan); Aki Kurumiya, Junki Esashi, Hayato Miyazaki, Hidehiro Kamiya, Tokyo Univ. of Agriculture and Technology (Japan)

Recently, an improvement in the light conversion efficiency of dye-sensitized solar cell (DSSC) by introducing Ag nanoparticles which possesses localized surface plasmon resonance effects into the electrodes has attracted wide attention. In order to effectively improve the properties of DSSC with Ag nanoparticles, appropriately designing their particle surface to control their dispersion stability during fabrication of electrodes and to maintain chemical stability of Ag nanoparticles are key issues. In this report, a new processing route to fabricate Ag nanoparticles those coated with thin SiO2 layer and dispersible in various organic solvents have been designed. First, Ag nanoparticles those have local hydrophilic pool structure and dispersible in various organic solvents have been fabricated through a layer-by-layer surface modification process on the Ag nanoparticles using cationic polyethyleneimine and anionic surfactant. An anionic surfactant that having an organic chain comprised from hydrophilic PEG chain and hydrophobic alkyl chain near the head group was chosen since it was reported to improve the stability of nanoparticles in various organic solvents. The surface modified Ag nanoparticles were then dispersed into toluene and treated with tetraethyl orthosilicate (TEOS). It is expected that the hydrolysis and condensation reaction of TEOS occurred in the local hydrophilic pool segment designed on Ag nanoparticles and successfully resulted to obtain Ag nanoparticles coated with thin SiO2 shell those were dispersible in various organic solvents.

9176-19, Session 6

Plasmonic Ag nanoparticles-decorated p-type Si wire array as photocathode for water splitting

Chih-Jung Chen, National Taiwan Univ. (Taiwan)

We utilized Ag nanoparticles decorated-Si wire array (Ag/Si) as the photocathode for water splitting. The p-type Si wafer was etched by inductively coupled plasma (ICP). The pitch size of Si wire array is ~2?m, and the diameter and length of single wire are ~1 ?m and 12 ?m respectively. The one dimensional structure of Si wire was promote the photoresponse by shortening diffusion length for minor carriers and providing major carriers for single conducting direction. We also decorated Ag nanoparticles on the Si wire array through simple redox reaction method. The overpotential of Ag/Si photocathode was decreased by the assistance from Ag co-catalyst. The onset potential of Ag/Si electrode shifted to ~0 V (vs RHE). In addition, the photocurrent of Ag/Si photocathode was further enhanced by surface plasma resonance (SPR) assistance. The two primary mechanisms of plasmonic enhanced-water splitting were hot electrons injection and plasmon-induced electromagnetic fields. The electrons near the Fermi level of Ag nanoparticles were excited to high energy state under solar illumination. These high energy electrons were so-called hot electrons. The hot electrons directly overcame Schottky barrier and injected into the conduction band of Si wire to increase the photocurrent. In the other way, the electron-hole pairs forming probability of Si wire was strongly affected by the surrounding electric fileds. The electric fields of SPR

inhomogeneously distribute on Ag nanoparticles. The charge-carriers easily generated near the interface of Si wire and Ag nanoparticles to reduce the recombination.

9176-20, Session 6

Nanoporous GaN for enhanced solar hydrogen production

Jonathan D. Benton, Jie Bai, Tao Wang, The Univ. of Sheffield (United Kingdom)

III-nitride semiconductor materials (InN, GaN, AlN) have the potential to span the majority of the solar spectrum due to their direct bandgaps spanning from 0.7 eV through to 6.2 eV. Moreover, III-V materials have demonstrated remarkable resistance to corrosion in various electrolyte solutions and have the required conduction and valence band positions making them ideal for photocatalytic hydrogen production. Porous materials for solar hydrogen have been widely reported to improve photocurrent. Here we report the fabrication of porous GaN/InGaN planar and nanostructured devices for solar hydrogen production that results in a significant increase in device performance.

Photoelectrochemical etching was employed to create the porous structure via the utilisation of a KOH solution as the etchant, a 300 W ozone-free xenon lamp as the light source and a platinum rod as the counter electrode. A controllable porous structure has been obtained on as-grown GaN/InGaN wafers and GaN/InGaN nanorods. Under photoelectrochemical testing with 1 sun illumination a lasting enhancement in photocurrent is obtained in both device architectures. A factor of up to 5 is observed in the as-grown devices as a result of the porous structure, which we attribute to the increased surface area and a scattering of incident radiation. The combination of a disordered pore structure within a nanorod array provides further gains in device performance of a factor of 2 attributed to the enhanced electron-hole separation observed in the nanorod structure.

9176-21, Session 6

Nanostructured Cu2O/SrTiO3 heterojunction for solar hydrogen production: experimental and first-principles analysis

Dipika Sharma, Anuradha Verma, Anamika Banerjee, Vibha R. Satsangi, Rohit Shrivastav, Dayalbagh Educational Institute (India); Umesh V. Waghmare, Jawaharlal Nehru Ctr. for Advanced Scientific Research (India); Sahab Dass Kaura, Dayalbagh Educational Institute (India)

Nanostructured thin films of pristine SrTiO3, Cu2O and Cu2O/SrTiO3 heterojunction with varying thickness of SrTiO3. SrTiO3 and Cu2O thin films were deposited on ITO glass substrate using sol–gel spin-coating technique and spray pyrolysis method respectively. Among various metal oxide semiconductors, cuprous oxide Cu2O and strontium titanate SrTiO3 were chosen for the present study on account of being abundant, non-toxic, and environmentally safe and possess staggered type band edges which are suitable for efficient charge separation. SrTiO3 is the wide band gap material (3.2 eV) while Cu2O is low band gap material (2.3eV), which is responsible for visible light absorption. All samples were characterized using X-ray diffractometer (XRD), Scanning electron microscopy (SEM) and UV–Vis spectrometry. The influence of surface modification of Cu2O with varying thickness of SrTiO3 on PEC performance has been investigated. Our results showed that the photocurrent density of the Cu2O/SrTiO3 heterojunction thin films with overall thickness of 343 nm was 2.52 mAcm-2 which is higher than that of pristine Cu2O 0.10 mAcm-2 at 0.8 V/SCE . The effective mass for electron and holes at the conduction band minima and the valence band maxima, were also calculated using DFT based calculations for Cu2O and SrTiO3. It was found that the electrons in SrTiO3 had large effective masses (i.e. weak mobility) as compared to electrons in Cu2O (i.e. strong mobility) at conduction band minima near ? point. The difference in the mobility of photogenerated electrons for bulk SrTiO3 and Cu2O may significantly contribute in photo-generated charge carrier separation at the Cu2O/SrTiO3 interface leading to the enhanced photocurrent density.

9176-22, Session 6

Plasma-enhanced CVD of visible-light active metal oxide nanostructures: growth, modification, and device applications

Andreas Mettenbörger, Thomas Fischer, Yakup Gönüllü, Ashish Lepcha, Sanjay Mathur, Univ. zu Köln (Germany)

Application of tailor-made molecular precursors in plasma-enhanced chemical vapor deposition (PE-CVD) techniques offers a viable solution for overcoming thermodynamic impediments involved in thin film growth. The use of cold plasmas enables the realization of various functional coatings whose application spectrum spans from transparent conductive coatings, scratch-proof films, photoactive to anti-bacterial materials. Over the past decade, we have developed several new precursor systems in order to demonstrate the competitive edge of molecule-based plasma coatings. Our work on a large number of metal oxide systems and their characterization towards microstructure, compositional and functional properties supports the advantages of chemical design in simplifying deposition processes and optimizing functional behaviour.

This talk will present how properties of hematite thin film can be changed by PE-CVD technique by changing the process parameter. In this work, thin films of hematite were prepared at different RF-power using iron pentacarbonyl as a precursor with oxygen as reactive gas. The resulting thin films were used as a photoelectrode in photoelectrochemical cell to study the solar water oxidation under illumination in 1M NaOH electrolytes. The ?-Fe2O3 photoanodes deposited at high RF-power, an enhancement in the photocurrent density was observed. These results demonstrate that the controlled growth of hematite film with tunable morphology provides an efficient photoanode for photoelectrochemical water splitting application which is obtained by the proper chosen of process parameters.

9176-23, Session 6

Facile synthesis of p-type Zn-doped ?-Fe2O3 films for solar water splitting

Chun-Lin Kuo, Yu-Kuei Hsu, National Dong Hwa Univ. (Taiwan); Yan-Gu Lin, national synchrotron radiation research center (Taiwan)

A facile and simple fabrication of Zn-doped alpha-Fe2O3 thin films as a photocathode for solar hydrogen generation was proposed in this report. Transparent Zn-doped alpha-Fe2O3 films were prepared by a deposition-annealing (DA) process where nontoxic iron(III) chloride represents the Fe precursor and zinc chloride represents an acceptor dopant, followed by annealing at 550 Celsius degree in air. In terms of the structural examination of as-grown samples, X-ray diffraction analysis demonstrated an increase in the lattice parameters of Zn incorporated in Fe2O3 by substituting Fe in the host lattice. No second phase was determined, indicating no phase separation in the ternary materials. Energy dispersive spectroscopy results demonstrated that Zn, Fe, and O elements existed in the deposits. Furthermore, impedance measurements show that the Zn-dopant serves as an hole acceptor and increases the acceptor concentration by increasing concentration of zinc precursor. Significantly, the photoelectrochemical measurements exhibited remarkable cathodic current, corresponding to the reduction reaction of hydrogen. Finally, the optimum photocurrent can be achieved by controlled variation of the Fe and Zni precursor concentration, annealing conditions, and the number of DA cycles. According to our investigation, the understandings of morphology effect on PEC activity give the blueprint for materials design in the application of solar hydrogen.

Materials for photoelectrochemical water splitting: The U.S. Department of Energy PEC working group *(Invited Paper)*

Heli Wang, National Renewable Energy Lab. (United States); Thomas F. Jaramillo, Stanford Univ. (United States); Eric L. Miller, U.S. Dept. of Energy (United States)

A durable photoelectrochemical (PEC) water splitting device with high solar-to-hydrogen (STH) conversion efficiency has been a significant materials challenge for decades. Critical requirements on semiconductor materials' band gap, band edges, optoelectronic efficiency, and stability must be satisfied simultaneously.

Metal oxide semiconductors may be stable and earth-abundant, STH efficiencies have been limited by issues related to the wide band gap, band-edge mismatch and the poor opotoelectronic quality in these materials. Tandem cell configurations have been developed to address the band-edges mismatch, more work is needed on overcoming the efficiency limitations due to absorption, charge mobility, recombination, interfacial kinetics, etc. On the other hand, crystalline III-V materials offer alternative pathway to efficient STH conversion, with suitable band gaps by justifying the range of compositions and optoelectronic quality. Moreover, the band edge mismatch has been successfully addressed using monolithic PEC/PV tandem cell design. Stability, however, remains a key issue. NREL, working with other members of the U.S DOE PEC Working Group have been investigating the corrosion of III-V materials and interfaces with a goal to develop surface modification methods for mitigating the corrosion issue. Approaches include coatings, ion bombardment, surface nitridation as well as electrolyte treatments.

Significant materials challenges remain, and effective usage of resources is needed. The PEC Working Group facilitates progress by bringing together diverse PEC researchers with common interests and goals, promoting collaborative activities, resource sharing, and joint publications.

9176-25, Session 7

Efficient and durable solar-driven hydrogen production with branched nanowire heterostructures

Alireza Kargar, Chulmin Choi, Univ. of California, San Diego (United States); Sung Joo Kim, Xiaoqing Pan, Univ. of Michigan (United States); Sungho Jin, Deli Wang, Univ. of California, San Diego (United States)

Branched nanowire (NW) heterostructures have recently been attracted considerable attention for solar water splitting and clean hydrogen production due to their unique properties such as nanoscale integration of different functional materials, greatly enhanced junction and surface area, enhanced gas evolution efficiency, broadband light absorption, etc. Moreover, branched NWs can be fabricated using facile and scalable fabrication methods such as hydrothermal or solvothermal growth methods. In this presentation, we show branched NWs of different compositions for core (or trunk) and branch NWs which were fabricated with facile and low-cost synthesis methods using cheap, non-toxic, and earth abundant materials including Si, CuO, Cu_2O, ZnO, TiO_2, and Fe_2O_3. The branched NW structures and the heterostructures' interfaces are investigated in detail using different characterization techniques such as SEM/HRSEM, TEM/HRTEM, STEM/HRSETM, etc. The photoelectrochemical (PEC) performances including photocurrent turn-on potential, photocurrent, solar conversion efficiency, and incident photon-to-current efficiency (IPCE) are studied systematically and optimized, based on different core and branch NW dimensions, for each specific branched NW heterostructure to provide efficient water splitting in a neutral medium. The electrode stability of different branched NWs is also investigated and long-term stability of over one day or several hours using a thin passivation layer or robust branched NWs are presented. The achieved results pave the way for accomplishing spontaneous overall solar water splitting for clean, efficient, cost-effective and durable solar hydrogen generation at large scales.

9176-26, Session 7

Synthesis and photo-induced charge and energy transfer in novel luminescent CdSe QD: metal oxide composite heterostructures *(Invited Paper)*

Jinkyu Han, Brookhaven National Lab. (United States); Lei Wang, Stony Brook Univ. (United States); Stanislaus S. Wong, Brookhaven National Lab. (United States) and Stony Brook Univ. (United States)

Recently, the generation of QD- metal oxide nanoscale heterostructures has become the focus of particular interest, because the unique and distinctive physical and chemical properties of QDs and of metal oxides can potentially be tuned and tailored so as to render significant improvement and performance enhancement as compared with single component systems for various applications including but not limited to photo-catalysis, chemical sensing, microelectronics, and photovoltaics. In this report, we successfully synthesized novel luminescent zero-dimensional (0D) CdSe nanocrystal (with their size-dependent absorption properties) – multi-dimensional metal oxide (including various rare earth-doped analogues with their corresponding chemically and structurally defined PL attributes) nanoscale heterostructures. In addition, we have characterized interfacial electronic and optical interactions between single components (e.g., either charge or energy transfer) in these heterostructures using PL emission and time-resolved PL spectroscopies. Furthermore, we have investigated the effects of varying different morphologies of metal oxides upon the optical interactions in the heterostructures, incorporating CdSe QDs and different morphological motifs of metal oxides, including 0D, 1D, and 3D architectures. We suggest that these nanoscale heterostructures enable not only the ability to tune the optoelectronic properties of nanomaterials for possible incorporation into nanoscale devices but also the potential to design new types of photovoltaic architectures with the capability of effectively harvesting UV light as well as for promoting highly efficient charge separation.

9177-1, Session 1

IR-imaging and non-destructive loss analysis on thin film solar modules and cells

Jens Adams, Frank W. Fecher, Felix Hoga, Claudia Buerhop-Lutz, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany); Christoph J. Brabec, ZAE-Bayern (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

CIGS thin film solar modules, despite their high efficiency, may contain three different kinds of macroscopic defects referred to as bulk defects, interface defects and interconnect defects. These occur due to the film's sensitivity to inhomogeneities during the manufacturing process and decreasing the electrical power output from a cell or module. In this study, we present infrared (IR) imaging and contactless loss analyses of defects contained in commercially manufactured thin film solar modules. We investigated different relations between the emitted IR-signal (using illuminated lock-in thermography ILIT) and the respective open circuit cell voltage (Voc) [1] as well as the maximum power point (Pmpp) [2]. A simulation study, using the 2D finite element method, provides a deeper understanding as to the impact on electrical performance when defects are present on the cell or module.

9177-2, Session 1

Test and Analysis of Thin Film Photovoltaic (TFPV) for UAV application

Mohammad Gadalla, Sayem Zafar, American Univ. of Sharjah (United Arab Emirates)

A study was conducted to investigate the performance of thin film flexible PV panels. The experimental study was conducted to simulate the performance of the panels for the conditions found during the unmanned aerial vehicle (UAV) flight in the city of Sharjah. Two 2 m and a single 1 m WaveSol Light PV panels were tested for the study. The 2 m panels are for each wing while the 1 m panel is for the horizontal stabilizer. WaveSol Light PV panels were considered for this research because of their relative light weight, high current and compatible voltage output. These PV panels also have a convenient width which can easily be mounted on the UAV wings and stabilizer. The panels were tested for power output at different angles and curvatures for varying solar flux. The curvature tests were performed to simulate the shape of the UAV's wing and horizontal tail airfoils. Different angles were also tested to study the power output during cruise and maneuvering. A detailed parametric study was also conducted to determine the power output with respect to the time of the day. The parametric study was important as it would help to predict the flight duration and the performance of the UAV for regular operations. The study predicted the optimal operating parameters for different angles and curvatures. It also established the time of the day yields the highest power output for its corresponding angle.

9177-3, Session 1

Synchronized thermography for multi-layer thin film characterization

Kimmo K. Leppänen, Juha M. Saarela, Tapio E. J. Fabritius, Univ. of Oulu (Finland)

Organic solar cells and organic LED´s are typically made of conductive and semi-conductive thin films. The uniformity requirement for these films is very high. In the case of multi-layer structures, surface characterization based methods (e.g. profilometer, atomic force microscope, scanning electron microscope) encounter remarkable challenges when attempting to detect uniformity differences because the defects can be inside the structure. To overcome this limitation, a synchronized heating and IR-imaging based system (called synchronized thermography = ST) was utilized for multi-layer structures. Indium Tin Oxide (ITO) was used as an example of conductive thin films and poly(3,4-ethylenedioxy-thiopene):poly(styrene-sulfonate) (PEDOT:PSS) was used as an example of a hole transporting layer. Uniformity differences were generated in these layers and ST was used to detect them. The results show that ST is capable of localizing small defects in a lateral direction in the stack using a single IR-image. Due to the remarkable conductivity differences of ITO and PEDOT:PSS, it can be estimated even in which layer the defect locates. This is a significant advantage in contrast to surface profiling measurements.

9177-4, Session 1

Photoluminescence of hydrogenated silicon with amorphous/nanocrystalline mixed phase

Andrey Emelyanov, Russian Research Ctr. Kurchatov Institute (Russian Federation); Pavel Forsh, Russian Research Ctr. Kurchatov Institute (Russian Federation) and Lomonosov Moscow State Univ. (Russian Federation); Mark Khenkin, Andrei G. Kazanskii, Lomonosov Moscow State Univ. (Russian Federation); Pavel Kashkarov, Russian Research Ctr. Kurchatov Institute (Russian Federation) and Lomonosov Moscow State Univ. (Russian Federation)

Hydrogenated amorphous silicon (a-Si:H) and nanocrystalline silicon (nc-Si:H), which consists of amorphous matrix with embedded silicon nanocrystals, are widely used in electronics and optoelectronics, in particular, in the production of photovoltaic cells and thin film transistors. nc-Si:H films with a small (10 - 15 %) volume fraction of Si nanocrystals are of particular interest. The focus of this work was the investigation of photoluminescence (PL) properties of nc-Si:H films with small volume fractions of the nanocrystalline inclusions.

The investigated nc-Si:H films were fabricated by means of PECVD technique. The volume ratio of gases in the reactor chamber RH=[H2]/[SiH4] was varied as follows: RH = 0 (reference a-Si:H film), 5, 8, 11 and 16. The structure of the films was studied from the analysis of the Raman scattering spectra measured by the micro-Raman spectrometer Horiba Jobin Ivon HR800. The PL spectra were recorded using a MS-3504i (SOLAR TII) spectrograph and a CCD camera (Hamamatsu) under excitation of 364 nm line of a continuous Ar-ion laser. During PL experiments samples were placed into vacuum cell of a DE-204N closed-cycle helium cryostat and cooled down to the temperature of 17 K.

Raman spectra analysis show that the volume fraction of crystalline phase in the films increases with the growth of RH from 0 (a-Si:H film) to 80 %. Using Raman spectra we have also estimated the average diameter of Si nanocrystals in the samples by the red shift of the maximum near 520.5 cm-1. The average diameter of Si nanocrystals is varied from 5 – 7 nm for the samples with RH > 5. A broad PL spectrum with the peak energy of about 1.35 eV is observed for a-Si:H at 17 K,

which is commonly attributed to recombination between electrons trapped in localized tail states of conduction band and holes trapped in localized tail states of valance band. The samples with RH > 5 also show an additional PL maximum near the photon energy of 1.52 eV. The crystalline phase volume fraction increase causes increasing of the PL maximum intensity. Observed maximum could be associated either with defect states on the boundary between Si nanocrystals and amorphous matrix or with the quantum confinement states in Si nanocrystals.

9177-5, Session 2

CIGS/organic single-junction and tandem hybrid solar cells

Manuel Reinhard, Uli Lemmer, Alexander Colsmann, Karlsruher Institut für Technologie (Germany)

Copper indium gallium diselenide (CIGS) solar cells are the most efficient thin film photovoltaic devices. In this work, we investigate CIGS/organic hybrid solar cells comprising semi-transparent metal top electrodes and wide-band gap organic semiconductors as buffer layer. Depositing the organic semiconductors from solution, we fabricate Cd-free CIGS solar cells exhibiting about the same efficiency as their fully inorganic counterparts comprising CdS, and significantly higher open-circuit voltages as compared to buffer-free devices. Although the organic molecules do not cover the CIGS surface homogeneously, their use enables prolonged charge carrier lifetimes according to impedance spectroscopy measurements.

Combining wide and narrow band gap absorbers in tandem solar cells is a promising approach to improve the energy conversion of sunlight. We therefore present hybrid tandem devices comprising monolithically connected CIGS bottom cells and polymer top cells. The thin polymer:fullerene bulk heterojunction absorber layers were transferred onto the rough CIGS surface by a soft-contact lamination technique. Sputtered or solution deposited top-cathodes complete the tandem devices with enhanced open circuit voltages.

Finally, we present CIGS solar cells incorporating solution-deposited transparent top cathodes. The utilized highly conductive polymer blend and the silver nanowire mesh exhibit excellent transparency in the near-UV region and form pinhole-free, homogeneous layers.

[Appl. Phys. Lett., 103 (2013) 143904; Appl. Phys. Lett. 102 (2013) 063304; Org. Electron. 14 (2013) 273-277]

9177-6, Session 2

Effects of sputtering technique on quaternary Sputtered Cu(In,Ga)Se2 Films

Jason D. Myers, Jesse A. Frantz, U.S. Naval Research Lab. (United States); Robel Y. Bekele, U.S. Naval Research Lab. (United States) and Univ. Research Foundation (United States); Vinh Q. Nguyen, Jas S. Sanghera, U.S. Naval Research Lab. (United States)

While Cu(In,Ga)Se2 (CIGS) has established itself as the thin film photovoltaic material of choice with current record efficiencies in excess of 20%, current high-efficiency laboratory-scale fabrication techniques, such as multi-stage evaporation, are ill suited to mass production. Quaternary-sputtering is a promising alternative technique for CIGS deposition, where a single sputtering target made from CIGS itself in the desired stoichiometry is used as the sole deposition source. Devices made using this technique do not require any additional post deposition selenium treatment and have demonstrated peak efficiency in our laboratory in excess of 10%, showing the potential of quaternary sputtering. However, device efficiency to date has been limited by high surface roughness in films produced by conventional RF sputtering. X-ray diffraction and microscopy studies of grain nucleation and growth have attributed this to the long deposition times required using this deposition technique, allowing films to reorganize and grow preferentially in the (112) orientation. In an effort to reduce deposition times, we have fabricated films using pulsed DC sputtering, which substantially reduces the substrate time-at-temperature during absorber formation. DC-sputtered films are observed to have reduced surface roughness and different internal morphology than RF-sputtered films. Comparisons between RF- and DC-sputtered films will be presented, contrasting their crystallinity, grain structure, and device performance.

9177-8, Session 2

Fabrication of ultra-thin (~1 μm) CdTe layer by close spaced sublimation (CSS) techniques for CdTe/CdS solar cell application

Mohammad Rezaul Karim, King Saud Univ. (Saudi Arabia)

The limitation of the fossil resources to generate electrical energy is forcing the researcher to pursue research in the area of power generation through solar cells. Cadmium telluride (CdTe) has evolved in recent time as promising candidate for solar cell material. This thesis work has focused on fabrication of the thin film CdTe solar cell. Main focus was the depositions of CdS window layer and CdTe absorber layer. Prior to the real fabrication of the cell, photovoltaic characteristics of the cells with ultra-thin CdTe layer have been predicted by simulation through AMPS (Analysis of Micro Electronics and Photonic Devices Simulation) software. The absorber layer has been deposited by close spaced sublimation (CSS) method. This Close spaced sublimation system was custom built by our group. Very fine, pin hole free CdTe ultra-thin films were deposited by CSS. The work also constitutes the deposition of CdS layer as a window layer by chemical bath deposition and its characterization. The effect of annealing has also been studied.

The work also focused on the reduction of the CdTe absorber layer and its effect on the performance of the cells. Moreover, the CdZnTe is introduced at the top of the CdTe absorber layer in order to improve the performance of the cell which has ultra-thin CdTe layer of around 1-2 ?m. The insertion of a wider bandgap material, such as CdZnTe (bandgap 2.20eV) with a negligible valance band-offset to CdTe, introduced prior to the back contact that could inhibit the recombination of generated carriers by bouncing back to the CdS/CdTe junction. An improvement in the open circuit voltage and efficiency has been recorded.

9177-9, Session 2

Influence of the heat treatment temperature on the crystal structure of CuInS2 thin films prepared by non-vacuum technology

Xiaoping Hu, Advance Technology & Materials Co., Ltd. (China)

In this study, CuInS2 semiconductor thin film for CIS thin film solar cell was prepared by sulfurizing CuIn precursor in non-vacuum system. The quality of CuInS2 semiconductor was improved by proper heattreatment. The crystalinity of CuInS2 was presented by Raman spectra. With the increase of the temperature of heattreatment, the In- rich defect phase showed decreasing. By 500oC heattreatment, the defect phase was almost disappeared. The open voltage of CuInS2 film changed from tens milivolts to 700 milivolts. The method would be useful in the manufacuture of CIS thin film solar cell in non-vacuum system.

9177-10, Session 3

Enhancement of perovskite-based solar cells employing core shell metal nanoparticles

Michael Saliba, Henry J. Snaith, Univ. of Oxford (United Kingdom)

In this study, we combined core–shell metal–dielectric nanoparticles within a thin-film solar cell technology employing a recently developed organometal lead halide absorber which shows great promise for high efficiency photovoltaic applications.

More specifically, plasmonic core-shell Au-SiO2 (80 nm @ 8 nm) nanoparticles were embedded into the mesoporous alumina structure of a perovskite solar cell.

At optimized conditions, devices with incorporated gold nanoparticles showed a significantly enhanced short-circuit photocurrent and average efficiencies of 9.5% as compared to control devices with 8.4% efficiency. However, we observed no significant enhancement in light absorption from the nanoparticles.

To investigate this effect further, we conducted a time-resolved and steady state temperature-dependent photoluminescence study resulting in the conclusion that the improved photocurrent was due to a reduced exciton binding energy, and thus enhanced generation of free charge carriers in the presence of metal nanoparticles.

This represents a new enhancement mechanism for metal nanoparticles incorporated into photovoltaics and may prove to be exceptionally useful for this new family of perovskite semiconductors where the exciton binding energy is in the order of 100 meV. We do note, however, that further work is required to fully understand the mechanism which is driving the enhanced solar cell.

9177-12, Session 3

Systematic study of metal-insulator-metal diodes with a native oxide

Evgeniy Donchev, Imperial College London (United Kingdom); Peter M. Gammon, The Univ. of Warwick (United Kingdom); Jing S. Pang, Peter K. Petrov, Neil M. Alford, Imperial College London (United Kingdom)

In this paper, a systematic analysis of native oxides within a Metal-Insulator-Metal (MIM) diode is carried out, with the goal of incorporating them into a nanoscale Rectenna (Rectifying Antenna). MIM structures have electrical properties that could be better suited to this application than other diode structures, including higher achievable cut-off frequencies. Controlled deposition of stoichiometric ultra-thin oxides is required for optimal MIM diode performance. The requirement of having a sub-10nm oxide scale can be met by using the native oxide, which forms on most metals exposed to an oxygen containing environment. This, therefore, provides a simplified MIM fabrication process as the complex, controlled oxide deposition step is omitted. We shall present the results of an investigation into the current-voltage characteristics of various MIM combinations that incorporate a native oxide, in order to establish whether the native oxide is of sufficient quality for good diode operation. The thin native oxide layers are formed by room temperature oxidation of the first metal layer, deposited by reactive magnetron sputtering. This is done in-situ, within the deposition chamber before depositing the second metal electrode. Using these structures, we study the established trend where the bigger the difference in metal workfunctions, the better the rectification properties of MIM structures, and hence the selection of the second metal is key to controlling the device's rectifying properties. We show how leakage current paths through the non-optimised native oxide scale control the net current-voltage response of the MIM devices. Furthermore, we will present the so-called diode figures of merit (asymmetry, non-linearity and responsivety) for each of the best performing structures and discuss the suitability of such structures for use in a nanoscale rectenna.

9177-13, Session 3

New donor-acceptor type fluorinated quinoxaline-based polymer solar cells with prominent air stability and efficiency

Jan Kai Chang, National Taiwan Univ. (Taiwan) and California Institute of Technology (United States); Wei-Hsuan Tseng, Hsieh-Chih Chen, Chih-I Wu, Chien-Liang Liu, Chih Ting Yeh, National Taiwan Univ. (Taiwan)

In this study, a new medium bandgap conjugated copolymer comprising of a rigidly fused BDT unit and a fluorinated quinoxaline moiety through a thiophene π?spacer has been rationally designed and synthesized by Stille coupling polymerization and thoroughly evaluated for use as a donor material in bulk-heterojunction polymer solar cells (BHJ PSCs). A comprehensive study of the structure-function relationship in the PSCs was also explored. Possessing an intrachain donor-accepter architecture, this polymer exhibits strong and broad absorption band across UV and visible region. Introducing highly electronegative fluorine atoms to quinoxaline moiety lowers both the highest occupied molecular orbital and the lowest unoccupied molecular orbital level of polymer, beneficial for attaining higher open-circuit voltage. Conventional architecture BHJ PSCs using PBDTQEH:PC71BM (1:1, w/w) displays a high power conversion efficiency of 5.90%. Compared with the same composition, device in the inverted configuration reveals a rather high PCE of 6.36% with a Voc of 0.78 V, a short-circuit current density of 12.72 mA cm-2, and a high fill factor of 64.3%. The inverted device also demonstrates outstanding air stability; the solar efficiency of the device remains above 74% of the original value after storage in air for 1000 h without any capsulation.

9177-14, Session 3

Microcrystalline silicon oxides for silicon-based solar cells: impact of the O/Si ratio on the electronic structure

David E. Starr, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Andreas Lambertz, Forschungszentrum Jülich GmbH (Germany); Regan G. Wilks, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Bernhard Holländer, Forschungszentrum Jülich GmbH (Germany); Jan-Hendrick Alsmeier, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Lothar Weinhardt, Karlsruher Institut für Technologie (Germany) and Univ. of Nevada, Las Vegas (United States); Monika Blum, Univ. of Nevada, Las Vegas (United States); Mihaela Gorgoi, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Wanli Yang, Lawrence Berkeley National Lab. (United States); Clemens Heske, Karlsruher Institut für Technologie (Germany) and Univ. of Nevada, Las Vegas (United States); Marcus Baer, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Univ. of Nevada, Las Vegas (United States) and Brandenburgische Technische Univ. Cottbus-Senftenberg (Germany)

Most Si-based solar cell structures contain emitter/contact/passivation layers, which consist of the same/similar material as the absorber. Ideally, these layers fulfill their desired task (i.e., induce a sufficiently high internal electric field, ensure a good electric contact, and passivate the interfaces of the absorber) without absorbing light. Usually this leads to a trade-off in which a higher transparency can only be realized at the expense of the layer's ability to properly fulfill its task. One alternative approach is to use hydrogenated microcrystalline silicon oxide (?c-SiOx:H), a mixture of microcrystalline silicon and amorphous silicon (sub)oxide. The crystalline Si regions allow charge transport, while the oxide matrix maintains a high transparency. To date, it is still unclear how in detail the oxygen content influences the electronic structure of the ?c-SiOx:H mixed phase material.

We have used a combination of complementary x-ray and electron spectroscopies to study the chemical and electronic structure of the ?c-SiOx:H (0 < x = O/Si < 1) system. Different information depths of the employed techniques help to reduce the impact of surface oxides on the spectral interpretation. For all samples, we find the valence band maximum to be located at a similar energy with respect to the Fermi

energy. However, for x > 0.5, we observe a pronounced decrease of Si 3s – Si 3p hybridization in favor of Si 3p – O 2p hybridization in the upper valence band. This coincides with a significant increase of the material's resistivity, possibly indicating the breakdown of the conducting crystalline Si network.

9177-15, Session 4

Strain dependence of the optical properties and band gap of transparent conducting BaSnO3 and SrSnO3

David J. Singh, Oak Ridge National Lab. (United States); Qiang Xu, Khuong P. Ong, A*STAR Institute of High Performance Computing (Singapore); Xiaofeng Fan, Jilin University (China)

N-type perovskite structure stannates based on BaSnO3 with doping by La and/or Sb, have attracted recent interest as transparent conductors. In analogy with materials like SrTiO3, the perovskite structure suggests the possibility of complex structural distortions under strain, which may then provide for strain tuning of properties. Here, we report calculations of the optical properties and band gaps as a function of strain for BaSnO3 and SrSnO3. We find that these materials behave very differently from perovskites like SrTiO3 in that there is a very strong sensitivity of the properties to volumetric strain, but practically no dependence on other strains. The results are discussed in relation to the s-electron character of the conduction band and simple formulas for the strain dependence of the gap are given.

9177-16, Session 4

Development of transparent and conductive Al doped Zn1-xMgxO thin film by sol-gel process with two-step annealing

Lei Meng, Shinsuke Miyajima, Makoto Konagai, Tokyo Institute of Technology (Japan)

Transparent conducting oxides are one integral part in various optoelectronic devices such as liquid crystal displays, light emitting diodes and thin film solar cells. Al doped ZnO (AZO) thin film is one promising candidate as front TCOs in Si thin film solar cell, because the lower cost than tin doped indium oxides and better resistance to hydrogen plasma than fluorine doped tin oxides in plasma assisted chemical vapor deposition fabrication process. In order to reduce the optical loss in AZO thin film at short wavelength range around 350nm due to low band gap energy of 3.4 eV, development of new TCOs thin film with wider band gap is in urgent demand. In this work, Al doped Zn1-xMgxO (AZMO) thin film was developed by using sol-gel process with two-step annealing. Effect of annealing temperature and atmosphere on structural, optical and electrical properties of thin film was systematically investigated. It was found that first annealing temperature determines film crystallinity and grain size, while second annealing plays a critical role in activating carrier. All of AZMO thin films show a (002) preferential orientation, a surface roughness of about 2 nm and a high transmittance of over 85% in wavelength range from 400nm to 1500 nm. The relevant mechanism was discussed. One low resistivity of 2.1?10-2??cm was achieved with a band gap energy of 3.6 eV. With further reduced resistivity, such AZMO thin film holds great potential to be applied as the transparent conductive layer in Si thin film solar cell.

9177-17, Session 4

High temperature annealed SnO2/Sn-Ag/ITO window electrodes for dye sensitized solar cells

Sheng-Hui Chen, Chun-Ko Chen, National Central Univ. (Taiwan)

In this study, a transparent conducting film (TCO) for SnO2/Sn-Ag/ITO glass was designed based on calculation of the film matrix. It was proven that there was higher transmission in the visible regions aided by the transparent heat mirror effect in the NIR region. As per the experimental results, the average transmittances were 77.7%/42.3% in the 400-750/800-1300 nm range for SnO2/9-nm Ag/40-nm ITO glass, and 70.82%/25.2% in the 400-700/800-1300 nm range for SnO2/12-nm Ag/40-nm ITO glass. Although these samples had 4 and 8 ohm/sq of sheet resistance, respectively, the transmittance would decay to 63.1%/27.4% and 67.2%/40.8% as a consequence of the metal clusters of Ag that formed after annealing at 500°C. After this SnO2/1-nm Sn-Ag/ITO glass samples were studied. It was found that Sn3Ag would form on an Ag layer after annealing. The transmittances of SnO2/1-nm Sn- 9-nm Ag/ITO and SnO2/1-nm Sn- 12-nm Ag/ITO glass after 500°C annealing were 77.9%/57.2% and 71.8%/36.8%, respectively. In addition, both of these materials had sheet resistances below the 10 ohm/square. Finally, SnO2/Sn-Ag/ITO glass was successfully fabricated after 500°C annealing to produce the transparent heat mirror design. The transmittance of this material with the transparent heat mirror design was greater than 70% in the spectra of 400-750 nm and less than 40% in the 800-1300 nm range, and the sheet resistance was less than 10 ohm/sq.

9177-18, Session 4

Metal nanowire-graphene composite transparent electrodes

Trent Mankowski, Zhaozhao Zhu, The Univ. of Arizona (United States); Kaushik Balakrishnan, College of Optical Sciences, The Univ. of Arizona (United States); Farid Touati, Mohieddine Benammar, Qatar Univ. (Qatar); Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States); Charles M. Falco, The Univ. of Arizona (United States)

Silver nanowires with 40 nm widths and copper nanowire with 150 nm were synthesized using low-temperature routes and deposited on top of ultrathin graphene films for use as transparent conductors. A systematic and detailed analysis involving nature of capping agent for the metal nanowires, annealing of films, and pre-treatments of substrates revealed critical conditions necessary for preparing high performance transparent conducting electrodes. The best electrodes show ~75 % transmission and sheet resistance ~10 Ω/?, already comparable to best available transparent electrodes. The metal nanowire-graphene composite electrodes are therefore well suited for fabrication of opto-electronic and electronics devices.

9177-19, Session 4

Transparent conducting electrodes based on narrow, ultra-long copper nanowires and graphene nanocomposites

Zhaozhao Zhu, Trent Mankowski, The Univ. of Arizona (United States); Kaushik Balakrishnan, College of Optical Sciences, The Univ. of Arizona (United States); Farid Touati, Mohieddine Benammar, Qatar Univ. (Qatar); Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States); Charles M. Falco, The Univ. of Arizona (United States)

High aspect ratio copper nanowires with ultralong lengths (up to 200 ?m) and narrow widths (< 50 nm) were synthesized in large quantities using solution based approach and integrated with graphene sheets towards producing transparent conducting electrodes. These transparent electrodes fabricated achieved high %T and have resistances values comparable to existing electrodes. Furthermore, the electrodes show no notable loss of performance under high temperature and humid conditions. The adaptations of such nanomaterials into smooth and ultrathin films lead to potential alternatives for tin-doped indium oxide

(ITO), which can be utilized in a wide range of solar cells, flexible displays and other opto-electronic devices.

9177-20, Session 5

Optimization of hybrid antireflection structure integrating surface texturing and multi-layer interference coating

Shigeru Kubota, Kensaku Kanomata, Takahiko Suzuki, Fumihiko Hirose, Yamagata Univ. (Japan)

The antireflection structure (ARS) for solar cells is categorized to mainly two different techniques, i.e., the surface texturing and the single- or multi-layer interference coating. Although the surface texturing attains a good broadband antireflective performance, the available materials for large-scale and low-cost fabrication is limited. When the material for texturing is different from that used in the solar cell, the occurrence of reflection due to optical mismatching is inevitable. Therefore, it may be worth making use of multi-layer interference coating, in addition to surface texturing, to reduce the effects of such optical mismatching. Here, we consider a novel hybrid ARS, which integrates moth eye texturing and multi-layer coat, for application to organic photovoltaics (OPVs). Using the optical simulation based on the finite-difference time-domain (FDTD) method, we conduct nearly global optimization of the geometric parameters characterizing hybrid ARS. The proposed optimization algorithm consists of two steps: in the first step, we optimize the period and height of moth eye array, in the absence of multi-layer coating. In the second step, we optimize the whole structure of hybrid ARS by using the solution obtained by the first step as the starting search point. The methods of the simple grid search and the Hooke and Jeeves pattern search are used for global and local searches, respectively. The design concept of hybrid ARS is highly beneficial for improving light trapping in the thin active layer of OPVs, and the same concept will be applicable to light trapping for other thin film solar cells.

9177-21, Session 5

Improving thin film amorphous silicon photovoltaic cell efficiency using plasmonic structures

Keyur K. Gandhi, Michail J. Beliatis, Simon J. Henley, S. Ravi P. Silva, Univ. of Surrey (United Kingdom)

We performed a systematic optoelectronic numerical study on plasmonic amorphous silicon thin film PV cells using commercial FDTD T-CAD software by optimising silver and gold metal nanoparticles with size (radius) between 10-50 nm. Fine tuning of the nanoparticle size increases the light coupling into the optical modes of the active layer as a result of multiple light scattering and localised surface plasmon resonance, due to the metal nanoparticle size. The simulated device configuration was 1?m wide and consists of 200nm thick n-i-p based amorphous silicon sandwiched between ITO (100nm) front electrode and aluminium (100nm) back electrode. Plasmonic metal nanoparticles of gold or silver are embedded between ITO and glass substrate. The entire device was simulated under AM1.5G solar spectrum between 300-800 nm wavelengths with 10nm spectral resolution. The localised surface plasmon resonance of silver (420nm) and gold (520nm) nanoparticles promotes light coupling which enhances the light trapping in the active layer. Optimisations of device architecture lead to a relative increase of 3.9% and 6.1% in device efficiency for 40nm silver and gold nanoparticles respectively. The optical analysis also suggests reduction of surface reflections by 7.7% and 9.2% and increased light absorption in a-Si:H of 4.9% and 6.1% which results in 14.6% and 15.9% increase in photogeneration rates compared to reference planar device. This computational study suggests that designing new device architectures incorporating plasmonic metal nanoparticle coatings can act as broadband antireflection coatings for thin film PV cell applications and also improves the light management in the cell.

9177-22, Session 5

Light trapping in thin-film solar cells: the role of guided modes

Thomas M. Sondergaard, Yao-Chung Tsao, Thomas G. Pedersen, Kjeld Pedersen, Aalborg Univ. (Denmark)

This paper studies theoretically light trapping in a solar cell configuration consisting of a 50-500 nanometer-thin planar silicon (aSi:H) film with a planar silver back-reflector, and scatterer(s) placed directly on the silicon surface. The usual picture for thicker films is that part of the light incident on the scatterer(s) can be coupled into the silicon film at a continuum of angles above the critical angle for the silicon-air interface, in which case light will be trapped and subsequently absorbed. However, for thin films a more appropriate picture is that of light being coupled into the guided modes of the air-silicon-silver geometry corresponding to discrete angles. The scattering of light into each guided mode, and out-of-plane scattering, will be quantified by the related scattering cross section. It will be shown that scattering-cross-section spectra have sharp resonances near cut-off wavelengths of guided modes, with more closely spaced resonances for thicker films. Total resonant cross sections can easily exceed physical cross sections by a factor 10. This study also includes light trapping due to coupling into the Surface-Plasmon-Polariton mode that exists due to the silver surface. It will be shown that peaks in scattering cross sections can be tuned via the geometry to the appropriate wavelength range where light trapping is advantageous due to weak absorption in the silicon, resulting in an optimum thickness around 250 nanometers. The theoretical calculations include material losses, and both dielectric and metal scatterers are considered. The calculations were carried out with Green's function integral equation methods.

9177-23, Session 5

Light trapping in photonic crystals

Ken X. Wang, Stanford Univ. (United States); Zongfu Yu, University of Wisconsin - Madison (United States); Victor Liu, PARC (United States); Aaswath Raman, Yi Cui, Stanford University (United States); Shanhui Fan, Stanford Univ. (United States)

In this work, we quantitatively establish the connection between absorption and DOS, and use this relation to guide photonic crystal absorber designs. To maximize absorption by light trapping, one should aim at maximizing the number of accessible modes supported by an absorber structure. Moreover, we show that to take full advantage of the benefit of the photonic DOS, one need to consider additional issues including accessibility to these photonic states, as well as the overlap of the photonic states with the absorber.

The main aim of our paper is to highlight the unique physics of light trapping in photonic crystals. There are at least two methods to increase absorption by light trapping in photonic crystals. The first method is to enhance the DOS. For relatively narrowband applications, for example, in crystalline silicon solar cells where light trapping is most crucial in the vicinity of the band edge, we can place the van Hove singularities at the desired wavelengths and achieve greater light trapping enhancement than the $4n^2$ limit. We may also stack multiple photonic crystals for combined, and possibly even greater, light trapping enhancement. For broadband applications, for example, to enhance absorption in a weak absorber across the entire visible solar spectrum, engineering (essentially redistributing) the DOS for the greatest benefit is a very difficult non-convex optimization problem. If the refractive index of the absorptive material is lower than its background, then overall DOS enhancement is expected; otherwise, the DOS of the photonic crystal is generally lower than the DOS in the bulk absorber, as in all the simulations in this work where we use a silicon-like material and air. One tradeoff is therefore the refractive index contrast between the higher-index absorber and the lower-index background: on one hand, larger index contrast gives rise to more prominent van Hove singularities; on the other hand, smaller index contrast means less reduction in the overall DOS.

The second method is to improve the coupling between the photonic states and the external radiation modes, in other words, the optical modes supported by the photonic crystal need to be leaky in order to contribute to light trapping. Those modes below the lightline in free space cannot couple to external radiation due to the mismatch of parallel wave vectors. However, one can increase the periodicity of the structure and essentially push more modes above the lightline. We have shown that this approach is very effective by a simple rotation of the photonic crystal lattice. Another method to improve coupling is to roughen the surface or to use a grating, which scatters the parallel wave vectors and helps the external radiation to couple into the modes that are previously inaccessible. We have shown that such a surface grating is achievable by simply varying the radii of dielectric rods in the first layer of the photonic crystal. We can further improve the coupling efficiency by combing the strategies presented above.

9177-24, Session 5

Bilayer structures optimization as antireflective coating for silicon solar cells

Sara Zuccon, Paola Zuppella, Alain J. Corso, Maria G. Pelizzo, IFN-CNR LUXOR Lab. (Italy)

The optimization of a silicon solar cell involves also the design of a proper antireflective coating (AR).

We have considered different bilayer structures. The use of bilayers is oriented to have an antireflective effect on a broader range of wavelengths compared to single film AR. The materials considered include silicon oxide, magnesium fluoride, silicon nitride and titanium oxide. The thickness of each film in each structure has been optimized by theoretical calculations in order to minimize the weighted reflectivity, Rw. This is calculated taking into account the optical reflectivity, the internal quantum efficiency of the silicon solar cell and the solar flux on all the range of wavelengths of interest.

Some of these optimized structures have been realized by e-beam vapor deposition. The improved optical performance of the samples have been verified at the UV-vis-nir spectrophotometer.

9177-25, Session 5

Si nanowire array antireflection layers for ultrathin crystalline Si solar cells

Minji Gwon, Yunae Cho, Dongwook Kim, Ewha Womans Univ. (Korea, Republic of)

We have investigated optical characteristics of 10-um-thick Si wafers with Si nanowire (NW) arrays on the front surface using the finite-difference time-domain (FDTD) simulations (Lumerical FDTD Solutions). We have carried out calculation studies to design optimal Si nanowire array for ultrathin crystalline Si (c-Si) solar cell applications. Optical reflectance, transmission, and absorption spectra were obtained for NW arrays with various diameter and period. The NW array significantly enhanced the absorption, with the aid of resonant guided modes, Fabry-Perot type interference, and diffraction. In addition, the optical spectra in visible wavelength range could be understood based on graded refractive index effect and coupled optical modes between neighboring NWs. Cross-sectional field profiles revealed that the NW diameter and the array period significantly influenced the optical field distributions. These results provide a design guideline for selecting optimal antireflective NW arrays maximizing the optical absorption in the planar absorber rather than in the NWs. Such NWs will increase the photocurrent of the ultrathin c-Si solar cells, while avoiding serious recombination loss at the NWs.

9177-302, Session Plen

The Renaissance of CdTe-based Photovoltaics

William Huber, GE Global Research (United States)

Over the past several years, CdTe-based photovoltaics have undergone a revolution. CdTe is a mature PV technology, spanning more than 55 years. Steady advancements in CdTe module manufacturing, coupled with CdTe's inherent manufacturing simplicity, have driven down the cost of commercial CdTe modules to under $0.55/W at present. Until recently however, CdTe module efficiencies have lagged behind competing technologies. For a decade, CdTe record efficiencies remained dormant, far behind poly Si as well as the competing thin film PV technology, CuInxGa1-xSe2 (CIGS). Over the past several years, CdTe record cell efficiencies have dramatically increased and are nearly at parity with poly Si and CIGS. Given the recent trajectory, CdTe is poised to become the most efficient polycrystalline PV technology in the very near future. This talk will highlight the advantages of CdTe for PV, key advancements in the field and opportunities for further improvements.

9177-26, Session PWed

Effects of steel counter electrode on performances of dye-sensitized solar cells

Jae-Ryung Lee, Young Jun Park, Je Hoon Bak, POSCO (Korea, Republic of)

Thin-film solar cells based on dyesensitized will play an important role because of their high efficiency and cost-reduction potential. TiO2-based dyesensitized thin-film PV technology has came to the performance level competitive against the poly-crystalline Si PV technology. We have improved the efficiency of DSC solar cells to 5.5 % on 25.0 cm? area, which is a new record and exceeds the efficiency of 1-TCO type of dyesensitized solar cells. The presentation will also address with our recent development of hybrid type low cost solar cells as well as flexible steel-based counterelectrode system.

9177-27, Session PWed

Fabrication of ZnS buffer layer for CIGS solar cells by highly deposited rate chemical bath deposition process

Wei-Tse Hsu, Shih-Cheng Chang, Sheng-Wen Chan, Chien-Chih Chiang, Lih-Ping Wang, Chou-Cheng Li, Jen-Chuan Chang, Song-Yeu Tsai, Industrial Technology Research Institute (Taiwan)

CIGS solar cells have shown the conversion efficiency beyond 20%, but the toxic material "CdS" was still used as a n-type buffer layer in the solar cell. Recently, ZnS/CIGS solar cells were developed rapidly and it could also show efficiency as high as 20.9%. But the zinc-based buffer layer has two drawbacks such as low deposition rate and insufficient coverage, which must be met for large mass production. In this study, ZnS buffer layers for CIGS solar cells were prepared by a high rate chemical bath deposition process. In this process, 30 nm ZnS thin film could be prepared within 5 minutes. Following, an extra ZnS thin film prepared by traditional process(5 minutes) was deposited on the as-grown ZnS thin film to passivate the defects. Scanning electronic microscopy and UV–visible–NIR spectrophotometer were employed to characterize the thin film quality. The results hint that the bi-layer thin film has good uniformity, good coverage and high transmittance. The optical bandgap of the as-grown ZnS thin films were measured to be 3.6eV. Besides, the bilayer ZnS/CIGS could show good efficiency without intrinsic ZnO layer. The efficiencies of bilayer-ZnS/CIGS solar cells could reach 10%, which was close to a reference CdS/CIGS solar cell(10.4%). The results hinted that the bilayer ZnS process showed promising potential to get good film quality and high throughput, which could be suitable to mass production for CIGS thin film solar cells.

9178-1, Session 1

Recent developments in luminescent solar concentrators *(Invited Paper)*

Wilfried G. J. H. M. van Sark, Utrecht Univ. (Netherlands)

Full spectrum absorption combined with effective generation and collection of charge carriers is a prerequisite for attaining high efficiency photovoltaic devices, while maintaining cost effectiveness in manufacturing. Spectrum modification using down shifting has been demonstrated in luminescent solar concentrators since the 1970s. These consist of a highly transparent plastic plate, in which luminescent species are dispersed, which absorb incident light and emit light at a red-shifted wavelength, with high quantum efficiency. Material issues have hampered efficiency improvements, in particular re-absorption of light emitted by luminescent species and stability of these species. In this contribution, I will focus on reviewing approaches to minimize re-absorption, which would allow surpassing the 10% luminescent solar concentrator efficiency barrier.

9178-2, Session 1

Singlet fission by novel chromophores in various molecular assemblies *(Invited Paper)*

Justin C. Johnson, Joel N. Schrauben, Joseph Ryerson, National Renewable Energy Lab. (United States); Josef Michl, Univ. of Colorado at Boulder (United States); Arthur J. Nozik, National Renewable Energy Lab. (United States) and Univ. of Colorado (United States)

Singlet fission, a process by which one photoexcited singlet becomes two triplets, has become a topic of intense interest recently as both an intriguing photophysical phenomenon and a route to improved solar photoconversion. Singlet fission is analogous to multiple exciton generation in semiconductor quantum dots and also downconversion by quantum cutting in lanthanides. We have investigated the model chromophores 1,3-diphenylisobenzofuran, a blue-absorbing biradicaloid, and cibalackrot, and indigo derivative, since they possess excited states whose energies and geometries should promote singlet fission while inhibiting competing processes like internal conversion or intersystem crossing. Chromophore design, while important, is only a first step toward demonstrating a practical singlet fission system. The unique modes of intermolecular coupling and environments surrounding the chromophores can have a strong influence on the singlet fission process, thus the way in which molecules are assembled is crucial. We have systematically studied 1,3-diphenylisobenzoran and cibalackrot assembled into covalent dimers, polymers, films of varying crystallinity, bulk crystals, and molecules attached to surfaces. Triplet formation times and yields span decades in these systems, from ~1 ps and 200% in specific polycrystalline films, to greater than 20 ns and negligible triplet yield in weakly coupled dimers. In order to extract useful work from the multiple excitons generated by singlet fission, a scheme for exciton dissociation and charge extraction or photon emission must be developed, and we explore certain design principles within the assemblies to achieve these goals.

9178-3, Session 1

Luminescent down-shifting layers with Eu2+ and Eu3+ doped strontium compound particles for photovoltaics

Anastasiia Solodovnyk, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany) and Erlangen Graduate School in Advanced Optical Technologies (Germany); Andre Hollmann, Andres Osvet, Karen K. Forberich, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Edda Stern, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany); Miroslaw Batentschuk, Robin Klupp Taylor, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Christoph J. Brabec, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany) and Erlangen Graduate School in Advanced Optical Technologies (Germany)

In this contribution we discuss luminescent down-shifting (LDS) systems consisting of a polymer matrix filled with phosphor particles. It is an elegant approach to make a use of potentially destructive or otherwise wasted high energy photons and diminish charge carrier losses caused by thermalization in photovoltaics. Sub-micron and micron sized particles of strontium aluminate doped with Eu^{2+} and strontium carbonate doped with Eu^{3+} ions are chosen for the application due to their suitable absorption in UV spectral region. These particles exhibit strong luminescence in visible range between 520 and 650 nm. The systems are carefully designed to meet critical optical requirements such as high transparency in the visible spectrum as well as sufficient absorption of UV light. They are coated on quartz glass substrates (20 x 20 x 1 mm) and can be easily laminated to different kinds of solar cells without any modification to well-established device fabrication processes. Optical characterization further confirms that particles of a few microns in size generate increased light scattering in layers due to the size which is comparable with visible light wavelengths. Dried thick layers of 20 to 100 µm are tested with CIGS and mc-Si cells. The concept of light conversion is experimentally proven. However, optical losses cause a reduction in the overall performance of the tested devices. Possible ways to bring down the amount of light scattering and, thus, to increase optical transmission for the studied system are also addressed and are a subject of future research.

9178-4, Session 2

2D honeycomb semiconductors with Dirac-type electrons and holes: fabrication, electronic structure, and possible applications *(Invited Paper)*

Daniel Vanmaekelbergh, Utrecht Univ. (Netherlands)

The interest in 2-dimensional systems with a honeycomb lattice and related Dirac-type electronic bands has exceeded the prototype graphene. Currently, 2-dimensional atomic and nanoscale systems are extensively investigated in the search for materials with novel electronic properties that can be tailored by geometry. I will show how atomically coherent honeycomb superlattices of rocksalt (PbSe, PbTe) and zincblende (CdSe, CdTe) semiconductors can be obtained by nanocrystal self-assembly, covalent attachment, and subsequent cation exchange. Atomistic and analytical theory predict that these systems combine Dirac-type electronic bands with the beneficial properties of a semiconductor; the systems have a genuine band gap as in a normal 2-D semiconductor, while the valence- and conduction bands transform into Dirac cones. Hence, photo-excitation should generate massless Dirac conduction electrons and valence holes. I will present the first experimental results on the opto-electrical characterisation of PbSe and CdSe honeycomb semiconductors and discuss possible applications.

9178-5, Session 2

Coherence-limited solar power conversion: the fundamental thermodynamic bounds and the consequences for solar rectennas

Jeffrey M. Gordon, Heylal Mashaal, Ben-Gurion Univ. of the Negev (Israel)

Solar rectifying antennas constitute a distinct solar power conversion paradigm where sunlight's spatial coherence is a basic constraining factor. In this presentation, we derive the fundamental thermodynamic limit for coherence-limited blackbody (principally solar) power conversion. Our results represent a natural extension of the eponymous Landsberg limit, originally derived for converters that are not constrained by the radiation's coherence, and are irradiated at maximum flux concentration (i.e., with a view factor of unity to the solar disk). We proceed by first expanding Landsberg's results to arbitrary target irradiance below the maximum allowed value, and then demonstrate how the results are modified when the converter can only process coherent radiation. The results are independent of the specific power conversion mechanism, and hence are valid for diffraction-limited as well as quantum converters (and not just classical heat engines or in the geometric optics regime). The derived upper bounds bode favorably for the potential of rectifying antennas as potentially high-efficiency solar converters.

9178-8, Session 3

Wrinkles and folds as photonics structures in polymer photovoltaics *(Invited Paper)*

Yueh-Lin Loo, Princeton Univ. (United States)

We exploit the elastic instabilities of polymer surfaces under compressive mechanical stress to generate wrinkles and deep folds with prescribed dimensions and at pre-specified coverage over large areas. These wrinkles and deep folds act as photonic structures; they increase light coupling into and trapping within polymer photovoltaics that are subsequently constructed atop such surface structures. Devices on surfaces comprising wrinkles and folds exhibit a 79% increase in the external quantum efficiency (EQE) in the visible compared to analogous devices constructed on flat surfaces. More significantly, we observe an exponential increase in near-infrared light absorption in these devices. In both experiments and in numerical simulations, we find the presence of wrinkles and deep folds to extend the useful range of energy conversion by > 200 nm for model bulk-heterojunctions comprising poly(3-hexylthiophene) and [6,6]-phenyl-C61-butyric acid methyl ester, corresponding to a 600% increase in the EQE in the near-infrared where light is otherwise minimally absorbed. Further numerical simulations indicate this enhanced light coupling and trapping phenomenon to be general; improvements are also predicted for polymer photovoltaics comprising low bandgap polymers. While we demonstrate this concept with polymer photovoltaics, the controlled introduction of compressive stress provides a straightforward and economical route to large-scale patterning of photonic structures for flexible opto-electronics.

9178-9, Session 3

Electrowetting based stationary sun tracking optics

Marco Stefancich, Harry Apostoleris, Carlo Maragliano, Matteo Chiesa, Masdar Institute of Science & Technology (United Arab Emirates)

Mechanically stationary optical tracking of a lightsource (e.g. the sun) can, among other applications, open the path to residential use of concentrator photovoltaics technology with its promise for higher conversion efficiency.

However, for this to happen, Etandue conservation requires some changes in the concentrator optics to combine high concentration with variable acceptance angle. This can be achieved by the use of a system that can be locally switched between a highly reflective to a highly transmissive state.

This can be achieved by electrically moving an index matching liquid inside an array of transparent microchannels, or inside a photonic crystal, thus manipulating the index contrast between the host medium and its content and, consequently, the optical transfer function of the system.

We discuss here the theory behind this optical switch, its possible realization and its use for a mechanically stationary sun tracking system presenting the initial experimental results.

9178-10, Session 3

Highly efficient selective solar absorbers/ emitters based on 2D metallic photonic crystals

Veronika Rinnerbauer, Johannes Kepler Univ. Linz (Austria) and Massachusetts Institute of Technology (United States); Veronika Stelmakh, Yi Xiang Yeng, Yichen Shen, Jay J. Senkevich, John D. Joannopoulos, Marin Soljacic, Ivan Celanovic, Massachusetts Institute of Technology (United States)

Spectrally selective components are critical elements for solid-state thermal-to-electrical energy conversion, such as thermophotovoltaics (TPV), solar-thermophotovoltaic and solar-thermal systems. The key to obtaining high efficiency in this class of high temperature energy conversion is the spectral and angular matching of the radiation properties of an emitter (i.e. sun or thermal radiation source) to those of an absorber (i.e. solar absorber and PV cell). Metallic photonic crystals offer the ability to tailor the photonic density of states and thereby thermal radiation – which allows for the efficient design of such highly selective and highly efficient radiation sources and absorbers.

We demonstrate an integrated double-sided absorber/emitter pair based on 2D PhCs fabricated on a single flat Ta substrate. Both PhCs on absorber and emitter side show broadband low reflectivity at small wavelengths and high reflectivity at long wavelengths, reducing losses due to re-emission at high temperatures, with a sharp cut-off between the two that can be tuned via the PhC geometry. The PhCs are optimized for a solar thermophotovoltaic (STPV) application with high operating temperatures (>1200 K). We demonstrate that at these temperatures, the selective PhC absorber obtains much higher thermal transfer efficiencies, and operates at lower irradiation than blackbody absorbers. Moreover, we propose a solar absorber with a PhC superlattice design achieving broadband high absorptivity and maximum thermal transfer efficiency, and its fabrication by nanoimprint lithography, facilitating precise control of the nanophotonic structures and of the ratio of absorber and emitter area, further reducing losses by re-emission and improving STPV system efficiency.

9178-11, Session 4

Enhanced carrier multiplication in quantum dots through controlled intraband cooling *(Invited Paper)*

Victor I. Klimov, Los Alamos National Lab. (United States)

Carrier multiplication (CM) is a process whereby absorption of a single photon produces multiple electron-hole pairs (excitons). Potentially, it can boost the efficiency of single-junction solar cells to above 40% by increasing the photocurrent. The first spectroscopic observation of efficient CM in PbSe quantum dots, QDs, (Schaller & Klimov, Phys. Rev. Lett., 2004) stimulated fervent activity in this area, including spectroscopic and theoretical studies of multiexciton generation as well as the development of practical devices exploiting CM. This presentation overviews recent progress in understanding CM in quantum-confined nanostructures. Specifically, I will discuss the effect of structural

parameters such as particle size, shape, and composition on CM yields. I will also describe a phenomenological framework for treating CM in terms of two competing energy relaxation pathways, which allows us to rationalize relative variations in CM efficiencies between quantum dots of different compositions, as well as the trends observed during elongation of the nanocrystals (that is, the transition from 0D quantum dots to quasi-1D nanorods). Finally, I will discuss recent efforts on increasing multiexciton production by controlling the competing process of intra-band cooling. This approach can be implemented using, for example, thick-shell PbSe/CdSe quantum dots that demonstrate a four-fold boost in the multiexciton yield compared to standard core-only QDs.

9178-12, Session 4

Exciton transport in colloidal quantum dot solids *(Invited Paper)*

William A. Tisdale, Massachusetts Institute of Technology (United States)

Colloidal quantum dots (QD), also known as semiconductor nanocrystals, are an intriguing material platform for solution-processable optoelectronic devices, such as solar cells, light-emitting diodes, thermoelectric modules, and flexible electronics. In QD thin films, the efficient movement of charge, heat, and excitonic energy is intimately linked to the QD surface chemistry and the amount of structural or energetic disorder in the material. In excitonic solar cells, the efficient diffusion of excitons to charge-separating interfaces is central to device operation. On the other hand, exciton diffusion to quenching interfaces in light-emitting diodes is a process that can limit luminescence efficiency. While the diffusion of singlet and triplet excitons in organic semiconductors has been studied extensively, exciton diffusion in colloidal QD thin films remains largely unexplored. In this talk, I will detail my group's combined experimental and computational efforts to obtain a deeper understanding of excitonic energy transport phenomena in colloidal QD materials. These efforts include spectrally-resolved transient photoluminescence spectroscopy, photoluminescence quenching, time-resolved optical imaging, and kinetic Monte Carlo simulation.

9178-13, Session 4

Recent progress in colloidal quantum dot photovoltaics *(Invited Paper)*

Alexander H. Ip, Edward H. Sargent, Univ. of Toronto (Canada)

Colloidal quantum dots (CQDs) are a unique materials system composed of nanometre scale semiconductor particles synthesized in and processed from solution. This allows the use of CQD inks to be painted onto flexible substrates for rapid, low-cost fabrication of solar cells. Uniquely, CQDs exhibit quantum size effect tunability. This allows the absorption range of CQD films to be tuned, based simply on nanocrystal size, across the entire solar spectrum, including within the infrared range. This makes quantum dots particularly attractive for solar cells in which multijunction approaches utilizing films of various bandgaps can increase photovoltaic efficiencies beyond the Shockley-Queisser limit.

Here we will review the basic concepts, recent advances and future directions in CQD photovoltaics. Since the first reports of CQD based solar cells nearly a decade ago, the power conversion efficiency has increased to over 8%. Progress in materials processing of CQDs has led to reductions in undesirable trap states and contributed to these improvements. Recent developments in doping CQDs have allowed construction of all-CQD quantum junction solar cells. Clever architectures have enhanced device operation and improved absorption of CQD films through photonic and plasmonic effects. Further improvements in this field will draw from materials chemistry, optical enhancements and fundamental physical understanding of CQDs.

9178-14, Session 4

Ultrafast spectroscopy of CuInSeS colloidal quantum dots: Auger recombination, carrier multiplication, and electron transfer

Nikolay S. Makarov, Hunter McDaniel, Istvan Robel, Victor I. Klimov, Los Alamos National Lab. (United States)

Heterojunctions of colloidal semiconductor quantum dots (QDs), and mesoporous titania (mp-TiO_2) are employed in various applications including light-emitting diodes, solar cells, solar fuels, and CO_2 reduction. The efficient separation of electrons and holes at the mp-TiO_2/QD junction is critical for outcompeting various loss mechanisms such as surface trapping.

Here, we investigate optical properties of CuInSeS QDs and QD-sensitized mp-TiO_2 films, which have recently been utilized in solar cells achieving power conversion efficiencies above 5%. We perform systematic transient absorption and time-resolved photoluminescence measurements on QDs with dimensions from 3 to 5 nm to study QD size- and composition-dependence of various excited state processes, including biexciton Auger recombination, carrier multiplication (CM), and electron transfer (ET) to TiO_2. Biexciton decay is found to be similar to that CdSe QDs of the same volume, which supports the assessment of previous reports on the generality of size-dependent trends in Auger recombination in the QDs. CM quantum yields approach 20% indicating that this material could enable photovoltaic efficiencies exceeding the Shockley-Queisser limit. CM threshold though is relatively large, ~3.8 bandgaps, somewhat larger than that in previously reported PbSe and PbS QDs and PbSe quantum rods. Size-dependent ET (20-40 ns time constant) is fairly slow, which highlights the need for efficient suppression of competing nonradiative processes that can be associated, for example, with surface traps in poorly passivated QDs. Yet, high electron extraction efficiency (>95%) can be achieved because in well-passivated CuInSeS quantum dots neutral excitons have significantly longer lifetimes of hundreds of nanoseconds.

9178-15, Session 4

Energy materials: core/shell structural photoelectrodes assembled with quantum dots for solar cells

Jianjun Tian, Shengen Zhang, Univ. of Science and Technology Beijing (China)

In the paper, a photoelectrode made of nanocable core-shell structure of ZnO nanorods (NRs) coated with TiO_2 nanosheets (NSs) was prepared. Anatase TiO_2 NSs with a thickness of ~10 nm and a length of ~100 nm are assembled onto the surface of ZnO NRs via a solvothermal method. The thin shell of TiO_2 shows a remarkable effect on QDSCs by increasing the surface area of ZnO NRs to allow for adsorbing more QDs, which leads to high short current density. Also, the unique material prepared here has an energy barrier that hinders the electrons in the ZnO from being transferred to the electrolyte or QDs, and thus, reduces the charge recombination rate, increases electron lifetime, and enhances open voltage In comparison with the case of ZnO NRs, the short-circuit current density, open-circuit voltage, fill factor, and charge recombination resistance of ZnO/TiO_2 nanocable photoelectrode increase by 3, 44, 48 and 220%, respectively. As a result, a power conversion efficiency of 2.7% in QDSCs with a core-shell structural nanocable photoelectrode has been obtained, which is as much as 230% of that obtained for ZnO NR photoelectrode.

Plasmonic structures to enhance light-harvesting in organic photovoltaic devices *(Invited Paper)*

Wounjhang Park, Univ. of Colorado at Boulder (United States)

This paper presents a review of recent progress in plasmonic nanostructures for enhanced light harvesting in organic photovoltaic (OPV) devices. Specifically, three subjects will be discussed: combined electrical and optical modeling, plasmonic enhancement of sub-gap absorption, and plasmonic enhancement of frequency conversion. Plasmonic nanostructures often exhibit highly non-uniform optical field profile. The resultant non-uniform carrier generation rates could significantly impact the deice performance. By rigorously modeling both plasmonic fields and carrier transport, we show how non-uniform optical fields affect OPV device performance. We then use the model to develop plasmonic nanostructures for enhanced sub-bandgap absorption. The sub-bandgap absorption has been shown to dramatically improve the energy conversion efficiencies of OPV devices. We used a simple and well-controlled plasmonic grating structure to tune the absorption band. Finally, we investigate the plasmon enhancement of frequency conversion. The nonlinear nature of the frequency conversion process leads to much greater enhancement by the plasmonic fields than the linear processes such as absorption and fluorescence. Our study reveals the mechanism of plasmon enhancement of luminescence upconversion process, providing a solid foundation for advanced engineering.

9178-17, Session 5

Scattering of long wavelengths into thin silicon photovoltaic films by silver nanoparticles

Richard M. Osgood, Katherine M. Bullion, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Vladimir Liberman, Richard P. Kingsborough, MIT Lincoln Lab. (United States); Stephen Giardini, Michael Ghebrebrhan, Peter J. Stenhouse, Joel B. Carlson, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Mordechai Rothschild, MIT Lincoln Lab. (United States); Steven E. Kooi, MIT Institute for Soldier Nanotechnologies (United States); Frank Jeffrey, Steven Braymen, PowerFilm, Inc. (United States); John D. Joannopoulos, Owen D. Miller, MIT Institute for Soldier Nanotechnologies (United States); Hardeep S. Gill, Jayant Kumar, Univ. of Massachusetts Lowell (United States)

Nanoparticles and nanostructures with plasmonic resonances are currently being employed to enhance the efficiency of solar cells [1]. Ag stripe arrays have been shown theoretically to enhance the short-circuit current of thin silicon layers [2]. Monolayers of Ag nanoparticles with diameter $d < 300$ nm have shown strong plasmonic resonances when coated in thin polymer layers with thicknesses $< d$ [3]. We study experimentally the diffuse vs. specular scattering from monolayers, sub-monolayer, and bilayer arrays of Ag nanoparticles (spheres and disks with diameters in the range 50 – 300 nm) coated onto the front side of thin (100 nm $< t <$ 500 nm) silicon films deposited on glass and flexible polymer substrates, the latter originating in a roll-to-roll manufacturing process. Ag nanoparticles are held in place and aggregation is prevented with a polymer overcoat. We observe interesting wavelength shifts between maxima in specular and diffuse scattering that depend on particle size and shape, indicating that the nanoparticles substantially modify the scattering into the thin silicon film. Using both simulation and optoelectronic measurements (spectrophotometry, electrical characterization with and without solar simulation), we predict the enhancement of long-wavelength scattering and overall efficiency from thin film silicon and other photovoltaic materials.

Plasmonic rear reflectors for thin-film solar cells: design principles from electromagnetic modelling

Claire E. R. Disney, Supriya Pillai, Craig M. Johnson, Martin A. Green, Qi Xu, The Univ. of New South Wales (Australia)

Nanosphere lithography (NSL) is an inexpensive technique for preparing two-dimensional patterns of nanoscale structures. These structures have been shown to enhance optical absorption in thin films such as those used in novel solar cell designs. NSL can be used to produce regular arrays of nanostructures over large areas with tight control over feature size and array periodicity. Arrays can be formed on a variety of substrates, allowing a range of absorber layer materials to be used.

Finite-difference-time-domain simulations using Lumerical software have been used to model a variety of structures in order to optimize their design for use with solar cells. This has been done by analyzing the generation rate within the absorber layer, calculating the idealized short circuit current normalized to the AM1.5 spectrum, and evaluating the spatial distribution of absorption within the structure.

The structures simulated include those where the nanospheres are removed, leaving a regular array of nanoholes in metal; those where the spheres are retained with a cap of metal over them; and those where the spheres are completely embedded in a metal layer. The performance of these structures was also compared to other rear reflector types or no reflector at all. Design parameters investigated include the metal and absorber layer type and thickness, array periodicity and feature size.

A variety of structures has shown promising increases in short-circuit current relative to other rear reflectors. Further simulations have investigated the sensitivity to semi-random variations to feature sizes within an array with similarly promising results.

9178-19, Session 5

Enhancing solar cell efficiency by lenses on the nano- and microscale

Martina Schmid, Phillip Manley, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

Plasmonics have found their application in solar cells: scattering, near-field enhancement and coupling into guided modes by metallic nanoparticles can help to improve the efficiency [1]. Large scale solar concentrators have allowed the enhancement of solar irradiation by several hundred times thereby boosting the solar cell efficiency to beyond 44% [2]. But what do the concepts of scattering nanoparticles and concentrating optics have in common?

From metallic nanoparticles we turn to dielectric particles and then make the link to concentrator optics looking at lenses on the mircoscale. The nano- and microlenses are investigated with respect to their interaction with light using 3D simulations with the finite element method solving Maxwell's equations as well as by ray tracing calculations. We find distinct similarities in the enhancement principles and will discuss their application to photovoltaics with a particular focus on Chalcopyrite solar cells. Cu(In,Ga)Se2 solar cells have achieved the highest conversion efficiency amongst polycrystalline thin-film materials [3] and thus provide a profound basis for applying novel concepts at the same time looking towards reduced material consumption of the rare element Indium.

9178-20, Session 6

Minority carrier lifetime of thin polycrystalline silicon nanowire films on polycrystalline silicon layer prepared by aluminum-induced crystallization

Tatsuya Yamazaki, Tokyo Institute of Technology (Japan); Shinya Kato, Japan Science and Technology Agency (Japan); Shinsuke Miyajima, Makoto Konagai, Tokyo Institute of Technology (Japan)

The silicon nanowires (SiNWs) film is one of the promising materials for photovoltaic application due to the potential of bandgap engineering and strong optical absorption. However the net surface recombination velocity of SiNWs is very high due to the large surface area. Therefore, the passivation layer which reduces the surface recombination velocity is required for solar cell application of SiNWs films. Conformally-deposited aluminum oxide (Al2O3) by atomic layer deposition (ALD) is suitable for this purpose due to the excellent passivation effect of Al2O3 for crystalline silicon. In this study, we demonstrate minority carrier lifetime measurement of poly-SiNWs films passivated with Al2O3. The poly-SiNWs films were prepared by using solid phase crystallization of amorphous silicon (a-Si) and subsequent metal assisted etching. A polycrystalline silicon template was prepared on a quartz substrate by aluminum induced crystallization (AIC) method. Subsequently, a 1-?m-thick undoped a-Si layer was deposited on the AIC-grown seed layer by RF sputtering. The undoped a-Si layer was crystallized by thermal annealing. Nanowire structure was prepared by metal assisted etching of this polycrystalline silicon layer. The carrier lifetime of bare poly-SiNWs films was unmeasurable due to the very small microwave photoconductance signal, suggesting that surface recombination is very high. On the other hand, the carrier lifetime of Al2O3 post-annealed SiNWs arrays was able to measure and the effective lifetime was found to be 5.76 ?s. This result clearly indicates that ALD- Al2O3 is effective to reduce the carrier recombination at the surface of the poly-SiNWs.

9178-21, Session 6

Influence of substrates on formation of polycrystalline silicon nanowire films

Shinya Kato, Japan Science and Technology Agency (Japan); Tatsuya Yamazaki, Shinsuke Miyajima, Makoto Konagai, Tokyo Institute of Technology (Japan)

There is growing interest in the development of thin film crystalline silicon (c-Si) solar cell. However short circuit current density (Isc) becomes smaller due to the reduction of light absorption for thin film c-Si solar cells. To increase Isc, polycrystalline silicon nanowires (poly-SiNWs) are effective due to its strong light confinement effect. In this study, we investigate the influence of substrates and film deposition techniques on formation of poly-SiNWs films. An undoped amorphous silicon (a-Si) film was deposited on a quartz substrate and a Si wafer (p-type, (100), 2-5 Wcm) by using electron beam evaporation and radio-frequency sputtering. Solid-phase crystallization of the a-Si films were carried out by thermal annealing under forming gas at 900oC for 30 min to form polycrystalline silicon films. These samples were dipped into the solution containing 4.8M HF and 0.001M AgNO3 to form with silver particles on the surface. Subsequently, these samples were chemically etched by using 4.8M HF and 0.15M H2O2 at room temperature. The remaining silver particles were removed by HNO3 etching. The oxide layer on the prepared poly-SiNWs was removed with HF solution. In the case of the electron beam evaporated a-Si on quartz substrates, the formation of poly-SiNWs was not observed and the structure was found to be porous silicon. For the other samples, poly-SiNWs were successfully prepared. These results indicate that substrates and deposition techniques are very important to prepared poly-SiNWs films.

9178-22, Session 6

Effect of tapered shape on performance of silicon nanowire solar cells

Yasuyoshi Kurokawa, Tokyo Institute of Technology (Japan); Shinya Kato, Japan Science and Technology Agency (Japan); Makoto Konagai, Tokyo Institute of Technology (Japan) and Japan Science and Technology Agency (Japan)

The influence of a tapered shape on the performance of SiNW solar cells with the diameter of 1-10 nanometers was investigated using the two-dimensional device simulator with taking bandgap widening owing to the quantum size effect into account. The heterojunction structure of transparent conductive oxide/p-type hydrogenated amorphous silicon oxide/n-type tapered SiNW embedded in SiO2/n-type hydrogenated amorphous silicon/Al electrode was assumed in this calculation. The diameter of the SiNW was changed linearly from the top to the bottom and the length was fixed at 10 um. To introduce the quantum effect into the electrical transport in SiNW solar cells, the Bohm quantum potential (BQP) method was adopted. In this method, we can tune the degree of quantum confinement by varying a proportionality factor (g) of quantum potential.

In the case of g=0, there is little electric field in a neutral region of the tapered SiNW, since the bandgap widening owing to quantum confinement does not occur. On the other hands, strong electric field appeared in the tapered SiNW in the case of g>0. At g=3.7, the bandgap of the SiNW was increased from 1.13 to 4.03 eV with decreasing the diameter of the SiNW from 10 to 1 nm. When there is no electric field in the neutral region and surface recombination velocity (S) on the whole surface of the SiNW increased, open-circuit voltage (Voc) was decreased remarkably. On the other hand, the strong electric field due to quantum confinement suppressed the reduction of Voc regardless of the increase of S. This result suggests that it is possible to reduce the influence of SiNW surface on the performance of the solar cell.

9178-23, Session 6

Fabrication of nano-walls for solar cell application

Yukimi Ichikawa, Hiroshi Tomizawa, Japan Science and Technology Agency (Japan); Shuhei Yoshiba, Masakazu Hirai, Japan Science and Technology Sgency (Japan); Makoto Konagai, Tokyo Institute of Technology (Japan)

We have studied a crystalline Si based tandem solar cell composed of a nano-wall top cell and a conventional p/n junction bottom cell. The effective bandgap of Si increases with decreasing width of the wall by the quantum confinement effect; it is expected that the bandgap increases to 1.5eV or higher when the wall width is narrower than 2nm. Applying these wide bandgap Si to the top cell, we expect higher conversion efficiency. It is, however, very difficult to fabricate such a narrow wall. In this work, we studied how to make nano-walls with a width of several nm by adopting top-down processes.

In the experiment, we used a liquid immersion lithography with ArF laser to make nano-wall patterns on a Si wafer, and obtained line and space patterns with a minimum line width of 50 nm. Then we etched it by a trench etcher to make vertical walls with a height of about 1000 nm. The width of the walls after etching is not narrow enough for the requirement of quantum confinement. Thus, thermal oxidation and oxide etching were repeated to narrow down the width of Si walls. For device application, surface passivation is another important issue. Thermal silicon oxide also works as a support for the nano-walls. Thus at the final step, we left silicon oxide around the walls, and then obtained an array of nano-walls with a width of 1.5-2.0 nm.

We will present the fabrication process of nano-walls in detail, and also some optical properties of the nano-walls such as photoluminescence and reflection.

9178-24, Session 6

Properties of Si/SiO2 superlattice nanodisc array prepared by nanosphere lithography

Takaya Higa, Tokyo Institute of Technology (Japan); Ryousuke Ishikawa, Japan Science and Technology Agency (Japan); Shinsuke Miyajima, Makoto Konagai, Tokyo Institute of Technology (Japan)

We investigated structural and optical properties of amorphous and crystallized silicon based superlattice nanodisc arrays for solar cell applications. Amorphous Si (a-Si)/silicon dioxide (a-SiO2) superlattice was deposited on quartz substrate using radio-frequency reactive sputtering at room temperature. The thickness of the a-SiO2 layer was kept constant at 3 nm. The thickness of the a-Si layer ranged from 1.4 to 8.8 nm. The period of the superlattice ranged from 10 to 200. The transmission electron microscope (TEM) image and the depth profiles of Si and O determined by electron energy-loss spectroscopy (EELS) of a sample clearly show the superlattice structure. Solid-phase crystallization of the amorphous superlattice was carried out by thermal annealing under forming gas for 2 hours at 1000 oC. To form superlattice nanodisc arrays, nanosphere lithography (NSL) was applied for the crystallized superlattice. In the NSL process, silica particles with a 1-um-diameter was employed as an etching mask. The closed packed silica particles were self-assembled by spin-coating on the superlattice surface. By etching of the superlattice with the mask using reactive ion etching (RIE), superlattice nanodisc arrays were successfully prepared. We also found that superlattice with pyramidal or columnar nanostructures can be fabricated by changing etching conditions. The results of optical measurement revealed that nanodisc structure improves the optical absorption in the superlattice. We also compared the optical properties with the simulation results using rigorous coupled wave analysis (RCWA). These obtained results suggest that the nanostructures prepared by NSL are important for optical confinement in the silicon-based superlattice.

9178-25, Session PWed

Enhanced near-infrared response of CdS/CdTe solar cell using Tm3+ and Yb3+ co-doped upconverting glass phosphors

Zhengda Pan, Don Whyte, Steven H. Morgan, Fisk Univ. (United States); Jiaojiao Li, Abdulaziz Alasward, Joseph D. Beach, Colin A. Wolden, Colorado School of Mines (United States)

The sub-bandgap transmission of long wavelength photons results in transmission loss which is a major loss for solar cell with bandgap larger than 1.25 eV. Aiming to reduce the sub-bandgap transmission loss and to overcome the classical efficiency limit of solar cells, Tm3+ and Yb3+ co-doped upconverting (UC) glass phosphors were used to convert near-infrared to visible light incident on a CdS/CdTe solar cell. Current-voltage measurements were performed on the solar cell. A photocurrent enhancement of 31 μA was obtained using the glass phosphor, illuminated by a 980 nm diode at 100 mW. This enhanced response corresponds to external quantum efficiency (EQE) of 0.04 %, which is expected to be increase with improved collection of the UC light. The photo-current observed was proportional to the UC light intensity from the glass UC phosphor. A non-linear relation between the output photo-current and the incident power of the infrared light was observed, similar to the relation between UC intensity and the incident power. UC efficiency of the glass phosphor was calculated using EQE values at both UC wavelength and 980 nm.

9178-27, Session PWed

Development of nanostructured luminophore coating for broadening of solar cell absorption spectrum

Andriy Kryuchyn, Institute for Information Recording (Ukraine); Ievgen V. Beliak, National Taras Shevchenko Univ. of Kyiv (Ukraine)

Design of the solar cells is a hot area of semiconductor physics and material science. One of the major concerns in this area is a substantial shift between the solar radiation spectra and optical absorption spectra of a photoelectric transducer that significantly reduces solar cell efficiency. We propose a concept which based on coating of conventional and cheap photoelectric transducer with a luminophor that transmits longer wavelengths of the sunlight, absorbs shorter wavelengths and converts them to longer ones by the value of the Stocks shift. While photoluminescent light is not collimated and thus losses may reach up to 50% of converted light, it was also proposed to make micropattern formation at photoelectric transducer surface.

We propose synthesizing of specific materials based on composite pyrazoline dyes with addition of polymethylmethacrylate, polystyrene and UV-laquers. It was revealed that synthesized luminophor coating are characterized by sufficiently enough spectral shift (200-400 nm), high quantum yield (near 80%) and stability under circumstances of long term radiation. Further research demonstrated potential of the significant characteristic's improvement by introducing of organic dye molecules in the white zeolite matrix with additional laser annealing at low intensity/ Experimental results have shown that photoluminescent spectrum of pyrazoline dye didn't change shape, bandwidth and amplitude for last 10 years.It was decided that obtained stability is being caused by porous matrix of white zeolite.

Simulation of the solar cell functioning helped to understand physics of the process and simplify problem of microrelief and luminophor optimal parameters search.

9178-28, Session PWed

Photovoltaic properties of copper containing and silver containing diamond like carbon nanocomposites

Sarunas Meskinis, Arvydas Ciegis, Andrius Vasiliauskas, Kestutis Slapikas, Tomas Tamulevicius, Sigitas Tamulevicius, Kaunas Univ. of Technology (Lithuania)

Nanoparticles of the group I metals such as silver, gold and copper received significant huge interest of the researchers due to the strong surface plasmon resonance in these materials. Particularly photovoltaic applications of these nanoparticles include possibility to increase light absorption efficiency of the solar cell active layer due to the light scattering and near field effects as well as direct injection of the plasmonic photoelectrons from the nanoparticles to the semiconductor. Stability of the plasmonic nanoparticles can be increased by using core-shell concept and ultra-thin protective layers. Particularly silver nanoparticle containing nanocomposite can be used for such a purpose. Above all diamond like carbon is good candidate for such application due to the chemical stability as well as good combination of the mechanical, optical and electrical properties. It is possible to grow diamond like carbon nanocomposite containing silver, copper or gold nanoparticles. Surface plasmon resonance effect was reported for these nanocomposites.

In present study copper containing and silver containing diamond like carbon (DLC:Cu and DCL:Ag) films were deposited by reactive magnetron sputtering. Direct current magnetron sputtering and high power pulsed magnetron sputtering was used. Structure and composition of films were studied by Raman scattering spectroscopy, X-ray diffractometry, energy dispersive X-ray spectroscopy and atomic force microscopy. Photovoltaic properties at different excitation wavelengths were investigated. Surface enhanced Raman scattering in DLC:Cu and DLC:Ag films was studied as a measure of the plasmonic enhancement of the electric field. Possible relations with structure, chemical composition and optical properties of the nanocomposites were considered.

9179-1, Session 1

The importance of reliability to the SunShot Initiative *(Invited Paper)*

Shubhra Bansal, Rebecca Jones-Albertus, U.S. Dept. of Energy (United States)

The U.S. Department of Energy's SunShot Initiative aims to make the cost of solar power competitive with conventional electricity sources by 2020. To meet this goal, it is estimated that photovoltaic systems must have a lifetime of 30 years with an annual performance degradation rate of 1%. Accordingly, the actual performance and reliability values are important levers in the cost of solar power. For example, if the annual degradation rate is 0.5% instead of 1%, installed system costs can be 7% higher and still meet the SunShot targets. This talk will further examine the influence of performance and reliability on the levelized cost of solar electricity and the goals of the SunShot Initiative.

The SunShot Initiative and Solar Energy Technologies Office invest over $20 million per year in projects focusing on cell performance, standards and reliability at the National Renewable Energy Laboratory, Sandia National Laboratory as well as universities and industry through the PREDICTS Funding Opportunity Announcement. In addition, many other funded projects have components focusing on reliability. An overview of this work will be presented.

9179-2, Session 1

Overview of the activities of the International PV Module Quality Assurance Task Group 3 on humidity, temperature, and voltage *(Invited Paper)*

John H. Wohlgemuth, Michael D. Kempe, Peter Hacke, National Renewable Energy Lab. (United States)

The Photovoltaic (PV) Module Quality Assurance Task Force is an international organization set up to develop tests that go beyond the IEC PV qualification tests to evaluate wear out of PV modules. The Qualification tests are designed to assure minimum performance and safety standards but are limited by the time and costs allowed for testing. These tests must not be so burdensome as to significantly limit the ability of quality PV modules to enter the market. The QA Task Force aims to develop tests that allow for relevant comparisons of different materials and components of modules as well as the whole modules themselves. A long term goal would be to have a set of tests capable of predicting the service live of PV modules. Task group 3 has been focusing on degradation modes and mechanisms associated with heat, humidity, and high voltage. This has included studying potential induced degradation and moisture ingress modeling highlighting the differences between the results of accelerated stress tests (such as damp heat) and the real use environment. Here we highlight the current activities of the group, our philosophical approach, methodology, recent findings, and future planned work.

9179-3, Session 1

Japanese Task Group 8 activities in international PV module quality assurance *(Invited Paper)*

Keiichiro Sakurai, Akihiro Takano, Masaaki Yamamichi, Hiroko Saito, Masahiko Tomita, Akira Terakawa, Hisanobu Yokoyama, Tadashi Obayashi, Keizou Asaoka, Mika Kambe, Hideki Yoshikawa, Michihiro Takayama, Yuna Koizumi, Shuuji Tokuda, Masayoshi Takani, Michio Kondo, Photovoltaic Power Generation Technology Research Association (Japan)

Activities of Japanese Task Group 8 in International PV Module Quality Assurance are conducted by Photovoltaic Power Generation Technology Research Association (PVTEC) in Japan. Japanese Task Group 8 consists of more than 10 members from Japanese national laboratory and companies.

Japanese Task Group 8 has been discussing difference between conventional damp heat test and outdoor exposure test results. Some results using flexible amorphous silicon modules showed that conventional damp heat test could not duplicate some defects observed in real outdoor field tests. One member, Fuji Electric, reported that "Damp heat and current injection tests" could duplicate some sort of defects observed outdoors. It combines damp heat test?85?, RH=95%?and current injection ?forward current, approx. Ipm?into the module. Current injection may introduce electrochemical reactions in the module under damp heat conditions and generate defects observed outdoors.

Japanese Task Group 8 is going to compare "Damp heat and current injection tests", "Damp heat and photo irradiation tests", and "Outdoor exposure tests" under the cooperation with Task Group 8 in U.S.A. Scope, time frame and progress of Japanese Task Group 8 activities are going to be presented.

9179-4, Session 1

Statistical analysis of degradation modes and mechanisms in various thin-film photovoltaic module technologies

Eric Schneller, Narendra S. Shiradkar, Camila L. Pereira, Neelkanth G. Dhere, Univ. of Central Florida (United States)

PV arrays of various thin film modules technologies such as CIGS, amorphous-Si (glass-glass package) and amorphous-Si (flexible package) have been deployed for over 10 years in hot and humid climate at Florida Solar Energy Center. The performance of selected modules from each array was characterized using visual inspection, dark I-V, flasher I-V, electroluminescence and Infrared imaging techniques. Failure modes such as interconnect failure, solder bond failure, corrosion, and delamination were identified. Failure Mode Effects Analysis was carried out on this data to identify the dominant failure modes and mechanisms in each PV module technology.

9179-5, Session 1

Analysis of the degradation and aging of a commercial photovoltaic installation

Alexander Z. Bradley, Babak Hamzavytehrany, William J Gambogi, DuPont (United States)

Simple and accurate methods are needed to monitor and assess photovoltaic (PV) systems. This becomes increasingly important to characterize and understand the value of the system with regard to safety, performance (including seasonal and geographical variations), and upkeep. It is also becoming important for assessing the secondary or resale value of PV systems. We report the results from an analysis of a commercial c-Si PV array owned and operated by DuPont. Our technical assessment consists of remote monitoring and field inspection with visual examination and thermal imaging to create a pareto chart of degradation modes. Degradation modes became evident as electrical, optical, physical or chemical defects developed with system age. This evaluation provided system data and documented key issues regarding safety and performance. A comparison of remote monitoring and site inspection is presented as well as laboratory analysis (nondestructive and destructive test methods) of modules removed from the service environment.

9179-6, Session 1

Comparison of environmental degradation in Hanwha 295 W and SunPower 320 W photovoltaic modules via accelerated lifecycle testing

Kelly Simmons-Potter, Teh Lai, Ryan P. Biggie, Wei-Jie Huang, Barrett G. Potter Jr., The Univ. of Arizona (United States)

The performance of lifecycle degradation testing of photovoltaic (PV) modules enables the prediction of PV performance lifetimes and return-on-investment for installations of PV systems. With a functional lifetime strongly dependent on field conditions, as well as on materials selection and design, an understanding of the relationship between these interrelated issues and the impact on performance degradation is an important factor in system selection, especially as new PV module designs are developed.

The current presentation will compare the results of an investigation of environmental aging effects in two commercially-available, full-sized, poly- and mono-crystalline Si PV modules. Specifically, we will examine accelerated degradation in a Hanwha HSL72P-PA-0-295K polycrystalline Si module with that of a SunPower 320EL-WHT-D monocrystallline Si module. Lifecycle tests were performed using a full-scale environmental chamber equipped with single-sun irradiance capability, temperature and humidity control. Time-dependent, photovoltaic performance (J-V) was evaluated over a recurring, compressed night-day cycle providing monthly solar insolation, temperature, and humidity conditions that were representative of the southwestern United States. The accelerated test corresponded to one year of exposure in a real-time, fielded module. Temperature and humidity maxima and minima used in the study ranged from 3°C, 32% Rh up to 37°C, 56% to simulate winter and summer extremes. Results show divergence from predicted performance, especially in the case of the monocrystalline Si, in which evidence of delamination was apparent within the first few month-cycles of the test. Initial correlations between accelerated test data and field-test data on similarly manufactured modules will also be discussed.

9179-7, Session 1

Outdoor Performance of CIGS Modules in Different Climates

Kristopher Toivola, Paul F. Robusto, Ajay Saproo, Bill Kessler, MiaSolé HT (United States)

Outdoor Product Reliability Testing for Miasole Glass-Glass CIGS Modules in different external environments is an important aspect is determining the overall product durability and quality. Miasole has implemented outdoor testing in Dry and Hot region (Phoenix, Arizona); Hot and Humid (Miami, Florida); Seasonally Cold with Snowfall (Medina, Ohio) and at Miasole Headquarters in San Clara, CA. Miasole used a second party to perform the outdoor testing except in Santa Clara. We will review the details of the test site setup and racking configuration. The On-Site Implementation that was done to monitor the module performance will be discussed. Also the data transfer and management of the data will be discussed and the methodology used in analyzing the data will be presented. The multi-year performance of Miasole modules will be shown in each of the different test regions.

9179-8, Session 2

Numerical simulation of wind flow over a photovoltaic solar panel using RANS equations *(Invited Paper)*

Andre L. T. Rezende, Leandro F. Chaves, Instituto Militar de Engenharia (Brazil); Neelkanth G. Dhere, Univ. of Central Florida (United States)

The aim of this study is the numerical simulation of wind flow over solar photovoltaic panels. At present there are 113 schools in Florida that use similar 10-kW photovoltaic (PV) solar energy systems installeds on their campus. The PV electricity is fed to the grid and reduces the consumption of grid electericity of the schools. Moreover, these schools serve as disaster relief shelters. During hurricanes or other disasters, grid electricity at the shelters may be interupted for a few weeks. The PV electricity can then serve to provide the minimum critical necessities during such periods. Because of strong winds and hurricanes in this region, it is essential to study the effect of flow of wind on photovoltaic panels. Such study can also be useful to design efficient protectors and supports to guard the panels.

Typicals flows phenomena such as vortex shedding and boundary layer separation may influence the distribution of wind load on PV panels. Because of the similar PV system design and construction, the geometry of the solar panel installations and wind conditions would be similar in the PV systems in 113 Florida schools. The wind speed in critical conditions can reach in excess of 55 m/s. This work consists of a steady state and incompressible flow numerical simulation through the Reynolds Averaged Navier-Stokes equations (RANS). The turbulence closure model uses the shear stress transport (SST) k-w. The main results of the simulations are the pressure and velocity fields that are involved in loads that panels are being subjected to.

9179-9, Session 2

Effect of shading on different PV technologies and how to minimize the impact

Yutao Zong, Arizona State Univ. (United States)

No Abstract Available

9179-10, Session 2

Finite element model simulations for studying the impact of shunts on thin film modules

Frank W. Fecher, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Claudia Buerhop-Lutz, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Macroscopic defects, like shunts, can lower the output power of thin film photovoltaic modules dramatically. Hence, it is important to understand the electrical influence of those shunts within a module and their impact on the module performance. However, detailed experimental investigations are hardly realizable as controlled productions of those shunts are not trivial.

Therefore, we developed a 2D electrical finite element analysis based model and studied the influence of a shunt on the module performance for different parameters (irradiance, shunt resistance, shunt size and shunt position) [1]. Most remarkable is the performance dependence on the shunt position inside the cell (resulting in a variation of up to 25 % for the shunted cell's contribution to the module power). Further investigations with our model showed that the origin of this position

dependence is caused by “circular” lateral currents that spread over the electrode layers of the neighboring cells.

By these investigations a profound understanding of the shunt’s influence in a thin film module is demonstrated. The results will be helpful for the interpretation of electroluminescence or thermography images, e.g. for predicting the output power and open circuit voltage of thin film modules.

Despite the fact that our simulations were designed for CIGS-modules, all results are qualitative valid for other thin film technologies, like CdTe, a-Si or organic photovoltaics.

Effect of shading on the switching of bypass diodes in PV modules

Narendra S. Shiradkar, Eric Schneller, Neelkanth G. Dhere, Univ. of Central Florida (United States); Vivek S. Gade, Jabil Circuit, Inc. (United States)

Bypass diodes are installed in Photovoltaic (PV) modules in order to prevent the application of reverse voltage across the shaded cells in the event of partial shading of the module. Crystalline silicon (c-Si) modules have one bypass diode per 18-20 cells while thin film modules have at most one bypass diode per module. Ideally, bypass diodes are expected to turn on as soon as a current mismatch is detected between various strings of cells inside the module, which typically occurs in the event of partial shading. However, limited information is available on the actual switching characteristics of bypass diodes in field. The presence of hotspots in field deployed c-Si modules despite of working bypass diodes suggests that the diodes may not be turning on whenever necessary. On the other hand, bypass diodes in thin film modules may only turn on in case of rectilinear shadows and may leave the module vulnerable in other types of shading scenarios. This paper presents simulations carried out to study the effect of bypass diode type, shading area and intensity on the switching of bypass diodes in c-Si as well as thin film modules. The simulation results were experimentally verified by measuring the I-V curves of these modules under different shading configurations and bypass diode types.

9179-12, Session 2

Angle of incidence effects on soiled PV modules

Jim Joseph John, Indian Institute of Technology Bombay (India) and Arizona State Univ. (United States); Vidyashree Rajasekar, Sravanthi Boppana, Sai Tatapudi, Govindasamy Tamizhmani, Arizona State Univ. (United States)

The transmission level of the incident light on the photovoltaic (PV) modules depends on the angle of incidence (AOI) and air/superstrate interface. The AOI dependence for the air/glass interface has already been well established. When the glass superstarte is covered by a soil/dust layer, the air/glass interface is altered and hence the AOI dependence will be changed to the air/soil/glass interface. In this work, PV modules retrieved from the field having different dust densities have been measured for the dependence of the AOI curves on the dust densities. It was determined that AOI curve is inversely related to the soil density. The critical AOI for the air/glass interface is about 57 degree and it shifts dramatically as the soil gravimetric density (g/m2) increases. The measured AOI curves were then fitted and validated with the analytical/empirical models reported in the literature.

9179-13, Session 2

Comparison of outdoor-measurement and modeling of the leakage current for potential induced degradation

Michael Köhl, Stephan Hoffmann, Fraunhofer-Institut für Solare Energiesysteme (Germany)

Leakage currents are a necessary but not sufficient indicator for potential induced degradation (PID). The influence of humidity and temperature on the potential induced leakage current has been investigated previously, yielding models for their correlation. Outdoor exposure of modules with high voltage bias in two different climate regions (Freiburg and Canary Island) with monitoring of the climatic data, the module temperatures as well as the leakage currents of the various models were used to evaluate a model for the cumulated leakage charge as function of the climatic parameters and module related parameters.

Combining models for temperature and humidity dependence yields a general model for the leakage current as function of temperature, humidity and voltage, which could be helpful for the outdoor stress estimation:

I = (fprecip *Rain + 1)*Imax /(1+(Imax /c -1)/ exp (Imax ??(rf-a) ? b))

With Imax = U/Ra(358 K) A ??exp [-(Ea / R)?(1/Ttest – 1/358 K)]

Rain is a rain indicator that has the value 1, if it is raining, or otherwise 0.

The integration of the measured leakage current and the comparison with the model is ongoing amount of leakage charge on a day with four hours of rain was 53 times higher in case of module M17 and 29 times higher for module M18 compared to a sunny day. The impact of rain events on the leakage current is very important because of the very good conductivity of water, and has to be taken into account when the progress of PID during outdoor exposure is evaluated for development of appropriate service life tests.

9179-14, Session 3

Research, test, and development activities performed by junction box bypass diode task force # 4 *(Invited Paper)*

Vivek S. Gade, Jabil Circuit, Inc. (United States)

The presentation provides latest update on the activities performed by the task force in the areas such as electrostatic discharge testing and standards, thermal runaway testing and design validation for such testing along with results of field related stress tests. Recommendations on additional tests to be included in the standards for bypass diode related stress testing is also discussed.

9179-15, Session 3

The impact of sodium and potassium incorporation on the degradation of CIGS solar cells

Mirjam Theelen, TNO (Netherlands) and Technische Univ. Delft (Netherlands); Nicolas Barreau, Institut des Matériaux Jean Rouxel (France); Henk Steijvers, Zeger Vroon, TNO (Netherlands); Miro Zeman, Technische Univ. Delft (Netherlands)

The incorporation of sodium and potassium into CIGS leads to enhanced cell performance, but the influence of these alkali on degradation is unclear. Therefore, three types of CIGS cells were prepared with different sodium and potassium contents (high, low and alkali poor) by changing the molybdenum microstructure [1] or adding a SiNx barrier for the alkali poor CIGS. The cells have been degraded in a hybrid damp heat – illumination setup, which allowed continuous in-situ monitoring of the degradation [2].

It was observed that the alkali poor samples had a relatively low initial efficiency, mainly caused by a lower Voc (average 11.4% & 553 mV for alkali free vs 13.2/11.9% & 646/607 mV for low/high alkali content). After 741 hours of degradation, it was observed that the alkali poor cells' efficiency had decreased to 7.8%, while the other cells had average efficiencies as low as 0.6% (low alkali) and 2.5% (high alkali).

In order to better understand the degradation behavior, SIMS measurements were executed on similar samples before and after degradation. It was observed that the sodium had migrated from the CIGS bulk to the CdS/CIGS interface and the ZnO:Al layer. This effect was of course very limited for the alkali poor samples, which is likely linked to the stability of these samples.

Alkali poor CIGS cells are thus much more stable than CIGS containing sodium and potassium.

9179-16, Session 3

Thermal performance of microinverters on dual-axis trackers

Mohammad A. Hossain, Timothy J. Peshek, Yifan Xu, Case Western Reserve Univ. (United States); Liang Ji, Underwriters Labs. Inc. (United States); Alexis Abramson, Roger H. French, Case Western Reserve Univ. (United States)

Time-series insolation, environmental, thermal and power data were analyzed in a statistical analytical approach to identify the thermal performance of microinverters on dual-axis trackers under real world operating condition. This study analyzed 24 microinverters connected to 8 different brands of photovoltaic (PV) modules from July through October 2013 at Solar Durability and Lifetime Extension (SDLE) SunFarm at Case Western Reserve University. Exploratory data analysis shows that the microinverters' temperature is strongly correlated with ambient temperature and PV module temperature, and moderately correlated with irradiance and AC power. Ambient temperature is the dominating factor in low irradiance morning time, where the irradiance is below 60 W/m2. Noontime data analysis reveals the variations of thermal behavior within the same brands of PV modules and microinverters, and suggests that the microinverters thermal trend is more strongly influenced by PV module temperature than AC power. Hierarchical clustering based on Euclidean distance measure principle was applied to noontime microinverters temperature data to group the similarly behaved microinverters. Microinverter temperature clustering shows that the clustering groups are more strongly influenced by PV module temperature than AC power. A linear regression model has been developed based on ambient temperature, PV module temperature, irradiance and AC power data to predict the microinverters temperature connected to different brands PV modules on dual-axis trackers. The difference between actual microinverter and predicted microinverter temperature lies between 0.4°C to 1.6°C at 95% confidence interval.

9179-17, Session 3

The influence of water and atmospheric gases on the degradation of aluminum doped zinc oxide layers

Mirjam Theelen, TNO (Netherlands) and Technische Univ. Delft (Netherlands); Zeger Vroon, TNO (Netherlands); Nicolas Barreau, Institut des Matériaux Jean Rouxel (France); Miro Zeman, Technische Univ. Delft (Netherlands)

Aluminum doped zinc oxide (ZnO:Al) is used in among thin film solar cells, because of its low price, high transparency and conductivity. However, it is known that contact with water leads to decreased transparency and/or conductivity.

We have studied the impact of water and atmospheric gases on the degradation of ZnO:Al.

In order to accelerate the degradation, ZnO:Al samples were exposed to 'damp heat' (85oC/85% relative humidity), to atmospheric gases air, carbon dioxide (CO2), oxygen and nitrogen and to water purged with these gases. The optical, electrical and structural characteristics were analyzed before, during and after degradation.

Damp heat exposure led to decreased mobility and thus conductivity due to increased potential barriers at the grain boundaries.

With the gas/water experiments, we showed that the driving forces behind ZnO:Al degradation is the combined presence of water and CO2, while those species individually barely lead to degradation: exposure to water without CO2 results in a small decrease in mobility, associated with slow diffusion of water down the grain boundaries, possibly forming Zn(OH)2. When CO2 was also present, the optical and electrical properties of ZnO:Al deteriorated very quickly, while a large increase of hydroxide and carbon was observed by SIMS depth profiling. We propose the formation of Zn5(OH)6(CO3)2. We showed that the impact of nitrogen and oxygen on ZnO:Al degradation is very small.

This study can help the optimization of barrier coatings, which should not only function as a water barrier, since porosity for CO2 should be taken into account as well.

9179-18, Session 4

Quantifying PV module microclimates, and translation into accelerated weathering protocols *(Invited Paper)*

Nancy Phillips, David M. Burns, 3M Co. (United States); Kurt P. Scott, Atlas Material Testing Technology (United States)

Long term reliability is not well addressed by current standards for PV modules or components, and developing accelerated stress protocols and test methods to address the wear out of key components is an active area of effort. A first step is to define the actual stresses placed on the module components in various mounting configurations and environments.

In this paper, we address the microclimate issue with the utilization of real world data from hot/dry, hot/wet, and temperate environments, with subsequent analysis to translate the microclimate data into a portfolio of practical weathering machine settings.

9179-19, Session 4

Investigation of the cross-linking of EVA using photoluminescence spectroscopy *(Invited Paper)*

Beate Röder, Rojonirina M. Ralaiarisoa, Jan C. Schlothauer, Humboldt-Univ. zu Berlin (Germany)

EVA foils with different degrees of crosslinking have been investigated using photoluminescence spectroscopy. The luminescence intensity is found to increase monotonously with the degree of crosslinking. The principal component analysis (PCA) is used to investigate whether further information beyond the luminescence intensity is contained in the spectra which may ultimately enhance the precision of crosslinking degree identification. The PCA results show a visible distinction of the different degrees of crosslinking, ordered along the PC1 axis. The data points of the 0%- sample are densely gathered and clearly apart from the data points of the other samples. These latter are more widely distributed. Although the samples with different cross linking degree are distinguishable. Applying a linear correlation between the intensity of the spectral peak at 450 nm, the degree of crosslinking for the EVA investigated here can be determined with an error of about 2% absolute and 12% relative. Enhanced discrimination can be gathered applying to the PCA results the Naive Bayes Classification.

9179-20, Session 4

Predicting edge seal field performance from accelerated testing

Kedar Y. Hardikar, MiaSolé (United States); Daniel J. Vitkavage, Lam Research Corp. (United States); Ajay Saproo, Todd A. Krajewski, MiaSolé (United States)

Degradation in performance of a PV module attributable to moisture ingress has received significant attention in PV reliability research. Assessment of field performance of PV modules against moisture ingress through product-level testing in temperature-humidity control chambers poses challenges. Development of a meaningful acceleration factor model is challenging due to different rates of degradation of components embedded in a PV module, when exposed to moisture. Test results are typically a convolution of moisture barrier performance of the edge seal and degradation of laminated components when exposed to moisture. It is desirable to have an alternate method by which moisture barrier performance of the edge seal in its end product form can be assessed in any given field conditions, independent of particular cell design. In this work, a relatively inexpensive test technique was developed to test the edge seal in its end product form in a manner that is decoupled from other components of the PV module. A theoretical framework was developed to assess moisture barrier performance of edge seal with desiccants subjected to different conditions. This framework enables the analysis of test results from accelerated tests and prediction of the field performance of the edge seal. Results from this study lead to the conclusion that the edge seal on certain Miasole glass-glass modules studied is effective for the most aggressive weather conditions examined, beyond the intended service lifetimes.

9179-21, Session 4

Effect of UV Aging on Degradation of Ethylene-vinyl Acetate (EVA) as Encapsulant in Photovoltaic (PV) Modules

Amir Badiee, Ricky D. Wildman, Ian A. Ashcroft, The Univ. of Nottingham (United Kingdom)

A lifetime of 20-30 years is generally regarded as a necessary for photovoltaic modules to achieve economic break even. As a consequence, understanding how to improve the durability and reliability of the modules is becoming a necessity. Photovoltaic modules are exposed to extremely harsh conditions of heat, humidity, and ultraviolet (UV) radiation which affect the properties of the encapsulant material and cause yellowing, delamination and degradation of the material, which knock on effects on the performance and the long-term reliability of photovoltaic modules. This study addresses the impact of UV on the properties and adhesion strength of Ethylene-vinyl Acetate (EVA). Fourier Transform Infrared Spectroscopy in Attenuated Total Reflectance (FTIR-ATR) mode was performed on aged samples, coupled with peel tests on Glass-EVA-back sheet samples. The samples were exposed to UV light from a xenon lamp at 0.68 W/m2 @ 340 nm with exposure up to 1000 hours. The FTIR-ATR measurement shows significant changes in the absorption at 1740 cm-1, 1720 cm-1 and 910 cm-1 which correspond to acetate, carboxylic acid and vinyl group respectively. It is shown that the UV exposure is the most significant aging factor. The rate of the photooxidation of EVA is compared by measuring the changes of absorbance at 1718 cm-1 with the UV irradiation time. The results of the peeling test show a decrease in adhesion strength of EVA as a result of UV aging.

9179-22, Session 4

Optical properties of PV backsheets: key indicators of module performance and durability

Thomas C. Felder, William J. Gambogi Jr., James G. Kopchick, Alexander Z. Bradley, Babak Hamzavytehrany, T. John Trout, DuPont (United States); R. Scott Peacock, Katherine Stika, DuPont (United States) and CCAS (United States); Abdulkerim Gok, Case Western Reserve University, Solar Durability and Lifetime Extension Center (United States); Roger H French, Case Western Reserve University (United States) and Case Western Reserve University, Solar Durability and Lifetime Extension Center (United States); Oakland Fu, Hongjie Hu, DuPont, China (China)

Polymeric backsheets are an important component affecting the performance and durability of photovoltaic modules. The optical properties of the backsheet should be considered in the design and performance of a photovoltaic module and the stability and durability of optical properties have an impact on power, safety and appearance. We collect data on reflectance, color, yellowness, transmittance and visual appearance initially, after durability testing and then compare these results with those from outdoor exposure. Changes in optical properties in fielded modules and accelerated durability testing are compared. IR spectroscopy is used to better understand chemical composition and changes to materials in the backsheet. This analysis is conducted on various backsheet materials in accelerated durability testing and compared to outdoor performance to better understand the relevant chemical changes and associated degradation mechanisms. The connection between optical properties and chemical changes is discussed.

9179-23, Session 4

Device to analyze leakage current pathways in photovoltaic modules in real-time

Neelkanth G. Dhere, Narendra S. Shiradkar, Eric Schneller, Univ. of Central Florida (United States)

High voltages used in PV systems especially those deployed in the hot and humid climate, have been identified as a contributing factor in long-term performance degradation of the PV system. This performance degradation is attributed to the high voltage between the cell circuit and the module frame. The Florida Solar Energy Center has pioneered the study of system voltage induced degradation also known as potential induced degradation (PID) in the hot a humid climate. Until now, studies have consisted of applying a high voltage between the cell circuit and module frame and measuring the total leakage current flowing through the module packaging materials. Since there are multiple leakage current pathways in the module, this single measurement has not been sufficient to understand the contribution of each leakage path to the total leakage current. It is well known that the choice of packaging materials, including the front glass, encapsulant and back sheet, has a significant effect on the magnitude of the leakage current, but their specific effect on each leakage pathway was not apparent. The results of a device used to measure the impedance of each path in real time are presented, so as to elucidate the effect of packaging materials and their configuration on the leakage current. This information will be useful in minimizing the system voltage induced degradation.

9179-24, Session 4

Chemical depth profiling of photovoltaic backsheets after accelerated laboratory weathering

Chiao-Chi Lin, Peter J Krommenhoek, Stephanie S Watson, Xiaohong Gu, National Institute of Standards and Technology (United States)

Polymeric multilayer backsheet provides protection for the backside of photovoltaic (PV) module from the damages of moisture and ultraviolet (UV). Due to the nature of multilayer, certain materials properties characterizations of each layer after aging in a multilayer backsheet could only be followed from its cross-section parallel to the backsheet thickness direction. In this study, commercial PPE backsheet films were aged on the NIST SPHERE (simulated Photodegradation via High Energy Radiant Exposure) with UV radiation under accelerated weathering conditions of 85°C and different relative humidity (R.H.) of 5 % R.H. (low) and 60 % R.H. (high). Cryo-mcrotome was used to obtain cross-sectional PPE samples with a flat surface parallel to thickness direction, and chemical depth profiling of multilayers was conducted by Raman microscope mapping. AFM quantum nanomechanical mapping technique was used complementarily for cross-sectional imaging. The results revealed that the PPE backsheet films were comprised of five main layers, including pigmented-PET, core PET, EVA, pigmented-EVA and another EVA, along with their interfaces. The UV degradation on the outer pigmented PET layers was clearly observed on the PPE films. The damages of UV and moisture were mostly confined and blocked by the pigmented-PET layer regardless of low or high R.H. The high R.H. exposed pigmented-PET/PET layers showed more significant deterioration caused by hydrolysis comparing with low R.H. Due to PET/EVA interface degradation in high R.H, there was minor moisture damage near the PET/EVA interface in the PET core layer. It was found moisture deteriorated EVA/pigmented-EVA/EVA layers dramatically, and the moisture ingress in EVA layers and their interfaces were significant. Based on the results of accelerated weathering, this study brings new understanding to the mechanisms of failure observed in polymeric multilayer backsheets during field exposure.

9179-25, Session 5

Junction box wiring and connector durability issues in photovoltaic modules *(Invited Paper)*

Juris P. Kalejs, American Capital Energy, Inc. (United States)

We report here on Photovoltaic (PV) module durability issues associated with junction boxes which are under study in Task 10 of the Module Quality Assurance (QA) Program at NREL. A number of failure modes are being identified in junction boxes in PV arrays in the field which have less than 5 years outdoor operation. Observed failure modes include melted contacts and plastic walls in the junction boxes, separated external connectors and broken latches. Standard IEC and UL tests for modules are designed to expose early mortality failures due to materials selection and design in the assembled module and their impact on performance and safety. Test standards for individual junction box components, when not part of a PV module, are still in development. We will give an overview of the reported field failures associated with junction boxes, and examine standard development as it may impact on testing for durability of junction box components over a 25 year life.

9179-26, Session 5

Above 3000 h outdoor stability analysis of organic solar cells applying water-based V2O5 hole transport layer

Gerardo Teran-Escobar, Raphael K. Arfaoui, Anderson de Souza Lima, Monica Lira-Cantu, Institut Català de Nanotecnologia (Spain) and Consejo Superior de Investigaciones Científcas (Spain)

We have synthesized a water-based V2O5 hydrate which was applied as hole transport layer, HTL, in organic solar cells, OSCs. The V2O5 is processed from a water-based solution of sodium metavanadate in air, resulting in a final thin film with a V2O5•0.5H2O formula. Inverted and normal configuration OSCs were prepared applying Ag back metal electrodes in both cases. Outdoor stability analyses showed T80 even after 1000 h of testing. The stability for the normal configuration OSC was better while the inverted configuration required the use of a UV filter in order to reach comparable response. The initial 20 % loss observed after the first 1000 h was attributed to interalyer mixing of the semiconductor oxides with the active layer, as revealed by depth profile Tof-SIMS analyses of the devices. The V2O5•nH2O thin film was also treated at different temperatures (120 °C, 240° C and 350 °C) and we present here the initial 3000 h stability of outdoor analyses which shows high dependency of the temperature treatment of the V2O5 layer.

9179-27, Session 5

Combined-environment influence on microcrack evolution in mono-crystalline silicon

Wei-Jie Huang, The Univ. of Arizona (United States); Zackary Fortuno, Mingyang Li, Univ of Arizona (United States); Jian Liu, Haitao Liao, Kelly Simmons-Potter, Barrett G. Potter Jr., The Univ. of Arizona (United States)

Microcracking, initiated during the processing of Si wafer materials for photovoltaic module production, is a significant contributor to performance degradation with time. Environmental conditions (stress state, chemistry) at the crack tip, have the potential to significantly influence crack propagation rate. Moreover, field-based degradation in encapsulant or backsheet materials and seals can produce time-dependent variations in internal module environment, coupling these degradation modes. A physics and chemistry-based understanding of correlations between environmental conditions and crack propagation characteristics would allow the assessment of this failure mode in the context of module degradation models that could assess performance changes under arbitrary environments.

The present work analyzes microcrack morphology evolution in p-type mono-crystalline Si wafers (280 micron thickness) subjected to static stress conditions under a range of temperatures and relative humidities. A microindenter is used to nucleate microcracks that are then subjected to a static bending tensile stress at the indentation surface of approximately 110 MPa via a custom-designed four-point bend apparatus capable of testing multiple specimens simultaneously. A suite of specimens is subjected to 25 C, 30% RH and 40 C, 70% RH conditions in a controlled environment chamber for up to 128 hours. Acceleration of microcrack propagation in the latter set of specimens is observed via scanning electron microscopy. These early results indicate the impact of local environment on microcrack development and the potential for “stress corrosion” behavior. Subsequent efforts focusing on an analysis of local surface chemistries and more varied environmental conditions and chemistries are now underway.

9179-28, Session 6

Overview of PV module manufacturing quality management system *(Invited Paper)*

Govind Ramu, SunPower Corp. (United States)

A quality management system for PV module production is one of the key elements to secure the long-term reliability of PV modules. This paper describes the key requirements for quality management systems

for PV module manufacturers to produce PV modules which secure the consistency of the design, production and product warranty.

Key requirements in the proposed standard include:

1) Focus on the organization's control of the PV module's design to align the expected lifetime with its relationship to the organization's warranty. Warranty claims must be addressed by product and process design or by financial means.

2) A product realization that includes appropriate certification (e.g. IEC qualification, including both type approval and safety testing), a design lifetime that enables compliance with warranty, and recycling provisions

3) Requirement to improve product traceability through the entire supply and delivery chain to enact positive control of the product for recalls and warranty claims.

4) An ongoing, periodic monitoring program to ensure consistency of aspects of manufacturing that may affect safety, performance, and reliability.

5) Special processes such as control of solder connections, safety tests and assignment of PV module power rating with allowed tolerance.

6) Resources to maintain the product warranty system

7) An electrostatic discharge (ESD) safe environment program, as required for raw material storage, processing, and assembly areas

8) Previous failure information incorporated into the requirements of the QMS

9) A method for selection of vendors that can provide quality materials or products

10) Incoming inspections of materials and sub assemblies

11) Routine tests on 100% of product to ensure consistency of initial quality

12) Manufacturing feasibility at the necessary scale, including risk analysis.

Control plan for solar simulators and how they are used in the performance rating of modules.

14) Use appropriate statistical tools and statistically significant sample sizes to make decisions that affect quality of process and products at all stages of the lifecycle.

15) Use of error proofing, Statistical process Control, control plan, Failure mode effects analysis, and 8 Discipline methodology to build PV modules with consistent quality and reliability.

A novel combined micro- and electro-luminescence characterization platform for PV materials and devices

Francis Ndi, Eric Teboul, HORIBA Scientific (United States)

Non destructive techniques are always an appealing option for characterizing PV materials and devices because they maintain the integrity of the material or device and therefore provide information about its functioning in its natural state without possible introduction of contaminants or other extrinsic effects. Of the available techniques, Photoluminescence and Electroluminescence are two of the popular optical methods for characterizing such devices.

In this paper we present results and describe a novel flexible microspectrometer set up that measures both micro-photoluminescence and electroluminescence from PV materials and devices on the same platform. Its unique design provides a direct coupling of the microscope excitation and emission collection head to the spectrometer providing extremely high throughputs - an attribute that is desirable when dealing with experimental materials and devices that tend to have low emission efficiencies. This platform also offers the flexibility to use different lasers for PL excitation and a luminescence measurement range of 200nm-1600nm and beyond. Furthermore the same platform can be conveniently used for cryostatic measurements for low temperature defect characterization and failure mode analysis.

In the past such measurements have been carried out using a modified imaging microscope couple to a spectrometer either by a fiber or some other means. The problem with this approach is that the microscope is an imaging device often optimized for imaging in the visible range of the spectrum. The optics that are used to correct image aberrations often get in the way of spectroscopy. The system here described solves this problem.

9179-31, Session 6

The vital role of manufacturing quality in the reliability of PV modules

Peter Rusch, SolarBuyer, LLC (United States)

The PV industry has never questioned the importance of design and material quality for the reliability and safety of PV modules. International standards developed by IEC and UL have been used for many years to evaluate the basic design quality of modules.

However, re-developing tests designed to asses design or material quality do not take into account the influence of day to day manufacturing quality on module reliability and performance. The financial crisis in October 2008 was followed by a drastic reduction in the price of PV modules in 2009 and 2010.

At the same time China was investing heavily in manufacturing capacity on the back of huge demand from Germany and Spain. China rapidly became the world's No.1 producer of solar modules. While China was in the midst of rapid expansion and dramatic cost-cuts, little or no attention was paid to manufacturing quality.

To address the lack of objective information about manufacturing quality, SolarBuyer established the industry's first independent technical due diligence structure for PV module manufacturers funded exclusively by investors and buyers. The database has grown to cover over 65 mainstream module manufacturers.

This work has highlighted that manufacturing quality is not consistent among manufacturers, and that quality often bears little correlation to the manufacturers' size or public perception of the brand. It also showed that the proliferation in types of materials and manufacturing methods used by manufacturers has been rapid and vast.

9179-32, Session 6

A review of manufacturing metrology for improved reliability of silicon photovoltaic modules

Kristopher O. Davis, U.S. Photovoltaic Manufacturing Consortium (United States) and Univ. of Central Florida (United States) and CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Joseph Walters, U.S. Photovoltaic Manufacturing Consortium (United States) and Univ. of Central Florida (United States); Marianne P. Rodgers, Univ. of Central Florida (United States); Hubert P. Siegneur, U.S. Photovoltaic Manufacturing Consortium (United States) and Univ. of Central Florida (United States); R. Paul Brooker, Nahid Mohajeri, Neelkanth G. Dhere, Univ. of Central Florida (United States); John H. Wohlgemuth, National Renewable Energy Lab. (United States); Eric Schneller, Narendra S. Shiradkar, Univ. of Central Florida (United States); Andrew C. Rudack, U.S. Photovoltaic Manufacturing Consortium (United States) and SEMATECH Inc. (United States); Winston V. Schoenfeld, U.S. Photovoltaic

Manufacturing Consortium (United States) and CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

The reliability and durability of crystalline silicon (c-Si) photovoltaic (PV) modules is dependent on the manufacturing materials and processes used by the entire supply chain. In this work, we review known failure modes and degradation mechanisms induced during wafer production, cell manufacturing and module manufacturing, and we investigate areas where metrology can be used to improve the reliability and durability by eliminating the probability of such failures occurring. This work is the culmination of a one-year collaboration between the U.S. Photovoltaic Manufacturing Consortium, University of Central Florida, National Renewable Energy Laboratory and DuPont.

Conference 9180: Laser Processing and Fabrication for Solar, Displays, and Optoelectronic Devices III

SPIE. OPTICS+ PHOTONICS SOLAR ENERGY+ TECHNOLOGY

Overview of laser processing in solar cell fabrication *(Invited Paper)*

Neelkanth G. Dhere, Eric Schneller, Univ. of Central Florida (United States); Aravinda Kar, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

This paper will provide an overview of various laser processing techniques used in the fabrication of solar cells. There are numerous applications of lasers that vary based on type of semiconductor used for the cell and the cell architecture, including laser doping, annealing, patterning, drilling and welding. For thin-film polycrystalline semiconductors such as CdTe and Cu(InGa)(SeS)2 laser annealing has been identified as a potential route to high quality devices. Also for thin-film solar cell technologies, including amorphous-silicon, laser patterning has been widely adopted in industrial processing for implementing monolithic interconnections and performing edge isolation. For silicon wafer based technologies there are a number of promising laser processing techniques, however most of these techniques are still in the development stages and are not yet incorporated into industrial production lines. These techniques that represent the next generation of high-efficiency crystalline silicon devices, include laser-fired contacts, laser doping of selective emitters, laser drilling for “wrap-through” device structures, and laser grooved buried contacts. This paper will present a review of each technique, the specific processing applications and the current state of development.

Laser processing of glass for consumer electronics: opportunities and challenges *(Invited Paper)*

Anping Liu, Corning Incorporated (United States)

Laser processing has demonstrated great capabilities for processing the flat panel display glass, strengthened glass, and flexible glass for consumer electronics. In this paper, a variety of laser processing techniques and their applications are discussed. The techniques include glass cutting, drilling, and surface modification. To assess each technique, a matrix of criteria, such as speed, surface quality, strength, and process stability is proposed. Based on the matrix, future needs for laser processing of glass are outlined.

9180-4, Session 1

Laser microprocessing technologies for automotive, flexible electronics, and solar energy sectors *(Invited Paper)*

Suwas Nikumb, National Research Council Canada (Canada); Ravi N. Bathe, International Advanced Research Ctr. for Powder Metallurgy and New Materials (India); George K. Knopf, Western Univ. Canada (Canada)

Laser micro processing technologies offer an important tool to fulfill the needs of many industrial sectors. In particular, there is growing interest in applications of these processes in the manufacturing areas such as printable electronics, solar energy panels and automotive parts fabrication. The technology is primarily driven by our understanding of the fundamental laser-material interaction, process control strategies and the advancement of significant know-how over the past few years. The wide-ranging operating parameters available with respect to power, pulse width variation, beam quality, higher repetition rates as well as precise control of the energy deposition through programmable pulse shaping technologies, enables pre-defined material removal, selective scribing of individual layer within a stacked multi-layer thin film structure, texturing of material surfaces as well as precise introduction of heat into the material to monitor its characteristic properties are a few examples. In this presentation, research results in the area of laser surface texturing of metals for added hydrodynamic lubricity to reduce friction, processing of ink-jet printed graphene oxide for flexible printed electronic circuit fabrication and scribing of multi-layer thin films for the development of photovoltaic CuInGaSe2 (CIGS) interconnects for solar panel devices will be discussed.

9180-5, Session 2

Influence of surface modification by laser beam interference ablation on characteristics of p-Si solar cells

Simonas Indrisiunas, Bogdan Voisiat, Alfonsas Reza, Irena Simkiene, Regina Mazeikiene, Algirdas Selskis, Gediminas Raciukaitis, Ctr. for Physical Sciences and Technology (Lithuania)

Recently, a lot of attention is paid how to increase the solar energy coupling within the active media of a solar cell. The promising mean is the use of photonic crystal structures to couple and localize the solar radiation. We present the results of novel Laser Beam Interference Ablation technique for surface modification of commercial poly-Si solar cells. This technique gives the opportunity of making high resolution structures with the feature size lower then the laser wavelength on the large surface area with only a single laser pulse.

Additional features on the cell surface with the size comparable with the wavelength of visible light affect light propagation in close vicinity to the cell surface. Therefore, diffuse reflection of the textured cells versus the number of laser pulses per exposure area was examined in details. Laser modified solar cells were characterized by scanning electron microscopy, optical and Raman spectroscopy as well as photo-electrically. The structuring of solar cells surface reduced the reflectance of the light up to 14%. Most of those modifications were related with modification in the anti-reflecting passivation layer of SiNx. Simulations on complex light scattering structures provide good agreement with experimental data. Optimization of laser texturing regime provides means to increase light coupling and preserve photo-electrical properties of solar cells. We discuss the influence of the laser process parameters on optical properties of the Si polycrystalline solar cells.

9180-6, Session 2

Laser doping of germanium for photodetector applications

Keye Sun, Yiliang Bao, Mool C. Gupta, Univ. of Virginia (United States)

A method of doping germanium using 1064 nm pulsed fiber laser was

demonstrated. The secondary ion mass spectrometry (SIMS) showed a p-n junction of 800 nm deep with a peak phosphorus concentration of 2?1019 cm-3. Germanium photodiodes were fabricated on the laser-doped p-n junctions. Low bulk and surface leakage values were obtained which were comparable to diodes fabricated by rapid thermal diffusion. Laser doping allows low thermal budget, minimization of surface desorption and selective doping without requiring photolithography. Laser doping was shown to be an effective method for fabrication of electronic and optoelectronic devices.

9180-7, Session 2

Formation of periodic structures on silicon by laser beam interference ablation technique for light control in solar cells

Bogdan Voisiat, Simonas Indrisiunas, Rasa Suzanoviciene, Irena Simkiene, Gediminas Raciukaitis, Ctr. for Physical Sciences and Technology (Lithuania)

Silicon remains as the main material used in solar cell production, because of its low cost, abundance in nature and well-established technologies. However, it reflects considerable part of light due to its high refraction index. Light harvesting pays an important role for further progress to high-efficient solar cells. Texturing of the substrate surface is an efficient method to enhance the light absorption leading to the higher solar-to-electricity conversion efficiency in crystalline silicon solar cells. We present the novel method for silicon surface texturing using the direct laser beam interference ablation in addition with selective chemical etching. This technique enables production of high aspect ration structures on a large surface area with just a single laser exposure. Characterization of laser textured surfaces was performed using SEM, Raman spectroscopy and absorption and reflection measurements. Theoretical simulation of light interaction with such structures was conducted in parallel and was used to adjust laser process for more efficient light harvesting.

9180-8, Session 2

New strategies in laser processing of TCOs for light management improvement in thin-film silicon solar cells *(Invited Paper)*

Sara Lauzurica, Isabel Sánchez-Aniorte, Miguel Morales, Carlos Molpeceres, Univ. Politécnica de Madrid (Spain); Marta Lluscà, Julian López-Vidrier, Sergi Hernández, Joan Bertomeu, Univ. de Barcelona (Spain)

Light confinement strategies in thin-film silicon solar cells play a crucial role in the performance of the devices. One way to reduce these optical losses is the texturing of the transparent conductive oxide (TCO) acting as front contact. On the other hand other losses arise from the mismatch between the incident light spectrum and the spectral properties of the absorbent material. This implies that low energy photons (below the bandgap value) are not absorbed, and therefore can not generate photocurrent. Upconversion techniques, in which two sub-bandgap photons are combined to give one photon with a better matching with the bandgap, has been proposed to overcome this problem.

In particular this work studies two strategies to improve light management in thin film silicon solar cells using laser technology. The first one addresses the problem of TCO surface texturing using fully commercial fast and ultrafast solid state laser sources. In particular AZO and ITO samples has been laser processed and the results has been optically evaluated measuring the haze factor of the treated samples. A comparison of the experimental results with those obtained through numerical modelling of the optical behaviour can lead to a full optimization of the morphological characteristics of the laser treated surface. On the other hand, laser annealing experiments of TCOs doped with rare earth ions are presented as a potential process to produce layers with upconversion properties, opening the possibility of its potential use in high efficiency solar cells.

9180-22, Session 2

Near-field assisted nanoscale patterning for improved absorption in thin film silicon solar cell

Vadakke M Murukeshan, Prabhathan Patinharekandy, Sidharthan Raghuraman, Nanyang Technological Univ. (Singapore)

Optics technology that focuses on energy sector has in the recent past seen the impact of nanoscale patterning, a challenging trend to achieve smaller features or devices with micro- or nano-scale features. This demands automatically the need for achieving much smaller features beyond the forecasted sub- 30nm fabrication methodologies and hence the push for smaller dimension has posed many challenges. In this context, a new branch of near- field optical concepts, such as evanescent wave and plasmonics, for improving patterning resolution has started developing which have been receiving considerable attention for its ability to produce high density sub-wavelength features. The most significant applications of these fundamental physics concepts have been in the applied engineering problems such as improved broad band light absorption thin silicon solar cells. The absorbance of near band gap light is small and hence structuring of thin film solar cell is very important for increasing the absorbance by light trapping. This presentation will cover the above said aspects and the proposed near filed assisted nanoscale patterning concepts and related configurations for achieving improved light absorption and conversion efficiency in thin film silicon solar cells.

The author acknowledges the financial support received through MOE (AcRF Tier1- RG10/34) and NTU-PhotoniTech RCA.

9180-9, Session 3

Using numerical modeling to improve the laser processing of photovoltaic devices *(Invited Paper)*

Todd A. Palmer, Ashwin S. Raghavan, Jared J. Blecher, The Pennsylvania State Univ. (United States); Edward W. Reutzel, Pennsylvania State Univ. (United States); Tarasankar DebRoy, The Pennsylvania State Univ. (United States)

Lasers are widely used in solar cell fabrication, to include the formation of aluminum-silicon ohmic contacts and the doping of selective emitters. The laser-materials interactions governing both of these processes are characterized by rapid heating, cooling, and solidification as well as significant alloying element vaporization and metal expulsion. However, the short time and length scales associated with these processes make it difficult for purely experimental methods to quantify the impact of these phenomena on the resulting properties and device performance. Numerical modeling techniques have been shown to be capable of providing previously unavailable insight into these complex laser-material interactions. For example, easy to use process maps of the fusion zone and heat affected zone profiles for a wide range of processing conditions can be produced to assist users in the proper selection of parameters for optimal device performance. In addition, significant insight into heat and mass transfer mechanisms and the connection between the processing conditions and device performance has been gained. A review of recent efforts in the development and application of numerical heat transfer and fluid flow models will be provided, along with the potential for future advances in the application of these models in new laser-based processing areas.

9180-10, Session 3

Large-scale atomistic simulations of the structural transformations and microstructure development in short pulse laser processing of metals *(Invited Paper)*

Leonid V. Zhigilei, Univ. of Virginia (United States)

In this project we study the ability of short pulse laser irradiation to modify the microstructure and morphology of the irradiated surface.

9180-11, Session 3

Laser processing and in situ diagnostics for crystallization: from thin films to nanostructures *(Invited Paper)*

Jae-Hyuck Yoo, Univ. of California, Berkeley (United States); Jung Bin In, Univ. of California, Berkeley (United States) and Korea Institute of Machinery & Materials (Korea, Republic of); Andy Cheng Zheng, Sang-Gil Ryu, Univ. of California, Berkeley (United States); David J. Hwang, Stony Brook Univ. (United States); Bin Xiang, Univ. of California, Berkeley (United States) and Univ. of Science and Technology of China (China); Andrew M. Minor, Costas P. Grigoropoulos, Univ. of California, Berkeley (United States)

Recent work on laser-induced crystallization of thin films and nanostructures is presented. Characterization of the morphology of the crystallized area reveals the optimum conditions for sequential lateral growth in a-Si thin films under high-pulsed laser irradiation. Silicon crystal grains of several micrometers in lateral dimensions can be obtained reproducibly. The pulsed laser crystallization is also a simple and inexpensive approach for producing circular microrings from a-Si films.

A laser beam shaping strategy is introduced to control the stochastic dewetting of ultrathin silicon film on a foreign substrate under thermal stimulation. Upon a single pulse irradiation of the shaped laser beam, the thermodynamically unstable ultrathin silicon film is dewetted from the glass substrate and transformed to a nanodome. The results suggest that the laser beam shaping strategy for the thermocapillary-induced de-wetting combined with the isotropic etching is a simple alternative for scalable manufacturing of array of nanostructures.

Laser-induced grain morphology change is observed in silicon nanopillars under a transmission electron microscopy (TEM) environment. The TEM is coupled with a near-field scanning optical microscopy (NSOM) pulsed laser processing system. This combination enables immediate scrutiny on the grain morphologies that the pulsed laser irradiation produces. The tip of the amorphous or polycrystalline silicon pillar is transformed into a single crystalline domain via melt-mediated crystallization. The microscopic observation provides a fundamental basis for laser-induced conversion of amorphous nanostructures into coarse-grained crystals.

9180-12, Session 3

Rapid sintering of copper nano ink for thin film transistor application using a laser in air environment *(Invited Paper)*

Jun Ho Yu, Jun Young Hwang, Heuiseok Kang, Kyung-Tae Kang, Korea Institute of Industrial Technology (Korea, Republic of)

Copper nanoparticles are preferred as a printable conductive material in printed electronics because they cost less than noble nano particles such as gold and silver. Only disadvantage is that copper is easily oxidized to Cu2O or CuO, which are much less electrically conductive compared than pure copper. To alleviate these problems, we propose a sintering process using a 532nm DPSS laser in the study. Copper nano ink was spin-coated on the glass substrate, and various irradiated laser powers and scan rates were applied in air environment. The resistivity of the Cu film, after DPSS laser sintering, was below 5.3 μΩcm which was about three times as much as that of pure copper

9180-13, Session 3

Sub-bandgap laser annealing of room temperature deposited polycrystalline CdTe

Brian J. Simonds, Sudhajit Misra, The Univ. of Utah (United States); Naba Paudel, The Univ. of Toledo (United States); Koen Vandewal, Alberto Salleo, Stanford Univ. (United States); Christos S. Ferekides, Univ. of South Florida (United States); Michael A. Scarpulla, The Univ. of Utah (United States)

The manufacturing costs of thin-film photovoltaics have steadily declined to the point where the electrically active thin-films are no longer the cost limiting factor. For instance, in CdTe solar cells the glass substrate is currently the single largest cost component. Lower cost substrates have been investigated but they typically cannot withstand very high temperatures. Therefore, current processing conditions must be modified if these substrates are to be utilized. Laser annealing (LA) further facilitates the use of these substrates by providing direct heating of the films without directly heating the substrate. We investigate room-temperature deposited CdTe and how post-deposition LA can be used to improve its structural and electronic quality. In these studies, continuous-wave, 1064nm laser light is used to anneal CdTe solar cell stacks before back contact deposition. X-ray diffraction studies show that LA reduces the concentration of structural defects associated with stacking faults. Additionally, photothermal deflection spectroscopy measurements show a reduction of sub-bandgap defects due to LA. Since the 1064nm light is only partially absorbed, in situ monitoring of the transmitted light during LA gives information on the annealing process. First principle optical modeling, combined with measured values of optical properties, allows for simulation of the observed transmission behavior. These results reveal an evolution of electronic defect annealing and surface roughness modification with laser exposure time. Two distinct LA regimes emerge: one at low power where electronic defect annealing saturates after about one minute exposure and another at high power where structural defects are annealed after several minutes exposure.

9180-14, Session 3

Laser transfer process for optoelectronic device applications

Mool C. Gupta, Univ. of Virginia (United States)

Laser transfer process has been considered for solar cell and other optoelectronic device fabrication. It can be applied for the formation of metal contacts and achieving doping. This presentation will discuss the laser transfer process mechanism and its examples for solar cell fabrication. It is a direct write process, thus eliminating the need for photolithography. Also, this can be a low temperature process so that wafer quality is not degraded.

9180-15, Session 3

Silicon PV module customization using laser technology for new BIPV applications

Juan J. García-Ballesteros, Sara Lauzurica, Miguel Morales, Univ. Politécnica de Madrid (Spain); Teodosio del Caño, Daniel Valencia, Leonardo Casado, ONYX Solar (Spain); Carlos Molpeceres, Univ. Politécnica de Madrid (Spain)

It is well known that lasers have helped to increase efficiency and to reduce production costs in the photovoltaic (PV) sector in the last two decades, appearing in most cases as the ideal tool to solve some of the critical bottlenecks of production both in thin film (TF) and crystalline silicon (c-Si) technologies. The accumulated experience in these fields has brought as a consequence the possibility of using laser technology to produce new Building Integrated Photovoltaics (BIPV) products with a high degree of customization. However, to produce efficiently these personalized products it is necessary the development of sophisticated laser processes able to transform standard products in customized items oriented to the BIPV market. In particular, the production of semitransparencies and/or freeform geometries in TF a-Si modules and standard c-Si modules is an application of great interest in this market.

In this work we present results of customization of both TF a-Si modules and standard crystalline and multicrystalline silicon modules using laser ablation and cutting processes. A comprehensive discussion about the laser processes parameterization to guarantee the functionality of the device is included. Finally some examples of final devices are presented with a full discussion of the process approach used in their fabrication.

9180-16, Session 4

Selective laser patterning in organic solar cells *(Invited Paper)*

Andreas Ostendorf, Susana Fernandes, Stella Maragkaki, Ruhr-Univ. Bochum (Germany)

Selective laser patterning for integrative serious connection has been industrially established in inorganic thinfilm solar cells based on glass substrates since a few years. In organic solar cells the used materials significantly differ in terms of their patterning behavior. also they are more susceptible to overheating. Especially challenging is the P1 process of TCO patterning on PET substrates due to the huge degree in evaporation temperatures between substrate and thinfilm. Due to their processability by wet chemical methods inverted architectures are often preferred in organic solar cells which allows the patterning by ultrashort laser pulses in substrate and superstrate configuration. Besides the pulse duration the wavelength of the laser is the most important parameter in order to avoid delamination and shoulders of the patterned rim. In our investigations we used a novel NOPA-laser system providing 20 fs pulses in the wavelength range tunable from 500-980 nm. The influence of several patterning parameters on the current-voltage-characteristics is presented.

9180-17, Session 4

Femtosecond laser processing for mobile display manufacturing

Eric P. Mottay, Clemens Hönninger, Amplitude Systèmes (France); Laurie Wilpliez, ALPhANOV (France); Jiyeon Choi, Sung-Hak Cho, Korea Institute of Machinery & Materials (Korea, Republic of); Robert Braunschweig, Amplitude Systèmes (France)

Displays are key components of many of today's mobile electronic devices such as smartphones, digital cameras, mp3 players, etc. As the market for mobile electronics expands, displays are required to fulfil more and more challenging requirements for power consumption, image quality and definition, as well as robustness.

The next generation of mobile displays offers a wider color gamut, better image contrast and lower power consumption. They also benefit from wider viewing angles, faster response and more compactness due to their thin multilayer architectures. New technologies, such as flexible displays, make extensive use of organic LEDs technology (OLED), and present significant manufacturing challenges. Production yield for such displays are currently very low; due to the complexity and the multilayer structure of the displays (up to 20 different materials). Many units come out of the production line with defects and are then discarded. The presence of dead, over-bright pixels and other imperfections are considered unacceptable in such a high added-value consumer item. As the technology extends to larger volumes and large panel displays, better production yield become critical for display manufacturers. Current laser processing technologies face limitations such as the sensitivity of organic material to heating and the low thickness of thin film layers.

Femtosecond lasers allow non-thermal ablation of materials, owing to the extremely short interaction time of the laser-matter interaction. Therefore machining precision can be significantly improved using femtosecond laser ablation as heat affected zone and debris generation is greatly reduced. In addition, non-thermal process is crucial for selective removal of multi-layer organic polymers that are susceptible to heat.

9180-18, Session 4

The effect of film properties and laser processing parameters on the laser ablation of molybdenum thin films

Eric Schneller, Rafael Rodrigues, Neelkanth G. Dhere, Univ. of Central Florida (United States); Aravinda Kar, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Molybdenum is commonly used as the electrical back contact for Cu(InGa)(SeS)2 thin-film solar cells. In order to create a monolithically interconnected device, scribing of the molybdenum layer is required. This scribe, known as the P1 scribe, is commonly carried out through laser processing. Optimization of this laser scribing has been carried out using a 532nm pulsed Nd:YAG laser. It was found that two specific regimes of processing resulted in defect free scribes. These regimes are low fluency and high pulse overlap, and high fluency and low pulse overlap. Film properties, including the microstructure, surface oxidation, and internal stress, were studied to understand their effect on the laser ablation process. It was observed that a thin layer of oxidation resulted in significant heat affected zone during the laser ablation process. A discussion of the optimal film properties and laser processing parameters is presented.

9180-19, Session 4

Laser-assisted processing of current and next generation transparent electrodes

David J. Hwang, Pyung-Cho Han, Hwan Lee, Andrew Mann, Tao Zhang, Stony Brook Univ. (United States)

Transparent conductive electrode is a critical component to realize modern optoelectronic devices including display, touchpad, and solar cells. While the most commonly used transparent electrode up to date is indium tin oxide (ITO) due to its superior optical transparency and electrical conductance, its brittleness and lithographic difficulty have posed a major challenge in manufacturing cost-effective flexible devices.

In this study, we attempt to address the aforementioned issues on the patterning of ITO film on flexible polymer substrate by direct scribing processes using short pulsed lasers. Laser parameters are rigorously tested to achieve desirable performance in terms of electrical isolation, minimal substrate damage and low degree of film delamination, considering fundamental thermo-mechanical aspects. In addition, thin coating layer of nanomaterials such as silver nanowires and carbon nanotubes is an emerging transparent electrode alternative for the next generation devices, due to its unique optical and electronic properties and low material cost. We will also report improved electrical performance by enhancing local connectivity within nanomaterials network utilizing a unique enhancement mechanism of laser field in the nanomaterials system.

9180-20, Session 4

Patterning of OPV modules by ultrafast laser

Peter Kubis, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Luca Lucera, Bayerisches Zentrum für Angewandte Energieforschung e.V. (Germany); Fei Guo, George Spyropolous, Monika M. Voigt, Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

In the last decade, the interest in the printable thin-film flexible organic photovoltaics (OPV) has increased enormously. Typically, photovoltaic technologies and especially OPV panels require sectioning into multiple in series interconnected cells. These interconnections can be realized with the help of 1- or 2-dimensional coating techniques but are limited in resolution. This leads to a considerable waste of the solar cell area because the interconnection area does not contribute to the photocurrent generation. However, the unique properties of ultrafast lasers are being increasingly used for material processing applications utilizing efficient, fast and localized energy deposition which leads to high ablation efficiency and accuracy in nearly all kinds of solid materials. We demonstrate a novel production process utilizing the properties of ultrafast laser ablation for OPV panels with unprecedented high module geometrical fill factor (GFF). With the combination of a precise laser beam positioning system and an ultrafast laser source operating in femtosecond regime a GFF of 97 % was reached. Further utilization of very well established slot die coating and remarkable IMI (ITO-Metal-ITO) flexible transparent electrodes allows P3HT:PCBM based large area flexible modules with high GFF and an overall efficiency exceeding 3 %. A variety of OPV module architectures like tandem and semitransparent devices are possible with the help of a sustainable and systematical procedure for the definition of ablation parameters.

Conference 9181: Light Manipulating Organic Materials and Devices

Wednesday - Thursday 20–21 August 2014

Part of Proceedings of SPIE Vol. 9181 Light Manipulating Organic Materials and Devices

9181-1, Session 1

Nonlinear absorption and refraction spectroscopic tools *(Invited Paper)*

Eric W. Van Stryland, Honghua Hu, Trenton R. Ensley, Matthew C. Reichert, Manuel R. Ferdinandus, David J. Hagan, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

We have a long history of developing techniques for the nonlinear characterization of materials. Recent work has been aimed at alleviating problems of removing background signals from solvents and substrates as well as increasing sensitivity to nonlinear refraction (NLR). In addition we are always looking for ways to increase the data rates to allow more rapid nonlinear spectroscopic measurements for absorption and refraction. Our interest is to measure both frequency degenerate and nondegenerate data.

The long-standing difficulty of measuring nonlinear refraction of solutes in low concentration solutions has been greatly reduced with the development of the Dual-Arm (DA) Z-scan techniques (ref..) which is a differential Z-scan method allowing the real-time subtraction of the solvent nonlinear refraction signal. This has increased our signal-to-noise for measuring the solute NLR by an order of magnitude.

While the Z-scan has been shown to be sensitive to NLR for optical phase distortions as small as ~10-3 waves, the EZ-scan and other variations have demonstrated sensitivities of 10x better; however, these techniques are considerably more difficult to implement. We recently introduced a new method for ultrafast NLR measurements based on the well-known photothermal beam deflection technique. We quickly found that this method was sensitive to better than 10-4 waves of phase distortion, and we are currently looking into ways to use this for rapid nonlinear dispersion measurements using white light continuum probes.

We will report on these techniques as well as some findings on various materials studied using them.

9181-2, Session 1

Thermal lensing characterization of absorption in nanodiamonds *(Invited Paper)*

Aristides Marcano, Gour S. Pati, Renu Tripathi, Yury Y. Markushin, Junwei Meng, Michael J. Williams, Delaware State Univ. (United States)

This paper reports on absorption properties of nanodiamonds of different dimensions and different concentrations of nitrogen vacancy centers. The absorption properties are measured using a photothermal lens method in the continuous wave and pulse regimes. The scattering-free character of this technique allows us to directly measure the amount of heat resulting from the absorption of electromagnetic radiation. Experiments are conducted using diode lasers at 445 nm and 670 nm for the continuous wave case, and a 1064 nm 20 ns Nd-YAG laser for the pulse regime. We use a pump-probe mode-mismatched experimental configuration where the pump beam is focused and the probe beam is collimated. We perform photothermal lens Z-scan experiments to improve the calibration of absorption and to determine the possible presence of nonlinear absorption in the sample. By comparing the results of the photothermal experiments with the conventional transmission-absorption method, we provide values for the quantum yield of scattering for the diamond nanoparticles.

9181-3, Session 1

Engineering the ground- and excited-state absorption spectra of broadband reverse saturable absorbers

Timothy M. Pritchett, Michael J. Ferry, William M. Shensky III, Andrew G. Mott, U.S. Army Research Lab. (United States); Chengkui Pei, Wenfang Sun, North Dakota State Univ. (United States)

In applications involving organic dyes exhibiting broadband reverse saturable absorption (RSA), it is frequently desirable to minimize the variation in strength of the dyes' linear absorption over the spectral range relevant to the application. At the same time, one would also like to maintain, if not increase, the strength of the dyes' excited-state absorption—which in many materials is already quite broad and relatively flat—over the same spectral range. Many square-planar platinum(II) complexes that exhibit RSA display linear absorption spectra featuring a low-energy tail that extends from the green region of the visible spectrum into the red or near-infrared and arises from singlet metal-to-ligand charge transfer (1MLCT) / ligand-to-ligand charge transfer (1LLCT) transitions. In an effort to "flatten" this absorption tail, we synthesized a series of octahedral iridium(III) complexes in which strong spin-orbit coupling induced by the iridium ion enables various singlet and triplet metal-to-ligand and ligand-to-ligand charge transfer (1,3MLCT/1,3LLCT) transitions. These give rise to a weak absorption tail between 500 and 750 nm which displays a slight "bump" in range 600-650 nm (in dichloromethane solution). The bump serves to broaden into the red the region over which single-photon absorption is sufficiently strong to populate the excited states. We discuss the design of the new chromophores, present their ground- and excited-state absorption spectra, report their photophysical parameters as determined from nanosecond and femtosecond transient difference absorption measurements and nanosecond and picosecond open-aperture Z scans, and employ these results to infer structure-property relationships for the new materials.

9181-4, Session 1

Synthesis of dual NIR two-photon absorptive [60]fullerenyl multiadducts for nonlinear light-transmittance reduction application

Seaho Jeon, Min Wang, Taizoon Canteenwala, Univ. of Massachusetts Lowell (United States); Loon-Seng Tan, Air Force Research Lab. (United States); Wei Ji, National University of Singapore (Singapore); Thomas M. Cooper, Air Force Research Lab. (United States); Long Chiang, Univ. of Massachusetts Lowell (United States)

We apply a novel molecular wrapping approach to fullerenyl hybrid triads to minimize solid aggregation in coating applications. Several C60-(antenna)x and C70-(antenna)x analogous compounds having branched hybrid triad C60(>DPAF-C18)(>CPAF-C2M) and tetrad C60(>DPAF-C18)(>CPAF-C2M)2 nanostructures, for example, were synthesized and characterized. The structural design was intended to facilitate the ultrafast fs intramolecular energy-transfer from photoexcited C60[>1(DPAF)*-C18](>CPAF-C2M)1or2 or C60(>DPAF-C18)[>1(CPAF)*-C2M]1or2 to the C60> cage moiety upon two-photon pumping at either 780 or 980 nm, respectively. The latter nanostructure showed approximately equal extinction coefficients of optical absorption over 400?550 nm that corresponds to near-IR two-photon based excitation wavelengths at 780?1100 nm for broadband nonlinear optical (NLO) applications. 2PA characteristics of these nanostructures at multiple NIR wavelengths provided support for their suitability in uses that includes

the 2PA ability of two antenna, DPAF (700?850 nm) and CPAF (850?1100 nm), and the fullerene cage at shorter wavelengths (600?700 nm).

9181-5, Session 1

Entangled two-photon absorption and virtual-state spectroscopy in diatomic molecules

Leslie Upton, Theodore G. Goodson III, Univ. of Michigan (United States)

As computational methods and experimental designs seek to utilize quantum theory to probe molecules, there is a need for more experimental and theoretical data for entangled two-photon absorption processes. With the use of nonclassical fields, we hypothesize that entangled photons can differentiate between differing absorption mechanisms of a molecule. Molecules that absorb photons via a virtual state do absorb entangled photons, while those that absorb via a permanent dipole do not. In order to explore this further, we utilize a modified entanagled two-photon absorption cross-section to compare homonuclear and heteronuclear diatomic molecules. For this study, we compare the entangled two-photon absorption cross-sections in N2 and NO.

9181-6, Session 2

Exciton fission in organic semiconductors *(Invited Paper)*

Xiaoyang Zhu, Columbia Univ. (United States)

The absorption of one photon by a semiconductor material usually creates one electron-hole pair, but this general rule breaks down in a few organic semiconductors, such as pentacene and tetracene, where one photon absorption may result in two electron-hole pairs in a process called singlet exciton. Recent measurements in our group by time-resolved two-photon photoemission (TR-2PPE) spectroscopy in crystalline pentacene and tetracene provided the first spectroscopic signatures in singlet fission of a critical intermediate known as the multiexciton state. More importantly, population of the multiexciton state is found to rise concurrently with that of the singlet state on the ultrafast time scale upon photo excitation. This observation provides an experimental foundation for a quantum coherent mechanism in which the electronic coupling creates a quantum superposition of the singlet and the multiexciton state immediately following optical excitation. We demonstrate the feasibility of harvesting the multiexciton state for multiple charge carriers or the triplets. We outline a set of design principles for molecular materials with high singlet fission yield and for the implementation of singlet fission in solar cells with power conversion efficiency beyond the Shockley-Queisser limit.

9181-7, Session 2

Ultrafast infrared spectroscopy of charge generation and transport in organic photovoltaic materials *(Invited Paper)*

John B. Asbury, Adam D. Rimshaw, The Pennsylvania State Univ. (United States)

Ultrafast infrared spectroscopy is used to examine electronic processes in organic photovoltaic (OPV) materials. We examine archetypal classes of electron acceptors in OPVs and reveal how their molecular structures determine whether hot CT state dissociation can influence the dynamics and yield of photo-generated electrons and holes. Furthermore, we tune the degree of aggregation and therefore charge carrier delocalization in OPV materials and elucidate the corresponding influence on the yield of photogenerated charge carriers in state of the art functional OPV materials and devices. The findings reveal that enhancing the degree of carrier delocalization leads to more efficient charge generation on time scales that are competitive with internal conversion to the excited state free energy surface minimum.

9181-8, Session 2

Molecular pixel system for full-color fluorescence generation *(Invited Paper)*

Soo Young Park, Seoul National Univ. (Korea, Republic of)

Current technology of color generation is based on the mixing of RGB colors emanating from different light sources and/or pixels. Unfortunately, simple mixing of RGB emitter molecules cannot provide the desired color mixing since the energy transfer between the RGB molecules are universal and unavoidable, which demands macroscopically isolated sub-pixels for the color mixed pixel. If we can find a way to completely block the energy transfer between different RGB molecules, it will make a Holy Grail for the color mixing in the molecular level. In this presentation, I will demonstrate this innovative concept of ‘molecular pixel’ which has recently been realized in my group by using functional molecules harnessing the process of excited-state intramolecular proton transfer (ESIPT).

Quantifying singlet fission in novel organic materials using nonlinear optics

Erik Busby, Jianlong Xia, Omer Yaffe, Bharat Kumar, Timothy Berkelbach, Columbia Univ. (United States); Qin Wu, John Miller, Brookhaven National Lab. (United States); Colin P. Nuckolls, Xiaoyang Zhu, David R. Reichman, Luis Campos, Columbia Univ. (United States); Matthew Y. Sfeir, Brookhaven National Lab. (United States)

Singlet fission is a form of multiple exciton generation in which two triplet excitons are produced from the decay of a photoexcited singlet exciton. In a small number of organic materials, most notably pentacene, this conversion process has been shown to occur with unity quantum yield on sub-ps timescales. However, a poorly understood mechanism for fission along with strict energy and geometry requirements have so far limited the observation of this process to a few classes of organic materials, with only a subset of these (most notably the polyacenes) showing both efficient fission and long-lived triplets. Here, we utilize novel organic materials to investigate how the efficiency of the fission process depends on the coupling and the energetic driving force between chromophores in both intra- and intermolecular singlet fission materials. We demonstrate how the triplet yield can be accurately quantified using a combination of traditional transient spectroscopies and recently developed excited state saturable absorption techniques. These results allow us to gain mechanistic insight into the fission process and suggest general strategies for generating new materials that can undergo efficient fission.

9181-10, Session 3

Ferroelectric liquid crystalline columns towards paintable organic ferroelectrics as characterized by nonlinear optics *(Invited Paper)*

Fumito Araoka, Daigo Miyajima, RIKEN (Japan); Takuzo Aida, The Univ. of Tokyo (Japan); Hideo Takezoe, Tokyo Institute of Technology (Japan)

Recently, we have discovered a novel ferroelectric liquid crystal (ferroelectric columnar LC: FCLC) phase in a self-organization system of polar stacks of tapered-paraffinic-wedge molecules. Its molecular design

allows hydrogen bonding among amide groups to connect the umbrella-like conical units of molecules, where the spontaneous polarization is stabilized because cyano-groups owing strong permanent dipole moment are pushed up along the columnar axis by strong binding force of the hydrogen bonding. This material system offers highly transparent and flat thin films with solution-based wet-process followed by electric field application such as corona poling, and hence may open the possibility of "paintable soft-matter nano-ferroelectrics"

Ferroelectricity in these wet-processed films was visualized with a relatively new nonlinear optical imaging technique, interferometric second-harmonic generation (SHG) microscopy, enabling the mapping of the distribution of the spontaneous polarization as well as its directional sense. Besides, detailed switching behavior of the system was discussed with SHG response together with classical electric measurements.

Stabilization mechanism of the spontaneous polarization and molecular dynamics of the ferroelectric switching have been investigated also with a nonlinear optical technique, visible-infrared sum-frequency generation (SFG) spectroscopy to probe resonant vibrational modes of molecular moieties packed in a non-centrosymmetric manner hereby contributing the ferroelectricity. These results are very important for further molecular design, particularly towards practical application.

9181-11, Session 3

Enhanced photoconductivity by melt quenching method for amorphous organic photorefractive materials

Sho Tsujimura, Kyoto Institute of Technology (Japan) and RIKEN (Japan); Takashi Fujihara, Takafumi Sassa, RIKEN (Japan); Kenji Kinashi, Wataru Sakai, Kyoto Institute of Technology (Japan); Koji Ishibashi, RIKEN (Japan); Naoto Tsutsumi, Kyoto Institute of Technology (Japan)

For many optical semiconductor field of study, high photoconductivity of amorphous organic semiconductor has strongly been desired to easily provide high device performances. This study is focused on a correlation between photoconductivity and bulk structures in amorphous organic photorefractive materials to probe the nature of the performance of photoconductivity.

The transient photocurrent experiments were carried out to evaluate the photoconductivity for two kinds of photorefractive (PR) sandwich cells fabricated through different cooling processes. PR composite films were consisted of photoconductive polymer, nonlinear optical dye, plasticizer, and sensitizer. PR composites sandwiched between two indium-tin-oxide glass plates on a hot plate were quenched or slowly cooled.

At the initial time of the transient photocurrent, the quenched sample exhibited higher photocurrent density than slowly-cooled one. This enhancement of photocurrent in quenched sample is due to an increase of carrier mobility and/or quantum efficiency. Thus, high performance of photorefractivity of quenched sample is expected. The quenched sample exhibited higher dielectric constant, which may give the proof of the difference of the bulk structures between quenched and slowly-cooled samples.

In conclusion, sample processing, in this case quenching and slowly cooling, for PR composites significantly relates to the photoconductive properties and thus PR performance of both samples will be differed. This processing method will be utilized in other amorphous organic PR materials to improve photoconductivity and photorefractivity.

9181-12, Session 3

Large optical second harmonic generation in a low-bandgap polymer

Maarten K Vanbel, KU Leuven (Belgium); Stefaan Vandendriessche, Pieter Willot, Guy Koeckelberghs, Thierry Verbiest, Katholieke Univ. Leuven (Belgium)

Recent research has focused on developing low-bandgap polymers for harvesting solar energy. Desirable properties including high power conversion efficiency, high quantum yields, high carrier mobilities and broad light absorption have been fine-tuned in these polymers. The resulting low-bandgap polymers display many advantages over classical materials, including low cost, light weight and easy processability. Research has focused on optimizing these properties, and as a result little attention has been paid to their nonlinear optical properties. For nonlinear optical applications the material must display low losses in the relevant wavelength range, as well as exhibit good thermal and temporal stability under the high incident laser powers typical of nonlinear optical experiments. We characterized the optical second harmonic generation of corona poled films of poly(cyclopenta[2,1-b;3,4-b'] dithiophen-4-ylidenedioctylmalonate). Despite the fact that this polymer is known to be amorphous, not displaying any form of order, we observed large nonlinear optical susceptibilities in these films. Coupled with the thermal and temporal stability of the polymer films, this unexpectedly large nonlinear optical response compares favorably to other novel nonlinear optical materials despite the lack of a typical donor-acceptor dye. The low absorption in the relevant wavelength region of the polymer is an additional advantage. Our results show the promise of low-bandgap polymers for nonlinear optical applications, opening an unexplored category of materials for nonlinear optical applications.

9181-13, Session 3

Dynamic amplification of light signals in photorefractive ferroelectric liquid crystals

Takeo Sasaki, Yumiko Naka, Tokyo Univ. of Science (Japan)

The photorefractive effect in photoconductive ferroelectric liquid crystals (FLCs) that contain photoconductive chiral compounds was investigated. Terthiophene compounds with chiral structure were chosen as the photoconductive chiral compounds and mixed with an achiral smectic C liquid crystal. The mixture exhibited the ferroelectric chiral smectic C phase. The photorefractivity of the mixture was investigated by two-beam coupling experiment. It was found that the FLC containing the photoconductive chiral compound exhibit a large gain coefficient of over 1200 cm-1 and a fast response time of. 900 microseconds. Optical image amplification was demonstrated. A laser beam carrying a moving image of the animation was amplified dynamically by the incident pump beam.

Photo-patterning system investigating acrylate-based resin viscosity versus polymerized structure resolution

Callie I. Fiedler, Univ. of Colorado at Boulder (United States)

Three-dimensional (3D) projection stereolithography (SLA) is a common photo-patterning tool used to fabricate diverse structures ranging from biological tissue scaffolds to micro-electromechanical systems (MEMS) using a variety of polymerizeable resins. To meet the continuing expansion of SLA applications, existing approaches must be improved in material versatility, structure fidelity, and fabrication time. Resin viscosity impacts nearly all performance specifications of SLA including attainable resolution, fabrication speed and efficacy of monomer removal via solvent. To achieve maximum resolution in an SLA system, it has been hypothesized that more viscous resins lead to enhanced feature resolution by increasing monomer diffusion time. Highly viscous organic resins (> 500 cps) cannot be easily removed from systems without damaging the photopolymerized structure. We investigate the trade-off between resin viscosity and transverse feature resolution using an enclosed, single photon SLA system. The viscosity of the acrylate-based resin is modified using plasticizers and binders to reduce and increase the resin viscosity, respectively. We control axial resolution using a silane-functionalized, polymerization-inhibiting window as a substitute for the typical blade system, thus allowing for arbitrary layer thicknesses. We also demonstrate structures fabricated using a syringe-pump

deposition method that not only conserves the amount of resin required for fabrication, but also allows for simple fabrication of multi-material structures.

9181-34, Session PWed

Self-actuated origami in an optically pre-patterned two-stage photopolymer

David J. Glugla, Robert R. McLeod, Univ. of Colorado at Boulder (United States)

Origami, traditionally seen only in the context of art, has recently gained popularity as a design tool for creating complex structures from simple and compact precursors. Realization of these complex objects is achieved via a two-step process of programming an initial crease pattern into the material, followed by actuation or folding. We explore this design procedure using a two-stage photopolymer sheet created via a base mediated Thiol-Michael click reaction, whereby the material crosslink density and modulus may be spatially programmed via a series of optical exposures. Although self-actuation has been demonstrated in a variety of materials, they typically require a complex array of actuators to effect the desired fold pattern. Using the ability to modify the crosslink density and modulus of a two-stage polymer, a complex crease pattern, consisting of stiff, high modulus glassy panels and soft, flexible hinges may be prepatterned into the polymer sheet via a simple series of photopatterning steps. Self-actuation and folding may then be achieved via swelling of the low crosslink density hinges. Control over the folding direction is realized by creating a gradient in the crosslink density through the depth of the polymer sheet. In order to extend this technique, we also explore the utility of numerical optimization techniques in designing the preprogrammed crease patterns and modeling the material behavior.

Design, synthesis, and optical properties of porphyrin-peptoid conjugates

Jiwon Seo, Gwangju Institute of Science and Technology (Korea, Republic of)

Porphyrins, a class of naturally occurring pigments, have been actively investigated due to their wide applications ranging from photosensitizers to new optoelectronic materials. In particular, much effort has been made to construct a defined arrangement of porphyrins. To date, most of the porphyrin displays are focused on two porphyrin π planes arranged in a side-by-side manner. In contrast, fewer face-to-face arrangement of porphyrins are reported possibly because of the lack of an efficient scaffolding material and synthetic accessibility.

Herein, we present an efficient strategy for (1) face-to-face arrangement of porphyrins, and (2) multivalent display of porphyrins on peptoid (or oligo-N-substituted glycine) helices. Distance, orientation, and numbers of porphyrins are precisely defined, which results in distinct optical and self-assembly properties of the porphyrin-peptoid conjugates. The conjugates will be useful for understanding the optoelectronic behavior of porphyrins and potentially for the development of an artificial light-harvesting system.

A toy model for the nonlinear optical response of molecules with modulated conjugation

Javier Perez-Moreno, Surbhi Hablani, Quanhang Chen, Jie Li, Skidmore College (United States)

In organic molecules, the optical response originates from the motion of the pi-electrons, which are constrained to move along the molecule's conjugated path. As an electron moves through the conjugated path it interacts with the rest of the charges such as its motion is very dependent on the shape of the molecule, and specifically on the shape of the conjugated path. Previous research indicated that to improve the second order nonlinear optical response, it is best to use different kinds of spacers along the conjugated path. In this paper we introduce a simple model that allows us to evaluate how different arrangements of spacers will influence the molecule's nonlinear optical properties. Our research confirms that indeed it is best to use different kinds of spacers along the conjugated path. However, we have found that the order in which the different spacers are aligned is important. We also propose a new strategy for making more efficient molecules by combining spacers with different stabilization energy.

Design and simulation of metal-insulator-metal nanoresonators for color filter applications

Saswatee Banerjee, Sumitomo Chemical Co., Ltd. (Japan)

Traditionally, liquid crystal display (LCD) systems employ color filters that are fabricated using organic dye and pigment based colorants. As a result, conventional color filters can lower the system performance by removing substantial amount of incident light through absorption. Also, the transmission bandwidth can be unacceptably large. Furthermore, there is a need to combine functions of multiple optical elements on one, facilitating miniaturization and compactness. Metal-insulator-metal (MIM) nanoresonators that can combine the functions of color filtering and polarizing can provide a useful solution to some of these issues.

An MIM nanoresonator structure is proposed for use as color filters [1]. However, the proposed structure uses high refractive index, inorganic materials in the insulator layer. Also, the bandwidth of transmission is not narrow enough to generate saturated color. Here, we simulated some MIM nanoresonator structures that might be realized using relatively low refractive index, polymeric materials and can function as polarizing, color filters in transmission mode. These structures might also yield narrower bandwidths of transmission.

The simulations are carried out using a monochromatic version of RC-FDTD [2]. This algorithm uses the 1st order Drude model [3] to evaluate the convolution operation needed to make FDTD stable for metals for which the real part of permittivity is negative. Unlike the conventional RC-FDTD [3], the Drude parameters are computed at each wavelength of the incident light using the corresponding handbook value of permittivity. Hence, this version of RC-FDTD allows us to use the handbook permittivity values at all wavelengths of operation.

Light transmission with self-assembly DNA monolayers through D-shaped optical fiber

Woohyun Jung, Yonsei Univ. (Korea, Republic of); Jun Young Son, Sungkyunkwan Univ. (Korea, Republic of); Bjorn Paulson, Yonsei Univ. (Korea, Republic of) and Photonic Devices Physics Laboratory, Yonsei University (Korea, Republic of); Ji-Hyun Hwang, Photonic Devices Physics Laboratory, Yonsei University (Korea, Republic of); Byung-Joo Kong, Yonsei Univ. (Korea, Republic of); Sung Ha Park, Sungkyunkwan Univ. (Korea, Republic of); Kyunghwan K. Oh, Yonsei Univ. (Korea, Republic of)

In recent years of DNA material research, synthesizing DNA molecular structures in an organic solvent for the mono-disperse, large area, thin-film processes has been an essential issue for optoelectronic device applications. In this study, we report a novel optical monitoring of DNA monolayers formed by a self-assembly process, where thermal history plays a key role. Discrete 2-D nanocrystal DNA structures were prepared on a side-polishing optical fiber with nanostructure patterned Au thin-film. The high evanescent field interaction between the guided light with surrounding DNA solution provided preferred directions along the 5-helix ribbon (5HR) DNA planes and double-crossover (DX) DNA planes to form DNA nanocrystals. The light guided along the fiber was received by an optical spectrum analyzer to enable spectral analyses, while morphology studies of the self-assembly DNA were performed by atomic force microscopy. We expect that this technique will provide an in-situ control of self-assembly processes for DNA and DNA-lipid complexes that will find wide applications in optoelectrical devices.

Miniaturized sub-volt electro-optic modulator based on silicon integrated nanophotonics and organic polymers

Xingyu Zhang, Amir Hosseini, The Univ. of Texas at Austin (United States); Jingdong Luo, Alex K. Y. Jen, Univ. of Washington (United States); Ray T. Chen, The Univ. of Texas at Austin (United States)

Recently, silicon-organic hybrid (SOH) technology has shown to enable compact and high performance integrated electro-optic (EO) modulators. Organic EO polymer based modulators are promising for low power consumption due to the very large EO coefficient (r33) of poled polymers. Silicon photonic crystal waveguides (PCWs) infiltrated with electro-optic (EO) polymers can further reduce the device size because of slow light effects. One problem of PCW modulators is their narrow operating optical bandwidth of <1nm due to the high group velocity dispersion in the slow-light optical spectrum range. One solution is to use lattice shifting approach to provide low-dispersion slow light (constant group velocity) over a wide optical spectrum range. In this letter we report a symmetric MZI modulator based on band-engineered slot PCW refilled with EO polymer, SEO125 from Soluxra, LLC. The r33 value of poled SEO125 thin films is around 125pm/V at the wavelength of 1310 nm. The design and synthesis of SEO125 encompasses recent development of highly efficient nonlinear optical chromophores with a few key molecular and material parameters, including large ? values, good near-infrared transparency, excellent chemical- and photo-stability, and improved processability in polymers. We demonstrate a slow-light enhanced effective in-device r33 of 1190pm/V over 8nm optical spectrum range. In addition, excluding the slow-light effect, we estimate a record high in-device material r33 of 89pm/V in the slot. What is more, the utilization of large slot width provides small slot capacitance, which effectively reduces the RF power consumption to 1.5nW, which is very competitive to the state-of-the-art.

Investigation of optical propagation loss in electrospun polymer nanofibers

Yuya Ishii, Shota Satozono, Ryohei Kaminose, Mitsuo Fukuda, Toyohashi Univ. of Technology (Japan)

One-dimensional nanostructures are attracting considerable attention because of unique optical interactions that arise from their subwavelength size, including light confinement, guiding, and amplification. These properties make one-dimensional nanostructures promising for applications in small optical devices such as light sources and waveguides. Electrospun polymer fibers have nanometer diameters and high aspect ratios, making them well suited for use in such optical devices. Several groups have demonstrated optical waveguiding in electrospun polymer nanofibers and evaluated propagation losses. The propagation losses are more than 10000 times higher than those of well-studied thick polymer optical fibers, although the origin of such high losses is unclear. In this work, we evaluate propagation loss in fibers at different wavelengths (?) and determine the origin of this phenomenon. We fabricate single electrospun polymer nanofibers of poly(methyl methacrylate) (PMMA) containing a small amount of Rhodamine 6G, and evaluate propagation loss at different ?. Propagation loss increased linearly with a function of ??4, and the intercept, which represents loss originating from the poor uniformity of individual fibers, is evaluated to be 6.9–22 dB cm?1 for seven single fibers. At a wavelength of 650 nm, the total propagation loss ranged from 29 to 43 dB cm?1, and the ratio of the intercept to the total loss was 19%–50%. The loss that increases as a function of ??4 is attributed to Rayleigh scattering loss resulting from density inhomogeneity of PMMA, so we concluded the high propagation loss in these fibers originates from both their poor uniformity and density inhomogeneity.

Characterization of the assembly self-assembled chiral molecules in thin films by nonlinear optical microscopy and second-harmonic generation

Maarten K. Vanbel, Thierry Verbiest, Katholieke Univ. Leuven (Belgium)

Chirality at a molecular level is represented by molecules which exhibit no mirror plane in their molecular structure. In research fields such as biochemistry, biology and catalysis, chirality is one of the key parameters in the functionality of molecules. Even more in nanotechnology, chirality and chiral surfaces play an important role in the device operation and its applications. These chiral surfaces can quite conveniently be characterized by nonlinear optical techniques such as second-harmonic generation-circular dichroism. This technique is based on the difference in absorption between left and right-handed circularly polarized light, with a higher sensitivity than the linear optical variant. Integrating this technique in a microscope body enables the characterization of the chirality of inhomogeneous structures and their depth dependence. By visualizing the assembly of the chiral enantiomers in a thin film, the microscopic properties can be linked to the macroscopic alignment of the molecules.

Helical oriented molecules are an excellent test case to link intrinsic chiral properties, due to the helical direction, to the macroscopic alignment of these molecules. These helical structures were considered as chiral model structure, which interact well with different substrates, such as glass, gold or graphite.

In this work, we show the visualization of self-organized chiral molecules by means of two-photon fluorescence and second-harmonic generation. Their chirality was investigated by second-harmonic generation-circular dichroism.

Improving optical limiting of cw lasers with fullerene functionalized gold nanoparticles

Maria Chiara Frare, Verena Weber, Christian Corrado De Filippo, Raffaella Signorini, Michele Maggini, Renato Bozio, Univ. degli Studi di Padova (Italy)

In recent years the increasing use of continuous wave (cw) lasers leads to the need of developing protection devices for the human eye. This kind of devices, known as optical limiters, requires smart materials that are able to reduce incoming light intensity and have fast responses and work in a wide range of wavelengths.

The limitation process exhibited by materials under cw illumination is predominantly refractive and generates a focusing or defocusing effect of the incident laser beam, usually associated with nonlinearity of thermo-optic origin. Metallic nanostructures have been studied for optical limiting devices because of their tunable optical properties.

We investigated a coupled system, consisting of dyads of gold nanoparticles (AuNPs) bound to thioled-fulleropyrrolidine (C60Py), to improve optical limiting properties of nanostructures by adding energy transfer mechanisms to the usual thermo-optic effect.

We measured the optical limiting behavior under cw illumination at 514 nm, resonant with the surface plasmon resonance at around 520 nm where the human eye is most sensitive, and thermal nonlinear optical properties, comparing results we previously obtained for AuNPs with those for AuNP-C60.

Closed aperture Z-scan measurements reveal that the non-local thermal nonlinear refraction process with a negative nonlinear index still contributes to the optical limiting action.

Time response of the material at varying input powers gives us information on the transmitted irradiance in a 300 milliseconds time interval (corresponding to the blinking time of the human eye) and shows a significant improvement of the AuNP-C60 of the AuNP alone.

9181-45, Session PWed

Strong photoluminescence characteristics of sulforhodamine B attached on photonic crystal

Kwang-Sun Kang, Kyungil Univ. (Korea, Republic of)

The optical properties of sulforhodamine B (SRH) attached on a photonic crystal by two step synthetic processes including a urethane bond formation between a 3-isocyanatopropyl triethoxysilane (ICPTES, -N=C=O) and a SRH with elevated temperature in pyridine and hydrolysis-condensation reactions between synthesized ICPTES/SRH (ICPSRH) and silica spheres. The reduction of an absorption peak at 2270 cm-1 representing asymmetric stretching vibration of –N=C=O indicates the progress of the reaction, and a new absorption peak at 1712 cm-1 characterizing –C=O stretching vibration indicates the formation of the urethane bond. The UV-visible absorption spectrum of the mixture of ICPTES and SRH show the broadened spectral line width by intermolecular interaction. The absorption peaks of SRH in methanol, ICPSRH-21h film and the silica sphere film attached the ICPSRH (ICPSRHS) are at 558, 562 and 550, respectively. The photoluminescence (PL) peak of the SRH in methanol shows a hypsochromic shift with the increase of the excitation wavelength. However, the PL peak for the ICPSRH exhibits a bathochromic shift as the excitation wavelength increases. The PL peak for the ICPSRHS shows no hypsochromic or bathochromic shift. The PL peaks for SRH in methanol, ICPSRH film and ICPSRHS film are at 568, 598 and 572 nm, respectively. The Stokes shifts of the SRH in methanol, ICPSRH-21h film, and ICPSRHS film are 10, 36 and 22 nm, respectively.

Nanopatterning of azo-polymers: light polarization and film thickness effects *(Invited Paper)*

Zouheir Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

Polymers contatining azobenzene derivatives have been the subject of intensive research for two decades owing to their unique “smartness”, i.e., the ability to tailor and/or control materials properties by photoisomerization. In particular, it was shown that photoisomerization creates optical anisotropy by nonpolar orientation, and poling by polar optical excitation (all optical poling), and it triggers molecular movement far below the glass transition temperature (Tg) of the polymer (photo-assisted poling), and polymer mass movement proceeds in spatial gradients of the excitation light (surface relief gratings). In solid polymers, photoisomerization of azobenzene derivatives creates free volume and drives efficient chromophore and polymer segmental and chain motion far below the polymer’s Tg; an effect which is at the origin of photo-assisted and all optical poling and surface relief gratings. Most of the studies reported to date on azo-polymers used single photon isomerization, and photoisomerization and photo-orientation can be achieved by by two- or multi-photon isomerization with potential applications in nanophotonics. In this presentation, I will discuss our recent work on light induced molecular movement and induced plasticity in azo-polymers by a single focused laser beam that has a longitudinal field. Nanoscale polymer movement is induced by a tightly focused laser beam in an azo-polymer film just at the diffraction limit of light. The deformation pattern which is produced by photoisomerization of the azo dye is strongly dependent on the incident laser polarization and the longitudinal focus position of the laser beam along the optical axis. The anisotropic nanofluidity of the polymer film and the optical gradient force played important roles in the light induced polymer movement. The limits of the size of the photo-induced deformation were explored, and it was found that the deformation depends on the laser intensity and the exposure time. The smallest deformation size achieved was 200 nm in full width of half maximum; a value which is nearly equal to the size of the diffraction limited laser spot. We also found that the deformation patterns induced by a longitudinal field (Ez) were strongly dependent on polymer film thickness. The polymer formed a dip at the center of the focused spot when the film thickness is thinner than 37 nm while the polymer formed a protrusion when the film thickness is thicker than 37 nm. These results imply that upward and downward forces are competing inside the polymer film and the balance between them finally decides the surface topology (dip versus protrusion) of the film.

9181-15, Session 4

Arbitrary 2D GRIN lens fabrication in diffusive photopolymers

Adam C. Urness, Univ. of Illinois at Urbana-Champaign (United States); William L. Wilson, Univ. of Illinois (United States) and Univ. of Illinois at Urbana-Champaign (United States); Robert R. McLeod, Univ. of Colorado at Boulder (United States); Ken Anderson, Akonia Holofraphics llc (United States)

We introduce a new method to make gradient index (GRIN) lenses in diffusive photopolymers with nearly arbitrary two-dimensional (2D) profiles. By modulating the 2D intensity pattern and power of the exposure with a deformable mirror device (DMD), the index profile of the GRIN lens can be controlled. Combined with the self-developing nature of the photophotopolymer, rapid “on-demand” printing of arbitrary micro-optics is enabled. We demonstrate the process by fabricating Zernike polynomials and multifocal lenses.

9181-16, Session 4

Tunable non-pixelated spatial polarization shaping including an integrated optical addressing unit

Frederik Schaal, Institut für Technische Optik (Germany); Michael Rutloh, Fraunhofer-Institut für Angewandte Polymerforschung (Germany); Susanne Weidenfeld, Univ. Stuttgart (Germany); Joachim Stumpe, Fraunhofer-Institut für Angewandte Polymerforschung (Germany); Wolfgang Osten, Institut für Technische Optik (Germany)

We present a device for tunable spatial polarization shaping, based on a red light photo-addressable cell, which contains bisazobenzenes moieties and liquid crystals. The birefringence of the photo-addressable cell can be locally modulated due to the intensity of the addressing light.

The exposure with linear polarized light causes a reversible and efficient orientation of the bisazobenzene moieties, always perpendicular to the electric field of the incident light causing the alignment of the LC. This new material allows the induction of optical anisotropy generated by the irradiation with the red light. Optical anisotropy of ? /2 is reversibly and locally generated by red polarized light.

Switchable or superposable addressing patterns are generated by a micro optical addressing unit based on a VCSEL array as a linear polarized lightsource (? ~650 nm) and diffractive beam shapers for pattern generation. This enables the creation of non-pixelated spatial polarization patterns with fewer artefacts compared to devices like spatial light modulators. The induced polarization pattern is characterized by mueller matrix ellipsometry, spatial resolved rotating quarter wave plate polarimetry and polarization microscopy. Due to the compact optical addressing unit the system can be integrated into the pupil of a microscope objective, e.g. to be used for switchable phase contrast methods.

9181-17, Session 4

Morphology-dependent optical properties of polymer and small molecule materials

Steven J. Brown, Ruth A. Schlitz, Univ. of California, Santa Barbara (United States); Carlos M. Monton, Univ. of California, San Diego (United States); Richard R. Grote, Jeffrey B. Driscoll, Columbia Univ. (United States); Michael L. Chabinyc, Univ. of California, Santa Barbara (United States); Ivan K. Schuller, Univ. of California, San Diego (United States); Richard M. Osgood Jr., Columbia Univ. (United States); Jon A. Schuller, Univ. of California, Santa Barbara (United States)

In the past few years there has been increased interest in using highly ordered materials and photonic architectures to maximize the performance of organic optoelectronics. Multiple reports have demonstrated morphology-dependent electronic properties, and identified optimal device designs given strong anisotropies. The impacts, strengths, and origins of morphology-dependent optical properties, by contrast, are substantially less well understood. Here we elucidate the relationship between structure and optical properties in polymer and small-molecule materials through a suite of optical characterizations, and theoretically demonstrate an organic photovoltaic architecture which exploits optical anisotropies to drastically increase absorption in thin-films.

We study polymer (P(NDI2OD-T2)) and small-molecule (copper pthalocyanine; CuPc) films which take on different morphologies depending on processing conditions. We perform a set of optical measurements, including UV-Vis-NIR transmittance, spectroscopic ellipsometry, and photoluminescence. Using angle-resolved spectroscopies while controlling morphology, we demonstrate highly anisotropic, morphology-dependent optical properties. Understanding the connection between material structure and optical properties will be crucial for our fundamental knowledge and use of these materials in any optical device architecture. As an example, we present theoretical studies of plasmon-based light trapping, highlighting the considerable improvement possible when materials are appropriately aligned with the highly anisotropic plasmon fields. Finally, we discuss ongoing efforts to use angle-resolved spectroscopy to measure the plasmon dispersion in oriented molecular films, thus demonstrating the strong interplay between molecular orientations and device geometries.

9181-18, Session 4

Nonlinear solid-state filter based on photochromism induced by 2-photon absorption in a dye-doped sol-gel

Raz Gvishi, Soreq Nuclear Research Ctr. (Israel); Peng Zhao, Honghua Hu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Galit Strum, Amir Tal, Shmuel Grinvald, Galit Bar, Soreq Nuclear Research Ctr. (Israel); Laura Beker, Vladimir Lokshin, Vladimir Khodorkovsky, CINaM - Ctr. Interdisciplinaire de Nanoscience de Marseille (France); Mark Sigalov, Ben-Gurion Univ. of the Negev (Israel); David J. Hagan, Eric W. Van Stryland, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

There is much interest in enhancement of the performance of nonlinear solid-state filters. In this work we present an advanced reversible nonlinear filter based on a dye-doped sol-gel matrix. The enhancement was achieved by using a combination of two absorption mechanisms in the same molecule; a photochromic absorption which is induced by 2-photon absorption (2PA). The 2PA serves as the trigger for initiating the photochromism through a Förster-resonance-energy-transfer (FRET) between the fluorescent donor and the photochromic acceptor. We synthesized a new bifunctional-chromophore that incorporated a Carbazole 2PA fluorescent donor and a Chromene photochromic acceptor, covalently linked together in a single molecule by a ~6 Å carboxyl group bridge. The bifunctional-chromophore was doped in an inorganic-organic hybrid matrix prepared by the fast-sol-gel process. These materials solidify without shrinkage or formation of cracks and present promising properties as optical matrices for smart filters. The dye-doped sol-gel disc presents high transparency in the visible region (“colorless”) which under UV-irradiation (one-photon absorption in the photochromic part of the molecule) transform to a strongly absorbing filter (“dark colored”), due to the conversion of the photochromic moiety to its “open” absorbing form. We have demonstrated that this ring-opening can also be induced by visible-light (620 nm) using the 2PA Carbazole-derivative portion of the molecule. We have studied fabrication routes and optical performance of these filters. We will present studies of the 2PA mechanism of the Carbazole-derivative, FRET efficiency of the combined-molecule as well as solutions of the individual moieties, and reversible dynamics of the photochromic moiety.

9181-19, Session 4

Light to work to electricity in azobenzene-functionalized linear polyimide copolymers

Jeong Jae Wie, Air Force Research Lab. (United States) and Azimuth Corp. (United States); David H. Wang, Air Force Research Lab. (United States) and UES, Inc. (United States); Vincent P. Tondiglia, Air Force Research Lab. (United States) and SAIC (United States); Nelson V. Tabiryan, Rafael O. Vergara-Toloza, BEAM Engineering for Advanced Measurements Co. (United States); Loon-Seng Tan, Timothy J. White, Air Force Research Lab. (United States)

Transduction of light energy into mechanical strain (photostriction) to electrical energy (piezoelectricity) has been reported. Herein, our focus is on employing materials with large displacement and high modulus to enhance photoactuation and energy transduction behaviors. Recently, we have reported on the synthesis and photomechanical response of azobenzene-functionalized polyimides. Structure-property relationships have been developed to correlate the role of crystallinity, free volume, alignment, backbone rigidity, and sub-Tg transitions to photomechanical effects observed as bending cantilevers and quantified in tensile testing. In the work presented here, we report on the synthesis and characterization of a series of azobenzene-functionalized linear polyimides. These materials were selected because of the comparatively large deflection (shape change) and elastic restoration in the dark. The displacement of these materials is further enhanced with processing (hot-drawing). The photomechanical response of these materials is large enough to stress a piezoelectric PVDF film. Subjecting the azobenzene-functionalized polyimide/PVDF system to sequenced lighting conditions (by employing a beam chopper) is shown to convert light energy, through the mechanical displacement, into electricity. The frequency of the response is shown to match the frequency of the light exposing the films.

9181-20, Session 5

Molecular magneto-optics *(Keynote Presentation)*

André P. Persoons, Katholieke Univ. Leuven (Belgium); Guy Koeckelberghs, KULeuven (Belgium); Palash Gangopadhyay, University of Arizona (United States)

A review is given on magneto-optical properties of π-conjugated polymers, in particular regioregular poly(3-alkyl)thiophenes. A theoretical formalism will be presented based upon persistent currents in organic macrocycles and cyclic structures to explain the strong Faraday rotation from thin films of these polymers. Detailed calculation on the π-electron distribution in macrocycles of poly(3-alkyl)thiophenes will be presented and related to persistent currents as previously shown to be present in mesoscopic rings of (not superconducting) metals. Synthetic aspects of these organic macrocycles, exciting new materials, will also presented at this conference. SQUID measurements on these macrocycles are undertaken to investigate the possibility of fluctuating magnetic moments in these new molecular structures. This could be the cause of giant Faraday rotation observed, as well as the ferromagnetism observed in regioregular poly(3-alkyl)thiophenes at cryogenic temperatures. Possible correlations between magnetic properties of macrocycles of π-conjugated thiophene rings and chirality of the macrocyles will be highlighted.

Experimental results on Faraday rotation studies from thin films of various polythiophene derivatives with high degree of regioregularity, but with random alkyl sidechains and of different morphologies will be presented. Possible correlations of the Faraday rotation and the supramolecular organization within these thin films will be discussed.

When appropriate, we will discuss some applications, e.g. various magneto-optic devices, or suggest directions for further research.

9181-21, Session 5

Magneto-optical properties of highly regioregular polythiophenes with different architectures *(Invited Paper)*

Nicolas Delbosc, Olivier Coulembier, Philippe Dubois, Univ. de Mons (Belgium); André P. Persoons, Katholieke Univ. Leuven (Belgium)

Since the discovery of semi-conductor properties of organic pi-conjugated systems, numerous applications of those materials have been exploited, from fundamental research to industrial commercialization. We can cite light emitting device, solar cells, electrochromic devices...

The magnetic behavior of those systems have only been studied since a short decade. Its origin lied in the existence of unpaired spins interacting together through the overlap of p-orbital creating pi-conjugation, in the chain and between the chain.

Poly-alkylthiophenes, the most studied pi-conjugated polymers in organic electronics, have been examined by Magneto-Optic polarimetry, ESR spectroscopy, SQUID magnetometry. All these measurements confirm the sensitivity of these materials to external magnetic fields , the presence of significant spin density and a different magnetic behavior dependent of the temperature .

Previous work has established some requirements to develop efficient magneto-optical materials, especially highly sensitive to very small external magnetic fields. The regioregularity of the poly-alkylthiophenes appears to be a most important parameter as well as the supramolecular organization - governed by the structure of the lateral alkyl chain - influence the magnitude of magnetization and coercivity .

Different architectures of polythiophene have been synthesized, statistical copolymer of thiophene to obtain very low semi-crystalline character polythiophene, and highly regioregular macrocyclic polythiophene to probe the existence of persistent currents.

9181-22, Session 5

Chiral Supramolecular Assemblies from Achiral and Chiral Molecules Investigated by Second Harmonic Generation at the Air-Water Interface

(Invited Paper)

Aurélie Bruyère, Univ. de Claude Bernard Lyon 1 (France); Laure Guy, ENS Lyon (France); Amina Bensalah-Ledoux, Stephan Guy, Univ de Claude Bernard Lyon I (France); Emmanuel Benichou, Pierre-François Brevet, Univ. Claude Bernard Lyon 1 (France)

We show, using Second Harmonic Generation (SHG) at the air-water interface, that chiral supramolecular assemblies can be formed under lateral compression from a monolayer of achiral molecules. The polarization analysis of the nonlinear optical intensity provides further insights into the origin of the response. We demonstrate that for two different amphiphilic compounds, namely 4-(4-(dihexadecylamino)styryl)-N-methylpyridinium iodide (DiA) and 5-(octadecyloxy)-2-(2-thiazolylazo) phenol (TARC18), the SHG response is of magnetic dipole nature and we present a nonlinear correlation method to monitor these supramolecular assemblies at the air-water interface.

9181-23, Session 6

All-organic plasmonics *(Invited Paper)*

Mikhail A. Noginov, Guohua Zhu, Lei Gu, John K. Kitur, Norfolk State Univ. (United States); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States); Evgenii E. Narimanov, Purdue Univ. (United States); Jarrett Vella Jr., Augustine M. Urbas, Air Force Research Lab. (United States)

Metallic response in the optical range (supporting localized or propagating surface plasmons), optical gain (compensating surface plasmon loss and providing for stimulated emission), and nonlinearity (enabling tuning) are the necessary ingredients of active plasmonics, whose applications range from sensing to future nanocircuitry operating at optical frequencies.

We show that all three critical functions can be realized in dye-doped polymers. Thus, population inversion and optical gain can be easily created in many laser dyes, negative (real) dielectric permittivity can be obtained in the vicinity of strong absorption bands, and index of refraction of dye-doped particles can be controlled by Q-switched laser pumping.

9181-24, Session 6

Optical properties of Alq3 films and Alq3/plasmonic heterostructures *(Invited Paper)*

Hans-Peter Wagner, Niranjala D. Wickremasinghe, Masoud Kaveh, Milhan Ajward, Xiaosheng Wang, Univ. of Cincinnati (United States); Heidrun Schmitzer, Xavier Univ. (United States); Qiang Gao, Chennupati Jagadish, The Australian National Univ. (Australia)

Tris (8-hydroxyquinoline) aluminum (Alq3) is a frequently used emissive material in organic light emitting devices. However, the contribution from interacting molecules to the photoemission is still rather unexplored. To gain more insight into such processes we investigate the radiation of optically excited excitons by intensity dependent time-integrated (TI) as well as time-resolved (TR) photoluminescence (PL) measurements at temperatures ranging from 15 to 300 K. The Alq3 films were grown by organic molecular beam deposition (OMBD) on Si substrates. At low temperature (15 K) we find a significant reduction of the light emission which is attributed to bimolecular quenching of singlet excitons which are captured in extended traps. At higher temperatures (150 K) the quenching effect is remarkably reduced due to thermally activated occupation of non-quenchable exciton states.

Alq3 is also an excellent organic component to fabricate plasmonic heterostructures. We investigate the mode properties of OMBD grown Alq3 waveguides comprising one or more thin metal layers using the m-line technique. The investigations show that strategically placed metal films can be used to selectively excite plasmonic and dielectric TM modes and to shift and suppress TE modes. We further explore the exciton dynamics in polytype wurzite/zincblende InP nanowires which are coated with few 10 nm thick Alq3 and Mg:Ag metal layers using TI and TR optical methods. The Alq3 spacer between nanowire and metal layer is used to passivate the nanowire surface and to control the energy-transfer from nanowire excitons to plasmon oscillations in the deposited metal film.

9181-25, Session 6

Plasmonic mode amplification using organic semiconductor gain media *(Invited Paper)*

Deirdre M. O'Carroll, Sarah Goodman, Jesse Kohl, Rutgers, The State Univ. of New Jersey (United States)

Coupling of gain materials to metallic nanostructures and thin films offers an avenue for amplification of plasmonic modes in both confined and extended geometries. In the past decade, a deeply sub-wavelength analogue to the laser, using surface plasmons instead of photons has been proposed and demonstrated. Additionally, propagating surface plasmon polaritons (SPPs) on extended metallic films have been amplified using gain media to achieve chip-scale propagation lengths. Here, we investigate amplification of resonant and propagating surface plasmon modes using organic polymer semiconductor gain media. These gain media are of interest because: (1) unlike laser dye molecules, they do not undergo significant concentration quenching in the solid-state and, therefore, can result in a high chromophore density in the optical near-field of the metal structure; (2) the oscillator strength and transition dipole orientation of the polymer gain medium can be manipulated offering selective coupling or excitation of particular plasmonic modes.

For resonant surface plasmon amplification, we fabricate gold nanorod-conjugated polymer core-shell nanoparticles through a miniemulsion synthesis process. A more distinct threshold in emitted intensity as a function of optical pump energy is observed from these hybrid structures compared to polymer nanoparticles and dissolved polymer molecules. This is attributed, in part, to the higher quality factor of the hybrid nanoparticle. Demonstrations of amplified SPP modes supported by conjugated polymer/metal/insulator asymmetric planar waveguides will also be reported. Theoretical work predicts increased SPP mode leakage by factors of up to 88 when the polymer undergoes stimulated emission. Gain measurements on fabricated structures support these findings.

9181-26, Session 6

Enabling enhanced emission and low threshold lasing of organic molecules using special Fano resonances of macroscopic photonic crystals

Bo Zhen, Song-Liang Chua, Jeongwon Lee, Massachusetts Institute of Technology (United States); Alejandro W. Rodriguez, Princeton Univ. (United States); Xiangdong Liang, Steven G. Johnson, John D. Joannopoulos, Marin Soljacic, Ofer Shapira, Massachusetts Institute of Technology (United States)

The nature of light interaction with matter can be dramatically altered in optical cavities, often inducing nonclassical behavior. In solid-state systems, excitons need to be spatially incorporated within nanostructured cavities to achieve such behavior. Although fascinating phenomena have been observed with inorganic nanostructures, the incorporation of organic molecules into the typically inorganic cavity is more challenging. Here,we present a unique optofluidic platform comprising organic molecules in solution suspended on a photonic crystal surface, which supports macroscopic Fano resonances and allows strong and tunable interactions with the molecules anywhere along the surface. We develop a theoretical framework of this system and present a rigorous comparison with experimental measurements, showing dramatic spectral and angular enhancement of emission. We then demonstrate that these enhancement mechanisms enable lasing of only a 100-nm thin layer of diluted solution of organic molecules with substantially reduced threshold intensity, which has important implications for organic light-emitting devices and molecular sensing.

9181-32, Session 6

Nonlinear optical photovoltaics

Jean-Michel Nunzi, Somayeh M. A. Mirzaee, Queen's Univ. (Canada)

Nonlinear absorption was investigated in a poly (3-hexylthiophene) (P3HT) PCBM fullerene blend, one of the most popular organic solar cell's materials. We observed three-photon absorption in the bulk hetero junction photodiode configuration. The output photocurrent of the photodiode was interpreted in terms of the three-photon absorption properties of the P3HT:PCBM blend at 1550 nm.

Can the concept be extrapolated to high efficiency solar cells?

We propose an optical antenna technology revisited with plasmonics and organic rectifiers that should permit the development of an ultra-high efficiency PV technology that is compatible with large-area fabrication (self assembling) and low-cost (plastic) technologies.

9181-28, Session 7

New frontier of organic electro-optic (EO) materials and devices: from molecular engineering to technology innovations *(Invited Paper)*

Alex K. Y. Jen, Univ. of Washington (United States)

For E-O materials to be useful for device applications, the material development should proceed in parallel with innovative device concepts and device fabrication process. Recently, the unique properties of organic NLO materials have also inspired the development of novel nanofabrication methods to replace more traditional techniques and has potential to lead to scalable nanophotonics based on organic NLO materials. Moreover, implementation of a clever designed device structures and fabrication process not only can significantly improve device performance but also reduce energy consumption during operation.

Recent development of highly efficient organic EO materials and devices has opened the way to promising opportunities to complement and improve current inorganic semiconductor based technologies. For example, organic EO materials can provide a full array of optical functions and can be processed at temperatures that are compatible with CMOS integrated circuits. In respond to exponentially increasing demands for operational bandwidth, structured organic EO materials are expected to play critical role in organic silicon hybrid nanophotonics in the near future. The ability to efficiently guide and control an optical signal in field confined nanoscale integrated devices will significantly boost the performance for structured organic EO materials. Integrated optical circuits based on organic silicon hybrid EO materials will enable low cost, mass production of novel nanophotonic devices for broadband optical signal processing and communications.

9181-29, Session 7

Design and fabrication strategies for high transparency polymer nanocomposites with dynamic tunable optical response *(Invited Paper)*

Michael R. Bockstaller, Alei Dang, Krzysztof Matyjaszewski, Chin Ming Hui, Carnegie Mellon Univ. (United States)

Recent progress in the molecular engineering of organic-inorganic hybrid materials facilitates the fabrication of hybrid materials with unprecedented control of the composite microstructure from the nano- to the micrometer lengthscale. This contribution will discuss strategies to harness the increased level of microstructural control to modulate the interaction of inorganic fillers with light and to facilitate dynamic property changes induced by light-filler interaction. Two examples from recent research in our group will be presented to illustrate how the strategic design or placement of inorganic fillers can be applied to control the electric field distribution such as to enhance or reduce absorption and scattering processes in microstructured hybrid materials. In the first example, the strategic arrangement of inorganic (metallic) elements in a polymeric matrix will be shown to facilitate optical resonant tunneling effects that give rise to tunable passbands in metallodielectric polymer composites. The second example will discuss opportunities to control light-filler interactions by means of tailoring the ligand-chemistry of particle fillers. A novel synthetic technique to precisely control the composition of polymeric ligands will be introduced and applied to the synthesis of high transparency composite materials with inorganic content in excess of 50% by volume. Augmenting the polymeric component with two-photon absorbing functionality will be shown to impart power-flux sensitivity to light-filler interactions that can be harnessed, for example, for the fabrication of dynamically responsive optical elements.

9181-30, Session 7

Small bending loss of thiacyanine polariton nanofibers

Hiroyuki Takeda, National Institute for Materials Science (Japan); Kazuaki Sakoda, National Institute for Materials Science (Japan) and Univ. of Tsukuba (Japan)

In this presentation, we give a firm theoretical proof of extremely small bending loss of thiacyanine nanofibers, which was recently found by Takazawa's experimental study (Takazawa et al., Phys. Rev. Lett. 105, 067401 (2010)).

For this purpose, we first analyzed the exciton-polariton dispersion relation of the thiacyanine nanofiber characterized by its highly anisotropic polaritonic refractive index. We formulated a plane-wave expansion method by which we could obtain the eigenfrequencies of polaritons as eigenvalues of a non-Hermitian and frequency-independent matrix (Takeda & Sakoda, Phys. Rev. B 86, 205319 (2012)). The group refractive index calculated from the slope of the dispersion curve agreed quite well with the Fabry-Perot interference patterns found in both the calculated and observed transmission spectra. We found that the dispersion relation of the anisotropic polariton was quite different from the isotropic case and depended strongly on the tilt angle of the optical transition dipole moment of the constituent molecules to the fiber axis.

Secondly, we theoretically examined the bending loss. We formulated a finite-difference frequency-domain method stabilized by a conformal transformation to calculate the bending loss as a function of the radius of curvature and the propagation frequency (Takeda & Sakoda, Opt. Express 21, 31420 (2013)). Our numerical results supported Takazawa's experimental observation. The present study clearly shows that the polariton nanofiber gives a novel possibility for bent waveguides to fabricate optical microcircuits and interconnection that cannot be attained by the conventional waveguides based on the index guiding.

9181-31, Session 7

Detuning of polar whispering gallery modes in polystyrene microspheres

Heidrun Schmitzer, Xavier Univ. (United States); Julie Lutti, Paola Borri, Wolfgang Langbein, Cardiff Univ. (United Kingdom); Hans-Peter Wagner, Univ. of Cincinnati (United States)

Optical whispering gallery modes (WGMs) in microcavity optical resonators are promising as pressure or force sensors for microfluidic flow applications. It is the high Q-factor of the WGMs which makes microcavity resonators extremely sensitive to changes in their shape or in their refractive index. Any of these changes will be detectable as a frequency shift of the resonating modes. If the resonating microsphere is subjected to mechanical stress, the induced frequency shift is directly related to the exerted force.

In this work, we investigate the detuning of polar WGMs in solid polystyrene microspheres (PMs) which are mounted between windows of a flow chamber as a function of axisymmetric stress. The stress on the PMs is varied by applying uniaxial stress on one window using a calibrated cantilever and by hydrostatically pressurizing the flow chamber liquid with a syringe creating a counteracting force on the side walls. The applied uniaxial stress reduces the geometrical circumference of the PM and increases locally the refractive index at the flattened poles. We observe that the polar WGMs shift to higher frequencies with increasing pressure and that the magnitude of this strain-induced shift depends on the mode order. Furthermore, an energy splitting between azimuthal modes occurs which is linearly increasing with pressure. A theoretical model based on a classical ray optics approach is presented which reproduces the main results of our experimental observations.

9182-1, Session 1

Large range reflection notch tuning in polymer stabilized cholesteric liquid crystals *(Keynote Presentation)*

Timothy J. White, Air Force Research Lab. (United States); Kyung Min Lee, Air Force Research Lab. (United States) and Azimuth Corp. (United States); Vincent P. Tondiglia, Air Force Research Lab. (United States) and SAIC (United States); Timothy J. Bunning, Air Force Research Lab. (United States)

We report on large range reflection notch tuning in polymer stabilized cholesteric liquid crystals. Tuning is observed in formulations based on negative dielectric anisotropy liquid crystals by stabilization with 3-10 wt% polymer in the presence of applied DC fields. The underlying mechanism is ionic charge trapping. The talk will survey improvements in tuning range, threshold voltage, and optical properties through monomer formulation, holographic photopolymerization, and the inclusion of additives.

9182-2, Session 1

Vertical-cavity surface-emitting laser with liquid crystal external cavity

Yi Xie, Jeroen Beeckman, Univ. Gent (Belgium); Krassimir Panajotov, Vrije Univ. Brussel (Belgium); Kristiaan Neyts, Univ. Gent (Belgium)

We have developed a technology to integrate a thin layer of liquid crystal (LC) on top of a Vertical Cavity Surface Emitting Laser (VCSEL). The VCSEL and the LC layer can be electrically driven independently. The LC layer can modulate the refractive index and therefore the polarization state of the VCSEL. Based on this technology, VCSEL devices with tuneable external cavity are achieved by using nematic LC incorporated with an additional reflector or chiral liquid crystal (CLC).

Firstly, an external cavity for the VCSEL is provided by a dielectric mirror (SiO_2/Ta_2O_5) and a thin layer of LC between it and the VCSEL. The reflection band position is designed for the emission wavelength of the VCSEL by choosing the right thickness of the periodic bi-layers. By changing the voltage across the LC layer, the optical length in the external cavity can be tuned. Therefore, the emitting properties of the LC-VCSEL, including polarization state, emission wavelength and threshold current, can be controlled by the voltage applied on the LC layer.

Secondly, the external cavity is formed by a layer of CLC. The concentration of the chiral dopant is chosen such that the CLC has a reflection band for one circular polarization for VCSEL emission wavelength. The CLC properties are temperature dependant so that the emission properties of the CLC-VCSEL can be controlled by device temperature. Compared with the stand-alone VCSEL, the CLC-VCSEL has a smaller threshold current, a larger wavelength tuning range and a purely circular polarization with a higher degree of polarization.

9182-3, Session 1

Light-induced effects in dye-doped liquid crystals: role of space charges *(Invited Paper)*

Francesco Simoni, Liana Lucchetti, Univ. Politecnica delle Marche (Italy)

The main motivations of the investigation performed on light-induced effects in dye-doped liquid crystals are: (i) the research of a suitable photo-alignment technique to be used in display technology and in optical memory devices; (ii) the discovery of the huge nonlinear response of mixtures doped by Methyl-Red making possible applications in the field of optical processing with extremely low power.

From the results of these investigations in nematics doped by Methyl-Red a basic question arises: is there a link between the transient reorientation leading to the extraordinarily large nonlinear response observed at low light intensity and the permanent photo-alignment observed at higher light doses?

We report here the simple demonstration that both effects have the same origin being dependent on the modification of the space charge density induced by light at the irradiated surface. This result is achieved by recording the effect of irradiation of this type of samples by applying an external voltage and comparing the results obtained under dc and ac conditions. In fact while the dc field favors the formation of a space charge at the sample surfaces, an ac field prevent its formation. With dc field our data show the occurrence of all the reorientation processes. On the contrary, when an ac field is applied, only photo-isomerization occurs being effective only in the high dose regime.

9182-4, Session 1

Laser effect within an optical spatial soliton in nematic liquid crystals *(Invited Paper)*

Jean-François Henninot, Univ. d'Artois (France); Mardia Ouali, Univ des Sciences et Technologies de Lille (France); Jean-François Blach, Univ. d'Artois (France); Majid Taki, Univ. des Sciences et Technologies de Lille (France)

The spatial solitons have been studied for two decades in nematic liquid crystals (NLC). The outstanding properties of these materials in terms of index modulation due to a high birefringence allowed a series of experimental studies in order to verify theoretical models. The results presented here follow the observation of the phenomenon of self-focusing as it has been observed in NLC doped with dyes [1]. It was shown that the index variation in the origin of the focusing process associated to a high non-locality stabilizes the solitons in a (2D+1) configuration. It is now worth the trouble for going further in the process to observe the behavior of such solitons in active medium and to study the conditions for obtaining gain in such a system. The addition of a dye to the NLC generates fluorescence. By inserting such a soliton in a cavity it is possible to study the mechanism for obtaining gain at relatively low power, the losses being limited by the lateral guide corresponding to the soliton. The presentation will be organized as follow: A first step has involved the study of processes of radiative and non-radiative losses of the soliton obtained by continuous pump. The second part is associated with the behavior of the soliton inserted in a resonant cavity. This part aims to define the optimal conditions for obtaining longitudinal cavity modes of a soliton confined between two mirrors. The search for stability conditions of the cavity will then be discussed.

9182-5, Session 1

Synthesis, liquid-crystalline behavior, and photoluminescence properties of novel Au(I) complex with naphthalene ring in a mesogenic core *(Invited Paper)*

Yuki Rokusha, Ritsumeikan Univ (Japan); Nana Sugimoto, Ritsumeikan Univ. (Japan); Shigeyuki Yamada, Ritsumeikan Univ (Japan); Osamu Tsutsumi, Ritsumeikan Univ. (Japan)

Gold(I) complexes show strong luminescence via intra- or intermolecular Au(I) Au(I) interaction (aurophilic interaction). Therefore, their quantum yields of photoluminescence are enhanced in the condensed phases, in where the molecules are packed closer than in solutions, and one can expect that the gold complexes are possible candidate materials for fabricating light-emitting devices. It has been reported that luminescent

properties of these complexes depend on the aggregation structure in the condensed phases; thus, the aggregation structure of the complexes should be controlled to make them suitable for luminescence. In order to control the aggregation structure of the gold complexes, we have designed and synthesized liquid-crystalline (LC) gold(I) complexes with disc-like or rod-like molecular shape. Disk-like LC molecules can be organized spontaneously into columnar structures, known as the discotic columnar phase. Because the molecules are stacked closely in the columnar phases, we considered that the columnar aggregation structure should be suitable for luminescence. The synthesized disk-like LC complexes showed no photoluminescence in dilute solutions. Luminescence was enhanced in the condensed phases: strong photoluminescence (? > 40 %) was observed at room temperature in the crystalline phase. We found that purple-yellow-red tricolor luminescence was obtained from a single material and the luminescent color can be controlled by thermal phase transition. In the rod-like LC complexes, intense photoluminescence (? > 50 %) was also observed. Very interestingly, when the rod-like gold complexes were introduced in side-chains of polymers as a mesogen of polymer LCs, white-color photoluminescence was observed from a single material.

9182-6, Session 2

Light-emitting liquid-crystal displays constructed from AIE luminogens *(Keynote Presentation)*

Dongyu Zhao, Hong Kong Univ. of Science and Technology (Hong Kong, China) and School of Chemistry and Environment Science, Beijing University of Aeronautics and Astronautics (China); Anjun Qin, South China Univ. of Technology (China); Ben Zhong Tang, Hong Kong Univ. of Science and Technology (Hong Kong, China) and South China Univ. of Technology (China); Wai Tung Leung, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Liquid crystal displays (LCDs) are widely used in many aspects of our life from handheld personal devices to flat-panel televisions. Since LCDs are passive display devices, they usually have narrow viewing angles and low brightness. Light-emitting LCDs (LELCDs) are envisioned as less energy consuming display devices. To realize LELCDs, fluorescent materials with strong solid-state emissions are required. Many luminophores, however, suffer from heavy aggregation-caused quenching effect in the solid state. In order to overcome the shortcoming, we synthesized a liquid-crystalline luminogen TPE-PPE consisting of a tetraphenylethylene core and four mesogenic peripherals. TPE-PPE shows aggregate-induced emission (AIE) and thermotropic liquid crystallinity. By doping a tiny amount of TPE-PPE into a nematic LC host PA0182, linearly polarized emission was obtained on the unidirectional orientated LC cell. The photoluminescence polarization ratio of the LC cell reached to 4.16 in the directions perpendicular and parallel to the rubbing direction. Through utilizing the emission anisotropy of TPE-PPE, two kinds of LELCD devices were successfully fabricated. This approach simplifies device design, lowers energy consumption, and increases brightness of LCD. The LELCD may find technology applications in the area of anti-counterfeiting.

9182-7, Session 2

Fast algorithms for liquid crystal modelling *(Invited Paper)*

Thomas P Bennett, University of Southampton (United Kingdom); Yogesh Murugesan, Univ. of Southampton (United Kingdom); Keith R Daly, University of Southampton (United Kingdom); Giovanni De Matteis, Northumbria University (United Kingdom); Giampaolo D'Alessandro, Univ. of Southampton (United Kingdom)

The geometry of modern liquid crystal devices can be quite removed from the idealised case of a planar liquid crystal cell: the device boundary may be structured in a way that induces bistability; the liquid crystal may contain suspensions of particles that enhance or modify its linear or nonlinear behaviour; there may be nanostructured surfaces or scaffolding immersed in the liquid crystal to produce tunable metamaterials.

Modelling these devices requires accurate and efficient computational tools to determine the director alignment. In this talk I will illustrate examples of how mathematical analysis of the liquid crystal dynamics equations can lead to approximate models that have a very large range of applicability and that can be solved numerically at a fraction of the cost of the original liquid crystal equations.

For example, it is well known that the Q-tensor equations for liquid crystal alignment are numerically stiff, i.e. they contain two very different time scales. The first relates to the collapse of the scalar order parameter to the nematic state, while the second describes the alignment of the liquid crystal under the influence of the boundaries and of external fields. Using the method of multiple scales it is possible to separate the two time scales and obtain approximate equations for the Q-tensor reorientation dynamics. Comparison with numerical simulations of the full equations show that the error in the approximation is smaller that one part in ten thousand, while the computational speed is increased a hundredfold.

9182-8, Session 2

Molecular dynamics in azobenzene liquid crystal polymer films studied by transient grating technique *(Invited Paper)*

Kenji Katayama, Shota Kuahara, Tomoki Ikeda, Chuo Univ. (Japan)

Transient grating (TG) technique is one of the time-resolved spectroscopic technique, which provides much information on the dynamics of photochemical or photophysical processes via a refractive index change in a time-resolved manner. We have developed a new type of transient grating, called heterodyne transient grating (HD-TG) method, featuring highly sensitive detection due to heterodyne detection, simple optical setup, and applicability for various sample conditions such as rough surface, heterogeneity, etc.[This method has been applied to liquid crystal (LC), and photopolymer, recently and the molecular dynamics was studied in a wide temporal range, from the nanosecond to second order.

Here, we studied the photo-induced molecular motion in a LC polymer film including azobenzene. The film was confined in a liquid crystal cell, while it is a photomobile film under a free standing condition, which is triggered by the photoisomerization of azobenezene. By observation of the refractive index change induced by a pulse laser, contraction of the film was observed on the order of several hundreds of nanoseconds, and the subsequent reorientation and molecular rotation dynamics was observed from a few microseconds to a hundred milliseconds. Finally, the cis isomer of azobenzene was thermally returned back to the trans isomer about a few seconds because the film could not be bent in the liquid crystal cell. Since the contraction, reorientation and molecular rotation took place before the cis to trans transformation, these processes correspond to the preliminary molecular motion preceding the macroscopic bending of the film.

9182-9, Session 2

Mechanoresponsive change in photoluminescent color of rod-like liquid-crystalline compounds and control of molecular orientation on photoaligned layer *(Invited Paper)*

Mizuho Kondo, Kentaro Okumoto, Seiya Miura, Mayuko Hashimoto, Ryohei Fukae, Nobuhiro Kawatsuki, Univ. of Hyogo (Japan)

Mechanochromic luminescence (MCL) is referred to the phenomenon whereby an isothermal change in photoluminescence in excess of two states, and at least one pathway is induced by mechanical stimuli such as grinding, shearing, pressing and stretching. This property is expected for mechanical sensor, cellular imaging, detection of microenvironmental changes, and optical memory. Various types of MCL compounds have been reported and recently, Kato and co-workers reported series of liquid-crystalline MCL compounds, which demonstrates mechanically induced change in photoluminescence by tuning molecularly assembled structures. On the other hand, we focused on liquid-crystalline MCL compounds on alignment layer. We have previously prepared two types of asymmetric oligothiophenes containing cyano- and pyridyl- molecular terminals and control their molecular orientation by using photoalignment layer. These molecules contain electronically push-pull structure and easy to be introduced in rodlike MCL compounds. Additionally, controlling the molecular alignment of MCL compounds with photoalignment layer have potential to succeed in functional MCL film such as polarized micropatterned MCL and directional detection of mechanical stimuli. Herein, we prepared asymmetric rodlike MCL compounds containing cyano- and pyridyl molecular terminal and explored their photoluminescence behavior under mechanical stimulus. Upon grinding, both powder of the cyano- and pyridyl-terminated compounds change its photoluminescent color and reverted to its initial color by heating above its melting point. The cyano-terminated MCL was aligned along the orientation direction of photoalignment layer and pyridyl-terminated MCL exhibited uniaxial alignment when it coated on photoaligned film containing carboxylic acid.

9182-36, Session 2

Large aperture and polarizer-free liquid crystal lenses for ophthalmic applications

Yi-Hsin Lin, Hung-Shan Chen, Yu-Jen Wang, Chia-Ming Chang, National Chiao Tung Univ. (Taiwan)

A large aperture and polarizer-free liquid crystal lens (LC lens) for ophthalmic application is demonstrated. The LC lens with electrically-controlled positive lens and negative lens power can not only provide for the correction of myopia but also for the correction of presbyopia. In 2013, we proposed a LC lens with 6mm aperture size and with the tunable lens power from -1.2 D ~ +2D. However, the aperture size is still small comparing to the existing ophthalmic lenses and tunable lens power is small. To overcome the hinder of the lenses power, multi-layered structure must be adopted. In this paper, we propose a polarizer free LC lens with 4 LC layers separated by three liquid crystal and polymer composite films (LCPCFs). The functions of LCPCF are as separators and alignment layers. A high resistive layer is also adopted to lower the voltage. The operating principles for adopted a LC lens in human eye system are introduced. The lens power for the aperture size of 10mm is -2.2D ~ +3.3D (5.5D in total). The lensing effects are shown and discussed. We believe this study provides a guideline to help the researchers and engineers to develop the large aperture LC lens for ophthalmic lens applications.

9182-11, Session 3

Imaging and visualization of complex nematic fields *(Keynote Presentation)*

Slobodan ?umer, Univ. of Ljubljana (Slovenia) and Jo?ef Stefan Institute (Slovenia); Miha ?an?ula, Univ. of Ljubljana (Slovenia); Simon ?opar, Univ. of Ljubljana (Slovenia) and Jo?ef Stefan Institute (Slovenia); Miha Ravnik, Univ. of Ljubljana (Slovenia)

Geometrical constrains and intrinsic chirality in nematic mesophases enable formation of stable and metastable defect structures of high complexity. Recently knots and links of arbitrary complexity have been formed using laser micro-manipulation of nematic braids entangling colloidal particles in nematic liquid crystals [Tkalec et al., Science 2011]. In frustrated chiral nematic phases stable and metastable toron and hopfion defects have been implemented by laser tweezers [Smalyukh et al., Nature Materials 2010; Chen et al., PRL2013]. In numerical studies we predicted numerous exotic structures in confined blue phases [Fukuda & Zumer, Nature Comms 2011 and PRL 2011] and stable knotted disclinations in cholesteric droplets with homeotropic boundary conditions [Sec et al., Nature Comms 2014]. Modelling studies based on the numerical minimisation of the phenomenological free energy, supported with the adapted topological theory [Copar & Zumer, PRL 2011] allow predicting all of the listed nematic defect structures. Crucial for the understanding of the structures is the visualisation of the nematic ordering. It will be illustrated how the director, order parameter, and their derivatives can be used to point out particular aspects of ordering [Copar et al., Liquid Crystals 2013]. Finally the numerically obtained structures will be used to simulate polarisation microscope images and in more detail the images that can be obtained with three-photon excitation fluorescence polarizing microscopy for selected types of polarization [Trivedi et al., Optics Express 2010].

9182-12, Session 3

Liquid crystal hyperbolic metamaterial for wide-angle negative-positive refraction and reflection *(Invited Paper)*

Grzegorz Pawlik, Wroclaw Univ. of Technology (Poland); Wiktor Walasik, Aix-Marseille Univ. (France); Karol Tarnowski, Antoni C. Mitus, Wroclaw Univ. of Technology (Poland); Iam-Choon Khoo, The Pennsylvania State Univ. (United States)

We show that nanosphere dispersed liquid crystal (NDLC) metamaterial can be characterized in near IR spectral region as an indefinite medium whose real parts of effective ordinary and extraordinary permittivities are opposite in signs. Based on this fact we design a novel electrooptic effect: external electric field driven switch between normal refraction, negative refraction and reflection of TM incident electromagnetic wave from the boundary vacuum/NDLC. A detailed analysis of its functionality is given based on effective medium theory combined with a study of negative refraction in anisotropic metamaterials, and Finite Elements simulations. Preliminary results of full-wave simulations are presented.

9182-13, Session 3

Optical vortex modulated by liquid crystal Q-plate fabricated via photo-alignment *(Invited Paper)*

Andy Y. G. Fuh, Yao-Han Huang, Ming-Shian Li, National Cheng Kung Univ. (Taiwan)

The electro-optical characterics of liquid crystal (LC) devices, q-plate (QP) and advanced LC q-plate (ALCQP) fabricated using axially symmetric photo-alignment are investigated. The experimrntal results show that the electrically tunable LC QP device could be modulated to control the shape and polarization of a linearly polarized Gaussian laser propagating through the sample, while an ALCQP device could be modulated to control the shape of a circularly polarized Gaussian laser beam. Notably, a Gaussian beam modulated by LC q-plate and ALCQP under suitable applied voltages can be changed to various beam shapes with helical wave-fronts, as demonstrated by Michelson's interference. Details of sample fabrications and experimental results are reported.

9182-14, Session 3

Tunable refractive index in an optically isotropic liquid crystal phase *(Invited Paper)*

Mamatha Nagaraj, The Univ. of Manchester (United Kingdom);

Verena Gortz, Lancaster Univ. (United Kingdom); John W. Goodby, The Univ. of York (United Kingdom); Helen F. Gleeson, The Univ. of Manchester (United Kingdom)

We present an electrically tunable refractive index observed in an isotropic liquid crystal phase, exhibited by a bent-core liquid crystal, known as the dark conglomerate (DC) phase. This unusual change in the refractive index has not been reported before in the DC phase of other bent-core liquid crystals. It occurs because of a series of electric-field-driven transformations that take place in the DC phase of the studied bent-core liquid crystal. These transformations give rise to a decrease in the refractive index of the system, when an electric field is applied across the device, and no change in the birefringence is seen during such behavior.

The electro-optic phenomenon corresponding to an unusual change in the refractive index without changing the birefringence of an optically isotropic phase could be exploited for number applications, where the applied electric field, by modulating the refractive index of the liquid crystal, changes the nature of the propagating light wave. These mainly include integrated optical modulators such as optical waveguides and for fiber-optic core, liquid crystal phase gratings and liquid crystal based tunable lenses.

The electro-optic phenomenon will be presented and the possibility of exploiting this for a number of liquid crystal based device applications will be discussed.

9182-15, Session 3

Harnessing optical vortex lattices in nematic liquid crystals *(Invited Paper)*

Marcel G. Clerc, Univ. de Chile (Chile); Stefania Residori, Umberto Bortolozzo, Institut Non Linéaire de Nice Sophia Antipolis (France); Raouf Barboza, Estefania Vidal, Univ. de Chile (Chile); Gaetano Assanto, University Roma Tre, (Italy)

By creating self-induced vortexlike defects in the nematic liquid crystal layer of a light valve, we demonstrate the realization of programable lattices of optical vortices with arbitrary distribution in space. On each lattice site, every matter vortex acts as a photonic spin-to-orbital momentum coupler and an array of circularly polarized input beams is converted into an output array of vortex beams with topological charges consistent with the matter lattice. The vortex arrangements are explained on the basis of light- induced matter defects of both signs and consistent topological rules.

9182-16, Session 4

Ultrahigh sensitivity in liquid-crystal-based immunodetection by surface modification of the alignment layer *(Invited Paper)*

Mon-Juan Lee, Chang Jung Christian Univ. (Taiwan); Hui-Wen Su, Shih-Hung Sun, Wei Lee, National Chiao Tung Univ. (Taiwan)

It is known that liquid crystals (LCs), with thermotropically calamitic nematics such as 5CB in particular, can be employed in biological sensing and applied to label-free immunodetection owing to their unique birefringent, anchoring, alignment and collective properties. Like all different kinds of immunoassays, both sensitivity and specificity are universally the most important key points of concern. For such a relevant LC-based immunodetection technique to be promising, it must be able to yield good performance as manifested by the resulting sensitivity and specificity. In order to warrant desired high sensitivity, various methods can be simultaneously adopted in the sample fabrication procedure.

In this invited talk, I shall report on our recent development of various approaches toward ultrahigh sensitivity in LC-based immunoassays for potential clinical applications. The approaches entail (1) the selection of the sensing mesogen; (2) an unconventional method for antibody–antigen reaction; (3) the surface modification of the surfactant layer for LC alignment. The measurements involve polarizing optical microscopy as well as the contact-angle measurement. Special attention will be paid to the conspicuousness of the optical texture varying with the cancer biomarker CA125 antibody/antigen concentration and to the extent of surface modification of the aligning layer on the substrate as revealed by the contact-angle data.

9182-17, Session 4

Contact angle measurements as a means of probing the surface alignment characteristics of liquid crystal materials on photoalignment layers *(Invited Paper)*

Kenneth L. Marshall, Oleg Didovets, Debra J. Saulnier, Univ. of Rochester (United States)

Photoalignment technology has been under increasingly intensive investigation over the past decade as an alternative to buffing for generating high-quality uniform molecular alignment in liquid crystal (LC) devices. This technology is especially applicable to LC devices for high-peak-power laser applications, as the 1054 nm laser damage thresholds of photoalignment layers can approach that of fused silica (over 60 J/cm2, 1 ns pulse). The high laser damage resistance of coumarin-based photoalignment layers enabled us to fabricate a wide variety of photoaligned LC devices for high peak power laser applications, including wave plates, beam shapers, apodizers, and radial polarization converters. Although considerable progress has been made in this area, materials selection and photoalignment processing conditions are still determined using a largely empirical, “trial-and-error” approach, which is a costly and time-consuming process. Because the contact angle of an LC droplet with an alignment surface yields important information about LC-surface physical interactions (e.g. surface polarity, wettability and LC surface tension), and these interactions can be correlated to important device parameters of interest (fast axis direction, pretilt angle, and anchoring energy) contact angle characterization has the potential to be a useful, convenient, and cost-effective metric to aid in material selection and process development for photoaligned LC device fabrication. In this paper, we will describe efforts to correlate the contact angle of LC materials with a wide range of physical properties with alignment quality in several photoalignment materials systems, and demonstrate how the technique could be used to optimize photoalignment exposure processes.

9182-18, Session 4

Nanoparticles forming liquid crystals *(Invited Paper)*

Ewa Gorecka, Univ. of Warsaw (Poland)

Research related to nanoparticles (NPs) is stimulated by their unusual optical, electronic and magnetic properties. The range of application could be broader if they form well defined, large-scale structures; such supercrystals are referred to as artificial solids. We show that spherical nanoparticles can organize into many diverse structures when substituted by mesogenic ligands, due to the selfsegragation of chemically non-compatible units. Nematic, smectic columnar and 3D superstructures were observed in which metal cores and organic parts self-segregate in space. The type of structure can be controlled by composition of grafting layer and temperature as well as by the metal core size and density of grafting layer. In special cases the distance between nanoparticles in the superlatice could be controlled by light induced conformational changes in organic grafting layer. In some cases birefringent supercrystals were observed that gave possibility to control the plasmonic properties by the light polarization. When the fluorescent ligands are attached to the metal surface the enhancement of fluorescence form the ligand was detected if ligands were alligned parallel to the NP surface. The mesogenic ligands can be also used for controlling of metal core growth (Ostwald effect).

9182-19, Session 4

Investigation of host liquid crystal composition on polymer stabilised blue phase properties *(Invited Paper)*

Suhana B. Mohd Said, Md Asiqur Rahman, Univ. of Malaya (Malaysia); Itaru Yamana, Munehiro Kimura, Nagaoka University of Technology (Japan)

Polymer stabilised blue phase liquid crystals (PSBPLCs) have been investigated for photonics and display applications for the following reasons: optical isotropy in the dark state, ease of fabrication due to the omission of the alignment layer, and sub-millisecond response length. Major barriers to the commercialisation of PSBPLCs are: hysteresis, residual birefringence, and most significantly, high driving voltage. We have chosen to lower the driving voltage through optimization of the mixture (host LC, chiral dopant and monomer). In this paper, investigation of the contribution of the host liquid crystal to the phase stability and electro-optic characteristics of the PSBP will be discussed. The following cases have been investigated:

1. A three component host liquid crystal (E8, PE-5CNF (4-Cyano-3-fluorophenyl 4-pentyl benzoate) and CPP-3FF (4-(trans-4-n-propyl cyclohexyl)-3',4'-difluoro-1,1'-biphenyl), LCC Corporation, Japan). For a ratio of E8:PE-CNF:CPP-3FF of 5:3:2, a large BPI window of >50.4 degrees C and low hysteresis was achieved, but the driving voltage was 79V.

2. A single host liquid crystal, 8OCB with chiral dopant CB15. For a ratio for 8OCB:CB15 of 1:1, this mixture demonstrated a significantly lower driving voltage of 65V, but exhibited a smaller BPI window of >27 degrees C. Decrease in the ratio of 8OCB:CB15 also induced the presence of a BPII phase in the mixture. A single host liquid crystal has the advantage of simplicity of composition, and lowered driving voltage. However, the hysteresis and blue phase temperature range needs to be optimised.

This investigation concludes upon the suggestion of liquid crystal characteristics which optimises the blue phase temperature range, low hysteresis, switching times and driving voltage.

9182-21, Session 4

How the physical anisotropy affects the bacteria movement *(Invited Paper)*

Tigran V. Galstian, Ismaël Duchesne, Simon Rainville, Univ. Laval (Canada)

Liquid crystals have been successfully used in light modulation applications. Their "sensing" capacities were less explored, particularly in the area of medical diagnostics. Given the numerous presence of liquid crystalline structures in the biological tissue, we have raised the question of the impact of the physical anisotropy of a liquid environment on the behavior of living microorganisms, such as bacteria. We have discovered that this may drastically change the behavior of bacteria. The corresponding studies may teach us how the human body is colonized by those bacteria. In this talk, we shall present various liquid crystalline media as host for living microorganisms and the study of the behavior of one example of them (E-coly bacteria) in a biocompatible liquid crystal composition.

9182-22, Session 5

Liquid crystal polymer dispersed liquid crystals *(Keynote Presentation)*

Nelson V. Tabiryan, Olena Uskova, Luciano De Sio, Uladzimir Hrozhyk, Rafael O. Vergara-Toloza, BEAM Engineering for Advanced Measurements Co. (United States); Timothy J. White, Timothy J. Bunning, Air Force Research Lab. (United States)

A Liquid Crystal polymer is used for realizing a new generation of Polymer-Dispersed Liquid Crystals (LCPDLC) with excellent optical/electro-optical properties and negligible scattering losses in both ON and OFF states. The polarized optical microscopy and the environmental scanning electronic microscopy show a regular and uniform morphology made of well oriented polymeric stripes without the evidence of micro-sized nematic liquid crystals droplets. Moreover, we have characterized the LCPDLC structures in terms of spectral analysis response, operating voltages and switching times. In comparison to conventional polymer liquid crystal composite systems, our LCPDLC structures exhibit low switching voltage (4-5V/µm), submillisecond (400?s) and symmetric response times. The stability of the alignment has been tested by applying a quite large electric field (8-9V/µm) as well as by performing temperature cycles across the nematic-isotropic phase transition point (80 °C). In both cases, the goodness of the LCPDLC alignment proved to be not affected by the tests. In addition, due to the robustness of the polymeric structure, the LCPDLC film can be easily removed (without affecting the optical quality) from the glass substrates and used in a free-standing configuration. The possibility to realize a stable and well oriented liquid crystal film with all the properties above described marks a breakthrough towards the realization of solid high speed photonic devices.

9182-23, Session 5

Liquid crystal phases and charge carrier mobilities for a series of monoalkoxy-ethyloxycarbonyl derivatives of the tetracyclic oligothiophene BTTT

Michael T. Springer, Rebecca A. Callahan, Renfan Shao, Yongqiang Shen, Univ. of Colorado at Boulder (United States); Garry Rumbles, National Renewable Energy Lab. (United States); Noel A. Clark, David M. Walba, Univ. of Colorado at Boulder (United States)

Organic photovoltaic devices suffer from inefficiencies resulting from non-uniform molecular alignment in thin films; controlling thin film morphology is a top priority for OPV. Liquid crystals can provide this control by utilizing the well-defined self-assembly of mesogens. Crystal phases (SmBcrystal, SmE, SmG, SmH) that lie below hexatic smectic phases (SmB, SmF, SmI) are particularly well aligned and in particular, the SmE phase shows relatively high charge carrier mobilities in, e.g., OFET devices. The SmE phase shows long-range order in three dimensions and it has recently been postulated that this order results from the interdigitation of alkyl chains between smectic layers. A similar result has been found for the polymer poly(2,5-bis(3-tetradecylthiophen-2-yl) thieno[3,2-b]thiophene) (pBTTT), where interdigitation of alkyl chains yields a highly ordered morphology. pBTTT has shown charge mobility values among the highest of any organic material, 1 cm2 V-1 s-1, and Hanna has recently reported carrier mobilities greater than 5 cm2 V-1 s-1 for a benzothienobenzothiophene derivative processed from a smectic liquid crystal phase. Here we report on an efficient synthesis of 2-alkoxy-BTTT analogs, and on the morphology and charge carrier mobilities in several smectic and plastic crystal phases observed in the system, including SmB, SmE, and SmG. Mobility and absorption data have also been acquired on spin-coated thin films of the materials.

9182-24, Session 5

Electrooptics of nematics formed by molecular dimers *(Invited Paper)*

Oleg D. Lavrentovich, Jie Xiang, Sergij V. Shiyanovskii, Kent State Univ. (United States); Corrie Omrie, Univ. of Aberdeen (United Kingdom); Volodymyr Borshch, Young-Ki Kim, Afsoon Jamali, Kent State Univ. (United States); Georg H. Mehl, Maria-Gabriela Tamba, The Univ. of Hull (United Kingdom)

Electrically induced reorientation of liquid crystal (LC) director caused by dielectric anisotropy is a fundamental phenomenon widely used in modern technologies. We report on the experimental observation of electrooptic effects in nematic liquid crystals formed by dimer molecules with flexible bridge connecting two rigid rod-like units. The materials exhibit three nematic phases: nematic, chiral nematic (when doped with chiral additives) and twist-bend nematic. The uniaxial nematic shows a regular Frederiks type of response while the twist bend nematic shows the first order Frederiks transition, in which the type of deformation is reduced to splay and saddle splay of the helicoidal axis by the periodic nature of director modulation. The electrooptic behavior is thus similar to dielectric reorientation of smectic A and short-pitch cholesterics. The chiral nematic demonstrates an electrooptic effect with a distinct heliconical deformation of the director. In the electric field, the director forms an oblique helicoid. The pitch and the conical angle of the oblique helicoid are both dependent on the applied electric field. The work is supported by NSF DMR grants 1121288 and 1104850, by DOE Grant No. DE-FG02-06ER 46331, Ohio Research Scholars Program Research Cluster on Surfaces in Advanced Materials and by KSU Trustees Fund.

9182-25, Session 5

New twist on the helical nanofilament phase of bent-core liquid crystals *(Invited Paper)*

Antal I. Jakli, Cuiyu Zhang, Oleg D. Lavrentovich, Kent State Univ. (United States)

The B4 phase of bent-core liquid crystals has been shown to be an assembly of twisted layers stacked to form helical nanofilaments. Interestingly, some of them have structural colors that cannot be explained by the nanofilaments alone. Cryogenic-transmission electron microscopy observations on 40-120 nm films of four bent-core liquid crystal materials show that the filaments are present even in contact with a carbon substrate with only minor deformation, thus representing bulk properties. We find that the subsequent arrays of nanofilaments are not parallel to each other, but rotate by an angle of 35-40 degrees with respect to each other. This doubly twisted structure can explain the structural color. Being principally different from the packing of molecules in the twist grain boundary and blue phases, the double-twist structure of helical nanofilaments expands the rich word of nanostructured organic materials.

9182-26, Session 5

Tailored liquid crystal devices for specific imaging applications *(Invited Paper)*

Avner Safrani, Iftach Klapp, Asi Solodar, Marwan Abuleil, Sivan Isaacs, Ibrahim Abdulhalim, Miri Gelbaor Kirzhner, Ben-Gurion Univ. of the Negev (Israel)

The emerging field of liquid crystals (LCs) photonics is becoming more and more active research field in which the strong electrooptic properties of LCs are harnessed for these applications such as the use of LC spatial light modulators (SLMs) in imaging, tunable focus LC lenses, tunable filters and polarization control devices in optical telecommunication and imaging. LCs can flow and fill small gaps; hence they can be integrated into nanophotonic structures in planar or cylindrical geometries such as in photonic crystal fibers.

Our group has been developing variety of specially designed LC devices integrated into imaging systems for specific applications such as (i) wideband tunable filters for hyperspectral imaging and frequency domain optical coherence tomography, (ii) discrete tunable filter for multispectral imaging, (iii) compact polarization rotator for polarimetric imaging, (iv) fast phase retarder for phase shift interferometry, (v) wideband achromatic waveplate, (vi) annular SLM for extended depth of focus, (vii) polarization independent LCFP tunable filter, and lately (vii) optically addressed SLMs. The main concepts of these devices and their functionality into imaging systems such as in skin spectropolarimetric imaging and full field optical coherence tomography will be reviewed in this talk.[1-5]

Infrared reflector based on liquid crystal polymers and its impact on thermal comfort conditions in buildings

Hitesh Khandelwal, Technische Univ. Eindhoven (Netherlands) and Dutch Polymer Institute (Netherlands); Franziska Roberz, Roel C. G. M. Loonen, Jan L. M. Hensen, Cees W. M. Bastiaansen, Dick J. Broer, Michael G. Debije, Albert P. H. J. Schenning, Technische Univ. Eindhoven (Netherlands)

An energy crisis is one of the most challenging problems throughout the world. There has been a huge increase in global demand of energy in last few years. Several attempts have been made to decrease the consumption of energy sources. One of the main energy consumption in building, cars, greenhouses and indoor spaces is by cooling devices to maintain the indoor temperature in comfortable zone. To reduce the consumption of tremendous amount of energy on cooling devices we need an improved control of transparent features (i.e. windows) for reduction of energy.1 Therefore, IR-Reflector is interesting for the rejection of infrared light and this device would be very attractive especially if working mechanism of IR Reflector does not affect light in the visible region without using any source of energy.

A very appealing method to selectively and precisely control infrared transmission is via the use of cholesteric liquid crystal polymer reflectors (Ch-LC polymer). Ch-LCs, also known as chiral-nematic LCs; reflect circularly polarized light as a result of their self-organizing molecular helices.2 Depending on the handedness of the pitch, left- or right-handed circularly polarized light is reflected. The pitch of the helix in these networks determines the wavelength of reflection, and can be modified in response to light3 and temperature4 resulting in a change in reflection wavelength. In contrast to existing alternatives they are characterized by a very sharp cut-off between the transmissive and the reflective state enable exact tailoring of the heat reflection. In my presentation, I will be discussing the fabrication of hyper-reflective infrared broadband and its implications on the temperature of buildings.

Micro-second electro-optic modulation in polymer/liquid-crystal nanocomposite films *(Keynote Presentation)*

Masanori Ozaki, Osaka Univ. (Japan); Yo Inoue, Kyoto Univ. (Japan); Hoe-Kyeong Kim, Hiroyuki Yoshida, Osaka Univ. (Japan)

We report a high-speed electro-optic modulation of the refractive index (RI) of a polymer/liquid-crystal composite film possessing a rise time < 30 microseconds and a decay time < 10 microseconds. The fast response was demonstrated in a polymerized LC film containing nano-sized LC droplets less than 20 nm inside a sponge-like anisotropic polymer matrix. The film was fabricated simply by irradiating ultraviolet light on a mixture comprising photo-polymerizable and conventional LCs. For the photo-polymerized LC matrix, a variety of films with various distribution of optical anisotropy can be used such as nematic, cholesteric and so on. In any case, only the effective RI can be tuned without disturbing a distribution of the molecular orientation in the polymerized LC matrix. For instance, in the composite film using the photopolymerized cholesteric LC as the matrix, a selective reflection can be controlled by modulating the effective RI without deforming the helical structure. Because of nano-sized droplets dispersed in the matrix, there is no light scattering and fast relaxation dynamics of the confined LC molecules enable a micro-second modulation of the selective reflection. Using dye-doped cholesteric matrix, micro-second tuning of lasing wavelength can also be achieved. The lasing color tuning previously reported in the chiral LCs has been based on the pitch-tuning, namely deformation of the helix, and the tuning response of the lasing is quite slow. Adapting the composite system proposed here, fast and continuous color modulation based on the RI-tuning can be performed.

9182-29, Session 6

Ultrafast all-optical switching with transparent liquid crystals

Shuo Zhao, Iam Choon Khoo, The Pennsylvania State Univ. (United States)

We present the results of our recent studies of ultrafast all-optical switching using laser induced refractive index change in transparent liquid crystals. The underlying mechanism involved is nematic flow induced director axis reorientation caused by Maxwell Stress imparted by the laser. This process is characterized by response times in the nanoseconds time scale. The feasibility of all-optical switching using such mechanism has been experimentally demonstrated along with quantitative theoretical modeling which gives very good agreement with the experimental results. In particular, we showed that the response times become shorter with increasing input laser power, with the shortest switching time around 20 nanoseconds – about 1 million times faster than the conventional electro-optical switching counterpart. Since the effect is non-resonant, it could be observed with laser of any wavelength in the entire visible – near IR region, and utilized for passive optical limiting and sensor protection application against agile frequency lasers.

9182-30, Session 6

Liquid crystal tunable THz wave plates *(Invited Paper)*

Yan-Qing Lu, Wei Hu, Nanjing Univ. (China)

We developed a serial of large birefringence (> 0.3) nematic liquid crystal (LC) mixtures in the wavelength range from 0.5 to 2 THz. Based on the obtained materials, some THz devices have been developed. Among them, a tunable THz wave plate is demonstrated. We use a metallic grating as front polarizer and electrode. A tree-layer graphene film is used as a transparent and polarization independent back electrode. Photoalignment technique is adopted to obtain a homogeneous LC alignment. If an electric field is applied, the phase retardation of the LC cell changes so that output THz beam is electrically controlled. For a 2 THz wave, the polarization state evolution in 0-50V voltage range is recorded, which clearly show the change from a linear polarization, to elliptical polarization, circular polarization then back to an orthogonal linear polarization. The function of a tunable THz half-wave plate (HWP) is well-displayed.

In comparison with previous reported LC THz phase shifters, our tunable wave plate shows some interesting advantages, (1) High birefringence LC mixture is used. (2) The polarization rotation and EO tuning are demonstrated with only 50 V driving voltage. (3) Unique cell structure containing a built-in metallic grating polarizer/electrode and a lost-cost three layer graphene electrode. (4) A post treatment technique is developed to greatly improve the transmission of graphene in THz band. (5) Photo alignment technique is employed. We believe our technologies may pave a road toward many new LC tunable THz apparatuses.

9182-31, Session 6

Liquid crystal claddings for passive temperature stabilization of silicon photonics

Joanna N. Ptasinski, Space and Naval Warfare Systems Ctr. Pacific (United States) and Univ. of California, San Diego (United States); Iam-Choon Khoo, The Pennsylvania State Univ. (United States); Yeshaiahu Fainman, Univ. of California, San Diego (United States)

Silicon photonics allows for high density component integration on a single chip and it brings promise for low-loss, high-bandwidth data processing in modern computing systems. As optics penetrates deeper into the chip, temperature stability becomes essential due to silicon's high thermo-optic coefficient, consequently leading to performance deterioration in the presence of rising temperature. This work explores passive thermal stabilization of silicon photonic devices using nematic liquid crystal (NLC) claddings. Liquid crystals possess large negative thermo-optic coefficients in addition to low absorption at the telecommunication wavelengths.

9182-32, Session 6

Glass-free 3D display with LCD: technique challenges, approaching solutions, and prospect *(Invited Paper)*

Jianying Zhou, Sun Yat-Sen Univ. (China)

Technical challenges for autostereoscopy, or glass-free 3D display system are presented. These challenges include the reduction of the cross talk between different viewing channels, the increase of the resolution for each viewing point as well as technological and cost competitiveness with flat 2D display systems. The approach with a back-light illuminated LCD system, including the design of multi-viewing points, the hybrid spatial and temporal control, the use of a new figure of merit to guide the optical systematic design with a genetic algorithm to achieve a smallest possible cross talk and a viewing zone with homogeneous intensity, is presented. We show that it is possible to achieve the display quality approaching a glass-assisted 3D system, and the integrated user-machine interaction is developed demonstrating the possibility that autostereoscopic display may experience a fresh development for the reason that it may become a rigid demand for the end users in the near future.

9182-33, Session 7

Lasing and waveguiding in smectic A liquid crystal optical fibers *(Keynote Presentation)*

Igor Musevic, Jo?ef Stefan Institute (Slovenia); Karthik Peddireddy, Max Planck Institute for Dynamics and Self-Organization (Germany); Venkata S. R. Jampani, Jo?ef Stefan Institute (Slovenia); Stephan Herminghaus, Christian Bahr, Max Planck Institute for Dynamics and Self-Organization (Germany); Marusa Vitek, Jo?ef Stefan Institute (Slovenia)

We demonstrate a new class of soft matter optical fibers, which are self-assembled in a form of smectic-A liquid crystal microtubes grown in an aqueous surfactant dispersion of a smectic-A liquid crystal. The diameter of the fibers is highly uniform and the fibers are highly birefringent. They are characterized by a line topological defect in the core of the fiber with an optical axis pointing from the defect core towards the surface. We demonstrate guiding of light along the fiber and Whispering Gallery Mode (WGM) lasing in a plane perpendicular to the fiber. The light guiding as well as the lasing threshold are significantly dependent on the polarization of the excitation beam. The observed threshold for WGM lasing is very low when the pump beam polarization is perpendicular to the direction of the laser dye alignment and is similar to the lasing threshold in nematic droplets. The smectic-A fibers are soft and flexible and can be manipulated with laser tweezers demonstrating a promising approach for realization of soft photonic circuits

9182-34, Session 7

Real-time holographic display using doped liquid crystals *(Invited Paper)*

Yikai Su, Shanghai Jiao Tong Univ. (China)

We discuss dynamic optical holographic displays based on liquid crystals doped with dye and quantum dot, respectively. Real-time holographic display is achieved with a response time of ~1ms in a dye-doped liquid crystal film without any applied electric field. Meanwhile, the reconstructed RGB images are combined into a color image. The dependences of the response time and diffraction efficiency on the polarizations of the control beams are investigated. We also demonstrate a quantum-dot-doped liquid crystal to improve the diffraction efficiency. The transient first-order diffraction efficiency is measured up to 20%. A reconstructed holographic video at a refresh rate of 25 Hz is demonstrated by the experiments.

9182-35, Session 7

Cholesteric liquid crystals with wide-band reflection properties *(Invited Paper)*

Huai Yang, Lanying Zhang, Peking Univ. (China)

Attributing to the unique helical supra-molecular structure, cholesteric liquid crystal (CLC) performs selective light reflection property and could reflect the circularly polarized incident light whose handedness is identical with the helical axis. But the bandwidth of a single-pitch CLC is usually less than a hundred nanometers, which is insufficient for its some applications. Recently in our group, a transparent polymeric film with ultra-broad wavelength reflection of infrared (IR) was prepared. Three polymerizable liquid crystal (LC) photo-polymerizable monomers: nematic monoacrylated, nematic diacrylated and smectic monoacrylated monomers were synthesized. The mixture of these monomers could organize themselves with smectic-like short-range ordering (SLSO) between the Ch and smectic A (SmA) phase. After mixing UV-absorbing dye and photo-initiator with the monomers of which the molecules of the Ch phase were oriented planarly, the mixture was cured under UV irradiation at the temperature just above the SLSO region. Since an UV-intensity gradient resulted from the dye, polymerization-rate gradient were achieved, and the more nematic diacrylated diffused to the region nearer the UV light in the film. Thus, the temperature region of the SLSO increased during UV irradiation and the resulted film had a very large pitch gradient which can reflect the circularly polarized incident light from 700 to 14000 nm.

9182-37, Session 7

Color sequential TFT-LCD toward an eco display, from perspective of liquid crystal and TFT driving *(Invited Paper)*

Han-Ping D. Shieh, National Chiao Tung Univ. (Taiwan)

High efficiency, low material cost, green are among key features for eco-displays. In this talk, the suppression of the serious color break-up (CBU) artifact and improvement of image quality, the human visual model for CBU, LC display without polarizing optics, novel image driving algorithm and TFT driving for an Eco Display will be presented. Novel TFT material, backlight and system toward 3D and interactive will be explored.

9182-40, Session 7

New developments in SmAPF materials

Eva D. Korblova, Maria Kolber, Joseph E. Maclennan, Matthew A. Glaser, Renfan Shao, Yongqiang Shen, Noel A. Clark, David M. Walba, Univ. of Colorado at Boulder (United States)

The first reported SmAPF phase, obtained from the mesogen W586, exhibited interesting and useful electrooptics.(1) Specifically, upon application of an electric field, a significant increase in birefringence is observed without rotation of apparent optic axis. Further study demonstrates great promise for this phase in applications requiring fast phase-only electrooptic modulation.

In order to tune properties of SmAPF materials for such applications, a search for new mesogens providing wider phase temperature ranges and improved modulation depth (birefringence change with field) alone or in mixtures, is in progress.

Several surprising and interesting discoveries have derived from this work. For example, a dramatic and unexpected odd-even effect in homologues of W586, which possesses a tricarbosilane-terminated alkoxy tail, provides insights into the nature of nanophase segregation in smectics.

In addition, new classes of SmAPF mesogens have been prepared in an effort to produce materials for applications. Details of the characterization and EO properties of the new materials will be presented.

9182-38, Session 8

The helical nanofilament phase for organic photovoltaics *(Keynote Presentation)*

Rebecca A. Callahan, Michael T. Springer, Eva D. Korblova, Renfan Shao, Univ. of Colorado at Boulder (United States); David Coffey, Garry Rumbles, National Renewable Energy Lab. (United States); Noel A. Clark, David M. Walba, Univ. of Colorado at Boulder (United States)

The helical nanofilament (HNF) liquid crystal phase represents a unique hierarchical assembly of bent-core mesogens.[1] In the bulk

HNF phase, smectic stacks possess spontaneous negative Gaussian curvature, limiting the width of the layers (~ 40nm, and the number of layers in a stack (~40 nm), providing long helical nanofilaments ~ 40 nm diameter, which then self-organize into a porous hexagonal array of HNFs. Furthermore, half the surface area of the HNFs is composed of layer edges, putting the aromatic sublayers in direct contact with the surroundings, which can contain any one of many nanophase segregated dopants up to concentrations ~ 50% by weight. These dopants can be soluble fullerenes such as PCBM, in which case the doped sample represents an ordered bulk hetereojunction (BHJ) system with possible application in organic photovoltaics (OPV). This gains added attractiveness due to the additional hypothesis, supported by solid state NMR data, that the aromatic core sublayers in the HNF phase are effectively crystalline in nature. Recent studies using flash photolysis time-resolved microwave conductivity suggesting efficient exciton splitting from excited PCBM in a prototypical HNF mesogen/PCBM BHJ, and reasonable hole carrier mobilities in the HNF phase, will be described.

Photoinduced deformation of uncrosslinked liquid crystal polymers *(Invited Paper)*

Yanlei Yu, Jiu-an Lv, Yuyun Liu, Fudan Univ. (China)

Photodeformable crosslinked liquid-crystalline polymers (CLCPs) are most promising materials for applications such as artificial muscles and soft actuators. Since on the one hand, they are able to show large and reversible shape deformation due to the cooperation of the rubber elasticity of polymer networks and high order of liquid-crystalline (LC) mesogens. On the other hand, they can convert light energy directly into mechanical work and act by remote, instant, and precise manipulation. In this work, novel azobenzene-containing side-chain liquid crystal polymers without any crosslinking were synthesized via ring opening metathesis polymerization (ROMP), which are benefit for the fabrication of micro and even nano soft actuators through micromachining technologies. We designed the such uncrosslinked LC polymers (UCLCPs) based on the following four factors: (1) ROMP that allows for controlled living polymerization was employed to synthesize the UCLCPs with a high molecular weight, thus they are easy to self-assemble into freestanding films without any chemical crosslinking; (2) azobenzene groups in the side chains create the photoresponsiveness and act as mesogens to form an LC phase; (3) mainchain of the UCLCPs has a rubbery-like structure, which endows the UCLCPs with a good elasticity; (4) flexible mainchains, sidechains with long spacers and end-groups enable the polymer excellent processability. Upon one-step annealing, the UCLCPs with azobenzene mesogenic side chains self-assembled into freestanding films, where the polymer backbone aligned parallel to the film surface and the side chains aligned atilt away from the surface. Such an ordered structure forms through the self-assembly of a smectic C phase. The resultant wide-area ordering configuration allows the polymer films to bend away from the light source rapidly and reversibly when the azobenzene units are photoisomerized.

Photo-aligned ferroelectric liquid crystals for modern photonics *(Invited Paper)*

Abhishek K. Srivastava, Vladimir G. Chigrinov, Hoi Sing Kwok, Hong Kong Univ. of Science and Technology (Hong Kong, China)

The latest demand of the community, which has changed dramatically in recent time, includes high-resolution displays (i.e. close to the human eye limits), low power consumption and undoubtedly the cost effective display and photonic devices. This is a big challenge for both scientists and engineers. The ferroelectric liquid crystal (FLC), because of the fast switching speed and low power consumption, is considered to be one of the potential candidates to serve as the building block for the modern devices. However, due to several limitations i.e. geometrical, optical and mechanical defects, these structures are less popular among the research and industrial regime. Recently, we have established that the Nano-scale photo-alignment technology could be used to improve characteristics of FLC systems. The photo-alignment, by different irradiance doses, offers good control on the anchoring energy and therefore provides good balance for elastic energy of the helix and the normalized anchoring energy. This balanced energy with proper selection of material parameter, that offer helix unwinding only in the presence of electric field i.e. ESHFLCs, offer high contrast ratio of >10K: 1 at the driving frequency of >3kHz.

By leveraging potentials of the Nano-scale photo-alignment and ESHFLCs, a concept for the field sequential color display (FSCD) has been developed that is characterized by the less power consumption, color triangle ~ 130% of NTSC and high contrast ratio. In addition to the FSCD some photonic elements have also been proposed that includes FLC grating, Fresnel lens, CD grating etc. Thus, these systems could find applications in variety of modern devices and modify the energy consumption statistics and image perceptions up to a large extent.

9182-43, Session 8

Topogical diversity of localized metastable states in chiral liquid crystals *(Invited Paper)*

Etienne Brasselet, Charles Loussert, Univ. Bordeaux 1 (France)

Liquid crystalline materials are well-known to exhibit various kinds of structural defects, whose space-variant optical properties are actually useful for a number of applications, including recently developed integrated optical vortex generators. In addition, since liquid crystal defects display well-defined topological features, their very existence also appears attractive in terms of information storage at the microscopic scale. An illustrative example is provided by frustrated chiral liquid crystals films, in which different localized metastable states can be written by either structured or unstructured light beams. We will present recent results regarding the controlled generation of multiple chiral topological states in liquid crystals.

Photonic density of states of a stack of cholesteric liquid crystals and isotropic medium layers

Koryun B. Oganesyan, Yerevan Physics Institute (Armenia); Ashot H. Gevorgyan, Yerevan State Univ. (Armenia); Ruben V. Karapetyan, A. M. Prokhorov General Physics Institute (Russian Federation); Gagik A. Vardanyan, Nanoclusters, Nanomaterials & Nanoscience Inc. (United States); Yuri S Chilingaryan, E A Santrosyan, Yerevan State University (Armenia); Yuri V Rostovtsev, University of North Texas (United States)

We calculated the photonic density of states (PDS) of the eigen

polarizations (EPs) in the system composed of a stack of layers of a cholesteric liquid crystal (CLC) and an isotropic medium. The problem was solved by the layer addition modified method of Ambartsumian. The reflection spectra and photonic density of states (PDS) peculiarities, as well as the peculiarities of absorption and emittance were investigated. We obtained the dependences of the PDS as a function of parameters characterizing absorption and gain. It was shown that the subject system can be used in lasers for obtaining low threshold lasers with tunable emittance wavelength in wide ranges. It is shown that the subject system can work as a low threshold laser or a multi-position trigger.

9182-45, Session PWed

Dependence of the electrooptical properties of polymer-dispersed vertical aligned liquid crystals on the surface affinity of the liquid crystal and monomer

Hyojin Lee, Ji-Hoon Lee, Chonbuk National Univ. (Korea, Republic of); Tae-Hoon Yoon, Pusan National Univ. (Korea, Republic of)

We examined the effect of the surface affinity of the liquid crystal (LC) and monomer molecules on the electrooptical properties of the vertical aligned polymer-dispersed liquid crystals (PDLC). The liquid crystal molecules with greater contact angle on the surface formed more spherical LC droplet. On the other hand, the liquid crystal with smaller contact angle compared to the monomers resulted in cylindrical LC droplet. The PDLC sample with cylindrical LC droplet showed rapid increase of transmittance by applying the electric field and showed greater transmittance compared to the PDLC sample with spherical droplet. Threshold voltage of the spherical droplet was smaller than the cylindrical droplet sample.

9182-46, Session PWed

Effect of UV curing conditions on polymerized tunable chiral nematic liquid crystals

Mohammad Mohammadimasoudi, Jeroen Beeckman, Kristiaan Neyts, Univ. Gent (Belgium)

Chiral nematic liquid crystals (CLCs) have attracted substantial interest as they spontaneously self-organize to form a helical structure with no complex fabrication procedure required. As such they exhibit a reflection band for a certain wavelength interval Δ? (= ΔnP) with P the period and Δn the birefringence. Since the photonic band gap (PBG) can be tuned by applying external factors (heat, voltage, light, elasticity) CLCs are potentially interesting for large area optical filters and shutters, reflective displays and tunable lasers. The material that is used is a mixture of photopolymerizable and nematic LC including a chiral dopant. By selecting the appropriate chiral dopant concentration, it is possible to make devices for different operation wavelengths.

In this work, a device which consists of a mixture of photo-polymerizable liquid crystal, non-reactive nematic liquid crystal and a chiral dopant is fabricated. The influences of UV illumination on a partially polymerized chiral liquid crystal, are investigated. A blue wavelength shift of the photonic band gap is obtained as a function of intensity, duration time of UV illumination and the thickness of the cells. The shift is opposite to what is reported by others. Interestingly the width and depth of the photonic band gap is unaffected by the change in UV curing conditions, which indicates that there is no degradation by the UV light.

9182-47, Session PWed

On a photonic density of states of cholesteric liquid crystal cells

Koryun B. Oganesyan, Alikhanyan National Science Lab. (Armenia); Ashot H. Gevorgyan, Yerevan State Univ. (Armenia); Ruben V. Karapetyan, A. M. Prokhorov General Physics Institute (Russian Federation); Gagik A. Vardanyan, Nanoclusters, Nanomaterials & Nanoscience Inc. (United States); Yuri S Chilingaryan, Yerevan State University (Armenia); Yuri V Rostovtsev, University of North Texas (United States)

The photonic density of states (PDS) of the eigen polarizations (EPs) in cholesteric liquid crystal (CLC) cells are calculated. The exact analytic expressions for the reflection and transmission matrices for the finite thickness CLC layer are used. We obtained the dependences for the PDS on the parameters characterizing absorption and gain, as well as the CLC cell thickness, CLC local dielectric anisotropy and CLC layer surrounding refractive index. The possibility of connections between the PDS and the density of the light energy accumulated in the medium are investigated and it was shown that these characteristics have analogous spectra and, besides, the influences of the problem parameters on these characteristics also were analogous. We have shown, that the decrement of the CLC layer surroundings refractive index leads to a sharp increase of the maximum PDS and, consequently, leads to a sharp decrement of the laser excitation threshold. The PDS dependence on the refraction coefficients of the substrates of the Fabry-Perot resonator filled with a CLC planar layer was investigated, too. It is shown that the subject system can work as a low threshold laser or a multi-position trigger.

Optical, electro-optical, and dielectric spectroscopy of polymer stabilized ferroelectric liquid crystals

Jamal Hemine, Univ. Hassan II Mohammedia - Casablanca (Morocco); Abdetylah Daoudi, Univ. du Littoral Côte d'Opale (France); Abdelhamid El Kaaouachi, Univ. Ibn Zohr (Morocco); Mimoun Ismaili, Univ. des Sciences et Technologies de Lille (France); Redouane Douali, Christiane Legrand, Univ. du Littoral Côte d'Opale (France)

Ferroelectric liquid crystals (FLCs) [1] have attracted a significant amount of attetion because of theire possible applications in fast switching devices. An application of FLCs that is only now being explored is optical imaging and recording. In this technology, a FLC material is placed between two conductor glass plates or transparent plastics. By applying an external electric field perpendicular to the electrodes, the coupling between ferroelectric polarization (electric dipole) and electric field was induced in the bulk of the cell [2, 3]. This causes an electric field to develop in the liquid crystal corresponding to the intensity of the light. The electric pattern can be transmitted by an electrode, which enables the image to be recorded. This technology is still being developed and is one of the most promising areas of FLC research. In recent years, Polymer Stabilized Ferroelectric Liquid Crystals (PSFLCs) [4-6] have been investigated in order to enhance and to improve their optic and electro-optic responses as well as their mechanic properties. These PSFLC materials, are also so-called "Composite materials", represent an exciting field of functional materials, providing a large range of emerging applications in display devices. To improve the electro-optical responses and mechanical properties of PSFLCs under applied electric field, great efforts have been made by several groups using different techniques. However, relatively few papers have been devoted to the dielectric spectroscopy. In this work, we present the linear dielectric relaxation characterizations of the pure FLC (0%) and PSFLCs with 4% and 8% polymer concentrations. In these studies, the linear dielctric permittivities can be determined, which allows to evaluate some physical parameters

of these materials, such as the twist elastic constant, elastic energy as well as the rotational viscosity. This study is also preceded, by using the optic microscopy analysis and electro-optic spectroscopy for all PSFLC systems investigated in this work.

Dielectric and phase behaviors of a blue phase liquid crystal

Sheng-Chieh Chen, Wei Lee, National Chiao Tung Univ. (Taiwan); Po-Chang Wu, College of Photonics, National Chiao Tung University (Taiwan)

Dielectric spectra of a blue phase liquid crystal were acquired at various temperatures in conjunction with observations of optical transmission spectra and birefringent textures. The temperature-dependent dielectric data at 10000 Hz were specifically retrieved for further analysis. It was found that the second derivatives of the real-part permittivity with respect to the temperature sharply revealed the phase transitions of the liquid crystal on the cooling process from the isotropic phase through the chiral nematic phase.

9182-50, Session PWed

Effect of hybrid polyimides on electro-optical performance of optically compensated bend display mode

Guan-Jhong Lin, National Taiwan Univ. (Taiwan); Tien-Jung Chen, Bo-Rung Lin, Jin-Jei Wu, National Taipei Univ. of Technology (Taiwan); Ying-Jay Yang, National Taiwan Univ. (Taiwan)

Optically compensated bend liquid crystal (LC) cells are fabricated by using the hybrid polyimides, which are mixed and coated on the substrate surface as the alignment layer. The transmittance and phase retardation are both inversely proportional to the mixed concentration of polyimides. With the rigorous calculation and simulation, the relationship between the initial phase retardation and pretilt angle (PA) is obtained. In addition, the response behavior is sensitive to the PA, and the optimum value of the concentration ratio is founded. This study provides a method for designers to arbitrarily control the PA, and makes the well electro-optical performance.

9182-51, Session PWed

Dielectric characterizations of electroclinic effect near to N*-SmA-SmC* multicritical point

Abdelhamid El Kaaouachi, Univ. Ibn Zohr (Morocco); Jamal Hemine, Univ. Hassan II Mohammedia - Casablanca (Morocco); Abdetylah Daoudi, Univ. du Littoral Côte d'Opale (France); Christiane Legrand, Univ. des Sciences et Technologies de Lille (France)

Electro-optic and dynamic properties of three pure ferroelectric liquid crystals (FLCs) [1] materials (C10, C11 and C12) exhibiting chiral smectic C (SmC*)-smectic A (SmA)-cholesteric (N*) phases have been investigated in the present work. From electro-optic studies, the tilt angle and spontaneous polarization were determined as a function of temperature. In the dielectric measurements carried out without a dc bias field, we studied the soft-mode relaxation mechanism in the paraelectric SmA phase. From experimental data and using the theoretical Landau model around the N*-SmA-SmC* phase transitions, we evaluated the soft mode rotational viscosity and the electroclinic coefficient [2, 3]. The main result in this work, is that a relaxation process usually observed in the SmA phase is also observed in the cholesteric phase (N*) phase for two C10 and C11 materials [4] and it is interpreted as a soft-mode-like mechanism. This mechanism is related to the appearance of smectic order fluctuations within N* phase whose amplitude is increased when approaching the N*-SmA-SmC* multicritical point.

Fast-response Fabry-Perot wavelength-tunable filter using vertical-alignment polymer-stabilized liquid crystal with a curing voltage

Yan-Min Li, Wing-Kit Choi, National Taiwan Univ. (Taiwan)

Electro-optical properties of a Vertical-Alignment Polymer-Stabilized Liquid Crystal (VA-PSLC) cell are investigated. With a curing voltage, the strong scattering effect of VA-PSLC cell is much reduced, and a wavelength tunable filter (WTF) can be achieved as VA-PSLC cell is placed into a Fabry-Perot cavity. When a high curing voltage is applied, the LC molecules perform a large-angle-tilt alignment causing the wavelength tuning range to decrease, which is consistent with what we expected. Furthermore, the response speed of a VA-PSLC cell is significantly improved by the polymer effect. Such a WTF can have potential applications in telecommunication systems where high speed is desirable.

Conference 9183: Organic Light Emitting Materials and Devices XVIII

Sunday - Wednesday 17–20 August 2014

Part of Proceedings of SPIE Vol. 9183 Organic Light Emitting Materials and Devices XVIII

9183-1, Session 1

Concepts for the material development for solution processable phosphorescent polymers and their application in PLEDs

Silvia Janietz, Hartmut Krueger, Armin Wedel, Fraunhofer-Institut für Angewandte Polymerforschung (Germany); Beatrice Salert, Manuel Thesen, Fraunhofer-IAP (Germany)

One example of organic electronics is the application of polymer based light emitting devices (PLEDs). PLEDs are very attractive for large area and fine-pixel displays, lighting and signage. The polymers are more amenable to solution processing by printing techniques which are favourable for low cost production in large areas. With phosphorescent emitters like Ir-complexes higher quantum efficiencies were obtained than with fluorescent systems, especially if multilayer stack systems with separated charge transport and emitting layers were applied in the case of small molecules. Polymers exhibit the ability to integrate all the active components like the hole-, electron-transport and phosphorescent molecules in only one layer. Here, the active components of a phosphorescent system - triplet emitter, hole- and electron transport molecules - can be linked as a side group to a polystyrene main chain. By varying the molecular structures of the side groups as well as the composition of the side chains with respect to the triplet emitter, hole- and electron transport structure, and by blending with suitable glass-forming, so-called small molecules, brightness, efficiency and lifetime of the produced OLEDs can be optimized.

By choosing the triplet emitter, such as iridium complexes, different emission colors can be specifically set. Different substituted triazine molecules were introduced as side chain into a polystyrene backbone and applied as electron transport material in PLED blendsytems. The influence of the alkyl chain lengths of the performance will be discussed. For an optimized blendsystem with an green emitting phosphorescent Ir-complex efficiencies of 60 cd/A and an lifetime improvement of 66.000 h @ 1000 cd/m2 were achieved.

9183-2, Session 1

Continuous synthesis of device-grade semiconducting polymers in droplet-based microreactors *(Invited Paper)*

John C. de Mello, Imperial College London (United Kingdom)

A method is reported for the controlled synthesis of device-grade semiconducting polymers, utilizing a droplet-based microfluidic reactor. Using poly(3-hexylthiophene) (P3HT) as a test material, the reactor is shown to provide a controlled and stable environment for polymer synthesis, enabling control of molecular weight via tuning of flow conditions, reagent composition or temperature. Molecular weights of up to 92 000 Da are readily attainable, without leakage or reactor fouling.

The method avoids the usual deterioration in materials quality that occurs when conventional batch syntheses are scaled from the sub-gram level to higher quantities, with a prototype five-channel reactor producing material of consistent molecular weight distribution and high structural order at a rate of ≈60 g/day. The droplet approach is especially well suited to the controlled synthesis of statistical and block co-polymers, providing greater control over stoichiometry than equivalent batch syntheses.

9183-3, Session 1

Polydopamine and melanin: nature's conjugated polymers *(Invited Paper)*

Alexander J. C. Kuehne, Tatjana Repenko, DWI an der RWTH Aachen e.V. (Germany)

Polydopamine can be oxidized to form melanin. Both polymers constitute high performance biological materials, which nature applies as universal adhesives, radical scavengers, and highly stable pigments. However, natural polydopamine and melanin are ill defined with regards to their molecular structure and melanin is highly crosslinked, which limits its solubility and therefore the chance for processing and application. I will present a facile synthetic method providing access to a linear and highly defined form of polydopamine via Kumada-coupling. The polymer can be converted into melanin by chemical and electrochemical oxidation. Polydopamine is exhibiting fluorescence in the blue spectrum, whereas the emission shifts to the near IR-spectrum after oxidation to melanin.

At the same time the controlled synthesis of linear polydopamine and melanin resolves a current dispute about the molecular structure of these polymers. Covalently and supramolecularly crosslinked networks as well as networks comprising dopamine trimers have been reported in synthetic systems. The procedure, which will be presented relies on Pd-catalyzed cross-coupling, yielding a strictly covalent linear polymer. The materials will help to resolve the current structural discrepancies observed in synthetic melanin and polydopamine materials.

9183-4, Session 1

The development of macromolecules for light-emitting diodes *(Invited Paper)*

Paul L. Burn, Ross D. Jansen-van Vuuren, Renjie Wang, Soniya D. Yambem, Shih-Chun Lo, Paul Meredith, Ebinazar B. Namdas, The Univ. of Queensland (Australia)

Innovation in materials has played a crucial role in development of organic light-emitting diodes, and most research has concentrated either on small organic molecules or conjugated polymers. We have pursued an alternative approach to materials for LEDs based on conjugated dendrimers. These molecules consist of a core, conjugated dendrons (branches) and surface groups, and by suitable choice of these components, efficient solution-processed LEDs can be made. In this presentation we will discuss light-emitting materials comprised of dendrimers. Such materials give insight into the effect of intermolecular interactions on the photophysical properties of phosphorescent materials. A combination of synthesis, physical, photophysical measurements, and device fabrication and testing will be described.

9183-5, Session 2

Development of new organic semiconducting materials for organic light-emitting diodes *(Invited Paper)*

Yun-Hi Kim, Gyeongsang National Univ. (Korea, Republic of)

Organic light-emitting diodes (OLEDs) are widely used as small size displays and are under development for large size television because of their advantages in emission with a wide viewing angle and color gamut. Phosphorescent emitters are used for green and red colors because of their high efficiency. The development of a deep blue emitter is especially important for displays, because the deep blue emission is more effective than normal blue to save energy when strong microcavity structures are adopted to enhance color purity. In order to develop the deep blue

emitter, we designed and synthesized anthracene-based florescent materials and Ir-based phosphorescent materials.

In this presentation, it will be reported synthesis and characterization of highly twisted anthracene derivatives with CIE of (0.155, 0.049) and deep-blue phosphorescent iridium complexes containing perfluorocarbonyl with CIE of (0.147, 0.116)

9183-6, Session 2

Efficient cyclometalated Pt complexes for displays and lighting applications *(Invited Paper)*

Jian Li, Arizona State Univ. (United States)

Photovoltaics and solid state lighting are examples of technologies that are enablers for a new sustainable energy economy, since these technologies would allow us to use a renewable energy source, and to use energy sources we already have more efficiently. The successful development of alternate low cost technology for current lighting devices will have a significant impact on the U. S. economy and national security. White organic light emitting diodes (OLEDs) with potentially high power efficiency are considered as strong candidate for the next generation of illumination devices. Moreover, the use of environmentally benign organic materials in white OLEDs and their potentially low fabrication cost makes them an attractive technological prospect. In this presentation, we will discuss our continuing efforts on the design, synthesis and characterization of novel platinum complexes for displays and lighting applications. The photo-physics, electrochemistry, electroluminescent properties and operational stability of these novel platinum complexes, including fluorine-free Pt-based deep blue emitters, will be discussed. The rational molecular design enables us to develop cyclometalated Pt complexes with both photon-to-photon (in thin film) and electron-to-photon (in device settings) conversion efficiency close to 100% for OLED applications. Our approaches to achieve high efficiency white OLED using a single emitter will be also included.

9183-7, Session 2

Bright coppertunities: efficient OLED devices with Cu(I)I-PyrPHOS-emitters *(Invited Paper)*

Manuela Wallesch, Karlsruhe Institute of Technology (Germany); Daniel Volz, Charlotte Fléchon, Daniel Zink, cynora GmbH (Germany); Stefan Bräse, Karlsruhe Institute of Technology (Germany); Thomas Baumann, cynora GmbH (Germany)

The mass market application of OLEDs is currently hindered because i) the materials are too expensive and contain rare metals such as iridium and ii) current processing techniques are elaborate and cannot easily be upscaled. Solution processable Cu(I)-complexes promise to solve both problems with one blow: Copper is an abundant metal, which offers new opportunities to develop materials for OLEDs. Due to their structural diversity, Cu(I) emitters allow for the design of materials with tunable properties. Beside this, it is also possible to adjust solution properties and introduce functionalities for cross-linking. The new materials feature exciting photophysical properties such as PLQY values close to unity and a tunable emission. The emission decay time is in the range of common emitters or lower, which is expected to reduce efficiency roll-off at high driving voltages.

Cu(I)-PyrPHOS-complexes also feature thermally-activated delayed fluorescence (TADF). As a consequence, they can make use of triplet and singlet excitons in a process called Singlet Harvesting, which paves the way for high efficiencies. Unlike Ir(III)-complexes such as Irppy3, triplet-triplet annihilation does not occur when using Cu(I), even in very high doping concentrations.

We demonstrate the feasibility of PyrPHOS-type Cu(I) complexes: We present strategies that enable a smart cross-linking process, where the Cu(I) emitters themselves play an important role. Also, we demonstrate high-brightness devices, which were operated at medium voltages, yielding 50.000 cd m-2. In a showcase example, we present a device with an external quantum efficiency greater than 20% with a solution processed Cu(I)-PyrPHOS-device without using outcoupling techniques.

Synthesis and electroluminescence properties of highly efficient dual core chromophores with side groups for blue emission *(Invited Paper)*

Jongwook Park, Hayoon Lee, Beomjin Kim, Seungho Kim, Joonghan Kim, Jaehyun Lee, Hwangyu Shin, The Catholic Univ. of Korea (Korea, Republic of)

Organic light-emitting diodes (OLEDs) based on organic small molecules are currently the subject of intense research efforts due to their promise in full-color large display applications. It is extremely difficult to produce highly efficient blue-light emitters with a long device lifetime because with a wide band gap their electronic levels are likely to be mismatched with the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of the other OLED layers, such as the hole transporting layer (HTL) and the electron transporting layer (ETL).

We recently reported the syntheses of new dual core chromophore materials containing anthracene and pyrene (AP dual core) that exhibit high PL efficiencies. In this study, highly efficient blue emitting materials consisting of dual core derivatives with phenyl and/or naphthyl side groups and asymmetric or symmetric structures were designed and synthesized. The asymmetric structures 1-naphthalen-1-yl-6-(10-phenyl-anthracen-9-yl)-pyrene (Ph-AP-Na) and 1-(10-naphthalen-1-yl-anthracen-9-yl)-6-phenyl-pyrene (Na-AP-Ph), and the symmetric structures 1-phenyl-6-(10-phenyl-anthracen-9-yl)-pyrene (Ph-AP-Ph) and 1-naphthalen-1-yl-6-(10-naphthalen-1-yl-anthracen-9-yl)-pyrene (Na-AP-Na) were synthesized.

Of the synthesized compounds, Na-AP-Na was found to exhibit the highest EL device efficiency of 5.46 cd A-1. Ph-AP-Na, Na-AP-Ph, Ph-AP-Ph, and Na-AP-Na exhibit EL maximum values of real blue color in the range 455 nm to 463 nm. The y values of their color coordinates are within the range 0.125 to 0.142, so these compounds exhibit good blue color coordinates for displays. The lifetime of Na-AP-Na device showed more than three times longer than AP dual core (1-anthracen-9-yl-pyrene) device.

Unusually high efficiency in blue fluorescence OLEDs with large delta E (S1-T1) molecules *(Invited Paper)*

Yong-Jin Pu, Yamagata Univ. (Japan)

Deep-blue fluorescent compounds are particularly important in organic light-emitting devices (OLEDs). We synthesized an donor-accepotor (DA) type blue-emitting compound, 1-(10-(4-methoxyphenyl)anthracen-9-yl)-4-(10-(4-cyanophenyl)anthracen-9-yl)benzene (BD3). For comparison, a non DA type compound, 1,4-bis(10-phenylanthracene-9-yl)benzene (BD1) and a weak DA type compound, 1-(10-phenylanthracen-9-yl)-4-(10-(4-cyanophenyl)anthracen-9-yl)-benzene (BD2), were also synthesized. The twisted conformations of the two anthracene units in the compounds, confirmed by single crystal x-ray analysis, effectively prevent the π-conjugation, and the compound showed deep-blue photoluminescence (PL) with a high PL quantum efficiency, almost independent on the solvent polarity, resulted from the absence of intramolecular charge transfer state. The DA type molecule BD3 in a non-doped device exhibited a maximum external quantum efficiency (EQE) of 4.2% with a slight roll-off, indicating good charge balance due to the DA type molecular design. In the doped device with CBP host, the BD3 exhibited higher EQE than 10% with Commission International de L'Eclairge (CIE) coordinates of (0.15, 0.06) and a narrow full-width at half-maximum of 45 nm, which is close to the CIE of the High Definition Television standard blue. These results provide a molecular design concept leading to highly efficient deep-blue-emitting molecules for OLED applications.

Surface analytical investigation on organometal triiodide perovskite *(Invited Paper)*

Yongli Gao, Univ. of Rochester (United States)

In a little over a year, there has been an unexpected breakthrough and rapid evolution of highly efficient solid-state hybrid solar cells based on organometal trihalide perovskite materials. This technology has the potential to produce solar cells with the very highest efficiencies while retaining the very lowest cost. We have measured the electronic density of states of CH3NH3PbI3 using ultraviolet photoelectron spectroscopy (UPS), inverse photoemission spectroscopy (IPES), and x-ray photoelectron spectroscopy (XPS). The valence band maximum (VBM) and conduction band minimum (CBM) positions are obtained from the UPS and IPES spectra, respectively, by liner extrapolation of the leading edges. With the Fermi level close to the VBM, the sample is slightly p-type, with the EVBM=0.76 eV, ECBM=-0.9 eV, and transport energy gap 1.7 eV. The ionization potential (IP) of 6.16 eV can be obtained from the sum of the UPS measured EVBM and the work function of 5.40 eV. The XPS spectra reveal an obvious deficiency of N is, whereas the concentrations of I and Pb are close to the expected values. The existence of O and excessive C indicate that the surface is contaminated, and the contamination is reduced by 12-20% by thermal annealing in vacuum. The interface between CH3NH3PbI3 and TiO2 is also investigated. As CH3NH3PbI3 layer thickness increases, one sees a gradual shift of the vacuum level cut-off. At the CH3NH3PbI3 thickness of 8.2 nm, the shift saturates, signaling the end of the interface dipole formation. The evolution of the VB is even more gradual, and it appears to mature only at the thickest layer. Given the UPS probing depth of ~1.5 nm and the typical interface formation in other systems, the saturation of the vacuum level cut-off at 8.2 nm in CH3NH3PbI3/TiO2 is surprisingly large. It points at the possibility that the films are not truly uniform. On the other hand, the interface dipole of 0.7 eV CH3NH3PbI3 and TiO2 is important for further understanding of the energy level alignment and charge transfer across the interface.
