Real and imaginary properties of epsilon-near-zero materials *(Invited Paper)*

Mark I. Stockman, Georgia State Univ. (United States)

From the fundamental principle of causality we show that epsilon-near-zero (ENZ) materials with very low (asymptotically zero) intrinsic dielectric loss do necessarily possess a very low (asymptotically zero) group velocity of electromagnetic wave propagation. This leads to the loss function being singular and causes high non-radiative damping of optical resonators and emitters (plasmonic nanoparticles, quantum dots, chromophore molecules) embedded into them or placed at their surfaces. Rough ENZ surfaces do not exhibit hot spots of local fields suggesting that surface modes are overdamped. Reflectors and waveguides also show very large losses both for realistic and idealized ENZ.

1. Introduction

Recently, materials at frequencies close to the bulk plasmon frequency, which are characterized by dielectric permittivity being small enough, and are usually referred to as Epsilon Near Zero (ENZ) materials, have attracted a great deal of attention, see, e.g., [1-3].

Their optical properties are expected to be quite remarkable: ENZ should totally reflect light at all angles, the phase velocity of light tends to infinity and, correspondingly, the light wave carries almost constant phase, the density of photonic states diverges at, a waveguide formed inside an ENZ material can confine light at deep sub-wavelength dimensions, there is no reflections even at sharp bands, and the unavoidable roughness of the waveguide walls does not significantly spoil the wave-guiding. As in many other cases in nanooptics cite[4], dielectric losses present a significant problem deteriorating these unique properties and limiting useful applications of ENZ materials.

2. Results

Following Ref. [5], we show that the fundamental principle of causality [as given by dictates that any ENZ material with a very low (asymptotically zero) loss at the observation frequency has necessarily asymptotically zero group velocity at that frequency. Physically, this leads to enhanced scattering and dissipative losses as given by the diverging energy-loss function. Paradoxically, a reduction of the intrinsic loss, leads to an increase of energy-loss function and further deterioration of performance of reflectors and waveguides built from ENZ materials. Both analytically and numerically we have shown that a realistic ENZ material ITO at the bulk plasma frequency causes high reflection and propagation losses. The singular loss function is also responsible for anomalously strong optical damping of resonant systems (plasmonic nanoparticles, dye molecules, quantum dots, etc.) embedded into or positioned at the surfaces of ENZ materials. In contrast to plasmonic metals, there are no pronounced hot spots of local fields at rough ENZ surfaces. Structured dielectric media with practically zero loss in the optical region cannot function as true ENZ materials because of the singular response; they necessarily are diffractive photonic crystals, and not refractive effective media. Obviously, this anomalous loss of ENZ materials can be gainfully used in energy absorbers, which begets analogy with heating of plasmas at plasma frequency with charged particles or electromagnetic waves. These losses and singularities are fundamental, local properties of the ENZ media, which cannot be eliminated by micro- or nano-structuring.

10343-2, Session 1

Universal spin-momentum locking of light *(Invited Paper)*

Todd Van Mechelen, Farid Kalhor, Ward D. Newman, Zubin Jacob, Purdue Univ. (United States)

We show the existence of an inherent property of evanescent electromagnetic waves: spin-momentum locking, where the direction of momentum fundamentally locks the polarization of the wave. We trace the ultimate origin of this phenomenon to complex dispersion and causality requirements on evanescent waves. We demonstrate that every case of evanescent waves in total internal reflection, surface states and optical fibers/waveguides possesses this intrinsic spin-momentum locking. We also introduce a universal right-handed triplet consisting of momentum, decay and spin for evanescent waves. We derive the Stokes parameters for evanescent waves which reveal an intriguing result - every fast decaying evanescent wave is inherently circularly polarized with its handedness tied to the direction of propagation. We also show the existence of a fundamental angle associated with total internal reflection (TIR) such that propagating waves locally inherit perfect circular polarized characteristics from the evanescent wave. This circular TIR condition occurs if and only if the ratio of permittivities of the two dielectric media exceeds the golden ratio. Our work leads to a unified understanding of this spin-momentum locking in various nanophotonic experiments and sheds light on the electromagnetic analogy with the quantum spin hall state for electrons.

10343-3, Session 1

High order plasmonic resonances in time-varying media *(Invited Paper)*

Alessandro Salandrino, E. Alexander Ramos, The Univ. of Kansas (United States)

The optical response of noble-metal nanoparticles in the visible spectrum is characterized by the presence localized surface plasmon resonances. Localized surface plasmons are non-propagating coherent oscillations of free-carriers coupled to the electromagnetic field arising as a consequence of confinement effects in sub-wavelength nanoparticles. Plasmonic nanoparticles in general support an infinite discrete set of orthogonal localized surface plasmon modes, yet in the case of structures of deep-subwavelength dimensions only the lowest order resonances of dipolar nature can be effectively excited by an incident electromagnetic wave. By reciprocity such high-order modes tend to be subradiant and therefore difficult to observe in far-field.

Here we discuss the novel localized surface plasmon dynamics that emerge when the electromagnetic properties of the plasmonic particle or of the background medium vary in time. We show in particular that such temporal permittivity variations lift the orthogonality of the localized surface plasmon modes and introduce coupling among different angular momentum states. Exploiting such dynamics we show how surface plasmon amplification of high order resonances can be achieved under the action of a spatially uniform optical pump of appropriate frequency. In addition we discuss the signature of the excitation of these high-order surface plasmon resonances in the temporal profile of the pump field. Possible implementations and potential applications are also presented, as well as extensions to other physical systems.

10343-4, Session 1

Index retrieval of finite thickness fishnet metamaterials tracking the phase accumulation

Eyal Feigenbaum, Anna M. Hiszpanski, Lawrence Livermore National Lab. (United States)

Currently used methods for effective index retrieval of a metamaterial (MM) are based on calculating the transmission and reflection of a MM slab. This 'black-box approach' leads to an uncertainty as to the number of cycles that have passed and as a result to a multi-branch uncertainty in the real part value of the effective index. Multiple approaches have been proposed to determine the correct branch. However, the validity of these existing methods is limited with respect to some currently studied MM implementations, e.g.: MM with a small number of layers; MM where the light transmission decreases with increasing optical wavelength (e.g., fishnet MM (FMM), especially for the negative index domain). Here we propose to depart from the 'black-box' retrieval approach and track the phase accumulation through the structure to avoid the multi-branch uncertainty. This approach is possible for structures where the energy flow through the structure is predominantly carried across the slab by only a single propagation mode, as in the case of the FMM, and other resonant guided waves networks (RGWNs). The algorithm is implemented based on FDTD and validated. It provides a look into the phase accumulation inside the structure, showing that the negative index is a net effect of positive and dominating negative phase accumulation at the metal and dielectric layers, accordingly. The details of the algorithm, as well as the newly revealed underlying physics would be further discussed.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-718700.

10343-5, Session 1

Dynamic properties of large light filament arrays for complex photonic meta-structures in air

Wiktor T. Walasik, Univ. at Buffalo (United States); Shermineh Rostami, Daniel Kepler, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Matthieu Baudelet, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States) and Univ. of Central Florida (United States); Martin C. Richardson, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Natalia M. Litchinitser, Univ. at Buffalo (United States)

High-power femtosecond filaments—laser-light beams capable of kilometer-long propagation—attract interest of nonlinear-optics community due to their numerous applications in remote sensing, lightning protection, virtual antennas, and waveguiding. Specific arrangements of filaments, into waveguides or hyperbolic metamaterials, allow for efficient control and guiding of electromagnetic radiation, radar-beam manipulation, and resolution enhancement. These applications require spatially uniform distribution of densely packed filaments.

In order to address this challenge, we investigate the dynamic properties of large rectangular filament arrays propagating in air depending on four parameters: the phase difference between the neighboring beams, the size of the array, separation between the beams, and excitation power. We demonstrate that, as a result of the mutual interaction between the filaments, the arrays where the nearest neighbor beams are out-of-phase are more robust than the arrays with all the beams in phase.

Our analysis of the array stability reveals that there exist certain trade-offs between the stability of a single filament and the stability of the entire array. We show that in the design of the experiment, the input parameters have to be chosen in such a way that they ensure a sufficiently high filling fraction, but caution has to be used in order not to compromise the overall array stability.

In addition, we show the possibility of filament formation by combining multiple beams with energies below the filamentation threshold. This approach offers additional control over filament formation and allows one to avoid the surface damage of external optics used for filamentation.

10343-6, Session 2

Meoscopic optics of two-dimensional random media *(Invited Paper)*

Hui Cao, Yale Univ. (United States)

In disordered media there are many fascinating counter-intuitive effects resulting from interferences of multiply scattered waves. One of them is the creation of transmission eigenchannels which can be broadly classified as open and closed. In general, the penetration depth and energy density distribution of multiply scattered waves inside a disordered medium are determined by the spatial profiles of the transmission eigenchannels that are excited by the incident light. The distinct spatial profiles of open and closed channels suggest that selective coupling of incident light to these channels enables an effective control of total transmission and energy distribution inside the random medium. Since the energy density determines the light-matter interactions inside a scattering system, manipulating its spatial distribution opens the door to tailoring optical excitations as well as linear and nonlinear optical processes such as absorption, emission, amplification, and frequency mixing inside turbid media.

We demonstrate experimentally an efficient control of light intensity distribution inside a random scattering system. The adaptive wavefront shaping technique is applied to a silicon waveguide containing scattering nanostructures, and the on-chip coupling scheme enables access to all input spatial modes. By selectively coupling the incident light to open or closed channels of the disordered system, we not only vary the total energy stored inside the system by 7.4 times, but also change the energy density distribution from an exponential decay to a linear decay and to a profile peaked near the center. This work provides an on-chip platform for controlling light-matter interactions in turbid media.

10343-7, Session 2

Space-time super-resolution imaging *(Invited Paper)*

Evgenii E. Narimanov, Andrei Rogov, Purdue Univ. (United States)

We present a new approach to super-resolution imaging, that allows to offset the performance loss due to material absorption by engineering the profile of the light source waveform.

10343-8, Session 2

Laser scanning using spatiotemporal beam dynamics in metasurfaces

Amr M. Shaltout, Konstantinos Lagoudakis, Soo Jin Kim, Jelena Vuckovic, Stanford Univ. (United States); Vladimir M. Shalaev, Purdue Univ. (United States); Mark L. Brongersma, Stanford Univ. (United States)

Laser scanning through controlled deflection of beam is a key element in various applications including 3D printing, rapid prototyping, LIDAR, autonomous vehicles, and imaging applications. Typical laser scanners require the utilization of a rotating mirror, or optical phased-array using electro-optic modulators which provides faster scanning speed (scanning

time ~microseconds). Current efforts are also taking place to implement metasurface based ultra-compact laser scanners using tunable nano-antennas exhibiting voltage-controlled free carrier modulation. This would dramatically reduce the size of the device keeping the speed of operation limited by the electronic control signal bandwidth as previous phased-array technologies.

To further enhance the scanning time, we present a novel methodology of beam steering based on light-matter interaction between metasurfaces and mode-locked lasers with a frequency-comb spectrum (i.e., equally-spaced phased-locked frequency lines). Over the past few years, metasurfaces interacting with CW lasers were successfully used to engineer far-field optical patterns through coherent interference of light scattered from an array of nano-antennas. Nevertheless, dynamic patterns can be generated if CW laser is replaced with a frequency-comb source. In this case, we demonstrate that coherent interference of light in the far-field is a 4D space-time process. A metasurface is thoughtfully designed to produce a constructively interfered laser beam at a narrow angle in the far-field leading to directivity of the beam. The temporal interference of phase-locked frequency comb causes the direction of the constructed beam to be at a time-dependent rotating angle, leading to laser scanning of ~90-deg angle-of-view over ~100ps time interval.

10343-9, Session 2

Removing material singularities in Schwarz-Christoffel coordinate transformations

Sophie Viaene, Vrije Univ. Brussel (Belgium) and Chalmers Univ. of Technology (Sweden); Vincent Ginis, Jan Danckaert, Vrije Univ. Brussel (Belgium); Philippe Tassin, Chalmers Univ. of Technology (Sweden)

Transformation optics has led to the design of impressive photonic devices that reproduce the desired effects of coordinate transformations by making use of tailored material properties. Unfortunately, these material properties are often required to take on extreme values which are difficult to implement without compromising the performance of the device. This is especially true for coordinate transformations that rely on singularities, such as those leading to invisibility cloaks and beam splitters. Previous work has shown that the detrimental effects due to material singularities may be mitigated by adding anisotropy to the initial design. However, this technique cannot be applied to devices that crucially rely on isotropy and symmetry, as is the case for our metamaterial slab waveguides that implement two-dimensional coordinate transformations of guided modes. Therefore, we mitigate the detrimental effects due to isolated singularities in an isotropic way. First, we systematically study the effect of isolated singularities, representing each of them as a local power map that induces vanishing or infinite material parameters. Second, we propose a beam splitter design consisting of a collection of local power maps, also known as a Schwarz-Christoffel coordinate transformation. By making use of full-wave numerical simulations, we show that the strategic replacement of singular power maps with analytic curve-factors allows for the removal of optical singularities without affecting the functionality of the design. The resulting waveguide devices have no need of extreme material properties to efficiently manipulate guided waves.

10343-10, Session 2

Experimental validation of tunable features in laser-induced plasma metamaterials

Roberto A. Colon Quinones, Mark A. Cappelli, Stanford Univ. (United States)

Measurements are presented which validate the use of gaseous plasma metasurfaces (MTS) as highly tunable reflectors. The plasma MTS considered here is an n x n array of laser produced plasma kernels generated by focusing the fundamental output from a 2 J/p Q-switched Nd:YAG laser through a multi-lens array (MLA) and into a gas of varying pressure. The tunability of these surfaces stems from the dispersive nature of plasmas arising from their variable electron density and electron momentum transfer collision frequency, and the concommitant effect on their Mie scattering resonance. Experiments were carried out in the low GHz regime to characterize the impedance or reflectivity of these surfaces for different values of electron density and collision frequency. The results of these experiments are compared to Mie scattering and effective-medium theory, and with finite element method (FEM) electromagnetic simulations to account for finite array dimensions.

10343-11, Session 3

Widely tunable semiconductor antennas for reconfigurable metasurfaces *(Invited Paper)*

Jon A. Schuller, Univ. of California, Santa Barbara (United States)

The ability to engineer the optical phase at subwavelength dimensions has led to metasurfaces that provide unprecedented control of electromagnetic waves. To reach their ultimate potential, metasurfaces must incorporate reconfigurable functions. The central challenge is achieving large tunability in subwavelength elements. Here, we describe two different approaches for achieving order-unity refractive index shifts: free-carrier refraction and thermo-optic tuning. We experimentally demonstrate wide tuning of single-particle infrared Mie resonances through doping, and demonstrate simulations of electrically reconfigurable III-V heterojunction metasurfaces based on these effects. We conclude with recent experimental demonstrations of dyamic, ultrawide tuning of Mie resonators based on two distinct thermo-optic effects: 1) modifying the electron mass and carrier density in InSb and 2) exploiting the anomalous temperature-dependent bandgap of PbTe.

10343-12, Session 3

All-dielectric photonic topological metamaterials and metasurfaces *(Invited Paper)*

Alexander B. Khanikaev, The City College of New York (United States)

The past few years have witnessed the discovery of photonic topological insulators, which transformed our views on propagation and scattering of electromagnetic waves. Here we show that judiciously designed all-dielectric photonic metamaterials and metasurfaces can exhibit a topological photonic state. The bianisotropy of the metamaterial is shown to result in emergence of a topological photonic band gap in the bulk and photonic states guided by edges and interfaces which appear to be one-way spin-polarized and immune to sharp bending. Experimental realizations of photonic topological metamaterials and metasurfaces for microwave and optical domains are used to test and confirm the topological properties.

10343-13, Session 3

Light concentration in subwavelength volume by dielectric transducer and local sensing of plasmonic systems

Andrey Karlovich Sarychev, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Sergey Vergeles, L.D. Landau Institute for Theoretical Physics (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation); Gennady Tartakovsky, Advanced Systems and Technologies, Inc. (United States)

The main achievement of the modern plasmonics is the concentration of light into nanospots that are much smaller than the wavelength. Nanospot concentration is beneficial for various applications: biomedical imaging and sensing, optical microscopy with single-molecule resolution, heat assisted magnetic recording (HAMR), QED studies, nanolasing, etc. Until now, plasmonic metal nanoantennae, sub-wavelength apertures or metallic near field concentrators (NFCs) are used for this purpose. The main advantage of the metal NFC is their capabilities to localize plasmonic modes, which can be excited by the incident transverse em wave. However, the metal NFCs have large optic loss so we propose a novel all-dielectric NFC, which allows focusing the light into a sub-wavelength hot nanospot, without the dissipative loss. The detrimental dephasing and thermal effects almost vanishes in the dielectric NFC opening new opportunities in the magnetic recording and quantum plasmonics. The ability to concentrate light is important not only to fundamental physics studies, but also to practical device applications. For example, microcavities can force the atoms or quantum dots to emit spontaneous photons in a desired direction or can provide an environment, where dissipative mechanisms such as spontaneous emission are overcome. The electric field is much enhanced in the proposed new device at the vertex of the dielectric beak, which is attached to the tablet dielectric resonator. The resonator in turn is pumped through the plane waveguide. The electric field is enhanced due to longitudinal polarization of the beak vertex, which is excited by em field of the pumped resonator.

10343-14, Session 3

High-Q resonances with low azimuthal indices in all-dielectric high-index nanoparticles

Kirill Koshelev, ITMO Univ. (Russian Federation) and The Academic Univ. (Russian Federation); Andrey A. Bogdanov, Zarina Sadrieva, ITMO Univ. (Russian Federation); Kirill B. Samusev, Mikhail V. Rybin, Mikhail F. Limonov, Ioffe Institute (Russian Federation); Yuri S. Kivshar, The Australian National Univ. (Australia)

Resent progress in all-dielectric nanophotonics opens many opportunities for the enhanced resonant phenomena with applications in nanophotonics [1]. However, usually dielectric resonators demonstrate low values of the quality factor (Q-factor) and low efficiencies of the Purcell effect for Mie-type resonant modes [2]. Here we report on a novel approach to achieve high-Q optical resonators based on all-dielectric high-index nanoparticles. We demonstrate that high-quality states could be formed through a mechanism of the hybridization of Mie resonances with low azimuthal indices (0, 1) leading to the substantial suppression of far-field radiation and high Q features of the resonators. This mechanism is somewhat related to the concept of bound states in the continuum [3] demonstrated recent for some optical structures.

We analyse the Q-factors of all-dielectric high–index resonators in two ways: (i) as a ratio of real and imaginary parts of complex eigenfrequencies [4], and (ii) by fitting the Fano type resonance in the numerical simulation of the scattering problem. Both methods give consistent results. We predict that for the ceramic resonators with permittivity 40, the Q-factor of the mode with a low azimuthal index could reach 5000.

10343-15, Session 3

Metasurface axicon lens design at visible wavelengths

Saleimah Alyammahi, Qiwen Zhan, Univ. of Dayton (United States)

The emerging field of metasurfaces is promising to realize novel optical devices with miniaturized flat format and added functionalities. Metasurfaces have been demonstrated to exhibit full control of amplitude, phase and polarization of electromagnetic waves. Using the metasurface, the wavefront of light can be manipulated permitting new functionalities such as focusing and steering of the beams and imaging. One optical component which can be designed using metasurfaces is the axicon. Axicons are conical lenses used to convert Gaussian beams into non-diffraction Bessel beams. These unique devices are utilized in different applications ranging from optical trapping and manipulation, medical imaging, and surgery. In this work, we study axicon lens design comprising of planar metasurfaces which generate non-diffracting Bessel beams at visible wavelengths. Dielectric metasurfaces have been used to achieve high efficiency and low optical loss. We measured the spot size of the resulted beams at different planes to demonstrate the non-diffraction properties of the resulted beams. We also investigated how the spot size is influenced by the axicon aperture. Furthermore, we examined the achromatic properties of the designed axicon. Comparing with the conventional lens, the metasurface axicon lens design enables the creation of flat optical device with wide range of depth of focus along its optical axis.

10343-16, Session 4

Nonlinear frequency conversion with all-dielectric nanoantennas *(Invited Paper)*

Dragomir N. Neshev, Sergey S. Kruk, Mohsen Rahmani, Maria del Rocio Camacho-Morales, Lei Wang, Lei Xu, Daria A. Smirnova, Alexander S. Solntsev, Yuri S. Kivshar, The Australian National Univ. (Australia)

Dielectric nanoantennas and metasurfaces have proven to be able to manipulate the wavefront of incoming waves with high transmission efficiency. The important next question is: Can they enable enhanced interaction with the light to transform its colour or to be able to control one light beam with another? Here we show how a dielectric nano-resonator of subwavelength size can enable enhanced light matter interaction for efficient nonlinear frequency conversion. In particular, we show how AlGaAs or silicon nanoantennas can enhance second and third harmonic generation, respectively. Importantly, by controlling the size of the antennas, we can achieve control of directionality and polarisation state of the emission of harmonics. Our results open novel applications in ultra-thin light sources, light switches and modulators, ultra-fast displays, and other nonlinear optical metadevices based on low loss subwavelength dielectric resonant nanoparticles.

10343-17, Session 4

Active and tunable Mie-resonant semiconductor metasurfaces *(Invited Paper)*

Isabelle Staude, Friedrich-Schiller-Univ. Jena (Germany)

Nanoparticles composed of high refractive index semiconductors can support electric and magnetic multipolar Mie-type resonances that can be tuned by the nanoresonator design [1]. Furthermore, such semiconductor nanoresonators can exhibit very low absorption losses at optical frequencies. Based on these properties, semiconductor nanoresonators represent versatile building blocks of functional photonic nanostructures with tailored optical response.

This talk will review our recent advances in controlling the generation and propagation of light with metasurfaces composed of high-index semiconductor nanoresonators. Such metasurfaces can impose a spatially variant phase shift onto an incident light field, thereby providing control over its wave front with high transmittance efficiency [2]. However, there are two important limitations: most semiconductor metasurfaces realized so far are passive, and their optical response is permanently encoded into the structure during fabrication. This talk will concentrate on strategies to integrate emitters into the metasurfaces and to obtain dynamic control of the metasurface optical response.

In particular, two approaches for active tuning of the metasurface response will be discussed, namely integration of the metasurface into a nematic-liquid-crystal cell [3] and ultrafast all-optical tuning based on the nonlinear optical response of the constituent semiconductor materials. Furthermore, I will show that Mie-resonant semiconductor metasurfaces allow for spatial and spectral tailoring of spontaneous emission from various types of emitters.

10343-18, Session 4

Directional second harmonic generation from AlGaAs nanoantennas

Maria del Rocio Camacho Morales, Mohsen Rahmani, Sergey S. Kruk, Lei Wang, The Australian National Univ. (Australia); Lei Xu, The Australian National Univ. (Australia) and Nankai Univ. (China); Daria A. Smirnova, Alexander S. Solntsev, Andrey E. Miroshnichenko, Hark Hoe Tan, Fouad Karouta, Shagufta Naureen, Kaushal D. Vora, The Australian National Univ. (Australia); Luca Carletti, Costantino De Angelis, Chennupati Jagadish, Univ. degli Studi di Brescia (Italy); Yuri S. Kivshar, Dragomir N. Neshev, The Australian National Univ. (Australia)

Optical nanoantennas possess great potential for controlling the spatial distribution of light in the linear regime as well as for frequency conversion of the incoming light in the nonlinear regime. However, the usually used plasmonic nanostructures are highly restricted by Ohmic losses and heat resistance. Dielectric nanoparticles like silicon and germanium can overcome these constrains [1,2], however second harmonic signal cannot be generated in these materials due to their centrosymmetric nature. GaAs-based III-V semiconductors, with non-centrosymmetric crystallinity, can produce second harmonic generation (SHG) [3]. Unfortunately, generating and studying SHG by AlGaAs nanocrystals in both backward and forward directions is very challenging due to difficulties to fabricate III-V semiconductors on low-refractive index substrate, like glass. Here, for the first time to our knowledge, we designed and fabricated AlGaAs nanoantennas on a glass substrate. This novel design allows the excitation, control and detection of backwards and forwards SHG nonlinear signals. Different complex spatial distribution in the SHG signal, including radial and azimuthal polarization originated from the excitation of electric and magnetic multipoles were observed. We have demonstrated an unprecedented SHG conversion efficiency of 10-4; a breakthrough that can open new opportunities for enhancing the performance of light emission and sensing [4].

Characterization of Si-disk magnetic nanoprobe by photoinduced force microscopy

Jinwei Zeng, Mohsen Rajaei, Mahsa Darvish, Mohammad Albooyeh, Brian Albee, Hemantha K. Wickramasinghe, Eric O. Potma, Filippo Capolino, Univ. of California, Irvine (United States)

Due to the weak magnetic responsibility of natural existing materials at optical frequency, optical magnetism remains a “dark state” of light which is largely unexplored. However, optical magnetism is also very desirable because of the many splendid possibilities it may lead to, including ultra-compact opto-magnetic storage devices, high speed magnetic imaging, magnetic tweezers etc. Here we design a Si nano-disk structure as the magnetic nanoprobe which supports magnetic resonance in visible range with the incident azimuthally polarized beam (APB). APB features a donut shape beam profile, with a strong longitudinal magnetic field and a vanishing electric field at the beam axis. Therefore, on the magnetic resonance while the probe is aligned to the APB axis, a longitudinal magnetic dipole is excited in the probe, and interacts with the incident APB inducing an exclusive magnetic force. Making such magnetic nanoprobe under APB illumination serves as an important first step to realize the proposed photoinduced magnetic force microscopy (PIMFM), which selectively exploits the interaction between matter and the magnetic field of light to characterize the optical magnetism in nanoscale. Such investigation of the optical magnetism in samples is dearly needed in many mechanical, chemical, and life-science applications.

10343-20, Session 4

Dynamically tunable topologically protected edge-states in silicon photonic crystals with liquid crystal background

Mikhail I. Shalaev, Wiktor T. Walasik, Sameerah Desnavi, Natalia M. Litchinitser, Univ. at Buffalo (United States)

Topological insulators are materials that conduct on the surface and insulate in its interior, while having non-trivial topological order. Remarkably, the edge states on the surface between topological (non-trivial) and conventional (trivial) materials are topologically protected from scattering on structural defects and disorders. First, these materials were theoretically predicted and then experimentally demonstrated in the field of electronics. However, most of the electronic materials exhibit topological properties only at very low temperatures.

Recently, it was shown that very similar topologically protected materials can be made in bosonic systems using photonic crystals. In conventional photonic crystals, imperfections, structural disorders, and surface roughness often lead to significant losses. To solve this problem, topologically protected photonic crystals might be used. At the same time, it is highly desirable to be able to control light propagation on optical chip. One way to facilitate such dynamic control is to use liquid crystals. Liquid crystals allow one to modify the refractive index with external electric field.

Here, we demonstrate dynamic control of topologically protected edge states by modifying refractive index of liquid crystal background media. Background index is changing depending on orientation of liquid crystal while preserving the topological order of the system. As a result of changing the refractive index, the spectral position of photonic bandgap and edge states change as well. Proposed concept might be implemented using conventional semiconductor technology and can be used for highly robust photonic energy transport in optical communication systems.

10343-21, Session 5

Polariton lasing in organic semiconductor microcavities *(Invited Paper)*

David G. Lidzey, The Univ. of Sheffield (United Kingdom)

A semiconductor-microcavity is an optical structure composed of two mirrors separated by a layer of semiconducting material. If the energy of the confined photon and excitonic transition are degenerate, interactions can occur in the strong-coupling regime, with the eigenstates of the system being cavity polaritons (a coherent superposition between light and matter).

Due to their bosonic nature, cavity polaritons are able to undergo condensation to a macroscopically occupied coherent state. Polariton condensates can be optically pumped and then undergo decay by emitting coherent light, very much like an optically pumped laser. Here, we demonstrate evidence of polariton condensation in a microcavity containing a dispersed molecular dye.

Our structures are based on two dielectric-mirrors placed either side of a film of the transparent matrix polymer polystyrene containing the fluorescent molecular dye BODIPY-Br. We first show using CW photoluminescence measurements that weakly-coupled excimer-like states in the BODIPY-Br, together with emission from the (0,1) vibrational transition are responsible for optically pumping polariton states along the lower polariton branch.

We then explore the non-linear emission from control thin-films and cavities using pulsed laser excitation. We obtain strong evidence of non-linear photoluminescence with increasing excitation density, associated with a six-fold linewidth narrowing and a continuous blue-shift attributed to polariton interactions with other polaritons and the exciton reservoir. We believe that there is a large number of molecular dyes that could dispersed into a polymer matrix allowing polariton condensation to be realised at wavelengths spanning the entire visible and near infrared.

10343-22, Session 5

Control of vibration-cavity polaritons in the frequency domain *(Invited Paper)*

Blake S. Simpkins, Kenan P. Fears, Adam Dunkelberger, U.S. Naval Research Lab. (United States); Wonmi Ahn, National Research Council (United States); Walter J. Dressick, Igor Vurgaftman, Jeffrey C. Owrutsky, U.S. Naval Research Lab. (United States)

We will focus on approaches which make use of light-matter interactions to alter the chemical behavior of a target molecular species. This is done through cavity coupling to a molecular vibration. Coupling vibrational transitions to resonant optical modes creates vibrational polaritons shifted from the uncoupled molecular resonances and provides a convenient way to modify the energetics of molecular vibrations. This approach is a viable method to explore controlling chemical reactivity and energy relaxation. Here, we demonstrate frequency domain results for vibrational bands strongly coupled to optical cavities. We experimentally and numerically describe strong coupling between a Fabry-Pérot cavity and several molecular species (e.g., poly-methylmethacrylate, thiocyanate, hexamethyl diisocyanate). We investigate strong and weak coupling regimes through examination of cavities loaded with varying concentrations of a urethane monomer. Rabi splittings are in excellent agreement with an analytical description using no fitting parameters. We show that coupling strength is a function of molecule/cavity mode overlap by systematically altering the position of a molecular slab throughout a first order cavity with results agreeing well with analytical and transfer matrix predictions. Further, remote molecule-molecule interaction will be explored by placing discrete and separated molecular layers throughout a cavity. In addition to establishing that coupling to an optical cavity modifies the energy levels accessible to the coupled molecules, this work points out the possibility of systematic and predictive modification of the excited-state kinetics of vibration-cavity polariton systems. Opening the field of polaritonic coupling to vibrational species promises to be a rich arena amenable to a wide variety of infrared-active bonds that can be studied in steady state and dynamically.

10343-23, Session 5

Effect of strong coupling on the photodegradation of poly(3-hexylthiophene)

Vanessa N. Peters, Md. Omar Faruk, Norfolk State Univ. (United States); Rohan Alexander, Univ. of Michigan (United States) and Norfolk State Univ. (United States); D'Angelo A. Peters, Norfolk State Univ. (United States) and Purdue Univ. (United States); Mikhail A. Noginov, Norfolk State Univ. (United States)

The effect of strong coupling on a chemical reaction, photodegradation of poly-3-hexylthiophene (p3ht), has been studied in a resonant cavity. The Fabry-Perot silver cavity was made to be resonant with the strong absorption band of the p3ht polymer. In comparison to a reference sample, p3ht film deposited on glass, the p3ht film inside the resonant cavity showed significant reduction in the rate of photodegradation (at tungsten lamp illumination, after proper normalization to the absorbed light intensity). No such effect was observed at excitation with the UV-enhanced xenon lamp.

10343-24, Session 5

Directional spontaneous emission of dye on top of thin silver grating

Ekembu K. Tanyi, Soheila Mashhadi, Norfolk State Univ. (United States); Sahana Das Bhattacharyya, Tal Galfsky, Vinod M. Menon, The City College of New York (United States); Natalia Noginova, Norfolk State Univ. (United States); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States); Mikhail A. Noginov, Norfolk State Univ. (United States)

We studied angular distribution of spontaneous emission of dye (R6G) embedded in the polymer (PMMA) spin-coated on top of a thin silver grating. We found that while the vertically polarized (TE) emission had a characteristic double-crescent pattern (with minimum of emission intensity in the normal direction), the horizontally polarized (TM) emission was confined to a narrow range of angles centered around the normal direction. The surface modes of the grating structure supporting out-coupled spontaneous emission have been studied in the angular reflectance experiments and COMSOL simulations. The correlation between the surface modes and the observed emission patterns will be discussed at the conference.

10343-25, Session 5

Vibrational energy relaxation of vibration-cavity polariton modes

Adam Dunkelberger, Kenan P. Fears, U.S. Naval Research Lab. (United States); Bryan T. Spann, National Institute of Standards and Technology (United States); Blake S. Simpkins, Jeffrey C. Owrutsky, U.S. Naval Research Lab. (United States)

Steady-state and transient infrared studies have been used to investigate coherent coupling between the vibrational modes of polymers, liquids, and solvated species and a Fabry-Perot optical cavity mode. The coupling is characterized in terms of the Rabi splitting that scales with the absorption strength of the vibrational band of the molecular species in the cavity. We use pump-probe infrared spectroscopy to identify how the vibrational energy relaxation of the mixed, cavity-vibration polarition states are modified compared to the vibrational bands for materials outside the cavity. For W(CO)¬6 in hexane, we observe so-called Rabi oscillations at early times due to quantum beating between the two polariton states. Transient infrared studies are used to observe excited-state absorption from both polariton modes and uncoupled reservoir modes. The polariton mode relaxes significantly more quickly than the uncoupled vibrational mode and the lifetime depends on the angle of incidence with respect to the IR pulses. The incoherent lifetime is also modified for anions (NCS-) in polymers. The experiments demonstrate that energy transfer and relaxation of molecular vibrational bands can be altered by coupling to optical cavities, which may be an avenue for controlling nonequilibrium excited state population and chemical reactivity.

10343-26, Session 5

Reconfigurable Mie resonators embedded in a tunable ENZ cavity

Prasad P. Iyer, Mihir Pendharkar, Chris J. Palmstrøm, Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Reconfigurable Mie resonator metasurfaces may give rise to new classes of programmable optical devices. Large phase and amplitude modulations can be achieved with high-Q resonances that are tunable by at least one line-width. We experimentally demonstrate narrow linewidth, reconfigurable Mie resonators comprising undoped InSb wires embedded inside a highly doped InSb Epsilon-Near-Zero (ENZ) cavity. We demonstrate a Q-factor increase of 400% by embedding a high index resonator within, instead of atop, an ENZ substrate. Systematic studies of varying width resonators reveal significant differences in coupling to the ENZ media for TM and TE resonators. A large refractive index modulation (μn ≥1.5) is achieved with heating (80-575K), stemming from variations in the effective mass of free-carriers. Thermally tuning the ENZ wavelength of the cavity by >2μm (13-15.5μm) emables reconfigurable tuning by multiple line-widths. This ultra-wide thermal tunability of high-Q embedded resonators may enable new class of active metadevices in the mid-infrared wavelength regime.

10343-27, Session 6

Active tuning of surface-phonon polariton resonances *(Invited Paper)*

Adam Dunkelberger, Chase T. Ellis, Daniel Ratchford, Alexander J. Giles, U.S. Naval Research Lab. (United States); Mijin Kim, Sotera Defense Solutions, Inc. (United States); Chul Soo Kim, U.S. Naval Research Lab. (United States); Bryan T. Spann, National Institute of Standards and Technology (United States); Igor Vurgaftman, Joseph G. Tischler, Jeffrey C. Owrutsky, Joshua D. Caldwell, U.S. Naval Research Lab. (United States)

The infrared spectra of SiC and InP are dominated by highly reflective reststhralen bands that occur between the transverse and longitudinal optical phonons. Through the LOPC effect, free carriers shift the reststrahlen band to higher frequencies. We have previously shown that photoinjected carriers transiently and reversibly modify the infrared reflectivity of bulk SiC. Within the reststrahlen band, SiC and InP nanostructures can exhibit surface-phonon polariton resonances. Here we report, for the first time, active tuning of SiC and InP surface-phonon polariton resonances via carrier photoinjection, achieving better modulation depths than active tuning in plasmonic systems. In SiC, ultraviolet excitation with femtosecond laser pulses induces >10 cm-1 shifts in the transverse dipole resonance (width = 7 cm-1). Time-resolved infrared reflection spectroscopy reveals that the photoinduced shifts decay in tens of ps, depending on the initial carrier density. Our results suggest that spatial redistribution of photoexcited carriers dominates the time dependence of the active tuning. In InP, continuous-wave visible excitation produces qualitatively similar resonance shifts. Substrate heating appears to limit the extent of the active tuning in InP. This work lays the foundation for further studies of the physics of active tuning and optimization of the tuning for infrared nanophotonics applications.

10343-28, Session 6

Harnessing the metal-insulator transition for tunable metamaterials *(Invited Paper)*

Nicholas A. Charipar, Heungsoo Kim, U.S. Naval Research Lab. (United States); Nicholas Bingham, National Research Council (United States); Ryan Suess, Nova Research (United States); Kristin M. Charipar, U.S. Naval Research Lab. (United States); Scott A. Mathews, U.S. Naval Research Lab (United States); Raymond C. Y. Auyeung, Alberto Piqué, U.S. Naval Research Lab. (United States)

The control of light-matter interaction through the use of subwavelength structures known as metamaterials has facilitated the ability to control electromagnetic radiation in ways not previously achievable. A plethora of passive metamaterials as well as examples of active or tunable metamaterials have been realized in recent years. However, the development of tunable metamaterials is still met with challenges due to lack of materials choices. To this end, materials that exhibit a metal-insulator transition are being explored as the active element for future metamaterials because of their characteristic abrupt change in electrical conductivity across their phase transition. The fast switching times (?t < 100 fs) and a change in resistivity of four orders or more make vanadium dioxide (VO2) an ideal candidate for active metamaterials. It is known that the properties associated with thin film metal-insulator transition materials are strongly dependent on the growth conditions. For this work, we have studied how growth conditions (such as gas partial pressure) influence the metal-insulator transition in VO2 thin films made by pulsed laser deposition. In addition, strain engineering during the growth process has been investigated as a method to tune the metal-insulator transition temperature. Examples of both the optical and electrical transient dynamics facilitating the metal-insulator transition will be presented together with specific examples of thin film metamaterial devices.

10343-29, Session 6

Dynamic metasurfaces for the near to long-wave infrared *(Invited Paper)*

Jason G. Valentine, Zachary Coppens, Zhihua Zhu, Vanderbilt Univ. (United States); Philip G. Evans, Oak Ridge National Lab. (United States); Richard F. Haglund, Vanderbilt Univ. (United States)

I will first discuss simultaneous spatial and temporal control of a metamaterial that is activated with spatially patterned ultraviolet (UV) light. The use of an all-optical modulation approach allows us to transfer the complexity associated with pixel-level control to the illumination source or an intermediate masking layer. Doing this dramatically reduces the nanophotonic material fabrication complexity and when combined with a projection system can allow optical property control over large areas. Modulation is achieved through photocarrier doping of zinc oxide (ZnO) which increases optical losses in the metamaterial and causes a transition from low to high absorption. Importantly, the ZnO layer has a long photo-carrier lifetime allowing for modulation of the metamaterial with low power continuous wave illumination.

I will then discuss phase-change based dynamic metasurfaces. By minimizing the thermal mass of the vanadium dioxide phase-change material (PCM) and placing the PCM at the nexus of a bowtie field concentrator, we realize a highly efficient metadevice in a perfect-absorber configuration, which enables an experimental tunable range up to 360 nm, as well as modulation depth of 37% at the resonant wavelength. Instead of complex optical pump-probe triggering or bulky temperature control stage, this tunable device uses the optical antennas as integrated heating elements leading to fast temporal and spatial management. This device could be a competitive candidate for signal processing, memory units, security recognition, holography and imaging.

10343-30, Session 6

Controlling metasurfaces on demand *(Invited Paper)*

Jonathan Bar David, Jacob Engelberg, Liron Stern, Noa Mazurski, Uriel Levy, The Hebrew Univ. of Jerusalem (Israel)

In this talk we demonstrate a variety of dielectric metasurfaces and show mechanisms for controlling their transfer function. We also discuss their spectral properties

10343-31, Session 7

Optoelectronic device applications of metafilms *(Invited Paper)*

Mark L. Brongersma, Geballe Lab. for Advanced Materials (GLAM) (United States)

Many conventional optoelectronic devices consist of thin, stacked films of metals and semiconductors. In this presentation, I will demonstrate how one can improve the performance of such devices by nano-structuring the constituent layers at length scales below the wavelength of light. The resulting metafilms and metasurfaces offer opportunities to dramatically modify the optical transmission, absorption, reflection, and refraction properties of device layers. This is accomplished by encoding the optical response of nanoscale resonant building blocks into the effective properties of the films and surfaces. To illustrate these points, I will show how nanopatterned metal and semiconductor layers may be used to enhance the performance of solar cells, photodetectors, and enable new imaging technologies. I will also demonstrate how the use of active nanoscale building blocks can facilitate the creation of active metafilm devices.

10343-32, Session 7

Laser printing of flat optics metasurfaces *(Invited Paper)*

Anders Kristensen, Xiaolong Zhu, Marcus Schultz Carstensen, Oseze Ester Mobolanle Iyore, DTU Nanotech (Denmark); Rodolphe Marie, Technical Univ. of Denmark (Denmark); Mehdi K. Hedayati, DTU Nanotech (Denmark); N. Asger Mortensen, DTU Fotonik (Denmark); Uriel Levy, The Hebrew Univ. of Jerusalem (Israel)

This paper describes digital printing of flat optics metasurfaces, by holographic laser post-writing on nano-textured, metal-coated optical metasurfaces. Holographic laser printing with a spatial light modulator (SLM) has several advantages over conventional raster-writing and dot-matrix display (DMD) writing: multiple pixel exposure, high power endurance and existing software for computer generated holograms (CGH). We present a technique for design and manufacturing of plasmonic Fresnel zone plates (FZP) based on ultrafast laser printing with a SLM. Here the design is scalable, such that tailoring a plasmonic FZP with different wavelengths and focus lengths is done with ease.

10343-33, Session 7

High-angle light bending and ultra-high NA lenses achieved through resonance interference effects in dielectric metasurfaces *(Invited Paper)*

Ramon Paniagua-Dominguez, Egor Khaidarov, Ye Feng Yu, Hanfang Hao, Reuben M. Bakker, Xinan Liang, Vytautas Valuckas, Yuan Hsing Fu, Arseniy I. Kuznetsov, A*STAR - Data Storage Institute (Singapore)

Optically resonant dielectric nanostructures represent a new and rapidly developing research direction in nanophotonics [1]. They show plenty of useful functionalities and can complement or even substitute resonant plasmonic nanoparticles for many potential application directions. The main advantages over conventional plasmonics are low losses, wide range of applicable dielectric materials and strong magnetic resonant response. In particular, the last feature opens a broad range of opportunities to control light scattering, transmission, reflection and phase characteristics through designed interference between electric and magnetic resonant modes. This has already led to demonstrations of low-loss dielectric Huygens' metasurfaces operating with very high efficiencies in transmission mode and generalized Brewster effect showing unconventional behaviour of dielectric metasurface in reflection mode [1]. In this presentation, we will review recent magnetic resonant phenomena obtained with high-index dielectric nanoantennas and metasurfaces and show how this might lead to new functionalities, which cannot be achieved neither with conventional metasurface approaches nor with conventional bulk optics. In particular, we demonstrate how the resonance interference effect can be used to control energy distribution between diffraction orders in a nanoantenna array, which leads to light bending at very high angles of >82 degrees with efficiency >50%. This property is used to design and experimentally demonstrate flat lenses having a free-space numerical aperture (NA) of >0.99, which strongly exceeds NA of existing flat lenses and bulk optics analogues. Applications of these new, ultra-high NA, flat dielectric lenses will also be discussed.

Solar metadevice with enhanced absorption, scattering, and spectral control

Richard M. Osgood III, Yassine Ait-El-Aoud, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Lalitha Parameswaran, Vladimir Liberman, Mordechai Rothschild, MIT Lincoln Lab. (United States); Andrew Luce, Nicholas LeGrand, Michael Okamoto, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Steven E. Kooi, MIT Institute for Soldier Nanotechnologies (United States); Diane M. Steeves, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States); Richard P. Kingsborough, MIT Lincoln Lab. (United States); Stephen A. Giardini, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States)

Light scattering from nanoparticles has been shown to strongly influence optical properties of many diverse systems, including monolayer arrays of plasmonic particles [1] and cuttlefish chromatophores, where large scattering effects have recently been observed from unusual nanostructured granules [2]. Random and ordered arrays of plasmonic particles have produced larger nanoscopic field enhancements responsible for the Surface Enhanced Raman Scattering effect. We explore metadevices, consisting of monolayers of patterned or semi-random plasmonic (Al and Ag) particles, to enhance scattering into and enhanced absorption of thin photovoltaic films. Without this nano-enhancement, absorption is limited by film thickness in the long-wavelength region. With lithographically patterned arrays of Al nano-islands, we observe a solar-weighted absorption enhancement of greater than 35% in 200-nm thick amorphous silicon layers on glass, and obtain absorption enhancement data from semi-random spuncast Ag nanoparticle arrays as well as arrays on glass. We model scattering and enhanced absorption, discussing how to scale to large areas.

Lightweight, portable thin-film solar blankets are of great economical value, providing size, weight and logistics advantages over heavy, brittle, standard solar cells. Typically two m2 in area, these solar blankets almost satisfy specifications, but still have limited absorption, and are too large and heavy. Our metadevice will enable the broader use of these solar blankets for commercial and military applications.

Sensitivities of large aperture multi-element plasmonic metasurface lenses

Bryan Adomanis, Stephen E. Nauyoks, Air Force Research Lab. (United States); D. Bruce Burckel, Sandia National Labs. (United States); Michael A. Marciniak, Air Force Research Lab. (United States)

Development of metasurface lenses has rapidly advanced in the few years since the first experimental demonstration, due to the excitement of full control of a propagating wavefront through an interface on the order of a wavelength or less. Lenses based on polarization conversion via plasmonic antennas are inherently limited in efficiency, and so a preponderance of recent efforts focus on more efficient dielectric-based designs. As a result, plasmonic metasurface lenses have been sparsely characterized. However, it has been found that expanding the design beyond a single interface offers hope for plasmonic structures, thanks to improvements such as adding impedance-matched layers and additional functional layers for polarization conversion. Before continuing development of these multi-layer structures, we wish to better understand dependencies of plasmonic designs. Thus, here we demonstrate the spectral, geometrical, angular and polarization sensitivities of 19 large-scale (5mm) variants of the original V-antenna lens design at 5μm and 8μm. Focal ratios of our cylindrical lenses range from F/5-F/40. Results are measured for several optical systems, including a single lens, a Keplerian beam expander, and a two-lens relay.

10343-36, Session 8

Merging micro- and nanooptics *(Invited Paper)*

Harald Giessen, Simon Thiele, Univ. Stuttgart (Germany)

We demonstrate miniaturized micro- and nano-optics. Our approach uses femtosecond 3D direct laser writing. Aberration-corrected performance for large angles of incidence is achieved, and our approach solves the common problem of off-axis coma in metasurfaces.

An inherent property of metasurfaces for optical imaging is coma [1]. Despite excellent on-axis performance, metasurfaces based on TiO2 nanoantennas that use dielectric Mie resonances do not give good imaging quality when going away from the optical axis or using large angles of incidence [2].

Using femtosecond 3D direct laser writing, we manufactured complex freeform microoptics with different diameters below 1 mm [3], see figure 1. The optical design and layout, the mechanical model, the manufactured lens, and the resolution performance are shown. A resolution of 780 nm with excellent contrast is even possible for large angles of view. Miniature phase plates are also possible [4]. Our smallest compound microscope objectives are as small as 100 μm in diameter and were fabricated directly on an imaging fiber with 125 μm diameter and 1600 single mode imaging strands [5]. Our systems can also be printed directly onto CMOS imaging sensors with sub-micron pixel sizes [5]. Furthermore, printing onto LED is also possible for illumination shaping [6]. It is also possible to print several lenses with different focal lengths and fields of view onto a single sensor, creating a foveated image that comprises teleeohoto-, normal- and wide angle-lenses [7]. One can also combine the lenses with quantum dots as integrated single photon source device [8]. We demonstrate further how to combine these structures with suitable nano-optics.

Acknowledgements This work has been supported by ERC Advanced Grant Complexplas, by DFG, BMBF (Printoptics), and BW-Stiftung.

Optoelectronic metasurfaces *(Invited Paper)*

Pierre Berini, Univ. of Ottawa (Canada)

Metasurfaces constructed from metallic nanostructures such as optical antennas and sub-wavelength gratings can be designed to operate efficiently as coupling structures for incident optical beams to surface plasmon polaritons (SPPs) propagating thereon. On a semiconductor, metallic metasurfaces can act simultaneously as a device electrode while ensuring strong optical field overlap with the active region. Additionally, SPP fields thereon can be confined to sub-wavelength dimensions and significantly enhanced relative to the exciting field. These features are very attractive for nanoscale optoelectronic device applications, such as photodetectors and modulators, as the excitation of SPPs alters conventional trade-offs between responsivity and speed, or modulation and speed, respectively. This is due to the facts that sub-wavelength confinement enables the active region to be shrunk to nano-scale dimensions, while good optoelectronic performance is maintained due to SPP field enhancement. We discuss recent progress on optoelectronic metasurfaces, particularly recent device demonstrations for high-speed reflection modulators based on a metal-oxide-semiconductor capacitor structure exploiting the carrier refraction effect in Si [1,2], and for Schottky contact sub-bandgap hot-hole infrared photodetectors on p-Si [3,4]. Potential application to non-contact Si CMOS electronic wafer testing will be discussed.

Cloaking of contact fingers on solar cells and OLEDs using free-form surfaces designed by coordinate transformations *(Invited Paper)*

Martin F. Schumann, Malte Langenhorst, Karlsruher Institut für Technologie (Germany); Michael Smeets, Kaining Ding, Forschungszentrum Jülich GmbH (Germany); Ulrich W. Paetzold, Benjamin Fritz, Karlsruher Institut für Technologie (Germany); Ralph Eckstein, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany); Guillaume Gomard, Martin Wegener, Karlsruher Institut für Technologie (Germany)

In transformation optics, coordinate transformations are usually mapped onto equivalent (meta-)material parameter distributions. In 2015, we introduced an approach mapping coordinate transformations onto dielectric free-form surfaces. We presented model experiments on cloaking of reflective contact fingers on solar cells. We now report on the fabrication of masters by 3D laser lithography used for soft imprinting. For prototype silicon heterojunction solar cells investigated under 1-sun illumination, we demonstrate the predicted 9% relative efficiency increase. We additionally show that our approach is adaptable to Lambertian sources, thereby cloaking light-emitting diode contacts to achieve spatially homogeneous emission.

10343-39, Session 8

Integrating quantum-dots and Mie resonators into a 2D metamaterial for sunlight downconversion

Antonio Capretti, Arnon Lesage, Tom Gregorkiewicz, Univ. van Amsterdam (Netherlands)

Dielectric Mie resonators and quantum-confined semiconductors enable an unrivaled control over light absorption and excited electron states, respectively. Here, we embed photoluminescent silicon nanocrystals (Si-NCs) into a planar array of SiO2 nanocylinders, and experimentally demonstrate a powerful concept: the resulting metamaterial preserves the Si-NC radiative properties and inherits the spectrally-selective absorption properties of the nanocylinders. This hierarchical approach provides increased photoluminescence (PL) intensity, without utilizing lossy plasmonic components.

Our metamaterial enables tunable absorption peaks up to 50% in the visible spectrum, when freestanding, and is predicted to reach total absorption by using an impedance-matched substrate. These absorption peaks occur in correspondence of the nanocylinder Mie resonances and of the grating condition in the array. We experimentally detect extinction peaks, driving enhanced absorption in the Si-NCs. Therefore, the metamaterial features increased PL intensity, obtained without affecting the PL properties such as lifetime, angular pattern and extraction efficiency. Remarkably, our best-performing metamaterial shows +30% PL intensity achieved with a lower amount (43%) of Si-NCs, compared to a planar film without nanocylinders. This results in a 3-fold average PL enhancement.

This spectral selectivity of absorption paves the way for an effective light down-conversion scheme to increase the efficiency of solar cells. The demonstrated principle is completely general and the Si-NCs can be replaced with other semiconductor quantum dots, rare-earth ions or organic molecules. Similarly, the dielectric medium can be adjusted on purpose. We envision the use of this hierarchical design for efficient photovoltaic, photocatalytic and artificial photosynthetic devices with enhanced efficiency.

10343-40, Session 8

A Monte Carlo approach for investigating the fabrications imperfections for metasurfaces

Li-Yi Hsu, Univ. of California, San Diego (United States)

In this paper, we introduce a method to compare the quality of concentrators in the realm of metasurfaces. Specifically, we generalize the concepts of the slope error and the intercept factor in the realm of ray-optics. After proposing definitions valid in physical optics, we put forward an approach to calculate them. As examples, we design in the optical domain three metasurfaces based on three different unit cells: cylindrical, rectangular and ellipsoidal elements. The concept allows for the comparison of the efficiency of the metasurfaces, their sensitivities to fabrication imperfections and can provide a guidance to design large scale and highly efficiency metasurface concentrators.

10343-42, Session 9

Nonlinear metasurfaces: materials and directional generation *(Invited Paper)*

Augustine M. Urbas, Air Force Research Lab. (United States)

Plasmonic and metamaterial systems are enabling to many relevant technologies. Detecting optical signals in the mid and long wave infrared, and the generation, detection and conversion of single photons for quantum information applications are significant to a range of Air Force technologies and drive the research to increase performance and functionality. We explore how nonlinear properties of metasurfaces can be engineered for quanutm information applications. We show that nonlinear multipole interference allows both a non-reciprocal and unidirectional nonlinear generation from nanoelements or their periodic arrangement, with the direction of nonlinear generation preserved with respect to a fixed laboratory coordinate system when reversing the direction of the fundamental field.. These effects arise due to the nonlinear response of the component materials and we are actively pursuing novel materials systems and growth procedures to produce structures with controlled response. A significant part of this work focuses on the characterization of time resolved nonlinear response in plasmonic and dielectric materials. We employ the beam deflection method to measure the nonlinear refraction and absorption of thin films. Beam deflection is a pump probe technique which offers extreme sensitivity to nonlinear response in materials. This allows us to measure the response of films at the dimensions relevant to our dimer designs deposited using the same techniques and reveal thickness and process dependent changes in the properties of nonlinear materials. This system is a useful example of where the engineering of materials response through structure to achieve desired optical properties can enable new potential technolgies.

10343-43, Session 9

Engineering optical nonlinearities in plasmonic titanium nitride thin films

Nathaniel Kinsey, Virginia Commonwealth Univ. (United States); Heather J. Ferguson, Univ. of Michigan (United States); Jennifer M. Reed, Air Force Research Lab. (United States); Manuel R. Ferdinandus, Air Force Institute of Technology (United States); Clayton T. DeVault, Urcan Guler, Alexei S. Lagutchev, Purdue Univ. (United States); Theodore Norris, Univ. of Michigan (United States); Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States); Augustine M. Urbas, Air Force Research Lab. (United States)

Recently, the development of alternative plasmonic materials has provided several candidates that possess optical properties that mimic those of gold, but are able to withstand temperatures in excess of 2800 °C before melting. These so-called refractory plasmonic materials, e.g. TiN, ZrN, HfN, and TaN, may provide a good solution for nonlinear plasmonics applications as they are able to support surface plasmon oscillations with competitive losses while maintaining a larger damage threshold than similar noble metals. Of the transition metal nitrides, TiN has received attention for applications in photovoltaics, data storage, waveguiding, and metamaterials.

Recently, it was shown that the effective third-order nonlinear optical properties of TiN were similar in strength to those found in silver or gold films but TiN is able to withstand a significantly higher irradiance. However, the mechanism and temporal response of the nonlinearity were not well understood. In this work, we extend the study of TiN to include the effect of material quality, as well as the temporal dependence, to highlight the design space for potential applications. By observing the dynamics of the various nonlinear mechanisms as a function of the film quality/stoichiometry, we were able to identify several distinct contributions to the observed response through the material's linear properties and band structure. Specifically, we observe both an instantaneous semiconductor-like response as well as a delayed hot-electron response whose sign, speed, and magnitude can be engineered by controlling the growth conditions. Consequently, the flexibility in both the linear and nonlinear optical properties offered by TiN combined with its competitive plasmonic response and enhanced damage threshold make it a promising material for future nonlinear nanophotonic applications.

10343-44, Session 9

Chiral metamaterials in the nonlinear regime: harmonic generation, multiphoton luminescence, and intensity-dependent optical activity *(Invited Paper)*

Wenshan Cai, Georgia Institute of Technology (United States)

The past few years have witnessed an explosive development of chiral photonic metamaterials that exhibit circular dichroism and optical rotation orders of magnitude larger than conventional materials. Though chirality is most commonly applied in linear optical regime, opposing circularly polarized waves can also display parity as a property of higher order optics. In this talk, we present a set of photonic metamaterials that possess pronounced chiroptical features in the nonlinear regime. In additional to the gigantic chiral properties such as the circular dichroism and polarization rotation, the metamaterials demonstrate a distinct contrast between harmonic responses from the two circular polarizations. These nano-engineered structures are further exploited for chiral-selective two-photon luminescence from quantum emitters and a photon-drag effect with helicity-sensitive generation of photocurrent. Finally, we report a noticeable shift in the circular dichroism and optical activity under a modest level of excitation power.

10343-45, Session 9

Organic molecular epsilon-near-zero ultrathin film: toward enhanced nonlinear optical response in visible spectral range

Yeon Ui Lee, Ewha Womans Univ. (Korea, Republic of); Hyo Jung Kim, Pusan National Univ. (Korea, Republic of); Jean-Charles Ribierre, Ewha Womans Univ. (Korea, Republic of); Young Chul Jun, Ulsan National Institute of Science and Technology (Korea, Republic of); Kenji Kamada, National Institute of Advanced Industrial Science and Technology (Japan); Jeong Weon Wu, Ewha Womans Univ. (Korea, Republic of); Anthony D’Aléo, Ewha Womans Univ. (Korea, Republic of) and Aix Marseille Univ. (France) and Ctr. National de la Recherche Scientifique (France)

Epsilon-near-zero (ENZ) materials exhibit optical response such as directional emission, modification of dipole radiation behavior and enhancement of third-order optical nonlinearity. Doped semiconductors and transparent conducting oxides are known to have ENZ response in mid-IR and near-IR spectral ranges, which is determined by the maximum density of carrier doping still maintaining good optical property. Here we introduce organic molecular materials showing an efficient ENZ response in visible spectral range. Organic molecular films of squaraine and cyanine are prepared by spin-coating to obtain high optical quality ultrathin films. Squaraine is dissolved in organic solvent while cyanine is prepared in aqueous polymer. Linear optical spectrum and spectroscopic ellipsometry measurements of both films evidenced ENZ in 500-600nm. Attenuated total internal reflection measurement further identified spectral ranges of negative dielectric constant. Third-order optical nonlinearity is known to be enhanced in ENZ regime, demonstrated in mid-IR and near-IR spectral ranges. We demonstrate an enhancement of third-order optical nonlinearity in visible wavelength by femtosecond Z-scan measurement. Both samples showed third-order nonlinear response enhanced at ENZ when compared with off-resonant value. In open-aperture measurement squaraine film showed both two-photon and saturable absorptions, while cyanine film showed saturable absorption only. In closed-aperture measurement squaraine film showed a well-behaved response while cyanine film signal was erratic presumably due to a break-down of J-aggregate at high intensity of optical field. Furthermore, molecular packing structure of both films is studied by grazing-incidence synchrotron radiation scattering measurement to relate ENZ properties and packing structure.

10343-46, Session 10

Plasmonic metasurfaces by evolutionary design *(Invited Paper)*

Teri W. Odom, Northwestern Univ. (United States)

Metasurfaces are an emerging class of flat optics that can manipulate light via subwavelength phase elements. Their 2D structures are usually determined by (1) calculating the phase change required at each location to obtain far-field properties from analytical equations and (2) structuring each building block to produce that wavefront change. However, computational or digital approaches to design metasurfaces based on search heuristics offer advantages in targeting and realizing properties not possible by analytical expressions. This talk will describe an evolutionary approach to design flat lenses based on subwavelength plasmonic building blocks. Our lattice evolution algorithm can achieve desired optical responses by tuning the arrangement of the phase units on a discrete square lattice. We will discuss two different systems with different classes of building units—holes and particles—to realize achromatic lattice lenses at up to three wavelengths and flat lenses in semiconductor plasmonic materials such as titanium nitride. We will describe prospects for scaling the production of these lenses as well as their ability to achieve dynamic optical responses.

10343-47, Session 10

Subwavelength Pancharatnam-Berry phase controlled metasurface for imaging with instantaneous SHG

Christian Schlickriede, Univ. Paderborn (Germany); Naomi Waterman, The Univ. of Birmingham (United Kingdom); Bernhard Reineke, Philip Georgi, Univ. Paderborn (Germany); Guixin Li, Southern Univ. of Science and Technology (China); Shuang Zhang, The Univ. of Birmingham (United Kingdom); Thomas Zentgraf, Univ. Paderborn (Germany)

We design and experimentally investigate a new plasmonic metasurface, which is able to work as a lens for nonlinear imaging with simultaneous frequency conversion for the incident near-infrared light. With our approach, we take advantage of the nonlinear Pancharatnam-Berry phase originating from the arrangement of meta-atoms with threefold rotational geometry. Due to the strong light-matter interaction of the plasmonic nanoantennas, the lenses have only a thickness of 30 nm. Furthermore, the nonlinear metalens shows different operation modes, which depend on the spin angular momentum of light. By using a particular polarization state, the nonlinear lens can either work as a focusing or defocusing lens while simultaneously converting the illumination light to SHG light. We investigate the beam propagation of our nonlinear metalens and determine the evolution of the real and virtual focal planes for illumination with Gaussian beams. To underline the strength and the design flexibility we fabricated and analyzed different types of more complex nonlinear devices featured by different focusing abilities. In addition to that, we present intriguing spin angular momentum depending nonlinear imaging abilities giving rise to real and virtual SHG images of real objects as well as nonlinear Fourier transformations. The images are thereby generated at visible wavelength, which enables this device for revealing new avenues in integrated nano-optoelectronics, quantum communication technologies or other future device applications. Nonlinear metalenses feature a symbiotic relationship between generation and modulation of frequency conversion within an ultrathin element.

10343-48, Session 10

Ultra-high refractive index in deep subwavelength coupled bi-layer free-standing flexible metamaterials

Leena Singh, Oklahoma State Univ. (United States)

We demonstrate an order of magnitude enhancement in refractive index of artificially designed metamaterials by exploiting the deep subwavelength coupling in a free-standing, thin-film metal-dielectric-metal checkboard structure. A record high refractive index of 183.2 is characterized at terahertz frequencies. The detailed investigations reveal that the enhancement of the effective refractive index of the structure via deep subwavelength coupling in a bilayer design is governed by a power law, which is an effective and simpler approach to design high index metamaterials. The approach relies on deep subwavelength coupling to obtain extremely high refractive index values that can lead to many practical applications in the field of imaging, lithography, design of delay lines and interferometers.

10343-49, Session 10

Bianisotropy: a new route towards non-reciprocal optical metasurfaces

Mark Lawrence, Jennifer A Dionne, Stanford Univ. (United States)

Directional light flow is fundamental to the development of photonic information processors. One all optical way of generating such nonreciprocal transport involves exploiting the nonlinear Kerr effect within an asymmetric arrangement of high Q resonators. However, current demonstrations involve optical paths that are tens to hundreds of microns in length.

Here, we show that Kerr based nonreciprocal devices can be further miniaturized to the nanoscale by working with Silicon nanoantenna-based metasurfaces. In the subwavelength regime structural asymmetry alone isn't enough to generate directionally-dependent field amplification. We overcome this limitation by overlapping a sub-radiant electric dipolar mode with a perpendicular super-radiant magnetic dipole. In this case, breaking out-of-plane inversion symmetry leads to nearfield coupling between the two excitations. Because of interference between nearfield and far field magneto-electric coupling, the electric dipole is suppressed (enhanced) for a normally incident plane wave propagating in the backward (forward) direction. When the metasurface is illuminated with powers of a few 100kW/cm2, the electric field strength within the Si becomes sufficient to change its refractive index, red-shifting the narrow transmission dip. For forward excitation the resonance is shifted by a significant portion of the FWHM, making the metasurface transparent. For backward excitation the much smaller shift renders the transmission very low.

We show, for the first time, that bianisotropy provides a means to achieve optical nonreciprocity at the nanoscale. Relying simply on collocated dipolar excitations, our scheme has, in principle, no lower size limitation and could be miniaturised further by making use of gain assisted plasmonics.

10343-50, Session 10

Nonlocal metasurfaces enable perfect anomalous reflection

Viktar S. Asadchy, Aalto Univ. (Finland) and Francisk Skorina Gomel State Univ. (Belarus); Andreas Wickberg, Karlsruher Institut für Technologie (Germany); Ana Díaz-Rubio, Aalto Univ. (Finland); Martin Wegener, Karlsruher Institut für Technologie (Germany); Sergei A. Tretyakov, Aalto Univ. (Finland)

Recently introduced generalized Snell's law provides wide possibilities for wavefront manipulations using metasurfaces. In contrast to conventional blazed gratings, their metasurface-based counterparts are planar (no grooves) and do not require complicated fabrication techniques. However, all previously demonstrated metasurfaces for anomalous reflection have revealed their deficiency due to parasitic energy coupling into non-desired diffraction modes. This negative effect becomes especially pronounced for metasurfaces designed to have a large separation angle between the incident and reflected beams. The reason is the used inaccurate approach for metasurface synthesis. It approximates that the surface is uniform on the sub-wavelength scale and the phase of the local reflection coefficient follows the linear profile dictated by the generalized reflection law. While the former assumption could be made, the latter one, as we show in the presentation, is incorrect. Moreover, the conventional synthesis approach does not take into account requirements on the amplitude of the local reflection coefficient. In the presentation, we will demonstrate an original alternative design scheme for metasurface gratings based on the generalized surface impedance model. It appears that perfect coupling of an incident plane wave into a single reflected plane wave requires energy channeling along the metasurface plane. To verify our design approach, we fabricate and measure an optical metasurface that reflects a normally incident beam at a very steep angle of 80 deg. The comparison of the two approaches shows that our new scheme provides double increase in the efficiency and complete absence of parasitic reflections.

10343-51, Session 10

Metasurface-based holograms and vortices

Cheng-Wei Qiu, National Univ. of Singapore (Singapore)

We experimentally report our recent progress on developing high-capacity and advanced holographic metasurfaces and vortex metasurfaces. Compared with traditional lens, such flat devices take the advantage from its ultrathin trait to realize the helicity-dependent optical vortex focusing metalens (consisting of 306,306 rotating nano-voids) that focuses three longitudinal vortices with distinct topological charges at different focal planes. The designed metasurface may find potential applications in multi-plane simultaneously particles manipulation, angular-momentum-based quantum information processing and integrated nano-optoelectronics. In the meantime, on-chip discrimination scheme of detecting the orbital angular momentum of light was experimentally demonstrated to focus the surface plasmons to different lateral positions, with reliable 120nm lateral shift between any two neighbouring topological charges of the incident vortex light. On the other hand, we also demonstrate how to incorporate multiple holographic images into one metasurface, via nonlinearity, spatial multiplexing, random phase mask, etc. Overall, those two major applications of metasurface may serve as competitive alternative to generate OAMs and holograms from traditional methods.

10343-72, Session 10

Embedded eigenstates and virtual absorption using metamaterials *(Invited Paper)*

Alexandr E. Krasnok, The Univ. of Texas at Austin (United

States); Francesco Monticone, Cornell Univ. (United States); Andrea Alù, The Univ. of Texas at Austin (United States)

We discuss the possibility of confining electromagnetic energy and enhancing the interactions of light and matter in nanostructures, based on the concept of embedded eigenstates within the radiation continuum. We discuss how metasurfaces and metamaterials may be able to trap light in plain sight, and how lossless structures may be able to store energy in the transient by engaging complex zeros in the scattering response of the system. We also shed light on the role that reciprocity plays in the response of these systems, and how these functionalities may play a pivotal role in low-energy nanophotonic opto-electronic and bio-sensing devices.

10343-52, Session 11

Reconfigurable chiroptical nanostructures *(Invited Paper)*

Nicholas A. Kotov, Univ. of Michigan (United States)

Chiral nanomaterials represent one of the most dynamic research areas in photonics. High values of polarization rotation observed for assemblies of plasmonic nanoparticles inspire the development of new chiroptical nanomaterials. Transition of this new physical phenomena to photonics technologies requires active modulation of the degree of polarization rotation. In this presentation I will demonstrate the possibility of reconfigurable chiroplasmonic systems based on three different platforms: scissor-like nanoparticle pairs, chiroptical nanocomposites, and kirigami optics. Advantages and disadvantages of the three platforms will be discussed using practical applications in biosensing and chiral photonics.

10343-53, Session 11

Towards all-optical chiral resolution with achiral plasmonic and dielectric nanostructures *(Invited Paper)*

Jennifer A. Dionne, Stanford Univ. (United States)

Light can exert differential forces on left- and right-handed enantiomers, promising an all-optical route towards chiral resolution and controlled assembly of chiral nanostructures. However, enantioselective optical forces on nano-specimens are challenging to both control and quantify, since their magnitudes are predicted to be sub-piconewton-scale with nanometer-scale spatial variation. Here we demonstrate new methods to both strengthen and visualize these forces using achiral nanostructures. First, we show how plasmonic optical tweezers can enable selective optical trapping of enantiomers. Our technique combines plasmonic optical tweezers with a chiral atomic force microscope (AFM) probe. Illumination of the plasmonic tweezers with left- and right- circularly polarized light (CPL) results in distinct forces on the chiral AFM tip: the total optical forces exerted on a left-handed chiral tip are 10 pN stronger when illuminated with left-CPL than with right-CPL. Additionally, the transverse optical forces on this chiral tip are attractive with left-CPL, but repulsive with right-CPL. We use the AFM tip to map such chiral optical forces over the plasmonic tweezers with 2 nm lateral spatial resolution, showing distinct force distributions in all three dimensions for each handedness. Then, we show how high-index dielectric nanostructures and metasurfaces can increase enantiomer separation yields more than 50 times beyond CPL in free space. Mie theory and a local optimization algorithm indicate that magnetic multipolar Mie resonances supported by sub-micron silicon spheres increase both the circular dichroism signal and Kuhn's dissymmetry factor compared to CPL in free space. Importantly, these enhancements maintain the total molecular absorption rate, enabling efficient selective photoexcitation. Combined, our results suggest that achiral photonic nanostructures can significantly enhance chiral light-matter interactions, potentially enabling controlled enantiopure chemical syntheses, single molecule chiral spectroscopy, and dynamic monitoring of structural changes of chiral molecules with sub-nanometer resolution.

10343-54, Session 11

Symmetry induced topological Weyl points in chiral nanophotonic metamaterials *(Invited Paper)*

Ortwin Hess, Imperial College London (United Kingdom)

No Abstract Available

10343-55, Session 11

Realizations of Weyl points in reciprocal metamaterial

Meng Xiao, Qian Lin, Stanford Univ. (United States); Wenjie Chen, Che Ting Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China); Shanhui Fan, Stanford Univ. (United States)

Weyl points as monopoles of Berry curvature in momentum space are stable under any perturbation which preserve the translational symmetry. Their experimental realizations like gyroid photonic crystals, on the other hand are quite complex. Here we show two experimentally feasible systems with Weyl points. We break the inversion symmetry in these systems and does not need any external magnetic field. In the first system, we show the existence of Weyl points in a class of non-central symmetric metamaterials. Here the inversion symmetry is broken by utilizing the chiral coupling between the electric and magnetic fields. The exploration of Weyl point in metamaterials as described by homogeneous effective material parameters is of fundamental interest since the wavevector space of such meta-material is non-compact, which is in contrast with the wavevector space of periodic systems which is always topologically compact. We find that such metamaterial can be realized with a simple system consisting of an array of metal wire in the shape of elliptical helix. Experimental detection of Weyl points in this system is also discussed. The second system we consider goes beyond the effective medium description. It is a chiral stacking of layered honeycomb structure. This system possesses both single Weyl points (including type-II nodes) and multiple Weyl points with topological charges of 2 and 3. We also experimentally show the robustness of the surface states against kz-preserving scattering in this system.

10343-56, Session 12

Experiment of synthetic Weyl points in optical regime

Hui Liu, Qiang Wang, Nanjing Univ. (China); Meng Xiao, Stanford Univ. (United States); Shi Ning Zhu, Nanjing Univ. (China); Che Ting Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Weyl fermions have not been found in nature as elementary particles, but they emerge as nodal points in the band structure of electronic and classical wave crystals. Novel phenomena such as Fermi arcs and chiral anomaly have fueled the interest in these topological points which are frequently perceived as monopoles in momentum space. We demonstrate that generalized Weyl points can exist in a parameter space and we report the first observation of such nodal points in one-dimensional photonic crystals in the optical range. The reflection phase inside the band gap of a truncated photonic crystal exhibits vortexes in the parameter space where the Weyl points are defined and they share the same topological charges as the Weyl points. These vortexes also guarantee the existence of interface states, the trajectory of which can be understood as "Fermi arcs" emerging from the Weyl nodes.

10343-57, Session 12

Multiplexing of adjacent vortex modes with the forked grating coupler

Christopher T. Nadovich, Derek J. Kosciolek, William D. Jemison, David T. Crouse, Clarkson Univ. (United States)

For OAM multiplexing in vortex fiber to reach practical commercial viability, simple silicon photonic interfaces with vortex fiber will be required. These interfaces must support multiplexing. Toward this goal, an efficient single-fed multimode Forked Grating Coupler (FGC) for coupling two different optical vortex OAM charges to or from the TE0 and TE1 rectangular waveguide modes has been developed. A simple, apodized device implemented with e-beam lithography and a conventional dual-etch processing on SOI wafer exhibits low crosstalk and reasonable mode match. Advanced designs using this concept are expected to further improve performance.

Forked Grating Couplers retain many of the advantages of conventional grating couplers, including convenience of placement, reasonable bandwidth, small size, and CMOS fab compatibility. Herein we propose a new kind of single-fed FGC design that can simultaneously couple to a pair of OAM modes, connecting these modes one-to-one onto a pair of TE modes in a “bus” waveguide on a photonic IC. The bussed modes can then be split/combined with an asymmetric coupler or other on-chip multiplexing techniques.

The simple multi-mode FGC concept presented can be applied for different multiplexed OAM charges so long as their integer charges must differ by +/-1. A basic, apodized device implemented with e-beam lithography and a conventional dual-etch processing of SOI wafer exhibits better than 20 dB crosstalk isolation and mode match efficiency better than 3 dB. Advanced designs using this concept are expected to further improve performance.

10343-58, Session 12

Singular optical beams enabled by photonic meta-structures *(Invited Paper)*

Natalia M. Litchinitser, Liang Feng, Pei Miao, Jingbo Sun, Zhifeng Zhang, Mikhail I. Shalaev, Wiktor T. Walasik, Univ. at Buffalo (United States); Stefano Longhi, Politecnico di Milano (Italy)

Recent developments in the field of nanostructured optical materials enable unprecedented control over light propagation and a possibility of “tailoring” the space for light propagation. In particular, the emergence of novel optical materials opens a new paradigm in studies of singular optics (or structured light), which is a fascinating emerging area of modern optics that considers spin and orbital angular momentum (OAM) properties of light and brings a new dimension to optical physics. We will discuss fundamental optical phenomena at the interface of singular and nonlinear optics in novel optical media and show that the unique optical properties of optical nanostructures open unlimited prospects to “tailor” light itself.

We present theoretical and experimental studies of light-matter interactions of vector and singular optical beams in optical nanostructures and microcavities. In particular, by exploiting the emerging non-Hermitian photonics design at an exceptional point, we demonstrate a microring laser generating a single-mode OAM vortex lasing with the ability to precisely define the topological charge of the OAM mode. We show that the polarization associated with OAM lasing can be further manipulated on demand, creating a radially polarized vortex emission. Such OAM microlaser could find applications in the next generation of integrated optoelectronic devices for optical communications in both quantum and classical regimes.

10343-59, Session 12

Conversion of optical spin-to-orbital angular momentum on metasurfaces

Feng Lin, Peking Univ. (China)

Abstract: The optical spin-orbit interaction is that a coupling of the intrinsic angular momentum (photon spin) and the extrinsic momentum (orbital angular momentum) [1-2]. The effect is usually observed when the light passes through an anisotropic and inhomogeneous medium. For instances, the optical spin Hall effect, beam displacement and momentum shift due to the optical spin, was observed at the medium interface. In metasurface structures, the surface plasmons travel along the path that can be defined to within a subwavelength scale by the geometric patterns of the structures, which generate a significant optical orbital angular momentum. In our work, on the Au thin film deposited on glass substrates, we fabricated the subwavelength holes by focused ion beam, which form the ring shape. Using the scanning near-field optical microscope, the different propagation modes of surface plasmons has been observed for the excitation light with the left and right handed circular polarization, respectively. Based on the conservation of total optical angular momentum in this circular system, the conversion effect of the spin and orbital angular momentum can be deduced from the measured and simulated distribution of electric fields.

Chiral nanophotonics of plasmonic and dielectric nanoclusters: from Landau-Lifshitz constraint to flat blazed gratings *(Invited Paper)*

Gennady B. Shvets, Cornell Univ. (United States)

Interference between multiple resonances can dramatically modify the optical response of plasmonic and dielectric nanoclusters. The coupling between resonances is often mediated by symmetry breaking, and the arising from it chirality. I will describe two photonic platforms that take advantage of intrinsic and extrinsic chirality: (a) asymmetric plasmonic nanoclusters that exhibit direction-dependent scattering, and (b) all-dielectric metasurfaces that exhibit highly asymmetric scattering into different diffractive orders. Platform (b) is also used to experimentally characterize “optical magnetism” that is prohibited by the Landau-Lifshitz constraint, and to separately extract magneto-electric and magnetic optical polarizability of asymmetric plasmonic nanoclusters.

10343-61, Session 13

Long range light matter interactions at hyperbolic meta surfaces *(Invited Paper)*

Girish Agarwal, Texas A&M Univ. (United States)

We show how long range light matter interactions can be realized at hyperbolic metasurfaces. We concentrate on the dipole-dipole interactions which are important for energy transfer studies and in quantum entanglement between qubits at metasurfaces. We apply this to get the electromagnetically induced transparency in artificial atoms at large distances. We will present experimental evidence for large range energy transfer.

10343-62, Session 13

Enhanced superconductivity in hyperbolic metamaterials *(Invited Paper)*

Vera N. Smolyaninova, Christopher Jensen, William Zimmerman, Towson Univ. (United States); Joseph C. Prestigiacomo, Michael S. Osofsky, Heungsoo Kim, Nabil D. Bassim, U.S. Naval Research Lab. (United States); Zhen Xing, Mumtaz Qazilbash, The College of William & Mary (United States); Igor I. Smolyaninov, Univ. of Maryland, College Park (United States)

One of the most important goals of condensed matter physics is materials by design, i.e. the ability to reliably predict and design materials with a set of desired properties. A striking example is the deterministic enhancement of the superconducting properties of materials. Recent experiments have demonstrated that the metamaterial approach is capable of achieving this goal, such as tripling the critical temperature Tc in Al-Al2O3 epsilon near zero (ENZ) core-shell metamaterials and hyperbolic metamaterial superconductors. Here, we demonstrate that an Al/Al2O3 hyperbolic metamaterial geometry is capable of a similar TC enhancement, while having superior transport and magnetic properties compared to the core-shell metamaterial superconductors. We will also report the Tc enhancement in hyperbolic metamaterials based on Sn/CaF multilayers. Reflectivity measurements were made to confirm the hyperbolic character of the fabricated metamaterials. Effect of metamaterial cell size on Tc will be discussed.

10343-63, Session 13

Loss compensation in metamaterials with extraordinary high- and low-momentum plasmic modes

Anatoliy O. Pinchuk, Univ. of Colorado at Colorado Springs (United States)

Hyperbolic metamaterials can propagate electromagnetic modes with unusually large wave numbers (extraordinary high-momentum modes). The extraordinary high-momentum modes are non-propagating or evanescent modes in common optical media. On the other hand, hyperbolic metamaterials can sustain propagating electromagnetic waves with unusually low wave numbers (extraordinary low-momentum modes). Both extraordinary high- and low-momentum modes are of special interest for a number of applications. For example, the development of these exotic modes, which are fundamental to the operation of hyperlenses, might lead to unprecedented sub-diffraction optical imaging systems. Hyperbolic metamaterials are also of special interest for radiative decay engineering.

The inevitable trade-off between optical mode confinement and the optical losses inherent to the metal component is a fundamental challenge for plasmonics and metamaterials. We have carried out numerical analysis of Rytov's dispersion equations to model loss-compensation in metal-semiconductor hyperbolic metamaterials with extraordinary high- and extraordinary low-momentum modes. Numerical results provide a framework for the design of loss compensation schemes in hyperbolic metamaterials with extraordinary high- and extraordinary low-momentum modes.

10343-64, Session 13

Hyperbolic metamaterial filter for angle-independent TM transmission in the infrared regime

Golsa Mirbagheri, Kaitlin J. Dunn, Derek J. Kosciolek, Clarkson Univ. (United States); Igor Bendoym, Phoebus Optoelectronics, LLC (United States); David T. Crouse, Clarkson Univ. (United States)

In this project we propose and fabricate a hyperbolic metamaterials-based narrowband notch filter for the infrared regime with a center wavelength that remains fixed as the angle of incidence changes from 0 to 30 degrees for TM polarization. This novel device modifies a conventional Bragg reflector by including a middle resonance layer that opens up a narrow, highly transmissive band. To achieve angular independence, a subwavelength sized array of silver wires are inserted in a vertical orientation and permeate all 7 Si and SiO2 layers of the structure.

In this work the theoretical underpinnings are explored using Maxwell-Garnett Theory, and simulated with 3D finite element full wave electromagnetic modeling software. Simulations demonstrate that the device is capable of up to 60% transmission at a fixed center wavelength for TM polarization in the infrared.

The device is fabricated using typical microfabrication techniques. The silver nanowires are fabricated via DC electrodeposition. The angle and polarization dependent transmission, reflection and absorption of the device are experimentally measured, and scanning electron microscopy images of the structure are shown.

Though the experimental validation of this device is performed for the infrared regime, scaling the structural sizes can extend the operating regime to higher and lower wavelengths. Whether used as a stand-alone filter, or integrated into a hyperspectral array, the angle-independent response of this filter has many uses in remote sensing applications.

10343-65, Session 13

Non-local effect of hyperbolic metamaterial structure on photo-induced intramolecular charge transfer emissions

Kwang Jin Lee, Yeon Ui Lee, Ewha Womans Univ. (Korea, Republic of); Fre?de?ric Fages, Aix-Marseille Univ. (France) and Ctr. National de la Recherche Scientifique (Gabon) and CINaM - Ctr. Interdisciplinaire de Nanoscience de Marseille (France); Jean-Charles Ribierre, Jeong Weon Wu, Ewha Womans Univ. (Korea, Republic of); Anthony D'Aléo, Ewha Womans Univ. (Korea, Republic of) and Aix Marseille Univ. (France) and Ctr. National de la Recherche Scientifique (France)

Metamaterial is one example of optical material system where non-local effect of optical response can be realized via effective medium description. Non-local effect based on hyperbolic metamaterial (HMM) has been utilized in manipulating the photophysical processes such as intramolecular charge transfer (ICT) dynamics, photodegradation and emission rate. Here, we report an example of non-local effect on spectral shift of emission. There are two different kinds of emissions, namely, emissions from local excited (LE) state and charge transfer (CT) state which are distinguished based on the excited state dipole moment of organic chromophore. In particular, we inspected the photophysical properties of 4-dicyanomethylene-2-methyl-6-(p-dimethylaminostyryl)-4H-pyran (DCM) dye dispersed in polymethylmethacryate (PMMA) matrix in order to identify the effect of non-local effect of HMM on spectral shift of charge transfer emission. There occurred around 6 nm blue shift of ICT emission from DCM fluorophore when located inside of PMMA matrix on top of HMM structures. Image dipole interaction dominant in CT state is responsible for the blue shift, which arises from a non-local dielectric constant surrounding the fluorophore, which is modified by HMM structure nearby. The amount of spectral shift was related to the variation of non-local dielectric constant and ionic radii of donor and acceptor in terms of Lippert-Mataga formalism. Furthermore, high energy LE state and low energy ICT state are identified by time resolved spectroscopy by taking into account of a change in Purcell factor at the same time.

10343-66, Session 14

Active plasmonic devices and processes *(Invited Paper)*

Naomi J. Halas, Rice Univ. (United States)

While graphene plasmonics has been well-studied in the IR, shifting the plasmon resonance of graphene to the visible region of the spectrum would require extremely small graphene structures with dimensions smaller than can be fabricated by the best currently available top-down fabrication methods. This is the length scale of polycyclic aromatic hydrocarbon (PAH) molecules, which can be regarded as picoscale versions of graphene, edge-passivated with hydrogen atoms. Recent theoretical studies have predicted that charged PAH molecules with partially filled orbitals can possess molecular plasmon resonances. While neutral PAH molecules exhibit large energy gaps, rendering them transparent in the visible region of the spectrum, the addition of removal of one or more electrons leads to strong absorption features in the visible wavelength range. Experimentally, PAHs can be incorporated into planar device geometries where they show outstanding potential as low-voltage, fast electrochromic media suitable for applications ranging from nanoscale optical components to large-area, color-changing walls or windows. There has been growing interest in the solar illumination of nanoparticles and nanostructured materials that capture light energy efficiently, enabling localized, confined heating at the liquid-vapor interface to vaporize liquids at high efficiency. Just as there are many fundamental aspects of this problem to investigate there are an increasing number of applications for this process, such as solar distillation. We will discuss how nanoparticle-mediated, light-induced phase separation can be used for water purification, transforming membrane distillation, an energy-intensive conventional process, to a far higher-efficiency, scalable, all-solar process.

10343-67, Session 14

Plasmonic nanofocusing facilitates ultrafast point-projection electron microscopy *(Invited Paper)*

Christoph Lienau, Carl von Ossietzky Univ. Oldenburg (Germany)

Ultrafast optical spectroscopy is now able of tracking even the fastest elementary processes such as the motion of electrons and/or holes in biomolecules or organic solar cells. Despite tremendous progress in sub-diffraction optical microscopy, a direct spatially resolved imaging of such processes is still out of reach since the spatial resolution of even the most advanced near-field imaging techniques is far beyond the Angström-resolution achieved, e.g., in aberration-corrected electron microscopy. As such, numerous efforts are currently ongoing in combining ultrafast optics and electron microscopy.

Recently, point-projection electron microscopy, realized by placing an object directly behind a nanoscopic electron source and recording a diffraction image on a distant screen, emerged as an interesting concept for improving the time resolution in ultrafast electron microscopy into the regime of few tens of femtoseconds or possibly even beyond. It avoids the need for electron lenses, makes the experimental setup compact and simple and minimizes temporal dispersion of the electron pulses.

Sharp metal tips, illuminated with few cycle laser pulses, are interesting electron sources for such experiments. Since direct laser illumination of their apex limits is necessarily diffraction limit, the tip-sample distance, however, is ultimately limited. We will show that nanofocusing of surface plasmons on a metal nano taper can circumvent this limitation by moving the far-field illumination to a grating coupler located several tens of microns away from the sharp taper apex acting as a point-like electron emitter. Here, we demonstrate for the first time the potential of this new technique for probing the dynamics of local electromagnetic fields at the surface of nanostructures with 10-nm spatial resolution and a temporal resolution of better than 30 fs.

Hybrid perovskite metamaterials *(Invited Paper)*

Cesare Soci, Nanyang Technological Univ. (Singapore)

We engineered the optical response of solution-processed metal-halide perovskite films using metamaterial design concepts. As a proof of principle we fabricated both, all-perovskite dielectric metasurfaces and hybrid metal-perovskite metamaterials, showing significantly enhanced luminescence and control of the spectral response throughout the visible region. Focused ion beam milling was used to directly engrave all-dielectric metamaterials onto thin films of methylammonium lead iodide perovskite (CH3NH3PbI3), spin-coated on quartz substrates: the resulting perovskite metasurfaces display rich structural color tuning and strong field enhancement, dependent on the geometrical parameters of the nanometer sized metamolecules. Photo- and cathodo-luminescence emission from such metasurfaces exhibit up to a five-fold Purcell enhancement with respect to the unstructured films. We also explored hybridization of perovskite films with plasmonic metamaterials and metal-semiconductor-metal slab waveguides to provide higher control over spectral enhancement and light extraction. These results suggest that sub-wavelength structuring and plasmonic hybridization are viable routes to engineer radiative emission properties and tunable structural colour in large-area photovoltaic and light-emitting perovskite devices.

Light manipulation with metasurface and meta-device *(Invited Paper)*

Pin Chieh Wu, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Wei-Yi Tsai, Hui-Hsin Hsiao, National Taiwan Univ. (Taiwan); Hui Jun Wu, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Chun Yen Liao, Hsiang-Chu Wang, National Taiwan Univ. (Taiwan); Ai Qun Liu, Nanyang Technological Univ. (Singapore); Greg Sun, Univ. of Massachusetts Boston (United States); Din Ping Tsai, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan)

The functionalities of traditional optical component are mainly based on the phase accumulation through the propagation length, leading to a bulky optical component such as converging lens and waveplate. Metasurfaces composed of planar structures with artificial design have attracted a huge number of interests due to their ability on controlling the electromagnetic phase as well as amplitude at a subwavelength scale. The feasible applications based on metasurfaces include nonlinear dynamics, light beam shaping, quantum interference etc. Beside those promising characteristics, people now intend to discover the field of meta-devices, where we can attain optical properties and functionalities through changing the feature characteristics of metasurfaces in demand. They therefore pave a potential way for the development of flat optical devices and integrated optoelectronic systems and toward the far-reaching applications which are impossible previously. In this talk, four research topics for photonic applications with metasurfaces and meta-devices will be performed and discussed: high efficiency anomalous beam deflector, highly dimensional holographic imaging, versatile polarization control and metadevices with active property.

10343-70, Session 14

Isotropic metamaterial perfect light absorber using 3D split ring resonator in the mid IR region

Renilkumar Mudachathi, Takuo Tanaka, RIKEN (Japan)

Electromagnetic metamaterials have been the subject of intense research

in the recent past owing to their exotic optical properties such as negative or zero refractive index and independently tailorable magnetic and electric response to the incident electromagnetic radiation. Unusual properties like these resulted in devices like electromagnetic cloak and flat super lenses. Metamaterials are often encountered with losses arising from metal and dielectric inclusions, which deteriorates its performance. By taking advantage of this intrinsic loss, the metamaterial could be designed to absorb electromagnetic radiation at any frequency of interest, which has huge potential in many applications like emitters, sensors, spatial light modulators, IR camouflage, thermophotovoltaics and wireless communication to name a few.

We present a perfect light absorber in the mid IR region of the spectrum with wide angle operation. The metamaterial absorber is essentially a three layer structure comprising of an impedance matching layer made up of 3D SRR, a dielectric dissipation layer realised using SiN and a metal ground plane of thickness 100nm which cancels any transmission. The 3D SRR is realised by the self folding of patterned metal strips on the release of residual stress. The SiN layer acts as a sacrificial layer to release the gold arms of length 2?m, width of 100nm and thickness of 50nm to form the ring structures using reactive ion etching. The SRR are then hovered on top of the gold ground plane by the unetched SiN pillars of height 200nm. The 3D SRR directly couples to the incident magnetic field, which generates an oscillating current in the ring which induces an anti parallel current in the metal ground plane. This creates a strong magnetic field coupling in the rings to form a dip in the reflection spectrum. We demonstrate the absorbance of more than 90% at a wavelength of 12.5?m and more than 96% at a wavelength of 8?m for the design with a cut at the metal ground plane.

Tunable plasmon induced transparency in a graphene-based waveguide structure and it's applications in sensing

Tao Wang, Xu Han, Huazhong Univ. of Science and Technology (China)

The plasmon induced transparency (PIT) effect, which generates a transparency window within a broad absorption spectrum, has attracted enormous attention because it's potentially important applications in the field of filters, sensors, and slow light. Various plasmonic structures have been proposed to realize the PIT effect, e.g. metamaterials, plasmonic waveguide side-coupled with nanocavities, metallic nanowire grating coupled with a dielectric waveguide layer. However, there are rarely related reports on the realization of dynamically tunable PIT effect and sensor in graphene nanoribbon waveguide structure based on the plasmonic edge modes coupling. In this paper, we propose dynamically tunable PIT in a graphene-based nanoribbon waveguide structure by changing the chemical potential of graphene. It is the direct destructive interference between the propagating plasmonic edge mode in the graphene nanoribbon waveguide and the rectangular resonators gives rise to the PIT effect. We calculate the transmission spectrum for the two-resonator-coupled system with different relaxation times and the Fermi levels. Moreover, a novel plasmonic refractive index sensor (RIS) has been proposed and investigated numerically based on the PIT effect in the mid-IR range. Our calculated results exhibit that large wavelength sensitivity as high as 2500 nm/RIU and a high figure of merit (FOM) of 10.50 can be achieved in this ultra-compact structure (< 0.05 ?m2) with large fabrication tolerance. This work not only paves a new way towards the realization of graphene-based integrated nanophotonic devices, but also has important applications in multi-channel-selective filters, sensors, and slow light.

Structural metamaterials with Saint-Venant edge effect reversal

Eduard Karpov, Larry Danso, Univ. of Illinois at Chicago (United States)

When a usual material is loaded statically at surfaces, fine fluctuations of surface strain diminish fast in the material volume with the distance to the surface, a common phenomenon known as the Saint-Venant edge effect. In this presentation, we explore highly nonlocal discrete lattices to demonstrate structural metamaterials featuring reversal of the Saint-Venant edge effect. In these materials, certain coarse patterns of surface strain may decay faster than the finer ones. This phenomenon is rooted in an anomalous behavior of Fourier modes of static deformation in the material, and creates opportunities for blockage, qualitative modification and in-situ recognition of surface load patterns. Potential applications and useful practical techniques of spectral analysis of deformation, density of states and phase diagram mapping are outlined.

10343-90, Session PWed

Bistability and thermal coupling in elastic metamaterials with negative compressibility

Michelle Chen, Johns Hopkins Univ. (United States); Eduard Karpov, Univ. of Illinois at Chicago (United States)

When elastic metamaterials are subjected to tension they may respond by undergoing contraction instead of expansion as an ordinary material would, and vice versa. This negative compressibility behavior can only occur if the system moves from one stable state to a different stable state as the force is applied, i.e., displays bistability. With a simple interatomic potential, we demonstrate that this negative behavior leading to a pinched hysteresis on the stress cycle diagram is a solid-to-solid condensation-type polymorphic phase transformation. In addition, we show that the negative compressibility may disappear in realistic dynamical systems, unless coupling with an external heat sink is strong enough to stabilize the newly formed phase. Such a material is an open thermodynamical system where the condensation process is accompanied by a fast return of the released heat into the ambient. Molecular dynamics with Verlet integration is used to study the dynamics of this behavior.

10343-91, Session PWed

Non-reciprocal manipulation of light with metamaterials in the deep UV light range

Hiroyuki Kurosawa, Shin-ichiro Inoue, National Institute of Information and Communications Technology (Japan)

We numerically studied the directional birefringence induced by the magneto-chiral (MCh) effect. The MCh effect gives rise to nonreciprocal transmittance, which is a key phenomenon to realize highly functional devices such as a one-way mirror. The MCh effect has been investigated in natural materials. However, several conditions such as low temperature and high magnetic fields are required to realize the MCh effect in the natural materials, which is not preferable for practical application. Recently, metamaterials with chirality and magnetism (magneto-chiral metamaterials) at microwave region exhibited an enhanced MCh effect at room temperature and convenient magnetic field strength. In the MCh metamaterial, the coupling of chiral and magnetic resonances plays the key role in realizing the enhanced MCh effect. However, the enhanced MCh effect is not realized in higher frequency region more than the microwave frequency. This is because the magnetic resonance does not exist in the higher frequency regions such as the optical region.

In this paper, we focus on the deep ultra-violet (DUV) light range. In the range, there are magnetic resonances associated with the optical transition. In order to realize the enhanced MCh effect in the DUV light range, both chiral and magnetic resonance are required. As the chiral resonance, we introduce plasmonic resonance of gammadion shaped nanostructure which consists of Aluminum. Combining the magnetic resonance and plasmonic chiral resonance, we for the first time demonstrate numerically that an enhancement of the MCh effect is realized in the DUV light range.

LiTaO3 microcubes based metamaterial perfect absorber

Nishant Shankhwar, Reena Dalal, Yogita Kalra, Ravindra K. Sinha, Delhi Technological Univ. (India)

In this paper we present the design of a metamaterial perfect absorber made up of an array of dielectric microcubes grown on a metallic substrate. The fundamental principle of operation of the proposed structure is Mie Resonance occurring in high permittivity particles in combination with the negative permittivity provided by the metallic substrate. The proposed structure is simpler than all other existing metamaterial perfect absorber structures. The geometrical parameters of the structure are between 1μm and 10 μm, hence it is not supposed to pose any challenge during fabrication. Moreover, the structure has been designed for terahertz spectrum which is the most unexplored part of the spectrum. The structure is made up of an array of microcubes of LiTaO3 whose permittivity is very high (~100) for wavelength range from 70 μm to 80 μm. This gives rise to Mie resonance in dielectric microcubes. The microcubes are arranged on a metallic (silver) substrate which provides a negative permittivity and ensure negligible transmission of light through the structure. Furthermore, structure has been optimized to the match the impedance of the free space so as to minimize the reflection as well.

10343-93, Session PWed

Ultrabroadband polarization-independent absorber based on hyperbolic metamaterial

Igor Leonardo Gomes de Souza, Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil)

We present an ultrathin ultraviolet spectrum absorber composed of multilayers of metal and dielectric with half-cylinder cross-section. The dielectric layers are SiO2 while the metallic ones are niquel, the structure has optimized characteristics of high absorption for both modes. Total absorbance of more than 94% for both electric and magnetic (TM) polarization at normal incidence is observed over a wide range of wavelengths. This property is retained well over a wide range of incidence angles up to approximately 70 degrees. The structure can maintain optimized absorption characteristics even with possible errors in the manufacturing process.

10343-94, Session PWed

Plasmonic nanoballs comprised of gold nanoparticle shells

Hiroshi Yabu, Tohoku Univ. (Japan)

Many efforts have been done to create three-dimensional (3D) metamaterials with piling up two-dimensional (2D) of metallic nanopatterns fabricated by state-of-art lithography techniques. This method is powerful and realizes electromagnetic responses to visible-near infrared (NIR) region of lights, but it has high angler dependency and requires fabrication elaborations. Bottom-up approaches including 3D arrangements of metal nanoparticles have been also one of the challenging to create 3D metamaterials. Nanoparticle arrangements based on DNA self-assembly, block-copolymer phase separation and other techniques have been developed, however, it is quite difficult to create useful "meta-atoms" for realizing 3D metamaterials.

We have demonstrated a simple fabrication method for SERS-active plasmonic nanoballs, which consisted of Au nanoparticles (NPs) and core-shell polystyrene and amino-terminated poly(butadiene) particles, by self-assembly. The amount of Au NPs introduced into the core-shell particles increased with the concentration of Au NPs added to the aqueous dispersion of the core-shell particles. When the amount of Au NPs increased, closely packed, three-dimensionally arranged and close-packed Au NPs arrays were formed in the shells. Strong SERS signals from para-mercaptophenol adsorbed onto this "plasmonic nanoballs" with multilayered Au NPs arrays were obtained by NIR light illumination.

Automated design of infrared digital metamaterials by genetic algorithm

Yuya Sugino, Atsushi Ishikawa, Yasuhiko Hayashi, Kenji Tsuruta, Okayama Univ. (Japan)

We demonstrate automated design scheme of infrared (IR) digital metamaterials and experimentally characterize their IR properties. The unit cell of a metamaterial consisted of 7 x 7 Au nano-pixels with an area of 200 nm x 200 nm, and their placements were coded as binary genes in the Genetic Algorithm (GA). The arrangement of each pixel was then searched by the GA combined with 3D electromagnetic numerical analysis to automatically construct the targeted metamaterial. The evaluation function in the optimization process was predefined such that three types of the metamaterials would exhibit pronounced resonant dips at 50, 60, and 75 THz, respectively in their transmission spectra. The GA optimization with a population size of 20 was repeated until the 50th generation where the fitness was fully converged. Based on the numerical results, the metamaterials were fabricated on a Si substrate over an area of 1 mm ? 1 mm by using an EB lithography, Cr/Au (2/20 nm) depositions, and liftoff process. In the FT-IR measurement, clear transmission dips of each metamaterial were observed near the targeted frequencies, although the synthesized pixel arrangements of the metamaterials were seemingly random. The corresponding numerical simulations revealed the important resonant behavior of each pixel and their hybridized systems. Our approach is fully computer-aided without artificial manipulation, thus paving the way toward the novel device design for next-generation plasmonic device applications.

Phase modulation in ultrathin lossy material

Tsung Lin Chung, Jia-Wern Chen, Hsiang-Chu Wang, Yu Han Chen, Chun Yen Liao, Mu-Ku Chen, National Taiwan Univ. (Taiwan); Cheng Hung Chu, Pin Chieh Wu, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Yi Chieh Lai, National Taiwan Univ. (Taiwan); Din Ping Tsai, National Taiwan Univ. (Taiwan) and Research Ctr. for Applied Sciences - Academia Sinica (Taiwan)

In metasurface optics, electromagnetic wave front can be modified by changing its phase, amplitude and polarization in a desired manner. Arrays of sub-wavelength optical antennas is the major method to control and reshape the wave front of reflection or refraction light. These antennas can take many forms such as metallic or dielectric nanostructures on top of metallic films. By adjusting the separation of arrays and spatial geometric parameters (shape, size, and orientation), the wave fronts can be designed at will. Recently metasurface based on ultra-thin films is proposed because of its abrupt change of optical properties with the film thickness far below the incident wavelength. For instance, the spectrum, leading to various color, can be tuned by adjusting the thickness of lossy material on the metallic mirror. Ultra thin film metasurface can be achieved only by lossy materials (imaginary part of the complex refractive index comparable to the real part). The phase difference of light on reflection or transmission at the interfaces between lossy materials can be more than 0 and ?. This optical property enables the phase modulation with thickness far below the incident wavelength. In this work, the idea using thickness of lossy material in few nanometers to modulate the phase of reflection light is demonstrated.

Aluminum plasmonic metasurfaces for control in reflection

Elena I. Chaikina, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico); Liliana Avalon Murillo, Efren Garcia, Univ. Autónoma de Baja California (Mexico); Eugenio R. Mendez, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

Unlike silver and gold, aluminum has material properties that present strong surface plasmon resonances in the ultraviolet that also span much of the visible region of the spectrum. This spectrally extended response, combined with its natural abundance, low cost, and amenability to manufacturing processes, makes aluminum a highly promising material for nanophotonic applications. In this work, we investigate numerically and experimentally the influence of the geometrical parameters of aluminum covered nanostructures on its optical properties.

The detailed comparison of numerical calculations with the results obtained with fabricated of Al-based nanostructures can be however quite challenging, due to remarkably sensitivity the plasmonic resonance to the presence of oxide on the metal. Here, we model the growth and stabilization of the aluminum oxide film and investigate their influence on the fabricated nanostructures. The nanostructures were fabricated by electron beam lithography method.

Guided modes analysis in metamaterial bounded optical waveguides

Juarez Caetano da Silva, Davi Araújo de Figueiredo, Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil)

We study the propagation characteristics of plasmonic waveguides employing analytical and numerical approaches. The analyzed structures are made of metallic nanowires or metal and dielectric thin layers claddings surrounding a semiconductor or dielectric core. The main parameters to be computed are the propagation distance, the confinement of the fields and the penetration distance into the metamaterial cladding. These structures are intended to exhibit low loss propagation guided modes from visible light to optical communication infrared radiation.

10343-99, Session PWed

Low-loss modes in a hyperbolic metamaterial

Samantha Koutsares, Ekembu K. Tanyi, Michael Admassu, Norfolk State Univ. (United States); Ilya V. Shadrivov, The Australian National Univ. (Australia); Roman Saveliev, ITMO Univ. (Russian Federation); Mikhail A. Noginov, Norfolk State Univ. (United States)

Metamaterials with hyperbolic dispersion have developed a significant amount of interest in the scientific community because they can propagate electromagnetic waves with very large wavevectors. Slabs of lamellar metal-dielectric hyperbolic metamaterials (HMMs) were shown to have the waveguide modes, termed volume plasmons or bulk plasmons, supported by the whole metamaterial structure. These modes, confined to the volume of the lamellar metal-dielectric stack, are of potential importance for signal propagation in plasmonic nanocircuits and stimulated emission at the nanoscale. At this time, we have studied coupling to the HMMs' volume modes in the Kretschmann geometry and shown that light can penetrate through tens of metallic and dielectric layers without substantial loss.

10343-100, Session PWed

Control of electric and magnetic dipole emission with metasurfaces

Soheila Mashhadi, David M. Keene, Antoine C. Hardy, Natalia Noginova, Norfolk State Univ. (United States)

Effect of plasmonic metasurfaces on spontaneous emission of Eu 3+ ions has been studied in patterned metal surfaces of various periodicity and geometry of the surface profile.Both electric and magnetic dipole transitions show strong modification of the angular radiation pattern with specific features determined by metasurface geometry.

10343-101, Session PWed

Spectral shifts of the first and second excited state transitions in R6G dye coupled with the cavity

Ekembu K. Tanyi, Norfolk State Univ. (United States); Erin Harrison, Univ. of Delaware (United States); Cansu On, Mikhail A. Noginov, Norfolk State Univ. (United States)

We have studied strong coupling of silver and aluminum Fabry-Perot cavities with the first (S0-->S1) and the second (S0-->S2) excited state transitions in R6G dye and analyzed the effect of the ENZ dielectric permittivity in Ag. We studied several cavities with different thicknesses in order to vary the level of coupling of the (S0-->S1) transition with the cavity, which according to perturbation theory, should affect the second (S0-->S2) excited state transitions as well. We observed a significant change of the (S0-->S2) excitation band for the Ag cavity of 182 nm: The maximum of the excitation band was shifted from 345 nm to 329 nm. This was not observed in the Al cavities of the same thickness, and we conclude that this strong spectral shift is due to its coupling with the cavity, supporting "full standing wave" resonance and not due to coupling of the (S0-->S1) transition with the cavity.

10343-102, Session PWed

Optically tunable Fano-resonant filter based on graphene

Alexander Grebenchukov, Anton Zaitsev, Mikhail M. Novoselov, Egor Kornilov, Mikhail K. Khodzitsky, ITMO Univ. (Russian Federation)

The ability to narrowband filtering in terahertz (THz) frequency range with effective tunability in terms of resonance frequency is important for many potential applications, such as biomolecule sensing or switching [1]. Currently, for THz filtering planar metamaterials with low quality factor are used [2], which impairs filter performance. Moreover majority of such metasurfaces exhibit static characteristics [3], which also limit their utilization. To overcome mentioned above drawbacks of planar metamaterials the reconfigurable metasuface that supports Fano resonance can be used. In this work, the hybrid graphene-metal Fano resonator is proposed and theoretically investigated. The Fano resonance was obtained by using asymmetric metal split ring covered by graphene as a unit cell of the filter. Tunability is reached by using graphene as reconfigurable medium. Graphene properties and, accordingly, properties of whole composite structure can be efficiently controlled by infrared optical pumping. The simulations of proposed graphene-based filter were performed by solving Maxwell's equations using finite element method for frequency range of 0.1-1 THz. As a result of modeling the high-Q dip in transmission spectrum of proposed filter with fine tuning of resonance frequency by varying the intensity of optical pump was obtained.

A numerical investigation of difference frequency generation in nonlinear multilayered metamaterials

Surawut Wicharn, Srinakharinwirot Univ. (Thailand); Jakkapol Visessamit, Prathan Buranasiri, King Mongkut's Institute of Technology Ladkrabang (Thailand)

In this paper, a second-order nonlinear interaction, difference-frequency generation (DFG), based on three-wave mixing (TWM) process in nonlinear multilayered metamaterials (NMMs) structure has been investigated numerically. The NMMs have been composed of two periodically alternated linear positive-index material (PIM) and nonlinear negative-index material (NIM) layers. To enhance DFG, the pump frequency (µ1) and the signal frequency (µ3) have been tuned into the negative-index and the positive-index regions, respectively, of NIM dispersion for satisfy a backward phase-matching (BPM) condition and meanwhile PIM layer thickness has been optimized to creating field enhancement effect inside the structure. Therefore, the pump and signal fields can efficiently generate a strong idler at frequency µ2 = µ3 x µ1 in backward direction. The numerical results have also confirmed that a conversion efficiency of this idler component is maximized when both conditions being achieved. According to this parametric interaction, the NMMs can be applied as a nonlinear meta-mirror for using as an important part of nonlinear frequency converters and optical signal amplifiers.

Interscale mixing microscopy: towards 2D imaging beyond the diffraction limit

Bo Fan, Christopher M. Roberts, Univ. of Massachusetts Lowell (United States); Nicolas Olivier, William P. Wardley, King's College London (United Kingdom); Sandeep Inampudi, Univ. of Massachusetts Lowell (United States); Wayne Dickson, Anatoly V. Zayats, King's College London (United Kingdom); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States)

The detection and visualization of subwavelength objects have numerous applications in imaging, spectroscopy, material science, biology, healthcare and security. However, resolution of conventional optical microscopes is fundamentally limited by diffraction to ?/(2NA). Several techniques based on first-order diffraction can enhance resolution of imaging of non-florescent objects with far field measurements to ~?/4. Interscale Mixing Microscopy (IMM) employs diffractive elements in the near field proximity of objects to fold information from the evanescent field into the propagation zone, and uses computer reconstruction to recover the properties of the object based on far field measurements. We have recently reported an analytical implementation and experimental realization of IMM for 1D objects with resolution of the order of ?/10 based on a single measurement. In this work we generalize the developed paradigm to imaging and spectroscopy of two-dimensional objects. In particular, we consider various 2D objects located in the proximity of finite 2D periodic gratings and explore the effect of size, shape, and position of the object as well as size, and shape of the gratings' openings on the accuracy of the imaging and spectroscopy. We demonstrate that 2D IMM can recover the position, and transparency of the subwavelength objects.

Design of fan-out diffractive optical elements based on dielectric geometric metasurfaces

Guoxing Zheng, Zile Li, Song Li, Ping'an He, Wuhan Univ. (China)

Previous demonstrated phase-only diffractive optical elements (DOEs), which control the phase by etching different depth into a transparent substrate, suffer from a contradiction between the complexity of fabrication procedures and the performance of DOEs. In this paper, we propose a novel metasurface-based DOEs, whose pixels are replaced by orientation-controllable silicon nanobrick arrays sitting on a transparent substrate. Such so called geometric metasurfaces (GEMS) can act as continuous-phase DOEs whilst only using structures of two-step-depth, which has great promise for designing high-performance DOEs. With the above principle, we report the realization of two different fan-out DOEs based on dielectric GEMS working in C-band fiber telecommunications window (1530-1565 nm) and visible range, respectively. In the first design, uniform 4x4 spot arrays with an extending angle of 59°x59° can be obtained in the far field. In the second design, visible spot arrays with different grayscale form a holographic image with high fidelity in the far field. Because of these advantages of the single-step fabrication procedure, continuous and accurate phase manipulation, and high conversion efficiency, GEMS-based fan-out DOEs could be utilized for various practical applications such as laser holographic keyboard, random spots generator for body motion, optical anti-counterfeiting, laser beam shaping and many other potential fields requiring phase control.

Ultra-broadband absorption with gradient metasurface

Tiancheng Han, Southwest Univ. (China)

Due to the advantages of perfect absorption and ultrathin structure, metamaterial absorber (MA) as an important branch of metamaterial-based devices, has been attracting great interest and making great progress in the past several years. For most practical applications, the absorption bandwidth is one of the most important performance metrics. Here, we demonstrate two kinds of ultra-broadband MAs that function in microwave and infrared spectrum, respectively. We first designed an ultra-broadband microwave absorber by combing four different metal-dielectric multilayered quadrangular frustum pyramids within a subwavelength period. Compared with the prior work [Appl. Phys. Lett. 100(10), 103506 (2012)], the proposed absorber demonstrates nearly the same performance (the total absorption exceeds 90% from 8 to 12 GHz and the full width at half maximum is 54.5%) with only 9 layers (at a total thickness of 4.122 mm), showing a great advantage compared to the former that has 20 layers at a total thickness of 5.05 mm. In addition, the absorption remains quasi-constant up to 60°. Then, we designed an ultra-broadband infrared absorber by combing four different pentagon patch metal-insulator-metal (MIM) resonators within a subwavelength period. Both the metal and dielectric thicknesses are very thin (<?/20) and are the same for each resonator of the patchwork. Compared with the previous infrared absorber [Opt. Express 22(S7), A1713-A1724 (2014)], the proposed absorber shows more than twice the absorption bandwidth. The total absorption exceeds 80% from 5.2 to 13.7 um and the full width at half maximum is 95% (from 5.1 to 14.1 ?m), much greater than those previously reported for infrared spectrum. Figure 1 demonstrates the simulation results of the proposed ultra-broadband absorbers. These pave the ways to the design of ultra-broadband efficient plasmonic absorbers from microwave to optical spectrum.

Compact three-layered film of passive radiation cooling for LED heat dissipation

Yung-Chiang Lan, Po Jui Chiu, Bo-Han Cheng, National Cheng Kung Univ. (Taiwan); Din Ping Tsai, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan) and National Taiwan Univ. (Taiwan)

In this work, a three-layered (Si-Ni3Si-Al) compact film with heat dissipation based on the method of passive radiation cooling for light emitting diode (LED) are developed and analyzed. The proposed film is designed with the feature of high absorptance at atmospheric transmission region (i.e. 8 um – 13 um). According to Kirchhoff's law of thermal radiation, the emissivity of the film will be equal to its absorptivity at thermal equilibrium. The corresponding admittance diagram and absorption spectra are also explored to elucidate the reason of high absorption. Electromagnetic and heat diffusion simulations based on the finite element method (COMSOL) are accomplished to verify that the design of proposed film can effectively decrease the temperature of LED with various input powers. Considering the typical LED in work (e.g. 1 mm square surface area with heat generation of 1 watt), the proposed film can achieve lower temperature with significantly reduced size as compared to LED with traditional heat sink. This work has potential applications in the field of thermal emitter, photovoltaic-based device and high power devices.

A highly efficient and broadband photonic circular polarizer in optical range

Hossein Alizadeh, Björn M. Reinhard, Boston Univ. (United States)

Miniaturization of bulky optical devices to micro and nano scales, has been at the forefront of cutting-edge research in the photonics community. The core idea of this line of research is to move towards ever smaller photonic components that can function even more efficiently than their bulky counterparts. One of such optical elements are Quarter Wave Plates, which convert a linearly polarized light to a circularly polarized light. Upon realization of nanoscale circular polarizers, they would find immediate applications in various areas, from Quantum information processing to nanoscale integrated chips and on-chip photonic communications. In this context, we present a novel nano-sized photonic element, that can function as a circular polarizer in the visible range of spectrum and with very high efficiency. More specifically, we demonstrate that when light impinges on two closely fabricated silicon nanowires, the optical modes of these structures interact and the subsequent lifting of degeneracy of the degenerate fundamental modes of subwavelength nanowires, induces a phase shift in the modes and converts the incident linearly polarized light to a circularly polarized one.

Design and analysis of tip slotted square patch nanoantenna

Shubhanshi Sharma, Nishant Shankhwar, Yogita Kalra, Ravindra K. Sinha, Delhi Technological Univ. (India)

In this paper, Tip slotted square patch nanoantenna has been designed and analysed to test its near field enhancement capabilities for implementation in infrared region. Here, near field resonant properties and far field characteristics of a tip slotted square patch nanoantenna have been studied. In this design, a gold square patch has been grown over a silica substrate. Being, chemically inert gold is the most suitable metal to make the patch. At higher frequency, metals cease to behave as perfect conductors and facilitate the formation of surface plasmons. Another advantage of using gold is that it offers low ohmic losses. The data for permittivity of silica has been taken from Palik (1999) and for Gold Drude's model has been used. Complete frequency domain analysis has been performed in COMSOL Multiphysics. As a result of which electric field intensity plots have been obtained which show that near-field enhancement within the slots are substantially high. Moreover, complete far field analysis has been performed and three-dimensional plots of the radiation pattern have been obtained. On account of simple geometry, the proposed structure is not supposed to pose any difficulty during fabrication. The design has been optimised to operate in infrared region to create scope for implementation in IR detection, solar energy harvesting and sensing application.

A hybrid phononic waveguide using multilayer structure at mid-infrared

Asma Al-Amri, Michael F. Finch, Claudio Augusto Barreto Saunders Filho, Brian A. Lail, Florida Institute of Technology (United States)

Surface phonon polaritons, SPhPs, results from the coupling or interaction of light with phonon resonance. There has been extensive research into utilizing surface plasmon polaritons, SPPs, for subwavelength confinement of propagating waveguide modes for photonic integrated circuits. This work investigates the use of a multilayer system or insulator-metal-insulator (IMI) heterostructure as a SPhP-enhanced infrared waveguide where the metal response is due to phonons in a polar dielectric's Reststrahlen band. In addition, an IMI heterostructure supports types of modes: an even mode and odd mode that have their own unique trade-offs. For the odd mode as the metal film thickness decreases the confinement of the SPhPs decreases, and thus resulting in an increase in the SPhPs propagation length. Conversely, the even mode shows the opposite behavior with decreasing metal film where the confinement increases as propagation length decreases. This endeavor investigates the trade-off between the even and odd IMI modes, and the characterization of propagation length and model confinement, as applied to a hybrid phononic waveguide.

Electrically controlled free space THz polarization modulation using vanadium dioxide metasurfaces

Muhammad Tayyab Nouman, Ji Hyun Hwang, Jae-Hyung Jang, Gwangju Institute of Science and Technology (Korea, Republic of)

We propose a metasurface device design to electronically control polarization of free space terahertz (THz) waves. The proposed metasurface device employs horizontally connected split ring resonators (SRR) on top of a 100-nm-thick Vanadium dioxide (VO2) film grown on a sapphire substrate. The horizontally connected SRRs offer a bandstop resonant transmission for horizontal polarization and a bandpass resonant transmission for the vertical polarization. The proposed design exploits insulator to metal transition (IMT) in VO2 films to electrically tune the resonant response of the THz metasurface. By applying a bias voltage across the top and bottom half of SRRs, the IMT in VO2 at the split gap of the SRRs can be triggered. Without an applied electric field, the VO2 acts as insulator with resistivity on the order of 10-1 ?-cm. Upon application of a large electric field, VO2 exhibits metallic property having resistivity of nearly 10-3 ?-cm. We demonstrate via full wave electromagnetic simulations that above resistivity modulation can significantly vary the SRR response for horizontal polarization while not affecting the response for vertical polarization. The variation of SRR resonant response results in phase modulation as large as 90° for horizontally polarized waves. Thus the polarization of transmitted waves can be switched between linear or circular polarization by applying a bias voltage. The proposed metasurface based modulator can offer huge improvement in modulation speed, compactness and integration capability compared to the previous designs mostly based on liquid crystal devices.
This work is supported by Samsung Research Funding Center of Samsung Electronics under Project Number SRFC-IT1401-08.

THz beam-steering using VO2 deep-subwavelength metamaterials

Sara Arezoomandan, Berardi Sensale-Rodriguez, Univ. of Utah (United States)

The demand for bandwidth is close to reach its limits if employing GHz-frequency carriers; from this perspective resorting to THz carriers for future wireless communication links seems inevitable. In this context, many researchers are trying to develop different components for THz communications, being one of those an efficient THz beam-steerer. Based on the generalized laws of reflection and refraction it is possible to employ metamaterial phase modulators so to construct a beam-steerer. By actively controlling the phase gradient imposed by the metasurface, the angle of transmission can be arbitrarily controlled thus beam-steering is possible. In this work, such phase gradient metasurface is constructed using unit-cells that are much smaller than a tenth of a wavelength and employing VO2, a phase-changing material as the reconfigurable material.

To systematically study the effect of the unit-cell dimensions, we introduce a variable, the unit-cell to wavelength ratio, design phase modulators by varying it, and study its effect on the directivity of the transmitted beam (under normal incidence of an incoming excitation). By decreasing the unit-cell to wavelength ratio, the directivity of the array can be improved. However, there is a compromise between this and loss, which is augmented. Overall, a good tradeoff occurs for unit cell dimensions in the order of lambda/20. VO2 when undergoing its insulator to metal transition can provide for the phase modulation required to practically implement such arrays.

Magneto-optical nanowire metamaterials

Bo Fan, Univ. of Massachusetts Lowell (United States); Mazhar E. Nasir, Anatoly V. Zayats, King's College London (United Kingdom); Viktor A. Podolskiy, Univ. of Massachusetts Lowell (United States)

Plasmonic nanowire metamaterials have been shown to enable multiple applications in sensing, emission modulation, and in nonlinear optics, in part due to unique dispersion of the modes propagating in metamaterials. In this work, we analyze the perspectives of incorporating magneto-optical (MO) materials into plasmonic nanowire platform. As illustrative purpose, we consider metamaterial on the glass substrate, where gold nanowires with Ni shell are submerged into alumina matrix. With the presence of static external magnetic field, optical response of the MO component of the composite can be described by the permittivity tensor with non-trivial off-diagonal components. External magnetic fields parallel and perpendicular to the wires were considered separately. Starting from the extension of Maxwell-Garnett formalism to wire media with large inclusion concentrations, we have developed an effective medium description of magneto-optical (MO) nanowire platform. The developed effective medium theory (EMT) was verified by comparing the predictions for transmission and reflection through a layer of MO nanowires to full-vectorial solutions of Maxwell equations with commercial finite-element solver. Results show that, similar to other lossy MO composites, combination of anisotropy, lossess and gyrotropy, yields non-reciprocal transmission in the metamaterial, providing the utility of the proposed material platform in the new emerging subfield of optics. The developed formalism can be readily used to calculate optical response of a wide variety of nanowire composites that incorporate MO components as well as to design such composites for particular applications.

Mass production compatible fabrication techniques of single-crystalline silver metamaterials and plasmonics devices

Ilya A. Rodionov, Bauman Moscow State Technical Univ. (Russian Federation) and All-Russian Research Institute of Automatics (Russian Federation); Ilya A. Rizhikov, Institute for Theoretical and Applied Electrodynamics (Russian Federation) and Bauman Moscow State Technical Univ. (Russian Federation); Alexander S. Baburin, Bauman Moscow State Technical Univ. (Russian Federation); Alexey P. Vinogradov, Institute for Theoretical and Applied Electrodynamics (Russian Federation) and All-Russian Research Institute of Automatics (Russian Federation); Alexander V. Baryshev, All-Russian Research Institute of Automatics (Russian Federation); Elena V. Ryzhova, Bauman Moscow State Technical Univ. (Russian Federation); Nikolay A. Orlikovsky, All-Russian Research Institute of Automatics (Russian Federation); Alexander M. Merzlikin, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Igor V. Trofimov, Alexander V. Zverev, Bauman Moscow State Technical Univ. (Russian Federation); Sergey S. Maklakov, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Anton I. Ivanov, Ivan A. Philippov, Aidar Gabidulin, Alina Dobronosova, Bauman Moscow State Technical Univ. (Russian Federation)

During last 20 years great results were obtained in metamaterials and plasmonics nanostructures fabrication. However, large ohmic losses in metals and mass production compatibility still represent the most serious challenges which impede progress in the fields of metamaterials and plasmonics. Many recent researches primarily focused on developing low-loss alternative materials, such as nitrides, II–VI semiconductors oxides, high-doped semiconductors, or two-dimensional materials. In this talk, we demonstrate that perfectly fabricated silver films could be an effective low-loss material system, as theoretically well-known. We present our research of silver films optical properties with various crystalline structure (from nanocrystalline to single-crystalline) and our new sub-50nm single-crystalline continuous low-loss low-cost silver film technology, which was optimized to give optical losses below ones reported by Jonson-Christy and sub-nm roughness to maximize SPP propagation length. Films were characterized by AFM, SEM, XRD, profilometry, spectroscopic ellipsometry and SPP propagation length. We manufacture a number of plasmonics and metamaterials nanodevices on transparent (quartz, sapphire, mica) and non-transparent (silicon) substrates using e-beam lithography and dry etch instead of common-used FIB technology. Furthermore, the developed technology is compatible with multilayer device manufacture. We eliminate negative influence of litho-etch steps on silver films quality and fabricate millimeter square devices with different topologies and perfect sub-100nm dimensions reproducibility. The technology is tried out on trial manufacture of spasers, plasmonic sensors and waveguides, metasurfaces, etc. These results could be used as a flexible device manufacture platform for a broad range of practical applications in optoelectronics, communication, photovoltaic and biotechnology.

Polarizing properties of chiral metasurface based on gammadion crosses with different geometry in THz frequency range

Maxim S. Masyukov, Anna V. Vozianova, Alexander Grebenchukov, Mikhail K. Khodzitsky, ITMO Univ. (Russian Federation)

Last decade the advances in application of terahertz (THz) technologies for wireless communications, biomedicine, remote sensing, imaging, etc. require the development of new optical components to simplify further progress [1]. Novel devices based on artificial materials (metamaterials) being developed to efficiently control terahertz electromagnetic radiation include frequency-selective surfaces, absorbers, polarization converters, cloaks, etc. Of particular interest is the creation of terahertz components for THz time-domain polarimetry to apply in new diagnostic methods of cancer and diabetes. Chiral metasurfaces may be overcompensated the lack of THz polarizing components due to through the availability of such properties as optical activity, circular dichroism, negative index of refraction, etc [2]. In this work the properties of chiral metasurfaces made from 2-D array of twisted gammadion crosses with different relation of ellipse semi axes of cross were considered in the frequency range of 0.1-1 THz. The total scattering matrixes for the metasurfaces were obtained by Finite Difference Time Domain method. The polarization azimuth rotation angle and ellipticity of structures were calculated from transmission coefficients. The influence of design of metasurface unit cell on polarizing properties was observed. It was shown that the changing of semi axes relation of ellipses of gammadion cross allows tuning operational frequency and creating multiband polarizer.

Interscale mixing microscopy: far field imaging beyond the diffraction limit *(Invited Paper)*

Viktor A. Podolskiy, Christopher M. Roberts, Univ. of Massachusetts Lowell (United States); Nicolas Olivier, William P. Wardley, King's College London (United Kingdom); Bo Fan, Univ. of Massachusetts Lowell (United States); Sandeep Inampudi, Univ. of Massachusetts Lowell (United States) and Northeastern Univ. (United States); Wayne Dickson, Anatoly V. Zayats, King's College London (United Kingdom)

Optical characterization of subwavelength objects is important for biology, nanotechnology, chemistry, and materials science. Unfortunately, the information about interaction of an isolated subwavelength object with light is contained in evanescent waves that exponentially decay away from the source. Numerous techniques have been proposed to access or restore this information. In interscale mixing microscopy (IMM), a diffraction grating positioned in the near field proximity of the object is used to convert the originally-evanescent waves into propagating modes that can be detected with far-field measurements. However, far-field signal needs to be post-processed to un-couple the diffraction-limited and subwavelength responses. Several techniques, based on multiple measurements, have been previously proposed. Here, we show that with simple Fourier-transform based post processing can be used to characterize position, and optical size of the object based on a single measurement. To verify the proposed formalism, three finite diffraction gratings were fabricated. Two of these gratings contained pre-engineered "defects" that played the role of "unknown objects", while the remaining grating was used as a reference. We demonstrate that we can identify the position and size of ~wavelength/10 object with far-field characterization. The same measurement provides a platform to analyze optical spectrum of the object. Although demonstrated in this work on example of 1D grating, IMM can be extended to 2D subwavelength imaging

10343-73, Session 15

Surface-assisted carrier excitation in plasmonic nanostructures

Tigran V. Shahbazyan, Jackson State Univ. (United States)

We present a quantum-mechanical model for surface-assisted carrier excitation by optical fields in plasmonic nanostructures of arbitrary shape. We obtain an explicit expression, in terms of local fields inside the metal structure, for surface absorbed power and surface scattering rate that determine the enhancement of carrier excitation efficiency near the metal-dielectric interface. We show that surface scattering is highly sensitive to the local field polarization and can be incorporated into metal dielectric function along with phonon and impurity scattering. We also show that the obtained surface scattering rate describes surface-assisted plasmon decay (Landau damping) in nanostructures larger than the nonlocality scale. Our model can be used for calculations of plasmon-assisted hot carrier generation rates in photovoltaics and photochemistry applications.

Fano metamaterial absorber for controlling mechanical resonances *(Invited Paper)*

Ertugrul Cubukcu, Hai Zhu, Univ. of California, San Diego (United States); Fei Yi, Huazhong Univ. of Science and Technology (China)

Resonant light absorption in photonic metamaterials can efficiently convert optical energy into heat based on the photothermal effect. Here, we present a plasmomechanical metamaterial that simultaneously supports thermomechanically coupled optical and mechanical resonances for controlling mechanical damping with light. In this metamaterial absorber with voltage tunable Fano resonances, we experimentally achieve optically pumped coherent mechanical oscillations based on a plasmomechanical parametric gain mechanism over a ~4 THz bandwidth. Via the reverse effect, optical dampening of mechanical resonance is also achieved. Our results provide a metamaterial based approach for optical manipulation of the dynamics of mechanical oscillators.

Mechanical metamaterials: recent advances and opportunities

Eduard Karpov, Univ. of Illinois at Chicago (United States)

Mechanical metamaterials and metastructures show responses to static loads that can be interpreted as a negative elastic modulus or a negative Poisson ratio by a combination of simple mechanical elements, bars and springs. One recent study [1-2], also uses a structural bistability at the unit cell level to deploy a load-induced polymorphic phase transformation in the entire sample. When properly designed, this phase transformation can lead to a contraction of the sample in the direction of an increasing load, a manifest of the negative extensibility phenomenon. In this presentation, we overview recent developments in mathematical analysis of mechanical metamaterials, discuss the paths toward design and fabrication of these interesting materials, and outline their opportunities for structural health monitoring and intelligent structures applications. Electric field distribution on surface of the artificial magnetic conductor: miniaturization process

Welyson Tiano Dos Santos Ramos, Renato Cardoso Mesquita, Elson José da Silva, Univ. Federal de Minas Gerais (Brazil)

Artificial Magnetic conductor (AMC) are a kind of metamaterial. In contrast metamaterials have properties that are not commonly found in nature. The use of the AMC brings new perspectives of application in solve antennas problems, such as growth of gain and reduction of the back lobe in the radiation pattern [1], obtaining antennas with low profile (0.019?) [2] , procurement multiband devices [3] and the physical and electrical miniaturization of the system [4].This paper presents a detailed study of the role of the geometric shape at resonance frequency of the Artificial Magnetic Conductor (AMC) through the analysis of the electric field distributions on the surface metallic patch inside the unit cell. The device has illuminated by a plane wave with polarization in the y direction. As reference, a square patch with a unit cell of size 10 mm x 10 mm has simulated and a resonance frequency of 5.75 GHz has obtained. The following geometric shapes were performed: square, circular, hexagonal, dipole, cross dipole, Cross of Jerusalem, meander and bowtie. We observed that the electric field distribution, due to polarization of the charges on metal surface of the High impedance surface, strongly contribute to the electrical miniaturization of the AMC. In particular, we propuse some simple geometries that provided considerable electrical miniaturization compared with square patch, about 1.5 GHz. The results are supported by finite element method (FEM), using the commercial software COMSOL Multiphysics and MATLAB.

Graphene metamaterials

F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

The extraordinary optical, opto-electronic, and magneto-optical properties of graphene render this material an excellent choice for the design of metamaterials with extraordinary capabilities. I will review in this presentation some of them, including the a new strategy for molecular sensing that relies on the strong plasmon-driven nonlinearity of nanographenes; a scenario in which radiative heat transfer is the fastest cooling mechanism, even beating relaxation to phonons; the generation of intense high harmonics from graphene, assisted by its plasmons; and the possibility of strong electro-optical modulation in the visible regime by combining ultrathin metal layers and graphene.

10343-78, Session 16

Near-field study in graphene/hBN moiré superlattices

Guangxin Ni, Univ. of San Diego (United States); Haomin Wang, Shanghai Institute of Microsystem and Information Technology (China); Jhih-Sheng Wu, Zhe Fei, Alexander S. McLeod, Univ. of California, San Diego (United States); Fritz Keilmann, Ludwig-Maximilians-Univ. (Germany); Xiaoming Xie, Shanghai Institute of Microsystem and Information Technology (China); Michael M. Fogler, Dimitri Basov, Univ. of California, San Diego (United States)

Moiré patterns are periodic superlattice structures that appear when two crystals with a minor lattice mismatch are superimposed. A prominent recent example is that of monolayer graphene placed on a crystal of hexagonal boron nitride (hBN). As a result of the moiré pattern superlattice created by this stacking, the electronic band structure of graphene is radically altered, acquiring satellite sub-Dirac cones at the superlattice zone boundaries. To probe dynamical response of the moiré graphene, we use infrared (IR) nano-imaging to explore propagation of surface plasmons, collective oscillations of electrons coupled to IR light. We show that interband transitions associated with the superlattice minibands in concert with free electrons in the Dirac bands produce two additive contributions to composite IR plasmons in graphene moiré superstructures. This novel form of collective modes is likely to be generic to other forms of moiré-forming superlattices, including van der Waals heterostructures.

10343-79, Session 16

Fractal metasurface enhanced graphene photodetector on glass substrate

Di Wang, Jieran Fang, Clayton T. DeVault, Ting-Fung Chung, Yong P. Chen, Alexandra Boltasseva, Vladimir M. Shalaev, Alexander V. Kildishev, Purdue Univ. (United States)

Graphene has been demonstrated to be a promising photodetection material because of its atomic-thin nature, broadband and uniform optical absorption, etc. Photovoltaic and photothermoelectric, which are considered to be the main contributors to photo current/voltage generation in graphene, enable photodetection through driving electrons via built-in electric field and thermoelectric power, respectively. Graphene photovoltaic/photothermoelectric detectors are ideal for ultrafast photodetection applications due to the high carrier mobilities in graphene and ultrashort time the electrons need to give away heat. Despite all the advantages for graphene photovoltaic/photothermoelectric detectors, the sensitivity in such detectors is relatively low, owing to the low optical absorption in the single atomic layer. In the past, our research group has used delicately designed snowflake-like fractal metasurface to realize broadband photovoltage enhancement in the visible spectral range, on SiO_2 thin film backed by Si substrates. We have also demonstrated that the enhancement from the proposed fractal metasurface is insensitive to the polarization of the incident light. In this current work, we have carried out experiments of the same fractal metasurface on transparent SiO_2 substrates, and obtained higher enhancement factor on the fractal metasurface than that achieved on SiO_2/Si substrates. Moreover, the device allows more than 70% of the incident light to transmit during the detection, enabling photodetection in the optical path without any significant distortion. Another possibility to make use of the large portion of transmitted light is to stack multiple such devices along the optical path to linearly scale up the sensitivity.

10343-80, Session 16

Highly confined phonon polaritons in atomically thin interfaces

Alexander M. Dubrovkin, Bo Qiang, Harish N. S. Krishnamoorthy, Nanyang Technological Univ. (Singapore); Nikolay I. Zheludev, Nanyang Technological Univ. (Singapore) and Optoelectronics Research Ctr. (United Kingdom); Qi Jie Wang, Nanyang Technological Univ. (Singapore)

We report the first observation of highly confined polaritons with wavelength two orders of magnitude shorter than the free space wavelength that propagates on the surface of silicon carbide crystals covered by a few atomic layers of molybdenum disulfide.

Confined surface polaritons attract increasing attention as a promising platform for nanoscale opto-electronic integrated circuits enabling strong light-mater interactions. Recently, a new approach for confining surface phonon-polaritons (SPhPs) in bulk polar crystals by ultrathin capping layer has been experimentally demonstrated in quartz/GST system. However, the ultimate performance of the device was limited by the film quality on few-nm thickness scale, and would also require a stronger polar crystal. In this work, we meet these requirements by placing nanometric layers of two-dimensional dielectric materials on a bulk silicon carbide substrate. To experimentally excite SPhPs we use mid-IR radiation of CO2-gas laser at frequencies between 930 and 897 cm-1. Scattering-type scanning near-field optical microscopy (s-SNOM) revealed deeply subwavelength confinement of SPhPs in the MoS2-SiC interface down to bi-layer of the layered dielectric. The confinement factor is highly sensitive to both the MoS2 thickness and the spectral line of excitation. We experimentally perform a systematic study of thickness and spectral dependency of the confinement, and fit the data with theoretically calculated dispersion.

Approach discussed in our work enables realization of ultimate light-matter interaction on the interface of nanometric layered dielectrics supported by bulk polar crystals down to the fundamental atomic limit, opening a new avenue on the surface polaritons confinement at nanoscale.

10343-81, Session 16

Plasmonic MXene for broadband absorber

Krishnakali Chaudhuri, Purdue Univ. (United States); Mohamed Alhabeb, Drexel Univ. (United States); Zhuoxian Wang, Vladimir M. Shalaev, Purdue Univ. (United States); Yury Gogotsi, Drexel Univ. (United States); Alexandra Boltasseva, Purdue Univ. (United States)

MXenes are a new family of 2D layered nanomaterials with chemical form of Mn+1XnTx (M is a transition metal, X is carbon and/or nitrogen). Due to its surface functional groups T (-OH, -O or -F), MXene shows surface hydrophilicity, in addition to high metallic conductivity, excellent mechanical and variable electronic properties. The limited exploration of this material class in the context of plasmonics and nanophotonics motivates the current discussion.

Application area of broadband absorbers has seen versatile use of plasmonics as well as new materials, but often in very complex geometries. Here, a simple, planar absorber structure has been developed, utilizing the resonances of nanostructured Ti3C2Tx, with a polarization-insensitive, extremely large bandwidth operation.

Aqueous dispersion of 2D sheets of Ti3C2Tx with lateral dimensions of 1-2 ?m is spin coated and dried in nitrogen to form a continuous film on desired substrate. Using the measured optical data for these films, we perform FEM simulations of Ti3C2 disks/pillar-like structures showing signatures of localized surface plasmon (LSP) type resonances in the NIR, tunable with varying dimensions. These resonances are then optimized for maximum absorption efficiency in the NIR. This simple disk array (diameter & thickness 0.4 ?m) demonstrates ~80% absorption across ~0.5-1.6 ?m. A further improvement is shown with the disk array sitting on a bilayer stack of a dielectric spacer (SiO2) and a metal (TiN) creating stronger resonances at desired wavelengths, that enable large enhancement of absorption efficiency, especially around the NIR tail (~4x) and a large bandwidth of operation (~1.5 ?m).

10343-82, Session 16

Flat and conformal meta-sheets for controlling light

Samad Jafar-Zanjani, Sandeep Inampudi, Hossein Mosallaei, Northeastern Univ. (United States)

Optical metasurfaces are periodic or graded pattern arrays of ultra-thin plasmonic and/or dielectric nanostructures, which are intended to scatter light in manners that cannot be achieved with conventional stratified media. Recent advancements in the theoretical knowledge and fabrication methods of two-dimensional materials, such as graphene, have provided the opportunity to scale down the principles of metasurfaces to atomic dimensions and to offer graded pattern meta-sheets. We present here engineered nanostructures to tailor the beaming pattern of light scattered through such meta-sheets. We obtain designs to precisely control both the in-plane scattering of surface waves associated with the sheets and also out-of-plane scattered far-field beams into a desired direction. We then determine a set of conductivity-balancing conditions to completely confine the surface waves to the meta-sheets at highly scattering sites and demonstrate that under such criterion the propagation of guided surface waves can be described simply using Fresnel equations of plane waves. Furthermore, we cascade three sinusoidally modulated reactance surfaces to realize a broad-beam leaky-wave antenna to completely scatter the surface waves to far-field and also control the steering direction. In addition, conformal patterned 2D sheets will be explored for the first time and how to successfully design and manipulate the light wavefront. For fast and accurate designs of the flat and conformal meta-sheets, we take advantage of our superior auxiliary differential equation finite-difference time-domain (ADE-FDTD) method. Also, an integral equations (IE) model will be applied for large-area system platforms design investigation.

10343-83, Session 17

Quantum plasmonics *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Recently it has been demonstrated that quantum mechanical effects can have a pronounced influence on the physical properties of plasmons. Examples include the charge transfer plasmon enabled by conductive coupling (tunneling) between two nearby nanoparticles and nonlocal screening of the plasmonic response of small nanoparticles and narrow nanoscale junctions. I will discuss a multitude of recent hot quantum plasmonics topics such as: how to fundamentally distinguish plasmons from excitons in small systems; molecular plasmons in polycyclic aromatic hydrocarbons; plasmon-phonon coupling; plasmons in doped semiconductor nanocrystals; plasmons in two-component hole liquids; plasmon-induced luminescence; and plasmon-induced hot carrier generation.

10343-84, Session 17

Sources and detectors near metasurfaces *(Invited Paper)*

Meir Orenstein, Technion-Israel Institute of Technology (Israel)

Sources and detectors are modified substantially when operating near metasurfaces. Here we discuss light emission from various 2-photon sources when embedded in or near a well engineered metasurface including antennas, plasmon polaritons of HBN, superconductor, epitaxial semiconductor nanoflags and hyperbolic metamaterials. We reort on substantial emission rate enhancement and the discuss the quantum nature of the emission

10343-85, Session 17

Metasurface route to quantum photonics

Pankaj K. Jha, Nir Shitrit, Jeonmin Kim, Xuexin Ren, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

Entanglement-based quantum technology is an emerging field of science and engineering that exploits subtle properties of quantum mechanics into practical classical-limits-free applications such as quantum computing, sensing and metrology. The up-to-date route for modern quantum photonics applications, which calls for ultracompact, integrated and scalable architecture, is an atom chip, i.e., microfabricated solid-state device to trap and manipulate cold atoms near an interface. On-chip quantum entanglement in this platform is achieved using cold controlled collisions between the atomic qubits which are significant at subwavelength separations. However, as other manifolds of quantum state engineering require selective addressing and controlled manipulation of individual qubit, entanglement of qubits separated by macroscopic distances at the chip level is still an outstanding challenge. Here, we report on a novel platform for on-chip quantum state engineering by harnessing the extraordinary light-molding capabilities of judiciously designed metasurfaces. We demonstrate robust generation of quantum entanglement between two atomic qubits trapped on a chip and separated by macroscopic distances, by engineering their coherent and dissipative interactions via the metasurface functionality. The metasurface route to quantum state engineering opens a new paradigm for on-chip quantum technology at the nanoscale by integrating high-end custom-designed ultrathin optical elements in atom chips.

10343-86, Session 17

Lasing in arrays of metal nanoparticles

Heikki Rekola, Tommi K. Hakala, Aaro I. Väkeväinen, Jani-Petri Martikainen, Marek Ne?ada, Antti J. Moilanen, Päivi Törmä, Aalto Univ. (Finland)

Plasmonic resonances supported by metallic nanoparticles have extremely small mode volumes and high field enhancements, making them an ideal platform for studying nanoscale lasing. However, these good measures of plasmonic resonances also make them bad in terms of practical implementations, as Ohmic and radiative losses have to be compensated with gain available in the small mode volume of the resonances. Here we show a way around these limitations by utilizing arrays of nanoparticles, which support delocalized resonances called Surface lattice resonances (SLRs). The structures are combined with organic dye molecules and optical pumping to realize lasing at visible wavelengths in both bright and dark modes of an array of silver nanoparticles, with linewidths down to 0.2 nm. [1]

The SLR modes are hybrids of the localized surface plasmon resonances of the nanoparticles, and the diffractive orders of the periodic structure. Both bright and dark (sub-radiant) modes are supported by the arrays. These dark modes offer even further reduced losses, as radiation away from the structure is suppressed. We show lasing in both bright and dark modes of the arrays, with access to the dark modes provided by the finite size of the array structure. By varying the array size, we show spatial coherence over the whole structure. We expect the SLR modes, which are both photonic and plasmonics in nature to become important for also other applications of plasmonics.

10343-87, Session 17

Valley photonic crystals

Jian-Wen Dong, Xiao-Dong Chen, Sun Yat-Sen Univ. (China)

Photonic crystals known as the periodic optical structures have been well exploited to manipulate the flow of light. For example, photonic net spin flow such as one-way transports and spin-directional locking have been realized in at the boundary of topologically-protected photonic crystals. But this is not the only way to achieve spin flow control. In this talk, without the assist of boundary, we will show the molding of spin flow of light in two kinds of valley photonic crystal by exploiting the valley degree of freedom. The coupled valley and spin physics in valley photonic crystal is illustrated through both analytical photonic Hamiltonian and bulk band structures. The photonic valley Hall effect, i.e., different spin states in two inequivalent but time-reversal valleys flow to opposite directions, is demonstrated in the bulk crystal. In addition, unidirectional spin flow is achieved by selective excitation of either spin or OAM chiral sources inside the topologically trivial valley photonic crystal instead of the assist of topologically non-triviality. We also show the independent control of valley and topology, resulting in a topologically-protected flat edge state in bianisotropic photonic metacrystal and a valley-protected back-scattering immune state in all-silicon photonic crystal. Valley photonic crystals may open up a new route towards the discovery of fundamentally novel states of light and possible revolutionary applications.

10343-117, Session 17

Quantum nanophotonics *(Invited Paper)*

Jelena Vuckovic, Jingyuan Zhang, Stanford Univ. (United States)

Nanophotonic structures that localize photons in sub-wavelength volumes are possible today thanks to modern nanofabrication and optical design techniques. Such structures enable studies of new regimes of light-matter interaction, quantum and nonlinear optics, and new applications in computing, communications, and sensing. The traditional quantum nanophotonics platform is based on InAs quantum dots inside GaAs photonic crystal cavities, but recently alternative material systems based on color centers in diamond and silicon carbide have emerged, which could potentially bring the described experiments to room temperature and facilitate scaling to large networks of resonators and emitters. Additionally, the use of inverse design nanophotonic methods that can efficiently perform physics-guided search through the full parameter space, leads to optical devices with properties superior to state of the art, including smaller footprints, better field localization, and novel functionalities.

10344-1, Session 1

Designing the metal nanoparticle (MNP)-non linear optical (NLO) material: future nanophotonics

Preeti Gupta, G.V. Pavan Kumar, Indian Institute of Science Education and Research Pune (India)

We have elucidated the role of plasmon resonance in the ETU system, and provides a straightforward method to directly measure the energy transfer rate and internal upconversion efficiency. We have also probe plasmon-coupled emission engineering of lanthanides using nano-optical tools and uniquely characterize and quantified the effects of size and shape on the plasmonic behaviour of nanoparticles, and allowed the study of properties inaccessible with bulk measurements, such as plasmon decay and polarization effects. We have unravel and provided quantitative information on the magnitude of the intrinsic polarization-induced scattering intensity variation and mode selectivity by single particle spectroscopy.

10344-2, Session 1

Nanoparticles induced light to vapor conversion for off-grid water purification: full multiphysics modeling *(Invited Paper)*

Alessandro Alabastri, Pratiksha Dongare, Seth Pedersen, Rice Univ. (United States); Katherine Zodrow, Montana Tech (United States); Nathaniel J. Hogan, Oara Neumann, Jinjian Wu, Qilin Li, Peter Nordlander, Naomi J. Halas, Rice Univ. (United States)

In the world, 1.1 billion people lack practical access to a fresh water supply. Membrane Distillation (MD) is a promising technique employed to purify or desalinize water. However the process is highly energy demanding due to water relatively large latent heat leading, at ambient conditions, to a limited evaporation rate. Broadly absorbing metal or carbon nanoparticles (NPs), when mixed with water, greatly enhance the evaporation rate if the solution is placed under focused sun irradiation. MD can be improved by including a thin layer of light-absorbing NPs on top of the membrane which separates salty and fresh water providing a sun powered, electrical energy free heat source along the whole device. In the process, only the water in contact with the NPs is heated, leading to an effective layer-by-layer vaporization effect. To prove the concept, alongside experiments, a full multiphysics model has been realized including the main physical mechanisms playing a role in the NP induced vaporization and water transport process. At this purpose, a Finite Element Method (FEM) approach was employed to analyze and predict the efficacy of the system, fully reproducing the employed device. Light-to-vapor conversion efficiencies of about 20% below 1 Sun of illumination and salt rejection of more than 99.5% have been found in desalination experiments and confirmed by theoretical investigations.

10344-3, Session 1

Photocurrent generation from TiN nanostructures by visible light *(Invited Paper)*

Satoshi Ishii, Satish L. Shinde, Tadaaki Nagao, National Institute for Materials Science (Japan)

Titanium nitride is a highly conductive ceramic which has been gaining tremendous attentions in plasmonics community. While the applications of titanium nitride for plasmonic metamaterials and photothermal effects have been studied, generation of hot electrons from titanium nitride has been elusive. Here we demonstrate experimentally that hot electrons can be optically excited from titanium nitride. We confirm the generation of hot electrons up to 800 nm in wavelength by measuring the photocurrent from titanium nitride thin films deposited on a zinc oxide thin film. A control sample where the titanium thin film is replaced with a gold thin film having the identical thickness is also fabricated and its photocurrent is much weaker than the titanium nitride sample in whole visible spectrum. Hence our results show that titanium nitride is superior than gold in generating hot electrons in visible range. Since titanium nitride is chemically stable and less expensive than gold, we anticipate that titanium nitride can replace gold in photoelectric applications such as visible light photocatalysis and solar water splitting.

10344-4, Session 1

Plasmonics: transformed quantum emitters *(Invited Paper)*

Ajay Singh, Jennifer A. Hollingsworth, Los Alamos National Lab. (United States)

Nanocrystal plasmonics enjoy scientific attention for enhancement of optical processes, such as luminescence, Raman scattering, optical switching, and absorption. In plasmonic nanomaterials, free carriers are driven to oscillate collectively at a resonate frequency in response to the oscillatory electromagnetic field of incident light, which is characterized as the localized surface plasmon resonance (LSPR). The excitation of LSPR are strongly confined to the size, shape, and composition of plasmonic nanocrystal. As a result, the resonant dipolar polarization modes (longitudinal and transverse) of the nanocrystals are dominant and correspond to strongly enhanced electric fields (hot spots) within and especially just outside the nanocrystals vicinity. This near field enhancement in the nanocrystal can be exploited to enhance (by coupling) the inherent properties (luminescence, absorption, vibrational state transitions etc.) of nearby molecules or materials such as the quantum emitters (QE). In case of quantum emitters, the LSPR resonance coupled to the emitter in the range from weak (Purcell effect quickens QE's emission rate) to strong (reversible exchange between field and emitter – Rabi oscillation) coupling. In order to understand these coupling regime (plasmon-photon interactions), we performed series of experiment by varying the QE (emission) and plasmonic nanocrystal size, shape, resonance frequency and studied their effect on the emission rate of the exciton.

10344-5, Session 1

Heat dissipation control in plasmonic systems

Alessandro Alabastri, Rice Univ. (United States); Andrea Toma, Mario Malerba, Eugenio Calandrini, Francesco De Angelis, Remo Proietti Zaccaria, Istituto Italiano di Tecnologia (Italy)

Metallic nanostructures can be utilized as heat nano-sources which can find application in different areas such as photocatalysis, nanochemistry or sensor devices. Here we apply a temperature dependent dielectric function model to different nanoparticles finding that the optical responses are strongly dependent on shape and aspect-ratio. Depending on the structures geometry, absorption efficiency can either increase or decrease with temperature. The electric permittivity, which dictates the optical response, is modified by the temperature which depends on the electric fields and currents induced in the metallic medium. When the intensity of the incident electromagnetic field is sizable, the induced non-linearity plays a major role and the effect on the final electric fields and temperature can be substantial. Moreover, the background temperature itself can be used to tune an antenna optical and thermal properties. In particular it was found that, by properly designing arrays of nano-antennas, the temperature dependence

of the heat released by each single antenna can be tailored and can exhibit opposite trends for different structures aspect ratio. In fact, high aspect ratio antennas exhibit a decreasing heat dissipation for increasing temperature. This effect may lead to materials with self-limiting heating properties which reduce the dissipation upon reaching high temperature values.

The calculation method employed here is flexible and matched experimental measurements. The same approach was used to successfully predict the role of the thermal boundary resistance in gold nanowires at low temperatures, thus confirming its validity as a tool for thermoplasmonic applications.

10344-6, Session 2

Large area fabrication of robust plasmonic color metasurfaces by a high-speed roll-to-roll method

Swathi Murthy, Inmold (Denmark); Henrik Pranov, Heliac (Denmark); Guggi Kofod, Inmold (Denmark); Rafael J. Taboryski, Technical Univ. of Denmark (Denmark)

Lab-scale plasmonic color printing using nano-structured and subsequently metallized surfaces has been demonstrated to provide vivid colors on structured surfaces. However, upscaling these structures for large area manufacturing is extremely challenging due to the requirement of nanometer precision of metal thickness. Here, we report for the first time, a novel plasmon resonance mode which is a hydridization between surface and gap plasmon resonances in Al nanostructures, for obtaining plasmonic colors. The existence of this hybrid mode makes the colors insensitive to the thickness of the metal layer, when this thickness exceeds the depths of the nano-pits on the surface. Thus, allowing for a robust high speed fabrication of plasmonic color metasurfaces. We have also demonstrated the feasibility of fabrication of these plasmonic color surfaces by a high-speed roll-to-roll method. First nanostructured polymer foils, comprising of 100nm deep nano-pits of varying diameter and pitch were fabricated by roll-to-roll extrusion coating at 10 m/min, followed by roll-to-roll metallization with 100 nm of Al at 350 m/min by a high vacuum thermal evaporation process and finally, a roll-to-roll lacquering process for protection of the metalized nanostructures. This can pave way for plasmonic meta-surfaces to be implemented in applications such as memory, SERS, flexible displays, photovoltaics, security, product branding etc.

10344-8, Session 2

Precipitation and spectral characteristics of silver nanoparticles and rare-earth ion doped oxide nanocrystals inside borate glasses

Ki-Soo Lim, Chang-Hyuck Bae, Chungbuk National Univ. (Korea, Republic of)

We prepared CaO-K2O-B2O3-ZnO-Al2O3 glass system doped with Ag2O, Eu2O3, and Yb2O3 using conventional melt-quenching method. Femtosecond laser irradiation and the following proper annealing produced silver nanoparticles showing surface plasmon band in the absorption spectra of the glass. The enhancement of the photoluminescence from Eu3+ ions was observed due to the local field effect. We also synthesized glass-ceramics containing ZnO nanocrystals by further thermal annealing in an electric furnace and observed much enhanced visible emission of Eu3+ ions due to the environment of nanocrystals instead of glass. Instead of this traditional furnace annealing, we used CO2 laser annealing by slow-speed scanning for the glass and obtained another oxide nanocrystals of ZnAl2O4 on the surface. Spectral characteristics of the enhanced down- and up-conversion emissions in the glass-ceramics under 365 nm and 980 nm excitation were explained by cross-relaxations, excited state absorptions, and energy transfer processes between Eu3+ and Yb3+ ions. TEM analyses revealed the size and presence of silver nanoparticles and oxide nanocrystals. XRD analysis showed the phase appearance of ZnO and ZnAl2O4 crystals and we discussed the effects of the annealing temperature and duration time for furnace and laser treatments.

10344-9, Session 2

DNA-assembled large-scale responsive multicomponent nanoparticle metamaterials *(Invited Paper)*

Qingyuan Lin, Jarad Mason, Vinayak P. Dravid, Chad A. Mirkin, Northwestern Univ. (United States)

The assembly of large-scale multicomponent nanoparticle superlattices with programmable geometries and arrangements remains a grant challenge in the field of colloidal nanocrystal synthesis. Here we combine top-down lithography and bottom-up DNA assembly to construct structurally sophisticated responsive three-dimensional multicomponent nanoparticle superlattices that are inaccessible with conventional solution assembly and lithographic techniques. Six designs of large-area ternary superlattices consisted of up to three different types of nanoparticle shapes were synthesized, demonstrating the versatility of such assembly strategy. In addition, the placement of each individual nanoparticles at the nano-scale and the crystal symmetry and size at the macro-scale were precisely defined at the same time, offering unprecedented control over the superlattice architectures. This general approach have potential to further extend to the assembly of superlattices with more than three elements, providing a powerful platform for the construction of metamaterials for optical, electronic, magnetic, and catalytic applications.

10344-10, Session 3

3D femtosecond laser printing for angular momentum generators *(Invited Paper)*

Xuewen Wang, Swinburne Univ. of Technology (Australia)

We propose to use femtosecond laser direct writing technique to realise dielectric optical elements from photo-resist materials for the generation of structured light from purely spin-orbital conversion transformations. This is illustrated by the fabrication and characterisation of spin-orbital optical angular momentum couplers generating optical vortices of topological charge from 1 to 20. The elements achieved using this techniques also were demonstrated its capabilities to working in the whole visible range with efficiency up to 85%. We also firstly demonstrated the abilities to combine the dynamic phase and geometric phase using the 3D fabrication capability of laser direct writing to create elements that generate different topological charges of optical vortices simultaneously with the shared aperture.

10344-11, Session 3

Formation and multi-imaging analysis of nascent surface structures generated by femtosecond laser irradiation in silicon

Felice Gesuele, Jijil J. J. Navas, Pasqualino Maddalena, Salvatore Amoruso, Univ. degli Studi di Napoli Federico II (Italy)

The formation of surface structures (both ordered and random) by means of femtosecond laser micro-structuring is a striking and extensively studied phenomenon at the base of several applications. Due to its great technological importance, silicon is one of the most investigated material forming a realm of surface structures depending on the processing conditions.

Here we report on the formation of periodic structures on the (100) crystalline silicon surface after irradiation with a low number of 1055 nm, 850 fs laser pulses, in high vacuum conditions. We focus our analysis on the nascent stage of surface structures formation. We employ a wide variety of microscopy techniques to retrieve the mechanical, optical and structural properties of realized structures. Sample topography is measured by means of an Atomic Force Microscope. Sample structural phase and amount of defects are revealed by performing a Raman micro-analysis carried out through a scanning confocal optical microscope, while confocal reflection images of the sample surface are also registered with the same optical setup.

Our analyses clearly show the creation of grating structures of near-wavelength (1.02μm) period consisting of alternating amorphous and crystalline periodic lines, with almost no material removal. The gratings originate from defects acting as scattering centres and generating energy modulation patters propagating along the direction of laser polarization.

A comparative analysis, carried out with silicon samples processed in ambient air at atmospheric pressure under the same experimental conditions, allows to gain insights on the fs laser surface structuring process of silicon.

10344-12, Session 3

Spectral analysis of volume holograms in materials with diffusion-based formation mechanisms by means of coupled wave theory and Kramers-Kronig relations

Vladimir N. Borisov, Aleksandr E. Angervaks, Aleksandr I. Ryskin, Andrey V. Veniaminov, ITMO Univ. (Russian Federation)

Volume holography has a potential in terms of production of precise optical diffraction elements and photonic-crystalline structures, and analysis of such structures is of considerable interest. The key role in that analysis is to obtain spectral dependences of optical parameters modulation. Solid materials with diffusion-based formation mechanisms of holograms (like PQ-PMMA or calcium fluoride crystals with color centers) are in a great interest since they potentially allow for large refractive index modulation. However, due to the complexity of photochemical and photophysical processes occurring during the recording of holograms, their spectral analysis is a challenging task.

In this research volume holograms were studied by capturing selectivity hypercontours (2D spectral and angular dependences of diffraction efficiency) and analyzing them by means of Kogelnik coupled wave theory. Selectivity hypercontours provide the most informative picture of the hologram properties, including spectral dependences of absorbance and refractive index modulation profiles. Measurements made at different times showed a hologram transformation in PQ-PMMA due to diffusion processes: holograms converted from predominantely amplitude to almost phase ones in the course of postexposure diffusion of PQ molecules. Thus, this technique allows for studying processes that are involved in the formation of holograms.

While absorbance modulation is in direct connection with the absorption spectra of the materials, an adequate description of phase modulation through Kramers-Kronig dispersion relations discovered in colored crystals. Kramers-Kronig relations are operable tool in cases where the nature of holograms formation is well studied. In turn, testing holograms formation hypotheses using Kramers-Kronig relations can prove their validity.

10344-13, Session 4

Long-range exciton transport in cesium lead halide perovskite nanocrystals organized in ordered nanoscale assemblies *(Invited Paper)*

Erika Penzo, Lawrence Berkeley National Lab. (United States); Anna Loiudice, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Edward S. Barnard, Nicholas Borys, Lawrence Berkeley National Lab. (United States); Raffaella Buonsanti, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Adam M. Schwartzberg, Stefano Cabrini, Alexander Weber-Bargioni, Lawrence Berkeley National Lab. (United States)

Fully inorganic cesium lead halide perovskite nanocrystals (NCs) are a novel colloidal material displaying remarkably bright photoluminescence (PL) characterized by high quantum yield (QY) of 50-90% and narrow emission line widths of 12-42 nm. In addition, compositional control and quantum-size effects allow for the precise and continuous tuning of bandgap energies over the entire visible spectral region.

The cubic perovskite crystal structure results in NCs with cubic shape, 4-15 nm in side length. Taking advantage of their affinity for hydrophobic surfaces, these NCs can be assembled in highly ordered monolayers in which the cubic NCs are organized in arrays with parallel edges. The close proximity of this arrangement and the high polarizabilty of these NCs allow for efficient exciton migration between adjacent NCs through Förster Resonant Energy Transfer (FRET). The monolayer layout confines the available paths for exciton transport in two dimensions, enabling the accurate study of the transport effects and mechanism using super-resolution based optical imaging techniques combined with steady-state and time-resolved spectroscopy. Evidence of FRET-like transport is found in accelerated relaxation times and spatial expansion of the excited state ensemble. FRET-mediated long-range exciton migration exceeding 200 nm is observed, and the impact of the inter-nanocrystal energetic disorder on the observed optical signatures is discussed.

This system allows for the first demonstration of such long-range exciton transport in NCs solids opening up new possibilities for high functionality optoelectronic devices based on cesium lead halide perovskite NCs.

10344-14, Session 4

Possibility of cost effective and energy efficient high quality natural white light sources with a new nano-phosphor

Dilip De, Covenant Univ. (Nigeria) and Sustainable Green Power Technologies (United States); Ikorya De, Univ. of the Free State (South Africa)

In this paper we present results authors' published initially on the white light emission with broad band (330-465 nm) excitation of the specially prepared nano-phosphor: Eu^{3+}:ZnS which is capped with sodium methyl carboxylate and on pure red-light emission from the nano-phosphor when capped with alpha methyl acrylic acid and prepared in a different method. Then we discuss possible methods of future improvement of the white light emission from the nano-phosphor. We then present the cost effective and energy efficient method of obtaining highest quality natural white light sources using such nano-phosphor and blue or near UV blue light emitting diodes. The latter discussion includes the driving circuit for the white LED and powering the LED by concentrated solar photovoltaics for completely clean energy natural white lighting sources.

10344-15, Session 4

Quantum-confined and pseudo Stark effects in the semiconductor conical quantum dot

Karen G. Dvoyan, Ani Tshantshapanyan, Branislav Vlahovic, North Carolina Central Univ. (United States); Gregory J. Salamo, Univ. of Arkansas (United States)

Electronic states and direct interband light absorption in GaAs conical quantum dot (QD) are theoretically investigated within the framework of the geometric adiabatic approximation both in strong and weak quantum confinement regimes. For the lower levels of the spectrum, the localization of the electron in the vicinity of the QD center of gravity is proved. The QD conical symmetry leads to appearance of an atypical linear term in the effective confining potential. The influence of a uniform electrical field on the system is also considered, and both quantum-confined and pseudo Stark

effects are discussed. For weak quantum confinement regime, the motion of the exciton center-of-gravity is quantized, which leads to appearance of additional Coulomb sub-levels. Dependencies of the absorption edge on the QD geometric parameters are obtained, and corresponding selection rules for quantum transitions are revealed.

10344-29, Session PWed

VOx nanofibers for IR detection

Seong Hyun Kim, Su Jae Lee, Electronics and Telecommunications Research Institute (Korea, Republic of); Bong-Jun Kim, Mobric Co. Ltd. (Korea, Republic of)

Various materials have been used for infrared detection. They are also manufactured in various structures. Among them, vanadium oxide is widely used in non-cooling type infrared image sensors. Among them, V_2O_5 type is used most commonly, and recently VO_2 is being studied. The vanadium oxide is not easy to make single phase because the phase varies considerably and the production conditions are complicated. The mix of these phases leads to performance degradation. At present, thin film vanadium oxide is mainly used. In the manufacturing process, since the thin film must be floated in the air, the process is difficult and the defect rate is high.

In this study, vanadium oxide in nanofiber form was studied. Fabricated nanofibers were able to change the phase according to the process conditions and space between the material and the substrate spontaneously occurred in the manufacturing process without artificially floating in the air. We also discuss the fabrication process using a random structure.

10344-30, Session PWed

Luminescence and transient lifetime studies for energy transfer of PbS QD films

Joanna S. Wang, Bruno Ullrich, Chandriker K. Dass, Air Force Research Lab. (United States); Anirban Das, Chien M. Wai, Univ. of Idaho (United States); Gail J. Brown, Joshua R. Hendrickson, Air Force Research Lab. (United States)

Nanoparticle colloidal solutions of quantum confined semiconductor materials have drawn great attention in scientific communities due to the size-tunability of their optical properties arising from the effect of quantum confinement. PbS quantum dots (QDs) are exciting candidates for quantum optics, particularly, due to size controllable parameters in the synthetic process which provides precisely tunable emission properties in the infrared region. PbS QDs in different sized pairs are deposited onto glass substrates to form thin films using supercritical fluid CO_2 (sc-CO_2) deposition and solvent deposition methods. Fluorescence and photoluminescence (PL) spectra of PbS QDs obtained from these closely packed films prepared by the sc-CO_2 method reveal effective Förster resonance energy transfer (FRET) between two different sized dots, while the films composed of three different sizes of dots show an even more effective FRET from the smallest to the largest ones. Energy transfer can be observed more directly by spectrally resolved PL decay of mixed dots. A mixed PbS film with 3.1 and 4.8 nm QDs was studied for FRET by time correlated single photon counting for transient lifetime measurements. The PL is quenched at the short wavelength, which decays faster than that recorded for the radiative emission decay of the long wavelength peak. The lifetime (decay constant)$^{-1}$ for the shorter wavelength is best fit using a biexponential equation. The long wavelength decay is best fit by a monoexponential equation. More theoretical and experimental work is required for a thorough understanding of the radiative lifetimes of PbS QDs in mixed QD systems.

10344-31, Session PWed

Magnetic field influence on the intensity of ZnO random lasing and exciton luminescence

Andrey P. Tarasov, Moscow Institute of Physics and Technology (Russian Federation) and Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation); Charus M. Briskina, Alexey Saveliev, Valery M. Markushev, Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation); Mikhail Shiryaev, M.V. Lomonosov Moscow State Univ. (Russian Federation)

There are a lot of theoretical and experimental investigations devoted to the influence of magnetic field on the exciton, particularly, in the case of ZnO, but they are mainly focused on very low temperatures and single crystals or heterostructures (such as quantum dots and wells). In our opinion, it is useful to perform such investigation at room temperature (RT) and using structures which are easier to prepare.

In our investigation, the influence of magnetic field on the exciton luminescence of ZnO microfilms at RT was studied. The samples had a disordered nanorod structure with nanorod diameter ~200 nm and length ~1 um. Nanorods were almost randomly oriented, diverging from the normal to the Si-substrate surface up to ~50 degrees.

The excitation of samples luminescence was performed by 3rd harmonic of pulsed Nd:YAG laser (pulse duration is ~10 ns, repetition rate is 15 Hz). Constant magnetic field with magnitude of 0.9 T was generated by a rather portable magnetic system. The excitation levels in the experiment lay in the range 5-39 μJ. Random lasing started appearing in the area of exciton band peak at the excitation of 5 μJ. Inserting the sample in magnetic field leaded to the increase of random lasing and the luminescence intensity. The value of enhancement is approximately 15-20% and varies only slightly with the excitation level rise.

The experimental results were analyzed on the base of the concept of the Zeeman effect and by estimation of exciton recombination probability using Schrödinger equation.

10344-32, Session PWed

Optical properties of cyanine dyes in nanotubes of chrysotile asbestos

Anton A. Starovoytov, ITMO Univ. (Russian Federation); Vladimir I. Belotitskii, Yuri A. Kumzerov, Anna A. Sysoeva, Ioffe Institute (Russian Federation); Tigran A. Vartanyan, ITMO Univ. (Russian Federation)

Incorporation of organic dye into porous materials has received increasing attention in recent years due to its potential application potential in lasers, artificial light-harvesting antennas, optical switches and sensors. The dye molecules embedded in nanopore system are well-isolated in comparison with molecules in thin films or solutions. Thus, photophysical properties of the dye molecules in nanoporous material would provide insights for fundamental understanding of such system.

We studied the absorption, linear dichroism, fluorescence (emission, anisotropy and decay lifetime) for monocarbocyanine dye embedded in chrysotile asbestos which consists of a regular arrangement of cylindrical nanopores (nanotubes) that form a one-dimensional nanopore system.

The Stokes shift for dye in asbestos is smaller than for the molecules in the ethanol solution. This circumstance reflects smaller polarity of the nanopore environment. The absorption and fluorescence spectra of dye in asbestos and solution have the similar shapes, but they have blue shift. We conclude that organic molecules in asbestos are well-isolated as monomer and free from aggregation.

For the studied monocarbocyanine the dipole moment of transition S0

? S1 is directed along the conjugated chain. According linearly polarized absorption and fluorescence spectra we conclude that the molecules oriented predominantly along asbestos nanotubes.

We investigated the fluorescence decay lifetime of dye molecules in asbestos and thin film. For asbestos samples the lifetime is longer due to the decrease of the nonradiative decay process. The main pathway of this process for cyanine is photostereoisomerization, which is hindered in pores.

10344-33, Session PWed

Biocompatible Er, Yb co-doped flouroapatite upconversion nanoparticles for imaging applications

Anjana R., Jayaraj M. K., Cochin Univ. of Science & Technology (India)

Design and characterization of new luminescent nanomaterials is an interesting area while considering its potential applications in display screens, solid state lasers, imaging, security printing and bio-assays. Upconversion luminescencent materials gives visible or NIR emission on NIR excitation. It is a multi-photon process in which more than one photon combines to give a single photon. The real energy levels of rare earth ions like Er3+, Tm3+, Ho3+ are involved in the energy transition and emission. In order to increase NIR absorption cross-section it is co-doped with ions like Yb3+ having higher NIR absorption cross section. Selection of suitable host lattice is also important for achieving efficient upconversion luminescence. The properties of host lattice and crystal field interaction with dopant ion will have strong influence on upconversion process.

Recently upconversion luminescent materials are widely being studied towards imaging applications. The biocompatibility of many of the common host is a major concern for imaging applications. Apatite crystals like hydroxyapatite [Ca10(PO4)6(OH)2] and fluorapatite [Ca10(PO4)6F2] are well known biomaterials and are components of bone and teeth. Also they are excellent host materials for lanthanide doping since the ionic radii of lanthanide is similar to that of Ca2+ hence successful incorporation of dopants within the lattice is possible. Er3+, Yb3+ co-doped fluorapatite nanoparticles were prepared by precipitation method. The particles show intense visible emission when excited with 980 nm laser. The crystal structure and morphology of the particle were determined using X-ray diffractometer and SEM. These particles with surface fictionalized can be used for imaging.

10344-34, Session PWed

ITO-Si heterojunction solar cell with nanocrystal line CdTe thin films

Andrii Pocherpailo, Sergii Kondratenko, Taras Shevchenko National Univ. of Kyiv (Ukraine)

ITO-Si heterojunction solar cell with nanocrystal line CdTe thin films grown by magnetron sputtering are studied. The electrical and optical properties of these solar celldevices, as determined by current–voltage and photovoltage spectroscopy, were found to change with temperature over a range of 80–300 K. The electron traps present in devices with a different morphology of the CdTe films have been investigated using transient photovoltage techniques with 650 nm pulse excitation. Solar cells with CdTe films with a thickness of 24 nm exhibits the highest efficiency of 11 % as compare with 9,4% for the reference ITO-Si cells without CdTe. We have proposed the model that explains the increase achieve of efficiency due to increase of the photovoltage while short-circuit current exhibits a week lowering. Also we have established the physical mechanism of the observed increase in the lifetime of photoexcited charge carriers.

10344-18, Session 5

Optical transmittance of metallic nanowires

Mazen S. Nairat, Mousa Imran, Al-Balqa Applied Univ. (Jordan)

Wave optical simulation has been performed to study the optical transmittance of an array of metallic nanowires. Comsol multiphysics is used to briefly analyze polarization dependency of an incident light on the transmittance of nickel nanowires. Parallel polarization along to the nanowires makes the array almost appears as opaque metal sheet. On the other hand, normal polarization perpendicular to the nanowires not only makes the array transparent but also causes dipolar coupling between the nanowires. Our results provide briefly transmittance as well as reflectance of specific layer of nickel nanowires. The determined unique feature of the nanowires could be implemented in several applications and technologies, for instance: developing nanosolar cells.

10344-19, Session 5

Precise control over the morphology and dopant distribution in colloidal metal oxide nanocrystals

Ajay Singh, Los Alamos National Lab. (United States); Delia J. Milliron, The Univ. of Texas at Austin (United States)

Colloidal synthesis of doped metal oxide nanocrystals provides a great opportunity and easy route to generate materials that has unique optoelectronic properties with promising applications such as smart windows, displays, sensing and photo-catalysis etc. By introducing the free carriers with different type of dopants (n- or p-type) in the metal oxide nanocrystals, their surface plasmon resonance can be tuned precisely from near IR to mid-IR range. Similarly like metals, the optical response of plasmonic metal oxide nanocrystals can be manipulated by controlling the shape, size of the nanocrystal and free electron concentration. The effect of nanocrystal shape and size on the enhancement of their local electrical field strength and surface plasmon resonance have paved the way for new technologies and better sensing opportunities. The sharp faceted nanocrystals exhibit enhanced electric fields at corners and edges, which give us an opportunity to explore different morphologies of the NC for sensing application. Here, we will be presenting a solution route to synthesize plasmonic metal oxide nanocrystal (doped Indium Oxide) with defined shape, size and radial distribution of dopant in the nanocrystals. Also, with co-doping (cation, anion or both) in these nanocrystals, we can shift the surface plasmon resonance to higher energies and can also influence the shape of the nanocrystals. Further, we will present near field enhancement property of single nanocrystals via EELS mapping and quantify both near field and far field plasmon property via COMSOL electromagnetic simulations.

10344-20, Session 5

Controlling the emission spectra of white CdSe quantum dots by growth time

Yu-Sheng Su, Shu-Ru Chung, National Formosa Univ. (Taiwan)

In the recent years, the phosphor-converted light emitting diodes (pc-WLEDs) applies to solid state lighting (SSL) due to their high efficacy and reliability. However, the color rendering index (CRI) of the current commercial WLED is not enough. Because that quantum dots (QDs) possess controllable emission wavelength, broad excitation band, and high quantum yield (QY). Therefore, QDs is seemed as alternative materials to replace traditional phosphors. Moreover, in order to enhance the color rendering index (CRI) of WLED, blending QDs with different emission wavelengths, such as G- and R-QDs, has been used frequently. Unfortunately, these procedures are complex and time-consuming, and the emission energy of smaller QDs can be reabsorbed by larger QDs, resulting in decreasing the emission intensity in green region. Therefore, creating a process to produce white light emission QDs with high QY is important. In this study, we have demonstrated a facile chemical route to prepare CdSe QDs with white light emission in low temperature at 180 oC, and the performance of white CdSe-based WLED is also exploded. An organic oleic acid (OA) is used to form Cd-OA complex first and hexadecylamine (HDA) and 1-octadecene (ODE) is used as surfactants. Meanwhile, by varying the reaction time from 1 s to 60 min, CdSe QDs with white light can be obtained. The result shows that the luminescence spectra compose two obvious emission peaks and entire visible light from 400 to 700 nm, when the reaction time less than 10 min. The wide emission wavelength combine two particle sizes of CdSe, magic and normal, and the magic-CdSe has band-edge and surface-state emission, while normal size only possess band-edge emission. The TEM characterization shows that the two different sizes with diameter of 1.5 nm and 2.7 nm for magic and normal size CdSe QDs can be obtained when the reaction time is 4 min. We can find that the magic size of CdSe is produced when the reaction time is less than 3 min. In the time ranges from 3 to 10 min, two sizes of CdSe QDs are formed, and with QY from 20 to 60 %. Prolong the reaction time to 60 min, only normal size of CdSe QD can be observed due to the Ostwald repining, and its QYs is 8 %. Based on the results we can conclude that the two emission peaks are generated from the coexistence of magic size and normal size CdSe to form the white light QDs, and the QY and emission wavelength of CdSe QDs can be increased with prolonging reaction time. The sample reacts for 2 (QY 30 %), 4 (QY 32 %) and 60 min (QY 8 %) are choosing to mixes with transparent acrylic-based UV curable resin for WLED fabrication. The Commission International d'Eclairage (CIE) chromaticity, color rendering index (CRI), and luminous efficacy for magic, mix, and normal size CdSe are (0.49, 0.44), 81, 1.5 lm/W, (0.35, 0.30), 86, 1.9 lm/W, and (0.39, 0.25), 40, 0.3 lm/W, respectively.

10344-21, Session 5

Tuning graphene photonic properties with a self-assembled molecular monolayer *(Invited Paper)*

Sylvain Le Liepvre, Tessnim Sghaier, CEA-Ctr. de SACLAY (France); Ping Du, David Kreher, Fabrice Mathevet, André-Jean Attias, Univ. Pierre et Marie Curie (France); Céline Fiorini-Debuisschert, Ludovic Douillard, Fabrice Charra, CEA-Ctr. de SACLAY (France)

Graphene, as a flexible 2D conductor with broadband transparency, has potential photonic applications in optical modulators, photodetectors, light harvesting or emitting devices. However, its zero-bandgap electronic structure limits graphene to a narrow range of roles centered on that of transparent electrode. Graphene needs to be combined with a complementary photonic material to create a hybrid component with novel properties for advanced photonics.

The molecular self-assembly is an original bottom-up approach toward novel materials displaying unusual properties. 2D self-organized molecular networks obtained on the graphene surface reach sufficiently high surface packing density (typically 0.5 molecules/nm2) to add macroscopic properties to the graphene layer.

The photonic properties of closely packed dye assemblies can be drastically altered compared with the isolated or diluted specie due to charge transfer processes, collective excitations, or conformational changes in the dye molecule. Hence, the possible fine tuning of inter-constituents distances and orientations offered by the design of self-assembling building blocks makes the self-assembly approach very appealing for adjusting graphene photonic properties.

By controlling the interactions between dye molecules, we obtained a nanostructured hybrid graphene/dye 2D material that displays an absorption peak in the visible range. Adjusting the dye-graphene distance through a molecular spacer thanks to a specifically designed dual-functionalized self-assembling building block, we demonstrated a fluorescent self-assembled monolayer on graphene.

This experimental proof of concept shows the suitability of self-assembly techniques for the development of multi-functional hybrid dye/graphene 2D materials for nanophotonics, optoelectronics, light emitting or harvesting devices.

10344-22, Session 5

All-dielectric cylindrical nanoantennas in the visible range

Reena Dalal, Nishant Shankhwar, Yogita Kalra, Ajeet Kumar, Delhi Technological Univ. (India); Ravindra K. Sinha, Delhi Technological Univ. (India) and Central Scientific Instruments Organisation (India)

All-dielectric nanoparticles have attained a lot of attention owing to the lesser loss and better quality than their metallic counterparts. As a result, they perceive applications in the field of nanoantennas, photovoltaics and nanolasers. In the dielectric nanoparticles, the electric and magnetic dipoles are created in dielectric nanoparticles when they interact with the light of a particular frequency. Kerker's type scattering is obtained where electric and magnetic dipoles interfere. In our design, Silicon cylindrical nanoparticles having radius of 70 nm and length 120 nm have been considered. The propagation of light is taken along the length of the cylinder. The scattering cross section has been obtained and plotted with respect to the wavelength. At the peaks of scattering spectra, electric and magnetic dipoles are created at the wavelengths of 500 nm and 600 nm, respectively. Both dipoles interfere at the wavelengths of 564 nm and 676 nm. At these wavelengths, far field scattering pattern has been calculated. At the wavelength 676 nm, forward scattering takes place because electric and magnetic dipoles are in phase at this wavelength. Further, directivity is enhanced by taking the planar array of the nanoparticles. It has been observed that directivity increases by increasing the size of the array. Also, there is an increase in the directivity by increasing the gap between the nanoparticles. This enhancement of directivity can lead to the design of all dielectric cylindrical nanoantennas

10344-35, Session 5

Third order optical nonlinearity investigation of germanium quantum dots embedded in silicon matrix

Liangmin Zhang, David Bishel, William Cheung, Joseph Mini Jr., Salvador Montes, California State Univ., Stanislaus (United States)

Germanium (Ge) nanoscrystals have smaller electron and hole effective masses and a larger dielectric constant than silicon (Si) nanocrystals. The effective Bohr radius of excitons is also much larger than that of Si, therefore, comparing with Si nanocrystals, the quantum confinement effect will be more prominent in Ge nanocrystals. In addition, the melting point (938.3°C) of Ge is lower than that of Si (1414°C), which implies that Ge nanocrystals can form at lower temperature during annealing process. The synthesis and characterization of Ge nanocrystals may open new possibilities for theoretical investigations and applications to optoelectronics and microelectronics.

The common way to investigate the properties of Ge nanocrystals is to incorporate these nanoclusters in a matrix using thermal deposition or sputtering techniques. We use the conventional radio frequency magnetron co-sputtering and post-annealing techniques to embed Ge nanocrystals into a silicon matrix. The thickness of thin films fabricated by these techniques varies from 150 – 300 nm. After fabrication, the samples are annealed inside a quartz tube for several minutes at 750oC - 800oC under nitrogen environment.

The samples are then characterized by X-ray diffraction, high resolution transmission electron microscopy (HRTEM), Raman scattering spectroscopy, and open-aperture z-scan techniques. These measurements clearly show the Ge nanocrystals are formed in the Si matrix. The average size of Ge nanocrystals is estimated to be 5.5 nm by HRTEM and X-ray diffraction. The average imaginary part of third-order susceptibility of these films is measured to be 2.9 x 10^(-10) esu using a femtosecond laser system.

10344-24, Session 6

Tuning the optical properties of colloidal quantum nanocrystal/Al2O3 composite films by atomic layer deposition

Milan Palei, Vincenzo Caligiuri, Stefan Kudera, Prachi Rastogi, Roman Krahne, Istituto Italiano di Tecnologia (Italy)

Colloidal semiconductor nanocrystal (NCs) are promising building blocks for electronics and optoelectronics devices such as LEDs, photodetectors, and solar cells.1 They possess shape tunable optical and electronic properties that can be controlled via the synthesis process. 2 This make them a promising material for light emitting, lasing and photovoltaic application. However, nanocrystal films typically suffer from surface oxidation, stability issues, and physico-chemical changes when exposed to ambient conditions.3 Hence it is essential to protect the NCs from such chemical and physical changes using surface coatings. Here we used low temperature atomic layer deposition (ALD) to deposit a dielectric material like alumina (Al2O3) on CdSe/CdS core-shell NC films.4 The infilling and over coating of the NC film with alumina changes the dielectric and optical properties of the layer, and can be used to prevent photoluminescence quenching. In this work, we study the dielectric constants of composite CdSe/CdS nanocrystal/alumina films by ellipsometry and correlate the results to changes in optical emission. The enhancement in photoluminescence of ALD coated NC films can be an important step towards potential applications in the field of optoelectronic devices.

10344-25, Session 6

Nanostructured organosilicon luminophores for efficient and fast elementary particles photodetectors

Sergey A. Ponomarenko, Institute of Synthetic Polymeric Materials (Russian Federation) and Lomonosov Moscow State Univ. (Russian Federation) and Luminescent Innovation Technologies LLC (Russian Federation); Oleg V. Borshchev, Nikolay M. Surin, Maxim S. Skorotetcky, Institute of Synthetic Polymeric Materials (Russian Federation) and Luminescent Innovation Technologies LLC (Russian Federation); Elena A. Kleymyuk, Institute of Synthetic Polymeric Materials (Russian Federation); Tatyana Y. Starikova, Institute of Synthetic Polymeric Materials (Russian Federation) and Lomonosov Moscow State Univ. (Russian Federation); Alexey S. Tereshenko, Luminescent Innovation Technologies LLC (Russian Federation)

Organic luminophores are widely used in various optoelectronic devices, which serve for photonics, nuclear and particle physics, quantum electronics, medical diagnostics, etc. Improving their spectral-luminescent characteristics for particular technical requirements of the devices is a challenging task. In this work, we report on a convenient solution of this problem by design, synthesis and application of nanostructured organosilicon luminophores (NOLs), which consist of two types of covalently bonded via silicon atoms organic luminophores with efficient Forster energy transfer between them. NOLs combine the best properties of organic luminophores and inorganic quantum dots: high absorption cross-section and photoluminescence quantum yield, fast luminescence decay time, good processability and low toxicity [S.A. Ponomarenko, et al., Sci. Rep. 2014, 4, 6549; T.Yu. Starikova, et al., J. Mater. Chem. C, 2016, 4, 4699]. A variety of organic luminophores allowed to design and synthesize a library of NOLs, absorbing from VUV to visible region and emitting at the desired wavelengths with maxima varying from 390 to 650 nm. Using NOLs in plastic scintillators and scintillating optical fibers, widely utilized for elementary particles detection, led to their high light output and fast decay time. Thin films of NOLs or their composites with optical plastics are transparent [M.S. Skorotetcky, et al., Silicon, 2015, 7, 191], which leads to efficient conversion of UV light in different types of photodetectors [N. Surin, at al., NIM A, 2014, 766, 160; Y. Jin, et al., NIM A, 2016, 824, 691]. Properties of NOLs and their constituent organic luminophores will be compared and discussed.

10344-26, Session 6

Structural and optical characterization of highly anisotropic low loss Al:ZnO/ZnO multilayered metamaterial with hyperbolic dispersion grown by pulsed layer deposition *(Invited Paper)*

Priscilla N. Kelly, San Diego State Univ. (United States); Wenrui Zhang, Mingzhao Liu, Brookhaven National Lab. (United States); Lyuba Kuznetsova, San Diego State Univ. (United States)

Transparent conductive oxide materials have shown unique optical properties, such as negative refraction [1], hyperbolic dispersion [2], and epsilon-near-zero dispersion [3] for incoming TM polarized light. In particular, aluminum-doped zinc oxide (Al:ZnO) has shown the most promising results over traditionally used noble metals. Pulsed layer deposition (PLD) is a popular technique due to its fast and controlled growth rate, as well as the stoichiometric target-to-substrate material transfer. But since it uses large and inhomogeneous kinetic energy, samples could be prone to macro- and microscopic defects. In this work, we investigate multilayered samples of Al:ZnO/ZnO grown by PLD with the goal of developing a low loss metamaterial with hyperbolic dispersion. Different fabrication conditions, such as Al:ZnO/ZnO ratio, the thickness of an individual layer, different substrates and deposition temperatures were investigated. Results of the cross-sectional Transmission Electron Microscopy indicate a clear layer-by-layer structure. Results of the ellipsometry analysis, based on fitting spectroscopy data using the Berreman formalism, show that the hyperbolic dispersion transition (Re ??>0, Re ??< 0) is achieved at ?c=1857 nm wavelength (Im (??)~0.03) for samples with 1:4 Al:ZnO/ZnO deposition ratio. The fitted dielectric functions for samples with various parameters show that a lower deposition temperature leads to a shorter transition wavelength. Results will be compared to our previous work [4] on designing Al:ZnO/ZnO multilayered metamaterial using atomic layer deposition. Potential applications for Al:ZnO/ZnO multilayered metamaterial will be discussed.

Integrated freestanding two-dimensional transition metal dichalcogenides *(Invited Paper)*

Gilles Lérondel, Univ. de Technologie Troyes (France)

Two-dimensional transition metal dichalcogenides (TMDs), which are atomically thin semiconductors consisting of transition metals M-(Mo, W, Sn, etc.) covalently bonded to chalcogens X-(S, Se, Te), have recently been the focus of extensive research activity due to their remarkable properties and especially emission properties. Nevertheless, such remarkable properties can strongly be altered once the atomically thin layer is deposited on a support.

In this study, we report on the integration of freestanding TMDs. Monolayer (1-L) MoS2, WS2, and WSe2 as representative TMDs are transferred on ZnO nanorods (NRs), used here as nanostructured substrates. The photoluminescence (PL) spectra of 1-L TMDs on NRs show a giant PL intensity enhancement, compared with those of 1-L TMDs on SiO2. The strong increases in Raman and PL intensities, along with the characteristic peak shifts, confirm the absence of stress in the TMDs on NRs. In depth analysis of the PL emission also reveals that the ratio between the exciton and trion peak intensity is almost not modified after transfer. The latter shows that the effect of charge transfer between the 1-L TMDs and ZnO NRs is here negligible. Furthermore, confocal PL and Raman spectroscopy reveal a fairly consistent distribution of PL and Raman intensities. These observations are in agreement with a very limited points contact between the support and the 1-L TMDs. The entire process reported here is scalable and may pave the way for the development of very efficient ultrathin optoelectronics.

10345-1, Session 1

Novel nanophotonic light sources *(Keynote Presentation)*

Marin Soljacic, Massachusetts Institute of Technology (United States)

Nanophotonic systems can support a wide variety of states of unusual properties. I will describe how some such states discovered recently could be useful for a variety of novel light sources.

10345-2, Session 1

On-chip and planar optics with alternative plasmonic materials *(Invited Paper)*

Soham Saha, Krishnakali Chaudhuri, Aveek Dutta, Clayton T. DeVault, Purdue Univ. (United States); Nathaniel Kinsey, Virginia Commonwealth Univ. (United States); Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States)

Plasmonic interconnects as well as metasurfaces manipulating the phase and amplitude of reflected and/or transmitted light, have attracted significant attention in the fields of planar optics and on-chip nanophotonics. The application space of plasmonics has recently been expanded by new materials classes including transparent conducting oxides (TCOs) and refractory transition metal nitrides (TMNs). These materials offer superior thermal stability, robustness, tailorability and CMOS compatibility, thus outperforming the conventional plasmonic components (e.g. gold and silver) in application-specific requirements. Here, we discuss recent progress in the areas of plasmonic interconnects, modulators and metasurfaces realized using TMNs and TCOs.

Ultrafast nonlinear responses near the epsilon near zero (ENZ) region have been recently demonstrated for Al doped zinc oxide (AZO) (TCO). This has spurred the development of ultrafast, on-chip modulators with TCOs as an active material. Building from on our previous work on LRSPP waveguides with ultrathin Titanium Nitride (TiN) (5.5mm propagation length) and Zirconium Nitride (ZrN), we will report solid-state hybrid mode waveguides using TiN as well as a modulator based on this waveguide which provides all-optical tunability, low optical losses at the telecommunication window, and CMOS-compatibility.

Successful integration of these alternative plasmonic components into the phase gradient metasurfaces platform without loss of performance have also been demonstrated. A metasurface employing ZrN brick antennas shows the photonic spin Hall Effect (PSHE), by reflecting the two circular polarizations in different directions. In another device, a metasurface based on nanostructures of Ga doped ZnO (TCO), functioning as a quarter-wave plate, have been realized.

10345-4, Session 1

Ultrafast carrier capture and Auger recombination in individual III-nitride nanowires *(Invited Paper)*

Stephane A. Boubanga Tombet, Los Alamos National Lab. (United States); Jeremy B. Wright, Ping Lu, Sandia National Labs. (United States); Michael R. C. Williams, Los Alamos National Lab. (United States); Changyi Li, George T. Wang, Sandia National Labs. (United States); Rohit P. Prasankumar, Los Alamos National Lab. (United States)

Group III-nitride (III-N) semiconductors are widely used in commercial optoelectronic devices to efficiently produce light, making them very attractive materials for solid-state lighting. III-N semiconductor nanowires (NWs) have garnered particular attention recently, as they can be synthesized with higher structural quality than conventional heteroepitaxial planar films, making them promising unconventional platforms for the growth of nonpolar QWs with low dislocation densities. The implementation and optimization of these GaN/InGaN NW heterostructure-based devices will require a detailed understanding of their physical properties, on which one can gain insight by studying the mechanisms governing dynamic processes in these nanosystems, such as carrier capture and recombination.

This can be done using ultrafast optical microscopy (UOM), which has previously been used to reveal the fundamental properties (both static and dynamic) of single NWs and NW heterostructures, as well as other nanomaterials. Here, we used UOM to study carrier dynamics in single GaN and GaN/InGaN nonpolar MQW core?shell NWs. We find that the time scale for initial carrier relaxation into the quantum wells strongly depends on the photoexcitation fluence, indicating that intraband Auger carrier?carrier scattering may govern carrier capture. The relaxation dynamics are also density dependent; three-carrier Auger recombination dominates the dynamics at high densities, while at lower densities bimolecular recombination is shown to be the main channel governing carrier relaxation. Our results thus shed new light on carrier dynamics in III-N MQW NW heterostructures, particularly by revealing the processes governing carrier capture and relaxation, which should impact future applications of these unique nanosystems.

10345-84, Session 1

Quantum well intermixed tunable wavelength single stripe laser diode

Thamer Tabbakh, Patrick L. LiKamWa, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

A single-quantum-well strained InGaAs/GaAs design grown on a n-doped GaAs substrate is used to fabricate a single waveguide laser diode consisting of two sections with different bandgap energies. In this experiment, half of the sample is coated with a 50nm thick silicon nitride film using plasma enhanced chemical vapor deposition, photolithography and reactive ion etching. Then a 200nm thick silicon dioxide layer is deposited by PECVD on the entire surface of the sample. After a rapid thermal annealing at 925°C for 30s, the silicon nitride coated section (A) is protected from the intermixing while the section (B) whose surface is in contact with silicon dioxide experiences a blue shift in the bandgap energy. A ridge waveguide stripe is then delineated by photolithography and wet chemical etching such that it passes through both sections. The device is then planarized using BCB resin and segmented gold contacts are deposited on top of the two sections of the waveguide top p-layer. After depositing the n-contacts on the back of the thinned down polished substrate, the device is cleaved to an overall length of 1450?m of which, 800μm of the waveguide length is in section A. By injecting 3mA in section B of the device, lasing is obtained at a wavelength of 950nm when the current in section A exceeds 18.8mA. While fixing the current in section A at 4.5mA, leads to a lasing threshold of 26mA at 910nm. The slope efficiencies are 0.06W/A and 0.18W/A for sections A and B respectively.

10345-5, Session 2

Metamaterial infrared detectors *(Invited Paper)*

Sanjay Krishna, The Ohio State Univ. (United States)

There is an increasing demand for high performance long wave infrared (LWIR) detectors with multispectral capability. Meta-materials and antenna based concepts offer some interesting solutions to win the signal to noise ratio and provide enhanced functionality at the pixel level. The long wave infrared region is appealing due to the low metallic loss, large penetration depth of the localized field and the larger feature sizes compared to the visible region. I will discuss approaches to realize multispectral detectors with examples of double metal meta-material design combined with Type II superlattice absorbers (collaboration with Padilla group at Duke University).

10345-6, Session 2

A random metasurface for an all polarizations flat lens

Matthieu Dupre, Junhee Park, Boubacar Kante, Univ. of California, San Diego (United States)

We consider gold plasmonic nanorods in the infrared domain. Such elements are very anisotropic and only polarizable along their longer dimension. Varying the nanorod length from 150 to 500 nm changes the resonant frequency of the element, which allows us to tune the phase-shift provided to an incident plane wave which electric field is parallel to the long axis. On the contrary, the nanorod is transparent to an incoming plane wave with a polarization perpendicular to its main axis. In order to provide a 0 to 2pi phase shift, we chose to work in reflection with metasurfaces made of elements with random positions and orientation. We emphasize that the length of each nanorod is not random, but strongly depends on the position of the element. It is chosen accordingly so that the reflected phase shift follows a parabolic law.

The focusing efficiency strongly depends on the density of nanorods but also of the dimensionality and of the symmetry of the metasurface. Using full wave simulations, we design ordered and random metalens and compare their characteristics. Unfortunately, simulating 2D large area metasurface is numerically challenging. Hence, we extract the transmission matrix parameters for single elements from our FDTD simulation, and model the metasurface as an array of two level atom scatterers

Finally, we present an experimental realization of such random metalens. The latter is made with conventional top-down fabrication techniques and e-beam lithography. We will show that the resulting lens focus light on diffraction limited focal spots for the two polarizations.

10345-7, Session 2

Saturation of magnetic response of parallel slabs Metamaterials

Mona H. Alsaleh, Raj K Vinnakota, Dentcho A Genov, Louisiana Tech Univ. (United States)

Metamaterials are nanocomposite materials i.e. metal- dielectric resonators in the form of split ring resonators (SRRs), parallel wires or slabs. These materials show unique optical responses such as strong magnetism at high frequency range. It is so important to have a material with negative permeability at optical frequency which is not available in nature. Decreasing the size of resonators is a crucial step toward increasing the magnetic resonance frequency (MRF), however, this scaling breaks down at high frequencies range causing a saturation of MRF. In this work, we present a transmission line theory to model the magnetic response for pair of metallic nanostripes separated by a dielectric material. The magnetic response of parallel stripes system is due to antiparallel current in the stripes which forms a circular current that induces a magnetic moment. The predicted model represents the magnetic response by a magnetic susceptibility and MRF. The theoretical results show excellent agreement with the exact numerical simulations calculated by utilizing commercial software (Comsol Multiphysics). Specifically, we studied MRF as a function of the resonator's sizes and our parametric study of the MRF shows that scaling down the resonator sizes increases MRF and as we further decreases the resonator's size, the MRF saturates at frequency ranging from (150 – 600) THz. This is explained by the fact that at high frequencies, within the infrared and optical range, the metal strips behave as capacitive elements which precludes the excitation of magnetic resonances for frequencies higher than the surface plasma frequency of the system.

10345-8, Session 2

Fluorescence enhancement in fluidic nanochannels for dynamic molecular optical detection *(Invited Paper)*

Pablo A. Postigo, Raquel Alvaro, Instituto de Microelectrónica de Madrid (Spain); Aritz Juarros, IK4 Tekniker (Spain); Santos Merino, IK4 Tekniker (Spain) and Instituto de Microelectrónica de Madrid (Spain)

We show the fabrication of a novel optofluidic chip that uses a a network of nanochannels optimized for the transport of DNA-stretched molecules. The molecules can move through the nanochannels in the femto-liter per second. The nanochannels are optically accessible via a transparent cover of pyrex, allowing fluorescence microscopy imaging of the travelling molecules. The nanochannels are surrounded by photonic crystal structures to enhance the emission of the fluorescent light. The photonic crystal structures provide an enhancement up to 2.5 times in the light emitted by fluorescent molecules in motion inside the nanochannels which increases to around 250 when normalized to the area of the nanochannels emitting fluorescence. The results may help to the detection of fluorescent molecules (like marked-DNA) in series by speeding it or allowing the use of less sophisticated equipment.

10345-9, Session 2

Whispering gallery mode polymer fiber refractive index sensors fabricated by near-field electrospinning

Joseph E. Cheeney, Stephen T. Hsieh, Nosang V. Myung, Elaine D. Haberer, Univ. of California, Riverside (United States)

Because of their ability to serve in chemical and biological applications, there is a growing need for sensitive, compact, readily fabricated, and inexpensive refractive index sensors. In recent years, devices that utilize whispering gallery modes (WGMs) have proven versatile in many such applications, however, these reports have typically used fabrication techniques that are either complex, do not produce sensitive devices, or are expensive. One possible solution is to use polymer materials in conjunction with near-field electrospinning (NFE). This direct-write fabrication approach enables fast, yet precise positioning of micron-sized fibers for low-cost, scalable sensor manufacturing. Moreover, NFE can be used to incorporate additional functionality such as emitters for optically active sensing or receptors for enhanced selectivity. Here, fluorescent dye-doped polymer fiber refractive index sensors that support WGMs within the fiber cross-section were demonstrated. Resonators were fabricated using NFE to draw fibers from a 25 wt% poly(vinyl) alcohol polymer solution doped with 0.38 mM rhodamine 6G onto a substrate patterned with deep trenches. The suspended fibers ranged from 2 to 22 μm in diameter and displayed circular cross sections. Using microphotoluminscence, high-Q resonant peaks were observed in the emission range of the dye, from 540-630 nm. Using size-dependent mode spacing predicted by finite-difference time domain simulations and polarized optical microscopy, the resonances were identified as first order WGMs. Refractive index sensing was evaluated using a range of glucose solution concentrations. The WGM resonators fabricated here have demonstrated the potential of near-field electrospun polymer-based fibers for sensitive sensing applications.

10345-10, Session 2

Active plasmonic antennas

Kai Braun, Florian Laible, Alfred J. Meixner, Monika Fleischer, Eberhard Karls Univ. Tübingen (Germany)

Within the last decade gap antennas have been widely studied and are commonly used due to the strongly enhanced coupled electrical fields within their gaps. Many emerging nanophotonic technologies depend on the careful control of this plasmonic coupling, including optical nanoantennas for high-sensitivity sensors and Raman enhanced applications. Typically the distances between the metallic nanostructures range from several tens of nm down to a few nm. Only recently several groups managed to produce and measure ultra narrow gaps, which show new phenomena such as coherent quantum tunneling and improved luminescence enhancement or additional radiative recombination channels. These effects will become crucial in nanoscale optoelectronics and may pave the way to single molecule opto-electronics.

In this work, we will present an approach based on tunneling feedback, which therefore offers excellent distance control down to several angstrom. In this configuration the shape of the plasmonic tips in the gap region is preselected. This way, the junction region and the plasmon resonances of the plasmonic tips can be changed, while the tunneling feedback gives rise to a controlled approach to sub-nanometer distances. Additionally the tunneling junction allows for further manipulation of the antenna via the applied bias voltage. We will present variations of different geometries under defined polarized illumination and show the dependency of the plasmon resonances on varied distances and the applied bias voltages.

10345-13, Session 3

Low-threshold lasing in coupled resonator optical waveguides with exceptional points of degeneracy

Mohamed A. K. Othman, Mohamed Y. Nada, Mehdi Veysi, Alexander Figotin, Filippo Capolino, Univ. of California, Irvine (United States)

Burgeoning interest in slow-light based photonic devices has spawned the concept of exceptional points in optical devices leading to many intriguing applications. In essence, exceptional points of degeneracy (EPD) are points in the spectrum of systems at which state eigenvectors coalesce. Aside from the EPD emergence in gain and loss balanced non-Hermitian systems such as those obeying the PT-symmetry; EPDs can still occur in lossless periodic structures without the presence of gain and loss. We demonstrate for the first time the emergence of EPDs in the eigenstates of lossless coupled resonator optical waveguides (CROWs) which enhance the performance of many devices, in particular optical amplifiers and lasers. Moreover, EPDs of various order can also be designed in CROWs by engineering the geometric parameters. First, we report a design of CROWs with periodic coupling and geometrical-symmetry breaking, in which EPDs of various orders can be found, and we investigate realistic considerations including losses and imperfections. We then show anomalous scaling law of the quality factor operating near a fourth order EPD, namely the degenerate band edge (DBE). We demonstrate that EPDs are associated with slow-light, in the sense that the group velocity of waves near EPD vanishes implying large local density of states. Furthermore, we demonstrate low threshold lasing operation and high slope efficiency when using a fourth EPD in laser cavity supporting the degenerate band edge (DBE). In fact, we also report that EPDs with various orders would lead also to unique scaling of the lasing threshold which can be beneficial for boosting the performance of lasers and sensors. As an example, we show a CROW design based on Silicon-on-insulator (SOI) technology and report the lasing action in such configuration using finite-different time domain (FDTD) along with the nonlinear rate equations in a four-level energy system describing the gain medium inside the CROW.

10345-14, Session 3

Ultrafast and quantum dynamics of plasmonic nanolasing and surface-plasmon polariton condensation *(Invited Paper)*

Ortwin Hess, Imperial College London (United Kingdom)

Nanoplasmonic stopped-light lasing is a recently established principle [1] that not only opens the door to ultrafast cavity-free nanolasing, ultra-thin lasing sufaces exploiting van Hove singularities [2] and cavity-free quantum-electrodynamics but also provides an entry point to quantum gain in quantum plasmonics. We show that engineered singularities in the density of optical states realised in a metal-dielectric-metal nano-waveguide structure lead to a stopped-light feedback mechanism that is the basis for the dynamics of the observed cavity-free photonic and surface-plasmon polariton nanolasing. The condensed surface plasmon polaritons are characterised by ultrafast spatio-temporally oscillating amplified surface-plasmon polaritons on ultrafast timescales <5 femtoseconds and with spatial periods on the nanoscale <100 nm.

10345-15, Session 4

Controlled and tunable multi-modal lasing from plasmonic superlattices *(Invited Paper)*

Teri W. Odom, Northwestern Univ. (United States)

Band structure engineering is critical for controlling the emission wavelengths and efficiency in electronic and photonic materials. Single band-edge states that show trapped slow light have been used as high-quality optical feedback for lasing from photonic bandgap crystals and metal-dielectric waveguides. Recently, we demonstrated that single band-edge lattice plasmons in periodic metal nanoparticle arrays could contribute to single-mode lasing at room-temperature with directional emission. However, the manipulation of more than a single band-edge mode for nanolasing has not been possible because of limited cavity designs. This talk will describe a new architecture based on plasmonic superlattices—finite-arrays of nanoparticles grouped into microscale arrays—to achieve tunable and controllable multi-modal lasing. The underlying mechanism was found to depend on trapped slow light at both zero and non-zero wavevectors. We will discuss how the spectral separation and spatial emission angles of the lasing modes can be exquisitely manipulated by changing patch periodicity.

Such characteristics may enable multi-frequency multiplexing and fast-processing of nanoscale coherent light for on-chip photonic integration.

10345-16, Session 4

Nanolasers based on high-quality factor plasmonic resonators

Amit Agrawal, Wenqi Zhu, Henri J. Lezec, Shawn Divitt, National Institute of Standards and Technology (United States); Ting Xu, Nanjing Univ. (China)

Coherent optical sources with small device footprints, narrow-linewidth, and room-temperature operation are desirable for potential applications in on-chip optical communications. Surface plasmons, under the form of both stationary localized surface plasmons or propagating surface plasmon polaritons (SPPs), offer an effective route towards achieving lasing at micro- and nano-scale dimensions when integrated with a suitable optical gain medium. However, intrinsic absorption and scattering losses limit the quality factors (Q) associated with plasmonic cavity resonators to <10, thereby deteriorating the threshold properties and emission linewidth of plasmonic lasers or requiring low-temperature operation. Recent publications utilizing the template-stripping approach to achieve ultra-smooth metal surfaces have pushed the Q-factors of plasmonic resonators beyond 300, resulting in successful room-temperature lasing operation. Here, we demonstrate novel plasmon resonator geometries consisting of ultra-smooth metal surfaces that support surface plasmon polariton modes exhibiting record-high quality factors (>750) in the visible frequency range. The resonators are utilized to achieve record narrow-linewidth, low-threshold surface-plasmon-polariton lasing at optical frequencies, as well as exhibit high figure-of-merit sensing. The open-cavity architecture of the plasmonic resonators also makes them suitable for high figure-of-merit optical sensing; for example, the evanescent interaction between analytes and localized electromagnetic fields within a lasing cavity can result in their detection with high sensitivity in a label-free manner.

10345-17, Session 4

Spatial intensity of plasmonic distributed feedback lasers

Ke Guo, Femius Koenderink, FOM Institute for Atomic and Molecular Physics (Netherlands)

Depending on the strength of diffractive coupling, distributed feedback (DFB) lasers can support different lasing modes with distinctive spatial intensity distributions. Compared with conventional DFB lasers, a plasmonic DFB laser can have quite different coupling strength due to the much stronger scattering from the plasmonic lattice and the metallic losses. Here we study the spatial intensity distribution and coupling strength of plasmonic DFB lasers depending on the size of the plasmonic nano-particles. We show that the plasmonic resonance supported by the nano-particles allows us to achieve large and complex coupling strength values with small lattices, offering easy approaches to the optimization of the plasmonic DFB lasers.

10345-18, Session 4

Dynamics and coherence of metal-clad nanolasers

Si Hui Pan, Univ. of California, San Diego (United States); Qing Gu, The Univ. of Texas at Dallas (United States); Abdelkrim El Amili, Felipe Vallini, Univ. of California, San Diego (United States)

Metal-clad nanolasers with high spontaneous emission factors (?) represent a class of ultra-compact light emitters with applications in fiber-optic communications, hybrid and all optical computing, imaging and sensing. In-depth studies on both the coherence and dynamical properties of these emitters are necessary before practical applications can be realized. However, the coherence characterization of a high-? nanolaser using the conventional measurement of output light intensity versus input pump intensity (L-L curve) is inherently difficult due to the diminishing kink in the measurement curve. We conducted the second order intensity correlation measurement, or g2(?) — a more definitive method to confirm coherence — on a high-? metallo-dielectric nanolaser under nanosecond optical pulse pumping. Our result indicates that full coherence is achieved at three times the threshold conventionally defined by the kink in the L-L curve. Additionally, we observed that the g2(?) peak width shrinks below and broadens above threshold. Rate-equation analyses reveal that the above-threshold broadening is due to the delayed threshold phenomenon, providing the first observation of dynamical hysteresis in a nanolaser. We propose that this dynamical phenomenon can be exploited to determine the lasing regimes of a unity-? nanolaser, whose threshold is inherently ambiguous and difficult to observe.

10345-19, Session 4

Large Purcell enhancement in perovskite plasmonic nanolaser

Sui Yang, Wei Bao, Xiaoze Liu, Jeongmin Kim, Rongkuo Zhao, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

Halide perovskite semiconductors are an emerging class of materials that have shown great promise as nanophotonic and optoelectronic devices owing to their remarkable properties such as high radiative efficiency and low trap-state density. For applications in optical information processing and communications, however, the challenging requirements that must be met simultaneously are compact size, ultrafast, scalability, and room temperature operation. Here we demonstrate a deep subwavelength perovskite plasmonic nanolaser at room temperature with ultralarge Purcell enhancement by a scalable solution process. The nanalser enables a strong optical confinement by hybridizing perovskite single crystals with surface plasmon. It thus not only downscales the device but also facilitates its emission efficiency dramatically exhibiting a clear single mode lasing behavior at room temperature. With such superior lasing activity, more importantly, the perovskite plasmonic nanolaser enables an expedited emission dynamics of the device and achieves experimental Purcell enhancement over 200, the largest experimental value in reported lasers so far. Such significantly accelerated spontaneous dynamics inherently enhances stimulated emission and facilitates laser gain compensation due to the intrinsic relationship between Einstein's coefficients. The capability to combine plasmonic confinement with ultrafast amplification through perovskites not only promises fundamental physics for accelerating light–matter interactions but also opens new avenues for applications from ultrafast integrated optical communications to implantable computing microchips.

10345-20, Session 4

Hybrid photonic crystal lasers for wavelength division multiplexing *(Invited Paper)*

Liam O'Faolain, Cork Institute of Technology (Ireland) and Univ. of St. Andrews (United Kingdom) and Tyndall National Institute (Ireland)

The last decade has seen huge growth in the use of optical datacommunications. Silicon Photonics has produced high speed modulators, photodetectors and the associated electronics and is proving itself to be one of the most promising technologies for cost-effective fabrication of photonic components and integrated circuits. However, there are some major challenges in terms of device performance and, in particular, the development of efficient light emission from silicon has been the subject of a large body of research. The need for Wavelength

Division Multiplexing in the datacenter is stimulating significant research efforts into unconventional lasers. Here we demonstrate a hybrid external cavity laser architecture that provides a high performance, cost-effective silicon photonics compatible laser. A photonic crystal cavity is used as a resonant reflector and due to the enhanced light-matter interaction in the high Q-factor Photonic Crystal (PhC) reflectors, the device operates in a highly non-linear mode. With suitable design, a self-tuning effect is realised that reduces the laser's sensitivity to external temperature fluctuations. PhC cavities provide very precise control of their resonant wavelengths by lithographic tuning. Hybrid integration provides a means to combine the III-V and silicon components. Flip-chip bonded versions of these lasers are suitable for integration with our previously demonstrated active and passive PhC components for the realization of more complex power-efficient Si photonic systems

10345-21, Session 4

Fabrication of low-threshold ZnO nanorod array random lasers

Hideki Fujiwara, Ryo Niyuki, Keiji Sasaki, Hokkaido Univ. (Japan)

Random lasers (RLs) have recently expected as unique speckle-free laser light sources for sensors and imaging. To improve the controllability of RLs, we have proposed a novel resonance-controlled RL, which were composed of agglomerated mono-dispersed spherical ZnO nanoparticles. Although the resonance-controlled RL has unique features such as quasi-single-mode and low lasing threshold, there is an issue that an optical input-output becomes difficult due to its randomness. In contrast, because a two-dimensional nanorod array can also induce light localization via in-plane multiple light scattering, the accessibility of excitation and lasing light in the vertical direction could be expected to be improved comparing with agglomerated nanoparticles. As the fabrication method of nanorod array structures, a laser-induced hydrothermal synthesis using a local heating by laser irradiation on a gold thin film has recently been proposed. Because, unlike the conventional hydrothermal synthesis method, this method can easily control the size of nanorods by the control of irradiated laser power and time, we attempted to realize the resonance-controlled two-dimensional RL in nanorod array structures, like our previous study. In the presentation, we will introduce our recent progress on resonance-controlled ZnO nanorod array RLs. In the experiments, we succeed to induce random lasing in ZnO nanorod array structures fabricated by a laser-induced hydrothermal synthesis, and find that their thresholds strongly depend on the growth time (nanorod size). These results suggest the possibility to control the RL properties simply by tuning the irradiated laser conditions.

10345-87, Session 4

Nanowire array lasers on silicon for optical links

Diana L. Huffaker, Cardiff Univ. (United Kingdom); Hyunseok Kim, Univ. of California, Los Angeles (United States); Wook-Jaee Lee, Cardiff Univ. (United Kingdom)

Semiconductor nanowire lasers have recently gained attention as ultra-compact coherent light sources in the field of nanophotonics. Because nanowires can be grown on lattice-mismatched substrates, directly integrating nanowires on silicon is regarded as one of the promising ways to monolithically integrate functional light sources on silicon photonic platforms. Here, we report InGaAs/InGaP core/shell nanowire array lasers directly grown on a silicon-on-insulator (SOI) platform operating at room temperature. The growth platform is prepared by dry etching SOI(111) substrates to pattern waveguides, output grating couplers, and mesas. Nanowires are then grown on silicon mesas as a one-dimensional photonic crystal array by selective-area epitaxy using metal-organic chemical vapor deposition (MOCVD). InGaAs nanowires are passivated by InGaP shells to enhance the radiative efficiency by reducing non-radiative surface recombination. Vertical InGaAs/InGaP core/shell nanowire arrays are grown on SOI platform, where the nanowire array is directly connected to a conventional SOI waveguide to demonstrate coupling characteristics. The nanowire array cavity is optically pumped by a pulsed laser with 660 nm wavelength, 30 ps duration, and 78 MHz repetition rate at room temperature. Photoluminescence measurements reveal that the lasing peak dominates other peaks be increasing the pump power, resulting in the lasing threshold of 90 uJ/cm2 and the side-mode suppression ratio (SMSR) of 16.7 dB at the pump fluence of 131 uJ/cm2. These results suggest that the proposed nanowire array lasers could be the enabling technology for ultracompact and energy-efficient optical links.

10345-22, Session 5

High temperature hyperbolic metamaterial for selective thermal emitters in thermophotovoltaic (TPV) systems *(Invited Paper)*

Manfred Eich, Technische Univ. Hamburg-Harburg (Germany) and Helmholtz-Zentrum Geesthacht (Germany); Alexander Y. Petrov, Technische Univ. Hamburg-Harburg (Germany); Pavel N. Dyachenko, Technische Univ Hamburg-Harburg (Germany); Sean Molesky, Univ. of Alberta (Canada); Zubin Jacob, Purdue Univ. (United States); Michael Störmer, Helmholtz-Zentrum Geesthacht (Germany); Tobias Krekeler, Martin Ritter, Technische Univ. Hamburg-Harburg (Germany)

In order to tailor thermophotovoltaic emitters to match specific photovoltaic receivers a spectrally selective emitter is required that has a close to black body emission at short wavelengths and substantially reduced emission at long wavelengths. We propose a hyperbolic metamaterial for this purpose which changes its emission properties close to the topological transition of its isofrequency surface. At short wavelengths the metamaterial has a permittivity close to one and thus efficiently absorbs and emits radiation. At longer wavelength, beyond the topological transition, the thermally excited hyperbolic modes have large wave vectors and radiation thus cannot leave metamaterial due to total internal reflection. To emit significant power at wavelengths usable for photovoltaic conversion (<2 μm) the far-field emitter should be heated to high temperatures and thus must be thermally stable.

We demonstrate selective band-edge emitters based on a W-HfO 2 layered metamaterial. The thicknesses of the tungsten and hafnium oxide are 20 and 100 nm correspondingly. The metamaterial selectivity comes from the change in effective permittivity and does not rely on the phase matching condition. Thus the metamaterial exhibits almost angle independent selective emission. Stability up to 1000°C is demonstrated in vacuum conditions. At higher temperature residual oxygen in vacuum diffuses through the HfO 2 cap layer and oxidizes the upper W layer of the metamaterial leading to degradation of the selective emission.

10345-23, Session 5

Perfect and tunable electromagnetic absorption using epsilon-near-zero metamaterials and graphene-polymer heterostructures *(Invited Paper)*

Michaël Lobet, Bruno Majérus, Luc Henrard, Michaël Sarrazin, Philippe Lambin, Univ. of Namur (Belgium)

No Abstract Available.

10345-24, Session 5

3D gradient refractive index micro-optics *(Invited Paper)*

Paul V. Braun, Christian Ocier, Univ. of Illinois at Urbana-Champaign (United States)

Via electrochemical etching of silicon, followed by materials conversion, 3D gradient refractive index micro-optics including flat lenses, Bragg mirrors, polarization sensitive optical splitters and structures with nearly arbitrary refractive index distributions were formed with a particular focus on micro-optics important for solar energy harvesting. The conversion from silicon to silica and titania enabled the optics to operate in the visible with minimal loss, something particularly important for solar energy harvesting applications. A detailed model was developed which enabled tight control over optical properties based only on the electrochemical etch conditions.

10345-25, Session 5

Near-unidirectional superemitters enabled by cascaded phonon-polariton resonances

Ganga C. R. Devarapu, Cork Institute of Technology (Ireland); Stavroula Foteinopoulou, The Univ. of New Mexico (United States)

Phonon-polariton (Reststrahlen-band) materials have been hitherto little explored for photonic applications, since they are near-perfect reflectors in bulk form. Judicious microstructures comprising these materials can support localized resonances, with a large infrared field enhancement, as their plasmonic counterparts do in the visible. We propose here a SiC micropyramid paradigm, which by virtue of a strongly-asymmetric cascaded coupling to these resonances, behaves as a near-unidirectional superemitter, with an emissivity enhanced by as much as fifteen times with respect to bulk SiC. Our proposed platforms will benefit the design of infrared sources and detectors as well as passive radiative cooling devices.

10345-26, Session 5

Measuring and exploiting optical anisotropies in nanophotonic photovoltaics

Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Nanophotonic coatings and structures provide an attractive approach for enhancing light-matter interactions in advanced photovoltaics. A little-discussed aspect of many photonic architectures is the presence of strong anisotropies in the electromagnetic field enhancements. These anisotropies are of particular importance in relation to nanostructured materials that possess intrinsic structure-dependent optical anisotropies. In this talk, we describe a novel class of momentum-resolved spectroscopies that provide new insight into structure-dependent optical properties of thin-film material and discuss approaches to exploit these effects in photovoltaic devices that incorporated nanophotonic enhancements.

Specifically, we use Fourier imaging techniques to measure or control the momentum distribution of in-coming or out-going light rays respectively. These techniques are applied to test-case organic photovoltaic materials that can be deposited with distinct morphologies depending on processing conditions. Using momentum-resolved photoluminescence, we determine the morphology-dependent orientation of transmission and absorption dipoles. We subsequently demonstrate the use of momentum-resolved reflectometry to perform "model-free" measurements of optical constants. The approach provides precise and accurate optical constants with quantified error estimates, obviating the complications associated with highly model-dependent, multi-parameter spectral fitting procedures used in ellipsometry. We conclude by describing ongoing efforts to exploit optical anisotropies to enhance light absorption in nanostructured photovoltaics.

10345-27, Session 5

Effectively infinite optical path-length created using a simple-cubic photonic crystal for extreme light-trapping *(Invited Paper)*

Shawn-Yu Lin, B. J. Frey, Rensselaer Polytechnic Institute (United States); Mei-Li Hsieh, National Chiao Tung Univ. (Taiwan); Ping Kuang, Rensselaer Polytechnic Institute (United States); J.-H. Jiang, Sajeev John, Univ. of Toronto (Canada)

In this talk, I will describe the fabrication of a TiO2 simple cubic photonic crystal and its use to experimentally validate a newly-discovered mechanism for extreme light-bending. Absorption enhancement was observed extending 1-2 orders of magnitude over that of a reference TiO2 film. Several enhancement peaks in the region from 600-950 nm were identified, which far exceed both the ergodic fundamental limit and the limit based on surface-gratings, with some peaks exceeding 100 times enhancement. These results are attributed to radically sharp refraction where the optical path length approaches infinity due to the Poynting vector lying nearly parallel to the photonic crystal interface. The observed phenomena follow directly from the simple cubic symmetry of the photonic crystal, and can be achieved by integrating the light-trapping architecture into the absorbing volume. These results are not dependent on the material used, and can be applied to any future light trapping applications such as phosphor-converted white light generation, water-splitting, or thin-film solar cells, where increased response in areas of weak absorption is desired.

10345-28, Session 6

Extra-ordinary modulators with 2D photonic materials *(Invited Paper)*

Volker J. Sorger, The George Washington Univ. (United States)

We show that nanophotonic device performance scales non-monotonically with critical length. Such scaling can be synergistic with the atomistic-scale of 2D materials. The naturally-low modal overlap factor can be engineered to approach 1% for electric in-plane field polarization waveguides, i.e. slot-waveguides. Moreover, we show that a polaritonic mode character (i.e. plasmonic) improves the modulator performance by about 10x due to (i), a lower contact resistance from synergistic use of one contact, and (ii) the higher modal group index. As an example we discuss our demonstration of the 1st sub-1Volt electro-optic modulator based on 2D material plasmonic hybrid integration on Silicon.

10345-29, Session 6

Fast and highly sensitive ionic polymer gated WS2-graphene photodetectors

Jake Mehew, Selim Unal, Elias Torres Alonso, Gareth F. Jones, Saad Fadhil Ramadhan, Monica Craciun, Saverio Russo, Univ. of Exeter (United Kingdom)

Student Contribution: The combination of graphene with semiconductor materials in heterostructure photodetectors, has enabled amplified detection of femtowatt light signals using micron-scale electronic devices. Presently, the speed of such detectors is limited by long-lived charge traps and impractical strategies, e.g. the use of large gate voltage pulses, have been employed to achieve bandwidths suitable for applications, such as video-frame-rate imaging.

In this work, we report graphene-few layer WS2 heterostructure photodetectors encapsulated in an ionic polymer, which are uniquely able to operate at bandwidths up to 1.5 kHz, whilst maintaining internal gain as large as 10^6. Highly mobile ions and a nanometre scale Debye length of the ionic polymer are used to screen charge traps and tune the Fermi level of graphene over an unprecedented range at the interface with WS2. We observe a responsivity R = 10^6 A/W and detectivity D* = 3.8x10^11 Jones, approaching that of single photon counters.

The combination of both high responsivity and fast response times makes these photodetectors suitable for video-frame-rate imaging applications.

10345-30, Session 6

MoS2 exciton-polaritonics in dielectric photonic structures *(Invited Paper)*

Ertugrul Cubukcu, Xingwang Zhang, Univ. of California, San Diego (United States)

Direct bandgap transition metal dichalcogenides such as monolayer MoS2 offer interesting optical properties arising from room-temperature stable excitons in these materials. In this talk, we will present our results on 1000 times enhanced and highly directional (~5 degrees) excitonic emission coupled to photonic Fano resonances of a dielectric system. We will also talk about electrical and dynamic control of coupling between charged excitons of MoS2 and photonic resonances. In the last part, we will discuss some recent results on waveguiding in monolayer materials based on leaky modes and exciton-polaritons and exciton diffusion effects.

10345-31, Session 6

Ultrafast radiative heat transfer

Renwen Yu, ICFO - Institut de Ciències Fotòniques (Spain) and The Barcelona Institute of Science and Technology (Spain); Alejandro Manjavacas, The Univ. of New Mexico (United States); F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and The Barcelona Institute of Science and Technology (Spain) and ICREA-Institució Catalana de Recerca i Estudis Avançats (Spain)

Light absorption in conducting materials produces heating of their conduction electrons, followed by relaxation into phonons within picoseconds, and subsequent diffusion into the surrounding media over longer timescales. This conventional picture of optical heating is supplemented by radiative cooling, which typically takes place at an even lower pace, only becoming relevant for structures held in vacuum or under extreme thermal isolation. Here, we reveal an ultrafast radiative cooling regime between neighboring plasmon-supporting graphene nanostructures in which noncontact heat transfer becomes a dominant channel. We predict that more than 50% of the electronic heat energy deposited on a graphene disk can be transferred to a neighboring nanoisland within a femtosecond timescale. This phenomenon is facilitated by the combination of low electronic heat capacity and large plasmonic field concentration in doped graphene. Similar effects should occur in other van der Waals materials, thus opening an unexplored avenue toward efficient heat management.

10345-32, Session 6

Electrical properties of SiO2-based graphene under monochromatic visible light irradiation

Xiangdi Li, Xianming Liu, Xueying Cao, Peng Zhang, Xiaohua Lei, Weimin Chen, Chongqing Univ. (China)

Graphene with atomic scale thickness is film material of optically transparent and electrically conductive, which can be typically used as electrodes when a situation calls for low resistance electrical contacts without blocking light (e.g. touch panels, photovoltaics). There were many reports about the electrical conductivity change when the graphene irradiated under ultraviolet light, which were not the actual working environment. It is necessary to understand the stability of electrical properties of graphene film under visible light irradiation.

The purpose of this study is to investigate the electrical properties of graphene transparent conductive film under visible light irradiation. Samples in the study were chemical vapor deposition (CVD) growth graphene on the surface copper foils and then transferred to the SiO2 substrate. The electric resistance measurements were performed using a two-probe configuration on the graphene films placed inside a vacuum chamber with optical windows. Three monochromatic visible lights with wavelength of 635nm, 520nm and 450nm representing red(R), green(G) and blue(B) lights were used as irradiation sources, which were widely used in back lit displays. The irradiated power density on the samples could be adjusted in the experiments. Results show that the graphene resistances increased slowly under light irradiation with all the three different wavelengths, while decreased slowly as well after the light was switched off. The relative rates of resistance change were different under irradiation with the same density but different wavelength. Blue light irradiation may result in the largest resistance change.

10345-33, Session 7

Enhanced nonlinearities in transparent conducting oxides for ultrafast photonics *(Keynote Presentation)*

Clayton T. DeVault, Purdue Univ. (United States); Nathaniel Kinsey, Virginia Commonwealth Univ. (United States); Lucia Caspani, Heriot-Watt Univ. (United Kingdom); Matteo Clerici, Heriot-Watt Univ. (United Kingdom) and Univ. of Glasgow (United Kingdom); Kaipurath Muhammad Rishad, Thomas Roger, Enrico Carnemolla, Heriot-Watt Univ. (United Kingdom); Jongbum Kim, Amr M. Shaltout, Purdue Univ. (United States); Monica Pietrzyk, Andrea Di Falco, Univ. of St. Andrews (United Kingdom); Daniele Faccio, Heriot-Watt Univ. (United Kingdom); Alexandra Boltasseva, Purdue Univ. (United States); Marcello Ferrera, Heriot-Watt Univ. (United Kingdom); Vladimir M. Shalaev, Purdue Univ. (United States)

Coherent control of nonlinear and ultrafast plasmon-polariton mediated interactions has attracted wide attention for its potential for enhancing functionality in nano-scale photonic devices and applications. Contemporary research in ultrafast and nonlinear plasmonics primarily utilizes noble metals, such as gold and silver, as material platforms because of their high performance both in linear and nonlinear optical properties. Unfortunately, noble metals possess numerous drawbacks including low melting points, chemical instabilities, and an incompatibility with standard CMOS processing techniques, all of which hamper their incorporation into functional plasmonic devices. Here we investigate the mid-infrared ultrafast and nonlinear properties of the alternative plasmonic material, aluminum-doped zinc oxide (AZO). By performing time-resolved pump-probe spectroscopy, we observe an unprecedentedly large and ultrafast (sub-picosecond) response in AZO thin films for both intra- and inter-band pumping frequencies. These two nonlinearities arise from distinct electron excitation dynamics and, as such, can be controlled simultaneously and independently to provide a novel method of dynamic tunability. We demonstrate this phenomenon with two-color excitation and find our AZO films exhibit a THz modulation bandwidth. We also probed the nonlinear response of AZO films at the epsilon-near-zero (ENZ) frequency and observed a dramatic increase in the Kerr nonlinearity with an induced refractive index change on the order of unity. In summary, our ultrafast and nonlinear studies strongly support AZO as an alternative plasmonic material with qualities pertinent to the development and realization of practical plasmonic technologies.

10345-34, Session 7

Molding optical wavefronts with nonlinear active photonic platforms *(Invited Paper)*

Xiang Zhang, Nir Shitrit, Univ. of California, Berkeley (United States)

The emerging photonic platform of gradient metasurfaces has paved the way for new era of light manipulation. By incorporating meta-atoms with strong nonlinear light-matter interactions, nonlinear gradient metasurfaces takes the molding of optical wavefronts to a higher level, enabling new functionalities that cannot be achieved with linear metasurfaces. Moreover, by harnessing nonlinear dynamics in active photonic waveguides, on-chip light control of complex wavefronts is accessible with nanoscale cross-sectional area in stark contrast with metasurface platforms. In this talk, we will review the recent progress in nonlinear gradient metasurfaces and active photonic waveguides for extreme molding of light.

10345-35, Session 7

Tunable chiral metasurfaces based on the transfer of electromagnetic angular momentum

Sophie Viaene, Vrije Univ. Brussel (Belgium) and Chalmers Univ. of Technology (Sweden); Vincent Ginis, Jan Danckaert, Vrije Univ. Brussel (Belgium); Philippe Tassin, Chalmers Univ. of Technology (Sweden)

Chiral metasurfaces are widely recognized for their realization of strong optical activity and asymmetric transmission. Unfortunately, their use in photonic applications is limited by the fact that most chiral metasurface designs are static, i.e., it is not possible to tune the chiral response with an external time-dependent signal. In this contribution, we investigate whether the electromagnetic torque due to a circularly polarized pump beam provides a viable mechanism for the active control of chiral torsional metasurfaces. Our torsional metasurface consists of two cross-wire surfaces, connected by filaments in such a way that elements within one unit cell can rotate with respect to each other. We show that, in presence of friction and restoring torques due to the filaments, a microwave pump beam may use its torque to temporally modify the angular orientation between the right and the left layers. In particular, we provide a full analysis of the nonlinear dynamics of the rightmost layer to determine the equilibrium orientations and their bifurcations as a function of the power and the frequency of the beam. A subsequent parameter sheet retrieval of the chiral response explicitly demonstrates its tunability in terms of the input power and frequency. Overall, our work shows that an electromagnetic torque due to circularly polarized microwaves may sufficiently tune the chiral response of the torsional metasurfaces with realistic pumping powers.

10345-36, Session 7

Enhanced nonlinear optical interactions in 2D-3D heteromaterials *(Invited Paper)*

Nicolae Coriolan Panoiu, Jian Wei You, Univ. College London (United Kingdom)

We briefly discuss some theoretical concepts and methods widely used in the study of optical nanostructures and explain how they can be extended to incorporate quadratic and cubic nonlinear optical effects in 2D materials. We illustrate how these tools can be used to design nonlinear photonic devices containing 2D materials in which orders-of-magnitude nonlinearity enhancement is achieved. Specifically, we demonstrate strongly enhanced nonlinear optical interactions in photonic nanostructures via resonant excitation of nonlinear waveguide modes, enhanced optical nonlinearity of nanostructures containing graphene and transition-metal dichalcogenide nanomaterials, and tunable Fano resonances for increased frequency conversion efficiency of hybrid 2D-3D photonic heteromaterials.

10345-37, Session 7

Nonlinear tuning of resonance in metamaterial absorbers *(Invited Paper)*

Subramaniam Anantha Ramakrishna, Sriram Guddala, Indian Institute of Technology Kanpur (India)

Metamaterials are structured composite materials that give rise to unique properties due to the resonant interaction of the structure with electromagnetic waves. As an example, arrays of structures can be tailored to have electric and magnetic resonances so as to have optimized impedance matching for high absorption at selected bands of frequency from visible to microwaves. The resonant structures have large localized fields that can enhance nonlinear responses of the constituent materials. The nonlinear response allows one to dynamically tune the resonance of the metamaterial structure and change its response.

Two cases of nonlinear and switchable resonant metamaterial absorbers will be presented:

(i) a metamaterial perfect absorber made of structured aluminum, where the nonlinearity originates in the change of conductivity of aluminum with increased temperatures. The thermal nonlinearity changes the behaviour of the metamaterial due to heating caused by the absorption of light.

(ii) a nonlinear metamaterial made of an array of gold discs separated from a continuous gold thin film by a thin film of ZnS, where the Kerr-nonlinearity of gold plays a defining role. This metamaterial acts as a reflective clamp whereby the reflected intensity does not increase beyond a point, for intense picosecond laser pulses. Strong local field enhancements in the ZnS film result in multi-photon fluorescence from ZnS and enhance the nonlinear response of ZnS. The enhanced nonlinear response of ZnS contributes an equal amount to the phenomenon although its intrinsic nonlinearity is four orders of magnitude smaller than that of gold.

Graphene terahertz photonics *(Invited Paper)*

Philippe Tassin, Chalmers Univ. of Technology (Sweden)

Graphene is an interesting material for terahertz photonics, because of its gate voltage tunability and its support of surface plasmon polaritons. I will review our recent work on graphene terahertz photonics. First we have studied the scattering behavior of graphene with an externally modulated conductivity and we show that this leads to a mechanism for tunable terahertz frequency combs. Second, we study the nonlocal response of graphene and its implications on surface plasmon excitations. Third, I discuss the potential of graphene plasmons, which are sensitive to the index of refraction of tiny amounts of an analyte on their surface.

10345-40, Session 8

Instantaneous and transient nonlinearities of graphene plasmons

Joel D. Cox, ICFO - Institut de Ciències Fotòniques (Spain); F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and ICREA-Institució Catalana de Recerca i Estudis Avançats (Spain)

Graphene exhibits a remarkably high intrinsic nonlinearity that can be pushed even further when the optical frequency is tuned to the plasmon resonances of the material. Atomistic simulations provide an accurate description of these phenomena, although their computational cost is prohibitive for large graphene nanostructures. In the weak-field, cw regime, an alternative formalism consists in relying on classical electromagnetism, using the local nonlinear conductivities extracted from perturbative models of extended graphene. We show that both of these approaches are in excellent agreement for sufficiently-large structures (10s of nm in lateral size) when describing second- and third-harmonic generation, as well as the Kerr nonlinearity. Additionally, we exploit an eigenmode decomposition of the optical field in the classical formalism to obtain analytical expressions for the plasmon-driven response of graphene ribbons and finite islands, in excellent agreement with atomistic calculations.

In contrast to the instantaneous nonlinear response, where input and output fields maintain relative coherences, a delayed nonlinearity also takes place as a consequence of the strong dependence of the graphene response on the temperature of its conduction electrons. Here we show that transient plasmons arising from the elevated electronic temperature in graphene upon ultrafast optical pumping can produce strong modulations of the optical absorption. Our nonperturbative time-domain simulations indicate that the strong incoherent nonlinearity associated with plasmons in doped graphene nanostructures can be used for all-optical switching in nonlinear optical devices.

10345-41, Session 8

Electromagnetic properties of multilayered nanostructured 2D materials: application to graphene

Bruno Majérus, Michaël Lobet, Mirko Cormann, Nicolas Reckinger, Philippe Lambin, Univ. of Namur (Belgium); Jérémy Butet, Gabriel D. Bernasconi, Raziman Thottungal Valapu, Olivier J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Luc Henrard, Univ. of Namur (Belgium)

The determination of the electromagnetic properties of 2D materials is of primary interest for applications in biosensing, shielding and optronics. Various methods have been proposed to numerically evaluate the electromagnetic response of nanostructured 2D materials. These methods generally model graphene either as an isotropic material with a given thickness or as a surface current.

In this work, we have compared several methods such as the surface current method, the discrete dipole approximation, the finite-difference time-domain method and rigorous coupled wave analysis to study graphene and graphene multilayers. We highlight the role of the layer thickness and of the anisotropy on the electromagnetic properties of graphene. We have also shown that a modification of the Brewster angle is observed, linked with the conducting nature of a graphene layer transferred to dielectric substrate. We propose a way to measure the surface conductivity of a conducting 2D material by optical measurement [1].

We then study the electromagnetic response of graphene nanostructures. The second-harmonic generation by graphene disk dimers has been investigated [2]. We show that SHG is greatly enhanced when the symmetry of this system is broken. In particular, applications such as nanorulers are suggested. Other features as the electron energy loss spectroscopy spectrum of nanostructured graphene are also explored.

Switchable infrared nanophotonic elements enabled by phase-change materials *(Invited Paper)*

Thomas Taubner, RWTH Aachen Univ. (Germany)

The strong confinement and enhancement of light when coupled to surface waves or nanoparticles is key for various applications in nanophotonics such as sensing, imaging or the manipulation of light fields. In the mid-infrared spectral range, metallic nanoantennas and materials supporting surface phonon polaritons (SPhPs) can be used as building blocks of such devices. Often, their optical functionality is only obtained at a fixed wavelength, determined by the geometric design and the material properties.

By using phase-change materials (PCMs) as tunable environment for nanophotonic resonators, their resonance frequency can be altered in a non-volatile, reversible way. PCMs offer a huge change in refractive index due to a phase transition from their amorphous to crystalline state, which can be thermally, optically or electrically triggered. We present results on thermal and optical switching, as well as addressing of individual IR resonances of both systems, metallic nanoantennas and resonators for SPhPs. SPhPs on polar dielectrics exhibit lower losses and larger Q-values compared to metallic nanoantennas, and their confinement can be even increased by adding ultrathin, switchable PCM layers. We show the all-optical, non-volatile, and reversible switching of the SPhPs by controlling the structural phase of the PCM [1], opening the door for re-configurable metasurfaces.

10345-44, Session 9

Chalcogenide active photonics *(Invited Paper)*

Robert Simpson, Weiling Dong, Hailong Liu, Sreekanth K. Valiyaveedu, Li Liu, Singapore Univ. of Technology & Design (Singapore); Tun Cao, Dalian Univ. of Technology

(China); Joel Yang, Singapore Univ. of Technology & Design (Singapore)

Chalcogenides are materials that substantially consist of sulfur, selenium, or tellurium. Their dielectric properties can be tuned by thermally induced structural phase transitions, photostructural transitions, and dissolution of metal dopants. We have designed active photonic structures using a range of 'tuneable' chalcogenides. The resonant frequency of aluminium plasmonic structures was tuned over a 100 nm band in the visible, metal-chalcogenide-metal structures provide tuning of over a band of 0.5 μm in the mid-infrared, and hyperbolic metamaterials incorporating chalcogenides provide a means to alter the radiative decay rate of fluorescent photons.

10345-45, Session 9

Thermal homeostasis using nanophotonic phase change materials *(Invited Paper)*

Michelle L. Povinelli, Shao-Hua Wu, Mingkun Chen, The Univ. of Southern California (United States); Michael Barako, Vladan Jankovic, Philip W. C. Hon, Luke A. Sweatlock, NG Next Northrop Grumman Corp. (United States)

We consider the design of nanostructured materials for thermal homeostasis, or the ability to maintain a temperature within a fixed range despite externally varying heat input. Our design uses nano- and microstructured phase-change materials to achieve a sharp change in thermal emission at a particular phase-transition temperature. We use electromagnetic simulations to calculate the thermal infrared absorption spectra for metal and insulator phases of the phase-change material. The results indicate a large increase in thermal emission at the phase transition. We then use numerical simulations of the heat equation to show that the sharp change in emission results in thermal homeostasis. For a varying external heat source, the material experiences much smaller temperature fluctuations than an unstructured or bulk material.

10345-46, Session 10

Optical modulation in silicon-vanadium dioxide photonic structures *(Invited Paper)*

Kevin J. Miller, Kent A. Hallman, Richard F. Haglund, Sharon M. Weiss, Vanderbilt Univ. (United States)

In principle, Tbps optical signal modulation could be achieved by integrating an ultrafast phase-change material into silicon photonics devices. Here we demonstrate high-speed all-optical and electro-optic hybrid silicon-vanadium dioxide (Si-VO2) ring resonator and waveguide modulators. The thermally induced insulator-to-metal transition (IMT) suggests that 10 dB modulation depths are achievable, although the dynamics of the IMT enforces a tradeoff between modulation depth and response time. The effects of placing VO2 atop or within the Si photonic structures will also be discussed.

10345-47, Session 10

Dynamic control of infrared optical absorption and thermal emission using phase-transition materials *(Invited Paper)*

Mikhail A. Kats, Univ. of Wisconsin-Madison (United States)

10345-48, Session 10

Photoinduced optical dynamics of phase-change vanadium oxides

Nardeep Kumar, Armando Rúa, Lee R. Chevres, Larry Theran, Brian Ayala, Félix E. Fernández, Sergiy I. Lysenko, Univ. de Puerto Rico Mayagüez (United States)

Using time- and angle-resolved hemispherical elastic light scattering technique we reveal complex pathways of photoinduced ultrafast insulator-to-metal and metal-to-insulator phase transition in VO2, V2O3 and V3O5 thin films. The structural dynamics was monitored with extraordinary detail by novel ultrafast diffraction conoscopy technique. The evolution of insulating and metallic phases in these correlated oxides is substantially different and significantly depends on optical excitation, temperature, size of grains and domains. Strong optical nonlinearity along with its complex transient dynamics makes vanadium oxides attractive for high-contrast all-optical switches, high-speed optical data storage and holographic devices. The characteristic time of optical nonlinearity can be tuned from ~500 fs to several picoseconds by altering the excitation fluence and wavelength, film thickness and size of grains and domains. Additional control of ultrafast phase transition dynamics can be achieved by photoacoustical generation of strain waives. In V2O3 at room temperature the strain wave produces metal-to-insulator transition, while in VO2 and V3O5 it triggers insulator`-to-metal one. Depending on material morphology and level of optical excitation, the optical signal shows coherent oscillations caused by photoacoustic wave at picosecond and nanosecond time scales. Complex nonlinear dynamics of correlated vanadium oxides can provide a way for precise tuning of transient optical and electronic properties of photonic devices.

10345-49, Session 10

Electrically driven hybrid photonic metamaterials for multifunctional control *(Invited Paper)*

Lei Kang, Liu Liu, Sawyer D. Campbell, Taiwei Yue, Qiang Ren, Theresa S. Mayer, Douglas H. Werner, The Pennsylvania State Univ. (United States)

The unique light-matter interaction in metamaterials, a type of artificial medium in which the geometrical features of subunits dominate their optical responses, have been utilized to achieve exotic material properties that are rare or nonexistent in natural materials. To enable practical applications, active materials have been introduced into metamaterial systems to advance tunability, switchability and nonlinearity, which has given rise to the concept of metadevices proposed recently. Nevertheless, practical examples of versatile photonic metamaterials remain exceedingly rare for two main reasons. On the one hand, in sharp contrast to the broad material options available at lower frequencies, it is much more uncommon to find active media that can provide pronounced dielectric property changes in optics under external stimuli, such as electric and magnetic fields. Vanadium dioxide (VO2), offering a large refractive index variation over a broad frequency range, due to its near room temperature insulator-to-metal transition (IMT), has been favored in recent studies on tunable metamaterials. On the other hand, it turns out that regulating responses of hybrid metamaterials to external forces in an integrated manner is not a straightforward task. Recently, metamaterial-enabled devices (i.e., metadevices) with 'self-sufficient' or 'self-contained' electrical and optical properties have enabled complex functionalities. Here, we present a design methodology along with the associated experimental validation of a VO2 thin film integrated optical metamaterial absorber as a hybrid photonic platform for electrically driven multifunctional control, including reflectance switching, a rewritable memory process and manageable localized camouflage. The nanoengineered topologically continuous metal structure simultaneously supports the optical resonance and electrical functionality that actuates the phase transition in VO2 through the process of Joule heating. This work provides a universal approach to creating self-sufficient and highly-versatile nanophotonic systems.

10345-50, Session 11

Topological photonics: from macro- to nano-scale *(Keynote Presentation)*

Gennady B. Shvets, Univ. of Texas at Austin (United States)

The 2016 Nobel Prize in Physics was awarded to Kosterlitz, Thouless, and Haldane for their pioneering theoretical work on the novel and counter-intuitive phases of matter that are now referred to as topological phases. Almost half a century after these researchers applied powerful mathematical techniques of topology to condensed matter systems, a new rapidly developing area is taking shape, now in the field of photonics. I will provide an overview of the field, with special emphasis on the photonic emulation of the canonical quantum topological phases such as the Hall, spin-Hall, and valley-Hall phases. The prospects for bringing topological photonics to nanoscale using 2D materials will also be discussed.

Topological steering of the lasing beam in surface lasers

Babak Bahari, Junhee Park, Felipe Vallini, Ricardo Tellez Limon, Ashok Kodigala, Thomas Lepetit, Yeshaiahu Fainman, Boubacar Kante, Univ. of California, San Diego (United States)

Steering the beam of a wave source has been demonstrated using mechanical and non-mechanical techniques. While mechanical techniques are bulky and slow, non-mechanical techniques rely on breaking the symmetry of the refractive index profile either using asymmetric structure or injecting a non-uniform current. In this contribution, we theoretically and experimentally demonstrated a new type of topological steering of light sources in which the phase offset is provided by Floquet-Bloch phase in periodic structure. It was shown that in periodic structures, there exist singular states in the radiation region of the band diagram that exhibit diverging quality factor. Thus light sources can operate at these states with lower power threshold. The existence of these singular states are topologically protected, and their momentum are very sensitive to any small perturbations, which is used to control the steering angle. By uniformly controlling some parameters in the system, such as a physical dimension or injecting current uniformly, the beam of the light source steers. Our experimental demonstrations open new paradigm in the implementation of light steering with applications in data communications, bio imaging and sensing.

10345-53, Session 11

Index ellipsoids at arbitrary k-points *(Keynote Presentation)*

Che Ting Chan, Wenjie Chen, Hong Kong Univ. of Science and Technology (Hong Kong, China)

The index ellipsoid gives the orientation and relative magnitude of refractive indices in a crystal. In all natural materials, the index ellipsoid is centered at k=0. This is expected to be true even for man-made crystals such as photonic crystals and metamaterials. For photonic crystals, we are used to see photonic band structures that are either gapped at low frequency (for metallic structures) or those having a linear dispersion emerging at k=0 (for dielectric structures). Metamaterials can have exotic values of permittivity and permeability that cannot be found in natural materials, and as such, they can have unconventional index ellipsoids. However, in most of the previously designed metamaterials, the equi-frequency surface either forms an ellipsoid (e.g. in double negative medium) or hyperboloid (hyperbolic medium) centered at k=0. If the local effective permittivity and permeability are well defined, we expect a linear dispersion at low frequency in the long wave limit, and ?-->0 as k-->0.

Here, we propose a new type of photonic crystal structure that possess one or more index ellipsoids positioned at nonzero k-points. Linear bands that go to zero frequency emerge from non-zero k-points as a consequence of artificial gauge potentials provided by the microscopic structure possessing special geometries. The number of ellipsoids and their positions within the Brillouin zone can be engineered by changing the connectivity of the metallic components. This gives us a new degree of freedom to tailor the optical response of man-made materials, leading to unusual wave propagation behaviors.

Topological photonics research at Sandia Lab

Ganapathi S. Subramania, Sandia National Labs. (United States); P. Duke Anderson, Sandia National Labs. (United States) and The Univ. of Southern California (United States)

Topological photonic structures in analogy to their electronic counterparts can provide new functionalities in nanophotonics. In particular, they can possess topologically protected photonic modes that can propagate unidirectionally without scattering and can have an extreme photonic density of states (PDOS). These unique properties can directly impact many photonic systems used in communications and quantum information processing applications such as single photon transport. Several theoretical works and experimental demonstrations of topological states have been done on macroscopic systems such as optical fiber arrays and microwave structures. Enabling such properties at optical frequencies and on chip-scale will be very important for practical applications of such phenomena. We present work conducted at Sandia lab towards the goal of optical frequency chipscale nanophotonic structures with topological properties. We will discuss implementation of topological photonic structures in semiconductor based systems (e.g. Si, GaAs and GaN).

Sandia National Laboratories is a multi-mission laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

10345-56, Session 12

Topological edge states of distorted photonic Kagome lattices

Xiang Ni, The City College of New York (United States); Andrea Alù, The Univ. of Texas at Austin (United States); Alexander B. Khanikaev, The City College of New York (United States)

We demonstrate that the distorted Kagome lattice formed by 2d array of dielectric rods embedded in air exhibits a new class of topological states characterized by a topological invariant number in Pauli vector space. The Kagome lattice can be considered as a two dimensional analogy of Su-Schrieffer–Heeger (SSH) which displays the topological transition by detuning the relative amplitudes of the inter-cell and intra-cell hopping terms. The surface d(k) as k sweeps through the whole Brillouin zone will enclose the origin in Pauli vector space and the topological number be nonzero if the inter-cell hopping amplitude is larger than the intra-cell hopping amplitude. While d(k) will exclude the origin and the topological number be zero if the case is reversed. The topological transition is accompanied by the opening of complete band gap in Brillouin zone, which may host topological edge states on either truncated end of the lattice or at the domain walls between topological nontrivial and trivial domains. To further validate the above conclusion, quasi 1d Kagome lattice is built by rolling 2d Kagome lattice sheet into cylinder and revealed to have SSH-like edge states at the ends of cylinder by Dimensional reduction method. The first-principles simulations based on the full wave finite element method (FEM) are used to design the lattice and confirm the analytic prediction.

10345-57, Session 12

Non-Hermitian defects in topologically protected photonic crystals *(Invited Paper)*

Tsampikos Kottos, Wesleyan Univ. (United States)

The development of non-Hermitian photonics and the implementation of spatio-temporal symmetries in optics has led to new avenues for the manipulation of light. Two of the most prominent subfields which utilize the above two developments are parity-time symmetric optics and topological photonics. In this presentation we will focus at the second framework and investigate the scattering properties of non-Hermitian photonic crystals with topologically protected defect modes. We will discuss two specific applications associated with perfect absorbers and topologically protected power switches.

10345-58, Session 13

Dipolar second order nonlinear effects from goldnano-antennas by controlling radiation phase *(Invited Paper)*

Sylvain D. Gennaro, Vincenzo Giannini, Themistoklis P. H. Sidiropoulos, Imperial College London (United Kingdom); Miguel Navarro-Cía, The Univ. of Birmingham (United Kingdom); Stefan A. Maier, Rupert F. Oulton, Imperial College London (United Kingdom)

No Abstract Available.

10345-59, Session 13

Shaping of higher harmonic radiation in dielectric nanoantennas

Massimiliano Guasoni, Univ. of Southampton (United Kingdom); Luca Carletti, Univ. degli Studi di Brescia (Italy); Dragomir N. Neshev, The Australian National Univ. (Australia); Costantino De Angelis, Univ. degli Studi di Brescia (Italy)

Higher harmonic generation (HHG) at nanoscale is of paramount importance for a plethora of applications.To overcome the issue of ohmic losses in plasmonic devices, last years have seen the development of dielectric nanoantennas that are in principle loss-free. In this framework, careful design of the antenna geometry is essential: different geometries lead indeed to different higher harmonic (HH) radiation patterns.Despite the efforts made in the last decade, most of the theoretical works on this subject have been limited to spherical particles or short cylinders with circular cross-section and in the limit of low refractive index difference between the antenna and the surrounding environment. These constraints are not realistic when dealing with high-index materials like AlGaAs (extremely suitable for HHG) and do not cover complex geometries that may reveal useful radiation features. In this work, we develop a novel theoretical model for the study of HHG in cylindrical nanoantennas. Our model applies whatever the cross-section shape and the refractive index of the material. The key idea is the decomposition of the electromagnetic field over the complete set of transverse modes of the antenna. For a given incident field at the fundamental harmonic we can predict the modes excited at the HH, each one related to a peculiar modal radiation pattern for which an analytical or semi-analytical formulation is provided. In conclusion, these results find useful application in the design of optimal geometries leading to ad-hoc HH radiation patterns at the nanoscale.

10345-60, Session 13

Reconfigurable silicon photonics: shaping light on a chip *(Invited Paper)*

Otto L. Muskens, Roman Bruck, Nicholas Dinsdale, Univ. of Southampton (United Kingdom); Kevin Vynck, Philippe Lalanne, Lab. Photonique, Numérique et Nanosciences (France); Goran Z. Mashanovich, Graham T. Reed, Univ. of Southampton (United Kingdom)

Defining elements with reconfigurable input-output characteristics is of importance to achieve flexible circuitry where light can be manipulated and routed using external control signals. We have developed an experimental approach for shaping of the transmission function of multimode silicon photonic waveguides by projecting a pattern of local nonlinear perturbations induced by an ultrafast laser pulse. Making use of the degrees of freedom offered by a spatial light modulator, the technique offers a new approach for studying light transport, for controlling its flow on ultrafast time scale, and for programming functions on a photonic chip.

10345-61, Session 14

Topological and complex birefringent metamaterial *(Keynote Presentation)*

Shanhui Fan, Alex Cerjan, Meng Xiao, Luqi Yuan, Qian Lin, Stanford Univ. (United States)

We discuss novel electromagnetic effects in topological metamaterial and in complex birefringent meta material. In particular, we discuss the creation of novel topology using meta-material geometry., We also discuss three-dimensional meta-materials with balanced gain and loss for the purpose of achieving arbitrary control of a pair of polarization states.

10345-62, Session 14

Topological and non-reciprocal photonics *(Keynote Presentation)*

Andrea Alù, The Univ. of Texas at Austin (United States)

In this talk, we will review our recent progress towards the concept, design and realization of magnet-free non-reciprocal photonic devices and arrays of them with strong topological protection, aimed at realizing reconfigurable, broadband isolators and circulators. We will discuss our approaches to design topological photonic metasurfaces based on spatio-temporal modulation, nonlinearities, and/or opto-mechanical interactions, and discuss our vision towards new transport phenomena for light, and new nanophotonic devices with enhanced non-reciprocal properties.

10345-64, Session 14

Entangled photons in 2D topological photonic systems *(Invited Paper)*

Sunil Mittal, Venkata Vikram Orre, Joint Quantum Institute, Univ. of Maryland (United States) and National Institute of Standards and Technology (United States); Mohammad Hafezi, Joint Quantum Institute, Univ. of Maryland (United States) and National Institute of Standards and Technology (United States)

Topological photonic systems using synthetic gauge fields have now been implemented using a variety of platforms, for example, using coupled ring resonators and helical waveguides in the optical domain, and also using metamaterials in the microwave domain. Edge states, a hallmark of topological phenomena, have been observed and the robustness of edge state transport against disorder has been quantitatively established. However, recent explorations of edge state physics have relied on measuring classical transport properties, such as transmission and delay statistics. Here, we discuss quantum transport of entangled photons in a 2D topological photonic system of coupled ring resonators. In particular, we consider transport of time-bin entangled photons through the system. Using numerical simulations, we show that in the presence of disorder, edge state transport preserves temporal correlations of input photons whereas bulk transport can lead to significant bunching or anti-bunching of photons. We present our experimental progress in this direction. Moreover, we discuss generation of entangled photons in this 2D topological system. The topological robustness of edge states could be used for efficient on-chip generation of wavelength-entangled photons.

10345-3, Session PWed

Polarization driven supramolecular chirality in soft-printed dielectric microstructures

Angelo Angelini, Politecnico di Torino (Italy); Federica Pirani, Politecnico di Torino (Italy) and Istituto Italiano de Tecnologia (Italy); Federico Ferrarese Lupi, Istituto Nazionale di Ricerca Metrologica (Italy); Francesca Frascella, Serena Ricciardi, Politecnico di Torino (Italy); Natascia De Leo, Luca Boarino, Istituto Nazionale di Ricerca Metrologica (Italy); Emiliano Descrovi, Politecnico di Torino (Italy)

The interaction of light with periodic and quasi-periodic dielectric structures has gained novel interest since the fabrication techniques have enabled the fabrication of large area surface patterns in which each element can be shaped to provide additional degrees of freedom over the emerging light. Such surfaces allow finely engineering the wave-front of visible light with an unprecedent degree of control, enabling the fabrication of ultrathin optical elements with complex optical functionalities. Polarization sensitive holographic patterns and dielectric meta-surfaces are examples of what can be done with those kinds of surfaces.

A fundamental limit of pre-patterned surfaces comes from the impossibility to modify their optical behavior after the initial structuration. Here we propose the use of photo-responsive dielectric materials to dynamically control the polarization state of light emerging from individual surface elements. We make use of a commercial azo polyelectrolyte (Pazo) dispersed in a passive polymeric matrix (PMMA) that is patterned in an array of micro-pillars. When a single pillar is exposed to UV-visible radiation, a supramolecular chirality is induced within the pillar, and light emerging from it takes memory of the writing beam polarization. A direct experimental observation of such effect and the fully reversibility of the induced chirality will be provided. The method proposed may enable the fabrication of optically active metasurfaces as well as fabrication of dynamically tunable holographic patterns.

10345-82, Session PWed

Incident femtosecond pulse chirp influence on nonlinear localization of laser energy in layered photonic crystal

Vyacheslav A. Trofimov, Tatiana M. Lysak, Evgenii M. Trykin, M.V. Lomonosov Moscow SU (Russian Federation)

We investigate laser energy localization in a layered photonic crystal with Kerr nonlinear response in dependence of chirp of an incident femtosecond pulse. Such kind of energy localization appears due to soliton formation in certain layers of photonic crystal. Layers position, in which a solitons appear, depend on the pulse chirp and the incident pulse intensity essentially. It is important to emphasize that a soliton occurs in separate layers. Therefore, its width must be less than a layer thickness. Consequently, an intensity of the incident pulse must be greater than its crucial value. A process of energy localization strongly depends on relation between the wave packet carrier frequency and a frequency characterizing a photonic crystal.

The problem under consideration is described by a nonlinear Schrödinger equation with respect to amplitude slowly varying in time. We investigate a femtosecond pulse interaction with photonic crystal numerically and analytically.

10345-83, Session PWed

Self-similar chirped laser pulse propagation in a medium with TOD and non-resonant TPA

Vyacheslav A. Trofimov, Aleksey A. Kalinovich, Irina G. Zakharova, M.V. Lomonosov Moscow SU (Russian Federation)

In this report we derive a self-similar both shape and chirp of a pulse propagating in a medium with non-resonant TPA under the condition of a TOD influence. The main feature of this soliton-like propagation of the laser pulse is a pulse chirp presence. In the frame-work of nonlinear Schrödinger equation we derive an approximate pulse shape and its chirp evolution in time. Consideration is shown that self-similar shape of a pulse is asymmetrical one and nonlinear time dependence of the pulse carrier frequency.

To confirm the results of our analytical consideration and to clarify its frame-work validity we make computer simulation. We show that the analytical result is valid along long distance propagation.

10345-85, Session PWed

Magnetic and magneto-optical properties on sub-micrometer thick Bi-doped iron garnets grown by liquid phase epitaxy

Nathan Beaulieu, Souren P. Pogossian, Univ. de Bretagne Occidentale (France); Lucile Soumah, Abdelmadjid Anane, Paolo Bortolotti, Vincent Cros, Unité Mixte de Physique CNRS/Thales (France); Jamal Ben Youssef, Univ. de Bretagne Occidentale (France)

Iron based garnets have unique magneto-optical (MO) properties that make them interesting for photonic applications such as the non-reciprocal Mach-Zehnder Interferometer [1]. The integration of garnets on the photonic circuit can be performed either by direct deposition on Si or by molecular bonding [2]. This second approach requires growing very smooth garnet films in order to obtain uniform bonding properties. The growth of thin films (thinner than 100 nm) is critical to perform nanostructuration on these materials, as they are very resilient to standard etching techniques. Usually, the growth of thin garnet films is performed by PLD [3], or off axis

sputtering [4]. Liquid phase epitaxy (LPE) is a well-established industrial process that can produce rapidly large area and uniform films, but the control of the growth rate is critical to obtain layers thinner than 100 nm.

Here we report on the growth and the characterization of submicrometer thick garnets with optimized MO characteristics using LPE. The study of the structural and magnetic properties as a function of the garnet film thickness revealed a dependence on the roughness, on the anisotropy and on the damping parameter. We measured the magneto-optical response using Faraday rotation at different wavelengths ranging from 635 to 1550 nm on samples from 40 nm to 1 μm thick. This study showed an enhanced Faraday rotation at lower thicknesses (thinner than 100 nm). Future cladding based photonic devices could be more compact using thin Bi-doped garnets. We also studied the magnetization dynamics of those films using broadband ferromagnetic resonance and observed a significant increase in the Gilbert damping for the thinnest films.

Modeling and simulation analysis of graphene integrated silicon waveguide

Swati Joshi, Brajesh Kumar Kaushik, Vikas Nehra, Indian Institute of Technology Roorkee (India)

The modern high density on-chip electrical interconnects are not able to meet current technology demands due to inherent RC limitation. Silicon photonics is an emerging technology with the prospects of combining electronics with photonics on a single chip to improve system performance and open up numerous design opportunities. Optical waveguides are the basic elements of photonic circuits for transmission of light over various distances. The potential of optical interconnects has been investigated immensely for the parameters such as compact design, strong light confinement, high bandwidth, low crosstalk, low loss propagation, in design of high density next-generation on-chip system. The performance of these parameters is a key factor for the growth of silicon photonics. Graphene, an allotrope of carbon with unique optoelectronic properties and silicon compatibility has prompted intense research in graphene based electrical and optical applications ranging from the terahertz to the visible spectral region. The fermi level of the graphene can be electrically and chemically controlled to modulate its conductivity. Graphene has been shown as a promising candidate in planar photonic circuit design to pave the way for realistic applications. The transmission properties of the waveguide are directly affected by its geometry, location, and tunability of graphene refractive index. This paper analyzes the graphene integrated waveguide properties such as mode profiles, effective index, propagation loss, bending behavior. We propose an optimized waveguide design to have mode field concentrated near graphene layer to maximize absorption through graphene for the compact electro-absorption modulator. The simulation results show agreement with the analytical models.

Photonic crystal Fano resonances for realizing optical switches, lasers, and non-reciprocal elements *(Invited Paper)*

Dagmawi A. Bekele, Jesper Mork, Yi Yu, Aurimas Sakanas, Luisa Ottaviano, Elizaveta Semenova, Kresten Yvind, Technical Univ. of Denmark (Denmark)

No Abstract Available.

10345-66, Session 15

Metawaveguide for asymmetric interferometric light-light switching *(Invited Paper)*

Han Zhao, Univ. at Buffalo (United States); William S. Fegadolli, California Institute of Technology (United States); Jiakai Yu, Zhifeng Zhang, Univ. at Buffalo (United States); Li Ge, The City Univ. of New York (United States); Axel Scherer, California Institute of Technology (United States); Liang Feng, Univ. at Buffalo (United States)

Here we report an experimental demonstration of a metawaveguide that operates exactly in the opposite way in a linear regime, where an intense laser field is interferometrically manipulated on demand by a weak control beam with a modulation extinction ratio up to approximately 60 dB. This asymmetric control results from operating near an exceptional point of the scattering matrix, which gives rise to intrinsic asymmetric reflections of the metawaveguide through delicate interplay between index and absorption. The designed metawaveguide promises low-power interferometric light-light switching for the next generation of optical devices and networks.

10345-67, Session 15

Quantum optical circulator controlled by a single chirally coupled atom *(Invited Paper)*

Juergen Volz, Vienna Ctr. for Quantum Science and Technology (Austria)

In our experiment, we implement a quantum optical circulator by coupling a single rubidium atom to a whispering-gallery-mode microresonator which is interfaced by two optical nanofibers. Due to the chiral (direction dependent) interaction between the atom and the resonator light, this realizes a four port optical circulator with a strong nonreciprocal behavior. The operation direction of the device is controlled by the atomic quantum state. This, in principle, allows the preparation of the circulator in a coherent superposition of its operational states and renders it a key element for routing and processing quantum information in integrated optical circuits.

10345-68, Session 15

Non reciprocal light propagation in a YIG based magnetic waveguide

Lucile Soumah, Unité Mixte de Physique CNRS/Thales (France); Lilia Qassym, Thales Research & Technology (France); Cécile Carretero, Eric Jacquet, Unité Mixte de Physique CNRS/Thales (France); Jamal Ben Youssef, Nathan Beaulieu, Univ. de Bretagne Occidentale (France); Richard Lebourgeois, Alfredo De Rossi, Sylvain Combrie, Thales Research & Technology (France); Paolo Bortolotti, Abdelmadjid Anane, Unité Mixte de Physique CNRS/Thales (France)

Magneto-optical (MO) materials are key elements for non-reciprocal photonic functionalities such as optical isolation. Commercial optical isolators are based on the Faraday effect of Yttrium Iron Garnet (YIG) single crystals. Integrating such materials on a photonic chip has proven to be challenging. Most studies have been using cladding effects where a MO material (usually YIG) is put in close proximity to a silicon photonic waveguide using either direct deposition or molecular bonding [1]. In the present work, we study an alternative configuration where the MO material is used as the optical wave guide medium for light propagation.

Using the Pulsed Laser Deposition technique we have grown Bi:YIG layers with thickness up to 120 nm on YAG (111) substrates. The structural, magnetic and magneto-optical properties have been fully characterized. They show the good quality and the large MO effect (Faraday rotation) of the films. Using spectroscopic ellipsometry, we obtained the refractive index of both, the film and the substrate, the contrast between those two values, respectively 2.3 and 1.8 is sufficient to induce confined propagation of the TM mode. The low film thickness allows for wave guide structuration using standard lithography technics and ion beam etching. Non reciprocal propagation experiments will be presented on 0.7 to 2 μm wide waveguides; we discuss the potential of this approach for compact optical isolators despite the large insertion losses in our first generation devices.

Structure-induced asymmetry between counterpropagating modes and the reciprocity principle in whistle-geometry ring lasers *(Invited Paper)*

Marek Osinski, The Univ. of New Mexico (United States)

A key feature of the whistle-geometry semiconductor ring lasers is their unidirectionality, caused by an asymmetry between the counterpropagating modes. The asymmetry between modal losses results in different lifetimes for the two counterpropagating modes, which might be misconstrued as a violation of the Helmholtz reciprocity principle and the time-reversal symmetry of Maxwell's equations. We have verified the unidirectionality of the whistle-geometry configuration through rigorous three-dimensional finite-difference time-domain simulations. An explanation will be given why this result does not violate the reciprocity principle.

10345-71, Session 16

Active parity-time symmetric systems *(Invited Paper)*

Mercedeh Khajavikhan, Demetrios N. Christodoulides, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

In recent years, non-Hermitian degeneracies, also known as exceptional points (EPs), have emerged as a new paradigm for engineering the response of optical systems. Among many different non-conservative photonic configurations, parity-time (PT) symmetric arrangements are of particular interest since they provide an excellent platform to explore the physics of exceptional points. In this talk, I will present some of the work in our group, where the intriguing properties of exceptional points that are arising in judiciously designed parity-time-symmetric systems are utilized to address two of the long standing challenges in the field of integrated photonics: enforcing single mode lasing in intrinsically multimode cavities, and enhancing sensitivity of micro-resonators.

10345-72, Session 16

Towards nanoscale optical nonreciprocity with PT-symmetric metamaterials

David R. Barton III, Stanford Univ. (United States); Hadiseh Alaeian, Northwestern Univ. (United States); Mark Lawrence, Jennifer A. Dionne, Stanford Univ. (United States)

Optical nonreciprocity is critical for the function of optical isolators and circulators, but is challenging to achieve in nanophotonic systems using conventional methods. Here, we investigate a nonlinear parity-time (PT)-symmetric plasmonic metamaterial as a novel diode structure. A metamaterial with 150 nm unit cell composed of five alternating layers of Silver and a high index dielectric (n=3.2) is used as a model system; the structure is made PT-symmetric by inclusion of loss or gain in alternating dielectric layers. Analytical calculations reveal a bandstructure and band gap tunable with the amount of loss and gain. In the linear regime, the structure exhibits unity transmission at a wavelength of 500 nm near the optical band gap; further, internal electric field intensities vary based on the illumination direction (i.e., illumination from the "loss" or "gain" side of the metamaterial) by up to an order of magnitude. To make this structure nonreciprocal, saturable gain and absorption are introduced in the dielectric layers. These nonlinearities allow for intensity-based tuning of the bandgap such that illumination from the loss side is in the band gap, but is in the band pass from the gain side. Full field finite element simulations reveal nonreciprocal transmission with a transmission difference of nearly 10 dB within three free space optical wavelengths. The angular response of this material is additionally studied for possible applications in nonreciprocal negative index lensing. This sub-two-micron PT metamaterial represents a new approach in designing nanoscale nonreciprocal elements based on planar plasmonic and high-index dielectric films.

10345-74, Session 16

Higher-order exceptional points in photonic systems

Hossein Hodaei, Absar U. Hassan, Steffen Wittek, Midya Parto, Hipolito Garcia-Gracia, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Ramy A. H. El-Ganainy, Michigan Technological Univ. (United States); Demetrios N. Christodoulides, Mercedeh Khajavikhan, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Student contribution: In recent years, non-Hermitian degeneracies, also known as exceptional points (EPs), have emerged as a new paradigm for engineering the response of optical systems. This class of degeneracies represents points in parameter space where the eigenvalues and their corresponding eigenvectors simultaneously coalesce [1,2]. Among the large set of non-conservative photonic systems, parity-time (PT) symmetric arrangements are of particular interest since they provide an excellent platform to study the physics and properties of non-Hermitian degeneracies [3,4]. So far, the abrupt nature of the phase transitions at EPs has led to a number of new functionalities such as loss-induced transparency [5], unidirectional invisibility [6,7], and single mode lasing [8-11]. In addition, it has been suggested that the bifurcation properties associated with second-order exceptional points can be utilized to achieve enhanced sensitivity in micro-resonator arrangements [11]. Of interest is to use even higher-order exceptional points that in principle could further amplify the effect of perturbations. While such higher-order singularities have been theoretically studied in a number of recent works [13,14], their experimental realization in the optical domain has so far remained out of reach. In this paper, for the first time, we show the emergence of third order exceptional points in ternary parity-time-symmetric coupled resonator lasers by judiciously designing the gain/loss distribution and coupling strengths following a recursive bosonic quantization procedure. Subsequently, the nature of the third order exceptional point is confirmed through the cubic root response

of this ternary system to external perturbations. Our work may pave the way towards the utilization of higher order exceptional points in designing ultrasensitive photonic arrangements.

PT symmetry in Kagome photonic lattices *(Invited Paper)*

Gia-Wei Chern, Univ. of Virginia (United States); Avadh Saxena, Los Alamos National Lab. (United States)

Photonic lattices composed of balanced gain and loss waveguides have attracted considerable attention due of their potential applications in optical beam engineering and image processing. These photonic lattices belong to a larger class of intriguing active metamaterials that exhibit the parity-time (PT) symmetry. Kagome lattice is a two-dimensional network of corner-sharing triangles and is often associated with geometrical frustration. In particular, the frustrated coupling between waveguide modes in a kagome array leads to a dispersionless flat band consisting of spatially localized modes. Recently, a PT-symmetric photonics lattice based on the kagome structure has been proposed by placing PT-symmetric dimers at the kagome lattice points. Each dimer corresponds to a pair of strongly coupled waveguides. With balanced arrangement of gain and loss on individual dimers, the system exhibits a PT-symmetric phase for finite gain/loss parameter up to a critical value. Here we discuss the linear and nonlinear optical beam propagations in this novel PT-symmetric kagome system. The linear beam evolution in this complex kagome waveguide array exhibits a novel oscillatory rotation of optical power along the propagation distance. Long-lived local chiral structures originating from the nearly flat bands of the kagome structure are observed when the lattice is subject to a narrow beam excitation. We further show that inclusion of Kerr-type nonlinearity leads to novel optical solitons.

Quantum dots in photonic crystals for Integrated quantum photonics *(Invited Paper)*

Je-Hyung Kim, Univ. of Maryland, College Park (United States); Christopher J. K. Richardson, Richard P. Leavitt, Lab. for Physical Sciences (United States); Edo Waks, Univ. of Maryland, College Park (United States)

Future quantum information processing will rely on solid-state architectures that integrate quantum emitters, channels, beamsplitters, and detectors so all excitation, extraction, processing, and detection is efficiently possible on a chip. Quantum dots have attracted much attention for bright solid-state quantum emitters with high single photon purity and indistinguishability, and slab-type photonic crystal structures have an ability to integrate these emitters to cavities and waveguides on a chip. By combining these systems, quantum dots in photonic crystals have played important roles in the rapidly growing field of integrated quantum photonics. However, achieving quantum devices incorporating multiple quantum dots on a chip is a quite challenging task due to the spectral randomness of quantum dots and fabrication errors in photonic crystals. Here, we demonstrate multiple, identical quantum emitters in photonic crystal devices that generate indistinguishable single photons on the same chip. Integration of photonic crystal cavities enhances both radiative recombination rates and off-chip collection efficiency of quantum dots, resulting in bright single photons at telecom wavelength. To address the challenge of spectral randomness, we design thermally-isolated multiple photonic crystal structures with optical heating pads. Together with local thermal tuning, local gas tuning techniques enable us to control multiple cavities and dots. We perform Hong-Ou-Mandel interference measurements to verify indistinguishable single photons from individual dots. In addition, we suggest the way for on-chip quantum interference between multiple quantum dots in photonic crystals. Our devices and techniques paves the way for the scalable, controllable quantum devices involving multiple, identical quantum emitters on a chip.

10345-78, Session 17

Entanglement optimization in plasmonically coupled quantum dots *(Invited Paper)*

Matthew A. Pelton, Univ. of Maryland, Baltimore County (United States)

Although the enhanced near fields produced by plasmon resonances in metal nanoparticles can enable strong local light-matter interactions, the strong dissipation of plasmon resonances would seem to be incompatible with quantum-mechanical phenomena such as entanglement. Counter to this intuition, the dissipation can in fact lead to the production of transient entanglement between the occupation states of dots coupled to a common plasmonic system. Building on previous results that showed entanglement between pairs of dots, we scale to larger systems of two, three, and more closely spaced dots. Moreover, we show that tuning the degree of coupling between each dot and the common plasmonic nanostructure enables entanglement to be created in the case where the entire system begins in its

ground state and is excited by a single laser pulse. Entanglement is achieved without the need for the dots to be individually addressable, and without the need for controlled quantum gates, postselective measurements, or engineering of the dissipative environment. Through analytical solutions and numerical simulation of a model Hamiltonian based on a cavity-quantum-electrodynamics approach, we determine system configurations that maximize pairwise entanglement among the quantum dots, illustrating in principle the potential for true "quantum plasmonics.

10345-79, Session 18

Quantum self-organized criticality and nonequilibrium light localization *(Invited Paper)*

Kosmas L. Tsakmakidis, Univ. of Ottawa (Canada); Pankaj K. Jha, Xiang Zhang, Univ. of California, Berkeley (United States); Hatice Altug, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Robert W. Boyd, Univ. of Ottawa (Canada)

Self-organized criticality emerges in dynamical complex systems driven out of equilibrium, and characterizes a wide range of classical phenomena in physics, geology and biology. However, for decades now, it remains a fundamental open question whether this broad property also finds a place in the quantum regime. In the talk, we shall present the first example of quantum self-organized criticality, emerging from quantum fluctuations and controlled by quantum coherence. We shall introduce a many-body quantum-coherently driven nanophotonic system where heavy photons interact in the presence of active nonlinearities. In this system, we shall show how quantum self-organized criticality emerges in an inherently new type of light localization, arising from two first-order phase transitions and being robust to dissipation, fluctuations and many-body interactions. The observed localization exhibits emergence of scale-invariant power laws and absence of finely-tuned control parameters. In analogy with the regime of quantum criticality at Tc = 0 in equilibrium static systems, we find that for our nonequilibrium dynamical system there exists a range of parameters for which the effective critical 'temperature' drops to zero, at which point we enter a fundamentally new regime of phase transitions – the quantum self-organized critical regime. We shall also approach the problem from a thermodynamic and information-theory perspective, deriving the multidimensional-state-vector Fokker-Planck (FP) equation for the distribution function of our problem, applying the maximum information entropy principle to make unbiased estimates on the probability distribution of microscopic states of our active nanosystem, and finally determining and analyzing the information gain and efficiency of the complex nanosystem close to its critical points.

10345-80, Session 18

All-dielectric transparent metasurfaces for holography and quantum tomography *(Invited Paper)*

Sergey S. Kruk, Lei Wang, Kai Wang, Matthew Parry, The Australian National Univ. (Australia); Hung-Pin Chung, The Australian National Univ. (Australia) and National Central Univ. (Taiwan); Hanzhi Tao, The Australian National Univ. (Australia) and Nanjing Univ. (China); Ivan I. Kravchenko, Andrey Sukhorukov, Dragomir N. Neshev, Yuri S. Kivshar, The Australian National Univ. (Australia)

Metasurfaces are ultra-thin patterned photonic structures that emerged recently as planar metadevices capable of reshaping and controlling incident light. They are composed of resonant subwavelength elements distributed across a flat surface. Due to the resonant scattering, each element can alter the phase, amplitude and polarization of the incoming light. Many designs and functionalities of metasurfaces suggested so far are based on plasmonic planar structures, however most of these metasurfaces demonstrate low efficiencies in transmission due to losses in their metallic components. In contrast, all-dielectric resonant nanophotonic structures avoid absorption losses, and can drastically enhance the overall efficiency, especially in the transmission regime. Here we utilize this platform to create flat optical elements such as vector beam q-plates, holograms and quantum polarization tomography devices. Holograms, in particular, showcase a potential of the metasurface platform as they rely on a complex wavefront engineering. Metasurface platform enables a new way to create highly efficient holograms with single-step patterning. Here, we design and realize experimentally greyscale meta-holograms with superior transmission properties. Another promising area for implementation of all-dielectric metasurfaces is quantum optics. We suggest and develop experimentally a new concept of quantum-polarization measurements with a single all-dielectric resonant metasurface. A metasurface enables full reconstruction of the state of entangled photon pairs based on the photon correlations with single-photon detectors. The subwavelength thin structure provides an ultimate miniaturization, scalability to a larger number of entangled photons, and gives the possibility to study the dynamics of quantum states in real-time.

10345-81, Session 18

Photonic band control in a quantum metamaterial *(Invited Paper)*

Didier Felbacq, Emmanuel Rousseau, Univ. Montpellier (France)

In the present work, we present a metamaterial made of a periodic collection of dielectric resonators in which a quantum oscillator (denoted QO in the following) is inserted.

The geometry at stake here is much more complicated than the textbook 1D cavity usually dealt with theoretically in quantum optics. We do provide a treatment essentially based on the scattering matrix non-perturbative approach, in order to investigate the various effects that could be expected to exist in such structures.The theoretical methods used are the Feshbach projection method associated with multiple scattering theory.

First, the phenomenology for one scatterer with a QO inserted is presented, then the collective behavior of a finite periodic set of such scatterers is investigated and it is shown that it is possible to open and close a conduction band according to the state of the oscillators when the inserted quantum oscillators are put in the inversion regime by means of a pump field. They add gain to the system, allowing to reach the amplification regime in the vicinity of the Mie resonances of the dielectric resonators. When the transition frequency is situated at the photonic band gap edge, it creates switchable conducting modes within the bandgap.

10346-1, Session 1

Plasmon-induced hot carrier generation and applications *(Invited Paper)*

Peter Nordlander, Rice Univ. (United States)

Plasmons can serve as efficient generators of hot electrons and holes that can be exploited in light harvesting applications. The physical mechanism for plasmon-induced hot carrier generation is plasmon decay. Plasmons can decay either radiatively or non-radiatively with a branching ratio that can be controlled by tuning the radiance of the plasmon mode. Non-radiative plasmon decay is a quantum mechanical process in which one plasmon quantum is transferred to the conduction electrons of the nanostructure by creating an electron-hole pair, i.e., excitation of an electron below the Fermi level of the metal into a state above the Fermi level but below the vacuum level. I will discuss the time-dependent relaxation of plasmon-induced hot carriers including electron-electron scattering, fluorescence, and electron-phonon coupling. I will also discuss recent applications of plasmon-induced hot carrier generation such as photocatalysis, and how photocatalytic efficiencies can be enhanced and quantified by placing catalytic reactors in the nearfield of a plasmonic antenna in an Antenna/Reactor geometry.

10346-2, Session 1

Novel numerical method for electron energy-loss spectroscopy calculation: EELS-FDTD *(Invited Paper)*

Nicolas Large, The Univ. of Texas at San Antonio (United States)

Electron energy-loss spectroscopy (EELS) is a unique tool that is extensively used to investigate the plasmonic response of metallic nanostructures since the early works in the '50s. To be able to interpret and theoretically investigate EELS results, a myriad of different numerical techniques have been developed for EELS simulations: boundary element method (BEM), discrete dipole approximation (DDA), finite-element method (FEM), Galerkin discontinuous time-domain method. Although these techniques are able to predict and reasonably reproduce experimental results, they possess significant drawbacks and are often limited to highly symmetrical geometries, non-penetrating trajectories, free-standing nanostructures, small nanostructures, and may present some complexity in their implementation and use.

Here, we present a novel approach for EELS calculations using the finite-difference time-domain (FDTD) method that goes beyond these limitations [1]. We benchmark our EELS-FDTD implementation by direct comparison with results from the well-established BEM and published experimental results. In particular, we compute EELS spectra for spherical nanoparticles, nanoparticle dimers, nanodisks supported by various substrates, and supported gold bowtie antennas. The flexibility our EELS-FDTD method allows for easily extending to more complex geometries and configurations. To illustrate this we investigate the plasmonic properties of (i) high density sub-10-nm-gap homo- and hetero-dimers, (ii) encapsulated gold nanoparticle chains, and (iii) hollow gold nanorods [2,3]. This implementation can also be directly exported beyond the FDTD framework and implemented within other numerical methods.

10346-3, Session 1

Femtosecond dynamics of plasmon-induced hot electrons in nanostructured titanium nitride

Brock Doiron, Yi Li, Andrei P. Mihai, Lesley F. Cohen, Peter K. Petrov, Neil M. Alford, Rupert F. Oulton, Stefan A. Maier, Imperial College London (United Kingdom)

Due to its high melting point and comparable optical properties to gold, titanium nitride (TiN) is a promising replacement for gold in high-energy plasmonic applications. This would not only pave the way to more durable plasmonic devices but facilitate the study of light-metal interactions in regimes once thought impossible. However, thin films of TiN are challenging to grow consistently due to their susceptibility to oxidation during growth. Here we report on the optical properties of high-quality TiN films achieved through a detailed analysis of the growth conditions on oxide formation. These TiN films are then used to explore the ultrafast hot electron relaxation dynamics. Although hot electron generation in TiN films has been investigated previously, the effects of plasmon-enhanced absorption on the excitation and relaxation of the hot electrons has yet to be explored. Using time-resolved pump-probe differential transmission measurements, the electron relaxation process is studied under both resonant and non-resonant conditions to determine the plasmon's influence on the energetics of the electron distribution and their interaction with the phonons of the material. Pump-probe studies used a Ti:Sapphire laser and optical parametric oscillator (OPO) with pulse widths of 150fs at 850nm (pump) and 1100nm (probe). Differential transmission is observable for several hundred picoseconds after a pump pulse in TiN compared to just a few picoseconds in Au. Preliminary results indicate plasmon-enhanced absorption increases the maximum electron temperature, causing a longer electron relaxation time due to the finite electron-phonon energy transfer rate.

10346-4, Session 1

Enabling new regimes of nanoparticle resonances through beam engineering

Jon A. Schuller, Univ. of California, Santa Barbara (United States)

Optical resonances in sub-wavelength nanoparticles enable a variety of plasmonic phenomena and devices. Conventionally, researchers tune the resonant properties of nanoparticles (NPs) by manipulating their size, shape, and composition. However, these light-matter interactions depend on two critical factors: 1) the physical properties of the nanostructure, and 2) the properties of the illuminating radiation. Here, we concentrate on the latter and demonstrate via electromagnetics calculations how unconventional light sources can be used to to selectively excite, enhance, and engineer resonant light-matter interactions in nanostructures. Specifically, we show how azimuthally and radially polarized light sources can be used to couple to "dark" modes and to achieve unprecedented magnetic field enhancements in single and dimer nanostructures.

10346-5, Session 2

3D plasmonic nanoarchitectures for extreme light concentrating *(Invited Paper)*

Wei-Chuan Shih, Univ. of Houston (United States)

Plasmon resonance, the collective oscillation of conduction band electrons, can be excited by shining light on some metallic nanostructures. Localized

surface plasmon resonance (LSPR). LSPR-based detection provides a sensitive reporting mechanism of the local refractive index changes due to surface binding. LSPR also provides a "boost" to light matter interactions near the surface of metallic nanostructures, typically known as "surface enhancement" in various spectroscopy. Over the past few decades, numerous studies have led to the current state of knowledge by largely attributing the enhancement to nanostructural "singularities", e.g., small gaps and sharp protrusions on the order of 10 nm. However, most of these studies relied on advanced lithography or colloidal surface chemistry to produce nanostructural singularities, aka "hot spots". Lithographic techniques such as focused ion beam is time-consuming and cost-prohibitive for scaling up. Colloidal surface chemistry produces assays that are challenging to translate into a "biochip".

My group has developed highly porous yet monolithic plasmonic nanostructures that feature intense and high-density hot spots, large surface area, and high structural integrity and reproducibility. We have applied them to several analytical Chem/Biosensing platforms for a range of sensing targets by various spectroscopic and imaging techniques. In this talk, I will mainly emphasize on the design, fabrication, modeling and simulation, and characterization of nanoporous gold nanoparticles and arrays.

10346-6, Session 2

Plasmonic nanogap structures studied via cathodoluminescence imaging

Stephen J. Bauman, Qigeng Yan, Mourad Benamara, Joseph B. Herzog, Univ. of Arkansas (United States)

Cathodoluminescence (CL) makes use of the beam raster capabilities of a scanning electron microscope to excite electrons in a sample and collects the luminescent light to produce images or obtain spectra that can reveal useful information about the sample. This technique has been shown to be particularly interesting for studying the plasmonic oscillations of metallic nanostructures. A recently developed fabrication technique has allowed for the creation of sub-10 nm gaps between metallic nanostructures for use as plasmonically active samples that can be tailored for various potential applications. The high degree of control over the geometries capable of being fabricated via this nanomasking technique allow for unique types of structures that are otherwise difficult to fabricate. In this work, the plasmonic response of metallic structures separated by sub-10 nm gaps is studied via CL imaging. Hyperspectral images can demonstrate the effectiveness with which various geometries produce specific wavelength resonances. The results can be helpful in determining which structures are optimal for specific applications based on these resonances. Also, the images can help to guide future fabrication, as the plasmon modes become better understood.

10346-8, Session 2

Maskless patterning using surface plasmon enhanced electron beamlets

Zhidong Du, Chen Chen, Liang Pan, Purdue Univ. (United States)

Optical lithography transfers fixed geometric patterns from a photo mask to photoresist wafers. Current tools cost more than 50 million US dollars each, and much more for the masks. To keep up with Moore's law, future tools and processes will become increasingly expensive. The next-generation extreme-UV tools have sufficient resolution, but current pilot tools will need substantial upgrades in source and process infrastructures to have sufficient throughput and yield. Patterning using parallel electron beams has emerged as a potential approach to meet the industry's patterning needs at advanced nodes, however researchers have not been able to find a robust method to generate and utilize a massive number of beamlets with satisfactory brightness and uniformity.

Here we report our recent research progress aiming to enable massively-parallel electron-beam lithography by using a novel nanoscale electron beam source array. We use plasmonic lenses to excite and focus surface electron waves to generate massively-parallel electron beamlets. Specifically, the proposed SPEP device consists of an array of plasmonic lens and electrostatic micro-lens pairs. Each pair independently produces a beamlet. During lithography, optical modulator dynamically controls the light incident onto the plasmonic lenses. The photons incident onto each plasmonic lens are concentrated into a diffraction-unlimited spot to excite the local electrons above their vacuum levels. Meanwhile, the electrostatic micro-lens extracts the excited electrons to form a focused beamlet to perform lithography. We investigate the fundamentals of localized electron excitation, build a proof-of-concept system and demonstrate lithography.

10346-9, Session 3

Tunable plasmonics and metasurfaces for applications in optical switching and space technology *(Invited Paper)*

Otto L. Muskens, Kai Sun, Christoph A. Riedel, Bigeng Chen, Cornelis Hendrik De Groot, Univ. of Southampton (United Kingdom)

Plasmonic nanoantennas are of interest because of their capability to enhance light-matter interactions. We present new results where antennas are used to obtain nanoscale devices with tunable characteristics. Applications of these devices include electrically controlled antennas, antennas integrated on silicon waveguides, and optical solar reflectors for spacecraft. By using tunable materials such as vanadium dioxide and doped-metal oxides, we demonstrate precise control and active tunability of the optical response. Experimental results are supported by combined electro-optical modelling at the nanoscale.

10346-10, Session 3

Measurement of Stokes parameters using plasmonic metasurface *(Invited Paper)*

Chih-Ming Wang, National Dong Hwa Univ. (Taiwan)

Recently, a plasmonic metasurface is proposed to generate versatile polarization. It is demonstrated that left-handed, right handed and linear polarization with various polarization angle can be generated using a single metasurface device. This fancy result makes a miniaturized stokes polarimeter possible. In this paper, a broadband plasmonic metasurface with Pancharatnam-Berry phase distribution is proposed to measure the polarization state of light through a birefringent plastic tape. It is shown that the polarization state of light through birefringent tape measured by plasmonic metasurface has a fair agreement with that measured by commercial polarimeter. This result shows that the metasurface has a potential as a miniaturized stokes polarimeter, meta-polarimeter.

10346-11, Session 3

Plasmon resonance sensors for compact plasmonic integrated device *(Invited Paper)*

Masanobu Haraguchi, Shun Kamada, Tokushima Univ. (Japan); Hiroyuki Okamoto, Nagaoka Univ. of Technology (Japan); Toshihiro Okamoto, Salah E. El-Zohary, Tokushima Univ. (Japan)

Surface plasmon polariton (SPP) provide the field enhancement and localization beyond the diffraction limit of light. By using SPP, we have numerically designed tiny resonance sensors as plasmonic integrated devices with silver or gold as metal material for near infrared region of light. We will present our recent work for the sensors. The sensors are the combination of the plasmon resonator and MIM channel plasmon waveguide with the gap of ~150 nm and the hight of ~1.5 micron. The typical area size of

sensor is order of 1 square micrometers and their sensitivity for temperature or stress change is comparable to current optical sensors. We have fabricated some fundamental structure of the device by using the electron beam lithography and will show experimental optical characteristics for IR region.

10346-12, Session 4

Metal-dielectric resonances in tip silicon metasurface and SERS based nanosensors *(Invited Paper)*

Andrey K. Sarychev, Andrey N. Lagarkov, Irina A. Boginskaya, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Igor V. Bykov, Institute for Theoretical and Applied Electromagnetics (Russian Federation); Andrey V. Ivanov, Ilya A. Ryzhikov, Marina V. Sedova, Institute for Theoretical and Applied Electrodynamics (Russian Federation); Ilya N. Kurochkin, N.M. Emanuel Institute of Biochemical Physics (Russian Federation)

We investigate the optical metasurface made of silicon tip-shaped grating. The geometric parameters are: period 3.0 μm, diagonal period 2.12 μm, height 0.3-0.7 μm, the tip angle 30º, tip curvature radius ≤ 10 nm, the effective area of the metasurface 2?2 mm. The metasurface can be considered as a diffraction grate. The diffraction pattern for red laser revivals 37 modes. The total reflection estimates as 0.32, where 0.26 corresponds to zero order reflectance and 0.06 - to the diffraction. In other words 19% of the reflected energy goes to the diffraction beams. The silicon tips cover only 8% of the total area of the metasurface. Hence, they provide very effective diffraction, which could be called the extraordinary optical diffraction. Our computer simulation gives very effective metal-dielectric resonances in the metal nano-particles placed on the silicone tips. The dielectric resonances in the cone are hybridized with plasmon modes. The conjugate of Au nanoparticles + DTNB molecules are deposited on pyramid grating. The conjugate has series of the well-defined Raman peaks, which we use as an effective SERS indicator.

10346-13, Session 4

Design of a colorimetric sensing platform using reflection mode plasmonic color filters

Renilkumar Mudachathi, Takuo Tanaka, RIKEN (Japan)

Extraordinary optical transmission (EOT) exhibited by nano hole arrays in plasmonic metasurfaces have been explored for the realization of colorimetric sensors which are useful for many applications like rapid diagnostics of infectious diseases and monitoring of food and environmental quality. We present a colorimetric sensing platform based on reflection mode plasmonic colour filter realized using aluminum as functional material. The plasmonic metasurface is designed in such a way that it produces intense narrow reflective peaks, which are highly sensitive to the ambient refractive index change. We demonstrate sharp colour changes for varying concentrations of sugar solutions.

In order to realize reflection mode plasmonic filter with narrow reflection peaks, we fabricated 2D arrays of aluminum nano square patches raised on top of PMMA nano pillars in the back ground of a perforated back reflector by systematically varying the metal patch size (D) and periodicity (P). In the single layer fabrication process the PMMA nano pillars were defined by electron beam lithography and subsequently aluminum thin film was deposited by thermal evaporation to form both the metal square patches and the fishnet like back reflector. The colour formation is based on the excitation of plasmonic light absorption at two distinct wavelengths leaving a central reflective peak that is coherently scattered by coupling to a strongly radiating dipole resonance. Pure colours both in the RGB and CMY colour schemes with extreme reflective peaks of high quality factor (FWHM of 100nm) across the visible spectrum are optimized. Sugar solutions of varying concentration is then introduced to the nano structures to produce visible colour changes to demonstrate the refractive index sensing using the proposed colorimetric sensing platform.

10346-14, Session 4

Nanoporous gold decorated with silver nanoparticle as large area efficient SERS substrate

Eugenio Calandrini, Paolo Ponzellini, Matteo Ardini, Istituto Italiano di Tecnologia (Italy); Sandro Cattarin, CNR-IENI (Italy); Francesco De Angelis, Denis Garoli, Istituto Italiano di Tecnologia (Italy)

In the last decade, the research efforts was focused on the quest of novel plasmonic materials. In particular metal nanostructure films can act as plasmonic platform embedding hot spots that are perfect for surface enhanced Raman scattering (SERS) with considerable signal improvements. Usually, hot spots confined within the interstices between the adjacent metal nanostructures are essential to enable highly sensitivity detection due to near-field coupling of localized surface plasmon resonance (LSPR). Unfortunately, such substrates have competing geometrical requirements including the narrowest interstice between neighboring units to provide maximum near-field coupling, and sufficient space to accommodate the target probes. Due to the exponential decay of electromagnetic fields normal to the metal surface, strong near-field coupling prefers to be obtained within the interstices with 1–2 nm separation. On the other hand, such small gaps are not favorable for the insertion of target molecules dissolved in the solvents. Numerous efforts have been made to address these issues and different nanostructures including nanoparticles, nanowires, nanopores, and their conjugations have been used as the precursors.

Herein, we fabricate hybrid nanostructure that addresses the issues discussed above and exhibits giant enhancement in Raman scattering. It consists of nanoporous gold (NPG) films decorated by silver nanoparticles that provide extremely narrow interstitial spaces contributing to significant near-field coupling and enhance Raman scattering by several orders of magnitude.

10346-15, Session 4

Refractive index sensing with graphene plasmons

Tobias Wenger, Giovanni Viola, Jari Kinaret, Mikael Fogelström, Philippe Tassin, Chalmers Univ. of Technology (Sweden)

We report on our theoretical work investigating graphene plasmons for refractive index sensing at room temperature. We have found that graphene plasmons are very sensitive to the index of refraction of the material in their immediate neighbourhood. This is the result of the strong field confinement of graphene in a volume that stretches about 100 nm away from the graphene sheet. We compare the sensitivity of graphene-plasmon-based refractive index sensors to gold-based plasmonic index sensors, and we find that graphene has a much stronger surface sensitivity.

10346-16, Session 4

Labeling and imaging brain tumor cells with Raman tags *(Invited Paper)*

Li-Ching Huang, Yung-Ching Chang, Shiuan-Yeh Chen, National Cheng Kung Univ. (Taiwan)

Glioblastomas (GBM) are highly lethal brain tumors which arise from astrocytes. These tumors are highly malignant due to quick reproduce rates and are extremely resistant to radiation and chemotherapies. The median survival of GBM patients is less than 16 months. In addition to strong resistance to conventional treatments, the other fundamental difficulty in removing GBM cells is their highly infiltrative nature. Therefore, imaging and locating these tumor cells is a challenging task. In this work, plasmonic nano-tags with stable Raman signals are fabricated and utilized to label GBM cells. The backbone of the Raman tags is a plasmonic core-satellite assembly which produces highly internal concentrated field for Raman enhancement. Compared to the conventional fluorescent dyes, the Raman tags are more stable and robust under laser illumination. The fabrication and functionalization of Raman tags is described and the Raman images of the labeled GBM cells are demonstrated.

10346-17, Session 5

Ultra-thin transition metal nitrides for plasmonic applications *(Invited Paper)*

Harsha Reddy, Deesha Shah, Purdue Univ. (United States); Nathaniel Kinsey, Virginia Commonwealth Univ. (United States); Vladimir M. Shalaev, Alexandra Boltasseva, Purdue Univ. (United States)

With continuing advances in nanofabrication methods, the sizes of metal components in plasmonic devices have been shrinking, now approaching only a few monolayers in thickness. The strong spatial confinement in such thin films is expected to lead to quantum and nonlocal effects. These ultra-thin films serve as ideal material platforms for probing various classical to quantum transitions. More importantly, they are extremely sensitive to external electrical and optical perturbations, making them an attractive platform to tune light-matter interactions at the nanoscale. However, a key to the study of these exotic light-matter interactions lies in producing metallic films only a few monolayers in thickness.

Producing such thin films with noble metals is extremely challenging due to the well-known issues of island formation. On the other hand, ultra-thin TiN films with thicknesses down to only 2 nm can be routinely grown, which is critical for enabling enhanced control over the plasmonic properties. We have experimentally characterized the optical constants of ultra-thin TiN films (<10 nm) of various thicknesses. All the films remained highly metallic with a carrier concentration on the order of 1022 cm-3 even in the thinnest film (2 nm). The ability to grow such thin films is the first step towards realizing the potential electrical and optical control of plasmonic properties. Furthermore, the extreme light confinement that can be achieved in ultra-thin films could enable several forbidden light-matter interactions. Together with its refractory properties and CMOS compatibility, ultra-thin TiN shows great promise for realizing various quantum and nonlocal nanophotonic applications.

10346-18, Session 5

Light twists around plasmonic nanowires *(Invited Paper)*

Laurens Kuipers, Kavli Institute of Nanoscience Delft (Netherlands)

We use a near-field microscope to visualize the nanoscale light patterns, both electric and magnetic fields [1,2]. The interplay between the various components of either the magnetic or the electric fields leads to optical entities that, in their size, put nanophotonics to shame: these optical singularities have a size zero. Interestingly, optical singularities near nanoscale structures exhibit a markedly different behavior from those in macroscopic beams [3,4]. We observe a distinctly different behavior around plasmonic nanowires to that above photonic crystal waveguides [5]. Moreover, we show that these singularities and their associated local helicity can be applied for new quantum technology as they can be used to deterministically couple a spin-transition to emission direction [6], useful for novel quantum technology [7]. In addition we show that plasmonic nanowires are better than dielectric waveguides for the transmission of ultrashort pulses [8]. This can also be used to induce nonlinear phenomena [9].

10346-20, Session 5

Numerical simulation of nonlocal optical response in light scattering by nanoparticle on the substrate

Ivan V. Lopushenko, M.V. Lomonosov Moscow SU (Russian Federation)

Thorough analysis of the plasmonic phenomena requires proper account for such effects as size dependent surface plasmon resonance shifts and intensity changes observed in metal nanoparticles, especially in systems with small feature sizes [1]. Recent theoretical advances, including Generalized Nonlocal Optical Response (GNOR) approach, allow to very accurately resolve these effects within the classical electromagnetics [2], thus paving the way for implementation of efficient low cost computational techniques.

We present a new GNOR-based numerical scheme of the flexible Discrete Sources Method [3] for analysis of light scattering by single plasmonic nanoparticle in the layered medium with rigorous account for both substrate-particle interaction and nonlocal effects. Key features of the proposed surface oriented approach include meshless algorithm without any surface integration procedures involved, the ability to track the real convergence of the solution via a posteriori error estimation, and the ability to consider very small plasmonic nanoparticles with size under 5nm.

Numerical simulations have been carried out in order to appropriately verify the created mathematical model and investigate the influence of nonlocal effect on the scattering properties of various plasmonic nanoparticles. We show that proposed method enables to accurately study the significant influence of such parameters as substrate material, size, shape and material of the particle on the position and intensity of plasmon resonance peak.

10346-21, Session 5

Revealing the femtosecond dynamics of metallic and molecular nanostructures *(Invited Paper)*

Benjamin Stadtmueller, Martin Aeschlimann, Technische Univ. Kaiserslautern (Germany)

The extensive effort to study and understand the optical response of metallic nanostructures is motivated by their potential to act as essential building blocks in novel electronic devices with nano-optical circuits. For instance, nanoscale antennas can act as source for the propagation of surface plasmon polariton (SPP) waves. These SPPs are coherent hybrid modes of the collective electronic motion and the electromagnetic fields and have the potential to mediate a coherent energy transfer between different nanostructures acting as source and receiver of a nanoscale device. Moreover, the optical excitation of nanostructures can lead to long lasting electronic coherences in these structures which can be manipulated by the phase properties of the external light field.

An ideal tool to study ultrafast phenomena in nanostructures on a nanoscale is time-resolved photoemission electron microscopy (PEEM) which allows us to investigate their ultrafast optical response with a spatial resolution far beyond the optical diffraction limit [1-3].

In a first work, the long-range energy transfer mechanism between two coupled plasmonic whispering gallery nano-antennas in an elliptical cavity has been investigated. Only one gold antenna is excited selectively when the structure is illuminated under grazing incidence. We demonstrate periodic energy transfer back and forth over a distance of twice the excitation wavelength mediated by the SPPs. The experimentally observed ultrafast dynamics is in accordance with simulations as well as a coupled-oscillator model and suggests the feasibility of long-range coherent coupling of pairs of quantum emitters.

In a second project, we move from metallic to molecular nanostructures and investigate the coherent electron dynamics of the metal-organic hybrid interface formed between the organic semiconductor Alq3 and the ferromagnetic Co surface. This interface is of particular interest for the field of molecular spintronics since it possess states with long spin-dependent relaxation times [4,5]. After optical excitation with visible light, we observe a coherence response in the interferometric correlation traces. Using two-dimensional spectroscopy in combination with PEEM, we can clearly identify two excited resonances with an energy spacing of about 77 meV and a linewidth of 11 meV and 48 meV, respectively. These homogeneous linewidth of these states correspond to coherence lifetimes of about 370 fs and 87 fs. These results underline the potential of organic molecules to significantly enhance coherent lifetimes of metallic surfaces.

A link between the superconducting transition and the optical range plasmonics of niobium *(Invited Paper)*

Chun Yen Liao, Univ. of Southampton (United Kingdom); Harish N. S. Krishnamoorthy, Nanyang Technological Univ. (Singapore); Vassili Savinov, Jun-Yu Ou, Univ. of Southampton (United Kingdom); Chunli Huang, Giorgio Adamo, Nanyang Technological Univ. (Singapore); Eric Plum, Kevin F. MacDonald, Univ. of Southampton (United Kingdom); Yidong Chong, Cesare Soci, Nanyang Technological Univ. (Singapore); Feodor V. Kusmartsev, Loughborough Univ. (United Kingdom); Din Ping Tsai, National Taiwan Univ. (Taiwan) and Academia Sinica (Taiwan); Nikolay I. Zheludev, Univ. of Southampton (United Kingdom)

Superconductivity is commonly expected to be insignificant in optics, where photon energy is orders of magnitude higher than the binding energy of the Cooper pairs, the superconducting charge carriers. By experimentally studying optical range plasmonic response of niobium, a conventional low-temperature superconductor, we show that, contrary to this expectation, superconductivity does affect plasmonic behaviour at optical frequencies. Our results shed a new light on properties of superconductors, suggesting that superconductivity may play a role in forming the optical dielectric response near the superconducting transition.

We study the temperature-induced changes in the optical properties of a nanostructured superconducting metamaterial as well as unstructured superconductor film. In the non-superconducting metamaterials, the temperature-related variations in the optical response have been shown to saturate below temperature 50K. In contrast, we show that both the position and the strength of niobium metamaterial resonances exhibit a pronounced dependence on temperature down to a few Kelvin, with a sharp change in behaviour around the superconducting transition temperature at 9K. Equivalently dramatic changes are also observed in the temperature-dependence of the dielectric constant of unstructured niobium film, measured in a separate experiment.

10346-23, Session 6

Mimicking general relativity through plasmonic spin hall effect

Hui Liu, Nanjing Univ. (China)

Based on the concept of drawing equivalence between different configurations in transformation optics, we introduce a conceptual framework to investigate radiation from accelerating particles using chains of metamaterial atoms with SOI on a metasurface. The framework allows a global geometric picture in visualizing different one-dimensional space-times in general relativity using our two-dimensional metasurface. In particular, chains of metamaterial atoms along different curved lines in generating a common SPP caustic represent the same particle motions observed in difference reference frames, with relative motion through a general-relativistic transformation, such as a Rindler transformation from a reference Minkowski space-time. Such a tool allows us to study particle motions in different space-times in general while the particular geometric understanding provides us unique ways in generating SPP.

10346-24, Session 6

Novel platforms for plasmonics *(Invited Paper)*

Alejandro Manjavacas, The Univ. of New Mexico (United States)

Photonic systems containing active and passive elements with balanced gain and loss, usually known as PT-symmetric systems, are attracting increased attention due to their exceptional properties including, to cite some, asymmetric propagation and reflection, unidirectional invisibility, switching, or extraordinary nonlinear behaviors. Here, we will discuss the optical response of finite nanostructures composed of pairs of active and passive nanospheres operating close to the PT-symmetry condition. We will show that, despite their highly regular geometry, these systems present very anisotropic optical response. We will also discuss how the geometrical arrangement of ensembles of nanostructures can give rise to unexpected collective modes displaying strongly localized responses. We will analyze different types of ordered arrays containing either a finite or an infinite number of structures.

10346-25, Session 7

Surface plasmon manipulated Smith-Purcell radiation on metallic periodic and gradient gratings *(Invited Paper)*

Yung-Chiang Lan, Yi-Chieh Lai, Bo Han Cheng, Hsin-Yu Kuo, Tzu Cheng Kuang, National Cheng Kung Univ. (Taiwan)

An electron beam passing over metallic gratings can emit Smith-Purcell radiations (SPRs). The emission frequency and angle of SPRs strongly depend on the period of gratings which is previously designed. The electron beam can also excite surface plasmons (SPs) at the metallic surface. Therefore, the electron beam excited SPs may affect SPRs when the frequencies of SPs are within the emission bands of SPRs. In this work, SPs manipulated SPRs on metallic periodic and gradient gratings are explored by FDTD simulation and theoretical analyses. Our investigations indicate that, for periodic gratings, the SPRs can be enhanced by exciting SP and mimic SP on the gratings if their frequencies are within the emission bands of SPRs. When using periodic metallic disk arrays as the gratings, the SPRs can also be enhanced and inhibited by exciting the resonant surface plasmon (RSP) modes on the top and bottom, respectively, of the metal disk. For gradient gratings, SPs enable the SPRs at designed frequencies to be focused or divergent in space by changing the incident direction of the electron beam. This work provides a way toward practical applications on frequency-selected devices such as multi-wavelength optoelectronic device, communication security and compact and tunable visible light source.

10346-26, Session 7

Instantaneous spatial variation of Green's tensor in complex nanostructures via eigenmode expansion *(Invited Paper)*

Parry Chen, David J. Bergman, Tel Aviv Univ. (Israel); Yonatan Sivan, Ben-Gurion Univ. of the Negev (Israel)

The spatial variation of Green's tensor of micro-structured media in both source and detector position and orientation over all 3D space on arbitrarily fine grid is obtained without repeated simulation. Total radiated fields even for arbitrary extended sources are simulated by simply projecting onto the structure's source-free eigenmodes. Eigenmodes are obtained from a linear eigenvalue problem, and is easily implemented on COMSOL. Maxwell equations are solved rigorously, thus circumventing implementation and interpretation issues associated with quasi-normal eigenmode methods. Rapidly converging results are obtained, facilitating analytic calculations involving Green's tensor, such as radiative heat transfer and van der Waals forces.

10346-27, Session 7

Plasmon-exciton energy transfer in nanoparticle-molecule aggregates

Maicol A. Ochoa, Univ. of Pennsylvania (United States); Abraham Nitzan, Univ. of Pennsylvania (United States) and Tel Aviv Univ. (Israel)

Plasmon-plasmon coupling in nanoscopic structures permits the manipulation of light at sub-wavelength distances, promising novel technological applications that span from medicine to quantum computing. In the presence of molecular media, plasmon-exciton interactions introduce additional complexities for the control and manipulation of light in plasmonic nanowaveguides. In this work, we have theoretically investigated within semiclassical models the energy transfer process between plasmonic spherical nanoparticles mediated by molecular media. In particular, we have characterized the lineshape for these complexes, as determined from measurements of scattered radiation and heating rate, and their dependence on molecular properties such as transition energy, relaxation and dephasing. In situations where the energy transfer mechanism is dominated by plasmon-exciton coupling, the effect of molecular density, distance, geometry and orientation were also evaluated. Our results indicate that the molecular media can dramatically change the linear response of plasmonic aggregates when the molecular energy gap is in resonance (or nearly in resonance) with the optically active hybrid states and can potentially activate dark modes from the aggregate.

10346-29, Session 7

Light conrol metasurfaces with randomly dispersed silver nanoparticles *(Invited Paper)*

Masayuki Naya, Takeharu Tani, Hideki Yasuda, Shinya Hakuta, Hirotoshi Yoshizawa, FUJIFILM Advanced Research Labs. (Japan)

We propose metasurfaces using randomly dispersed silver nano discs [1]. Wavelength of optical response can be artificially controlled by changing aspect ratio (diameter/thickness) and dispersion density of silver nano discs. These structures are easy to fabricate in a large area using conventional wet-coating methods. We applied these structures to a transparent solar insulation film and an anti-reflection film for visible light. Utilizing reflection wavelength selectivity of this structure, we have developed a transparent solar insulation film which strongly reflects infrared light whereas transmit visible light. We also have developed silver nanodiscs metasurface for anti reflection film for visible light. We show that the effective refractive index of metasurcface layer was about 0.5 in the visible wavelength. The reflectance of 0.3% at wavelength of 550nm, which is 25 times smaller than the reflectance of normal glass, was demonstrated in the experiment.

We also propose ring-like silver particles randomly dispersed structure for controlling far infrared light. The properties were calculated by employing an electromagnetic optical simulation based on the finite difference time domain (FDTD) method. It was confirmed by calculation that the reflectance of optimized structure is 80% at wavelength of 5500nm and the visible light transmittance is 80% at wavelength of 500nm. Preliminary experimental results qualitatively agree with the simulation.

10346-30, Session 8

New material platforms for dielectric nanoantennas and metasurfaces *(Invited Paper)*

Naresh K. Emani, Hanfang Hao, Egor Khaidarov, Ramon Paniagua-Dominguez, Yuan Hsing Fu, Reuben M. Bakker, Vytautas Valuckas, Arseniy I. Kuznetsov, A*STAR - Data Storage Institute (Singapore)

Optically resonant dielectric nanostructures is a new direction in nanophotonic research which gives a strong promise to compliment or substitute plasmonics in many potential application areas [1]. The main advantages of resonant dielectric nanostructures over conventional plasmonics are low losses, wide range of applicable dielectric materials and strong magnetic resonant response. So far most of research in this field has been conducted with silicon as a material for nanostructures due to its one of the highest value of refractive index at optical frequencies and CMOS compatibility. However, while silicon is an excellent material of choice for operation in the near-IR spectral range its applicability for visible frequencies is limited by increasing losses inside the material. Also, being an indirect bandgap semiconductor it is not a suitable material for making active nanoantenna devices. For these reasons in recent studies research focus starts shifting towards other appropriate materials such as III-V semiconductors, e.g. GaAs or GaP, and wide-bandgap semiconductors such as TiO_2. In this presentation we will discuss applicability of different dielectric/semiconductor material platforms for obtaining resonant nanoantennas and metasurfaces operating in the visible frequency range. We will first show that titanium dioxide metasurfaces can be designed to obtain sharp resonances and full phase control at all three RGB wavelengths through Huygens' metasurface approach, which pave the way towards realization of thin multi-layer metasurfaces with multi-colour operation. Then we will introduce a new III-V material platform based on GaN, which is highly transparent through the whole visible spectrum, and show high-efficiency operation of GaN metasurfaces in the blue and green parts of the visible spectrum. Finally we will discuss active nanoantennas based on GaAs and show the path towards achieving laser emission from resonant semiconductor nanoantenna structures.

Mode-matched multi-resonant 2.5D plasmonic nano-terrace array for surface-enhanced spectroscopy

Weihua Zhang, Shuang Zhou, Jie Bian, Nanjing Univ. (China)

Plasmonic nanostructures can function as a resonant optical antenna, which can trap the far-field propagating field into nanoscale spots in the near-field regime with a large field enhancement and vice versa.[1] This unique property makes plasmonic nanostructures a powerful platform for enhancing both the excitation and emission processes of various optical effects. However, most of the applications are based on the large local field enhancement at the excitation frequency, despite that the total enhancement is also dependent on the enhancement at the emission frequency. This severely limits the performance of the plasmonic substrates.

To tackle this issue, we designed and numerically studied a new type of multi-resonant plasmonic nanostructure, the tri-level plasmonic nano-terrace array (3L-PNTA), which is a 2.5D structure consisting of an array of vertically coupled plasmonic nanotiles on dielectric nanoterrace substrate. [2] The results show that the 3L-PNTA supports multiple resonances, which can be independently tuned by changing different geometrical parameters. On the resonances, local light intensity can be enhanced by more than two orders of magnitude in the nanogaps between the plasmonic nanotiles due to the strong vertical couplings. Moreover, the enhanced fields associated with different resonant modes are spatially overlapped, allowing the 3L-PNTA to enhance optical processes at both excitation and emission wavelengths, simultaneously. This makes the 3L-PNTA a perfect multi-resonant plasmonic nanostructure for enhancing various optical processes.

Multimode metasurfaces: from direct observation of the phase front to advanced optical functions *(Invited Paper)*

Chen Yan, Xiaolong Wang, Kuang-Yu Yang, Luc Driencourt, T. V. Raziman, Olivier J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Planar photonic metasurfaces, exhibiting artificial optical effects at the interface, are enabling a broad variety of possibilities as optical elements, communications, and signal processing. The signal we perceive from a metasurface is determined by the phases of the different nanostructures that compose the system. This phase controls the spatial radiation distribution following Huygens'principle and has been utilized in planar optical devices exhibiting negative refraction, cloaking, and holographic elements to name a few.

In this presentation, we will first demonstrate the quantitative direct measurement of the phase front produced by a metasurface using digital holography microscopy. We will then show that by designing and tuning the multipolar components of the nanostructured building blocks, it is possible to also control the spectral response as well as the polarization state of the system. By composing a metasurface with such complex nanostructures fabricated in silver, we are able to control the scattered light and channel different colors into different directions. In the second series of experiments, we specifically study the multipolar radiation of a bianisotropic scatterer and use it for the efficient splitting of circularly polarized light, similar to a photonic spin Hall effect. Since the near-field enhancement and circularly polarized scattering in this case occur at the individual antenna level, this planar surface is capable of extracting the fluorescence and controlling the spin-polarized emission from nearby emitters, as will be demonstrated experimentally. These results have practical implications for controlling the optical activity and can potentially enable new polarization-dependent light-emitting devices for applications in imaging, optical communication, and optical displays.

10346-33, Session 9

Surface plasmon polaritons for opto-mechanical control of nanoparticles *(Invited Paper)*

Mihail I. Petrov, Aliaksandra Ivinskaya, Natalia Kostina, Andrey A. Bogdanov, ITMO Univ. (Russian Federation); Sergey Sukhov, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); Pavel Ginzburg, Tel Aviv Univ. (Israel) and ITMO Univ. (Russian Federation); Alexander S. Shalin, ITMO Univ. (Russian Federation) and Institute of Radio Engineering and Electronics (Russian Federation) and Ulyanovsk State Univ. (Russian Federation)

The talk will be focused on new concepts of opto-mechanical manipulation of nanoparticles mediated by their coupling to propagating surface plasmon polariton (SPP) modes. This approach gives a broad range of new opportunities for opto-mechanics, which will be illustrated by several important effects. In particular, we will show that one can achieve optical pulling force acting on nanoparticle due to its coupling to SPP mode [Laser and Photonics Reviews, 10(1), 116–122]. The unidirectional excitation of SPP modes controlled by the optical spin-orbital locking effect results in strong recoil force, which pulls it in the direction of laser beam incidence. Moreover, the generation of SPP modes allows getting unique trapping and anti-trapping regimes when nanoparticles is placed near metal surface in the Gaussian beam [Light: Science & Applications (2017) 6, e16258]. The switching of the trapping regimes strongly depends on the wavelength of light, and on the nanoparticle sizes, which make it prospective for optical sorting near flat metallic interfaces. We also suggest utilizing the efficient generation of SPP modes for transverse optical binding effect, which is usually attributed to the interference of photons in homogenous space. We show that strong transverse optical binding can be observed near planar metallic surface due to the SPP interference. As the result the nanoparticles will form bounded states (nanoparticle molecules) at the distances defined by the SPP wave vector. The discussed results show the new opportunities for opto-mechanical control and manipulation through SPP modes generation.

Tuning the characteristics of surface plasmon polariton nanolasers by tailoring the dispersion relation *(Invited Paper)*

Tien-Chang Lu, National Chiao Tung Univ. (Taiwan)

Nanolasers with ultra-compact footprint are able to provide high intensity coherent light, which have various potential applications in high capacity signal processing, biosensing, and sub-wavelength imaging. Among various nanolasers, those lasers with cavities surrounded with metals have shown to have superior light emission properties due to the surface plasmon effect providing better field confinement capability and allowing exotic light-matter interaction. In this talk, we report robust ultraviolet ZnO nanolaser by using silver (Ag) [1] and aluminum (Al) [2] to strongly shrink the mode volume. The nanolasers operated at room temperature and even high temperature (353K) shows several distinct features including an extremely small mode volume, large Purcell factor and group index. Comparison of characteristics between Ag- and Al-based will also be made.

Ultrafast carrier dynamics in bimetallic nanostructures-enhanced methylammonium lead bromide perovskites

Rizia Bardhan, Holly Zarick, Vanderbilt Univ. (United States); Abdelaziz Boulesbaa, Alexander A. Puretzky, Oak Ridge National Lab. (United States); Eric M. Talbert, Naiya Soetan, Vanderbilt Univ. (United States); David B. Geohegan, Oak Ridge National Lab. (United States)

An unprecedented rise in efficiency has been observed in methylammonium lead trihalide (MAPbX3, X=I, Cl, Br) perovskite solar cells (PSCs) reaching >20% recently. While MAPbI3 perovskites have been the primary focus in PSCs, the poor stability and rapid degradation in humidity has remained a major obstacle in MAPbI3. MAPbBr3 is a promising alternative to MAPbI3 with a large 2.2 eV bandgap which gives rise to a high open circuit voltage, long exciton diffusion length (>1.2 ?m) enabling good charge transport in devices, and higher moisture stability due to its stable cubic phase and low ionic mobility relative to the pseudocubic MAPbI3. However, a relatively large exciton binding energy (76 meV) and poor light absorption beyond its band edge at 550 nm has limited the efficiencies for MAPbBr3 solar cells. In this work, we examine the impact of hybrid bimetallic Au/Ag core/shell plasmonic nanostructures on the carrier dynamics of methylammonium lead tribromide (MAPbBr3) mesoporous PSCs.1 Plasmon-enhanced PSCs incorporated with Au/Ag nanostructures demonstrated improved light harvesting and increased power conversion efficiency by 26% relative to reference devices. Two complementary spectral techniques, transient absorption spectroscopy (TAS) and time-resolved photoluminescence (trPL), were employed to gain a mechanistic understanding of plasmonic enhancement processes. TAS revealed a decrease in photobleach formation time which suggests that the nanostructures improve hot carrier thermalization to an equilibrium distribution, relieving hot phonon bottleneck in MAPbBr3 perovskites. TAS also showed a decrease in carrier decay lifetimes indicating nanostructures enhance photoinduced carrier generation and promote efficient electron injection into TiO2 prior to bulk recombination. Further, nanostructure-incorporated perovskite films demonstrated quenching in steady-state PL and decreases in trPL carrier lifetimes, providing further evidence of improved carrier injection in plasmon-enhanced mesoporous PSCs.

Enhanced photovoltaics in metamaterial devices using transparent conducting oxides

Nicholas Sharac, Heungsoo Kim, Chase T. Ellis, Alexander Vlasov, Jeffrey P. Calame, Joshua D. Caldwell, Joseph G. Tischler, Marc Curry, U.S. Naval Research Lab. (United States)

The cost effectiveness, flexibility, and lightness of weight of future photovoltaic devices can be achieved by utilizing surface plasmons to enhance solar cell efficiencies of thin film devices. By tuning the plasmon resonance, enhanced light concentration can occur at frequencies complimentary to those of traditional devices such as Si, so as to optimize light trapping from the sun. Here, we present light trapping metamaterial structures consisting of metallic gratings which couple light through a thin insulating dielectric layer and into a thin doped transparent conducting oxide (TCO) film, which forms a Schottky contact with Si. This configuration absorbs light in the visible through interband transitions (normal operation) and uses hot electrons in the IR. Reflectance data for two different configurations (top and bottom side gratings) show pitch dependent resonances in the visible and IR, which exhibit modes, shown from simulations, to be localized to the ITO film. Current-voltage curves show increased electrical activity under both white light and IR broad band, suggesting plasmon enhanced absorption in the IR as a result of our metamaterial structure. By tailoring the geometric properties of the grating in addition to the thickness and doping of the ITO film, the optical properties of the structure can be tuned to maximize light absorption. By also utilizing a bottom side configuration, we show that the metal gratings can be used in conjunction with TCO films without obstructing any potential collected sunlight.

Infrared localized surface plasmon polariton nanostructures for various applications *(Invited Paper)*

Min-Hsiung Shih, Academia Sinica (Taiwan)

In the presentation, we will present and discuss the localized surface plasmon polariton (LSPP) resonances in the Ag/SiO2/Ag nanostructures for narrow-band emitters, tunable polarizer and high performed biosensor. The Ag/SiO2/Ag sandwich nanostructure was designed and fabricated to exhibit the LSPP modes in an infrared wavelength regime. By manipulating the geometry, the high-performance, wide-angle, polarization-independent LSPP resonant waves are flexible for various applications.

The two-dimensional metallic broadband absorbers with the Ag/SiO2/Ag multi-sized nanodisk structures will be first presented. The absorptivity of such structure can be increased by tailoring the ratio of disk size to the unit cell area. The metallic disk exhibits a localized surface plasmon polariton (LSPP) mode for both TE and TM polarizations. By manipulating the ratios and disk sizes, a high-performance, wide-angle, polarization-independent multiple band absorber was experimentally achieved. The metallic nanodisk structure can be also applied an efficient narrow-band thermal emitter in the IR region. The metallic nanodisk would be a perfect thermal emitter at a specific wavelength, which can be tuned by varying the diameter of the disk.

We also discuss that oval-shape nanodisk LSPP structure can be used as an efficient angle-independent polarizer in the mid-infrared wavelength regime. For the optimum design, we can obtain a degree of polarization of 99% both experimentally and theoretically. A high extinction ratio between 20 and 40 dB can be obtained by changing the axis ratio of the oval disc between 0.65 and 0.85. The wavelength of polarized light can be tuned in a wide range by changing the structural parameters.

10346-38, Session 10

Plasmonic nonlinear optical components *(Invited Paper)*

Euclides Almeida, Yehiam Prior, Weizmann Institute of Science (Israel)

The ability to control the amplitude, phase and polarization states of light on subwavelength scales established metasurfaces as miniaturized alternatives to standard, the relatively large optical components. So far, most of these ultrathin elements operate in the linear regime, and do not change the frequency of the light transmitted or reflected from them. Using our better control over the response of the metasurfaces, we demonstrate a special class of metasurfaces that act as frequency-converting optical components [1-3]. Through nonlinear generation, plasmonic meta-atoms are used as the metasurfaces' building blocks and a 2ϖ phase shift can be imparted on the nonlinear wave. Similar to the linear metasurfaces case, the laws governing nonlinear optics can be generalized to include nonlinear phase gradients. In phase matched interactions for example, the anomalous signal generated in a collinear wave mixing scheme is emitted into another direction [2]. We demonstrate optical elements such as blazed gratings and lenses operating through four-wave mixing and third-harmonic generation. Additionally, we devise a novel type of computer-generated hologram that can reconstruct complex images at the third harmonic frequency of the reading beam [3]. Polarization-multiplexed, three-dimensional and dynamical

nonlinear holograms are fabricated in ultrathin elements by multilayer nanolithography, paving the way to a class of devices that can manipulate optical beams in unprecedented ways.

Femtosecond controlling mechanism of surface plasmon polaritons

Kuidong Wang, Long Chen, Haijuan Zhang, Jie Chen, Shanghai Jiao Tong Univ. (China)

Femtosecond controlling of surface plasmon polaritons (SPPs) has become a promising route for the development of high-speed plasmonic switches. However, the applications of femtosecond plasmonic modulation are limited by the relatively slow modulation speed and the requirements of high optical powers, such as in high speed integrated plasmonic circuits. Moreover, the mechanism of the femtosecond modulation remains unresolved. With time-resolved optical pump-probe technique, two sets of experiments were performed to improve the modulation speed and minimize the requirement of the optical power for femtosecond plasmonic modulation. In the first set of experiments, an ultrafast plasmonic modulation with a 70-fs switching time on an aluminum-coated grating was achieved in frequency degenerate experiments via light-SPP interaction, which is about one-third of the value reported previously. We found that the high-speed plasmonic modulation primarily results from the coherent nonlinearities which are related to the anharmonicity of the SPPs. The switching time was measured experimentally with a range of laser pulse widths and estimated theoretically to be even shorter and ultimately limited by the plasmon damping time. In the second set of experiments, the modulation depth of 8.66% was achieved with pump fluence of 1.5 mJ/cm2 via plasmon-enhanced optical nonlinearities, which is 7 times higher than that achieved from light-SPP interaction. This preliminary results suggest that the plasmonic effects could strongly enhance the modulation depth in plasmonic switching.

10346-40, Session 10

Adiabatic nanofocusing in hybrid gap plasmon waveguides

Michael P. Nielsen, Lucas Lafone, Aliaksandra Rakovich, Themistoklis P. H. Sidiropoulos, Mohsen Rahmani, Stefan A. Maier, Rupert F. Oulton, Imperial College London (United Kingdom)

We present an experimental demonstration of a silicon hybrid gap plasmon waveguide for efficient adiabatic nanofocusing. Formed of a gap in a thin metal film atop an unetched silicon-on-insulator (SOI) substrate, a recent theoretical proposal showed that these waveguides had unique advantages for nanofocusing applications. A schematic of the structure can be seen in Figure 1(a). At large gap widths, in excess of 100nm, the mode propagates primarily in the underlying silicon away from the metallic films, leading to propagation lengths of tens or even hundreds of micrometres. When the waveguide width is reduced below 100nm, the mode becomes concentrated in the gap, leading to mode areas far below the diffraction limit. This provides a new degree of freedom in waveguide dispersion engineering as the localisation of the mode is purely controlled by the gap width. Moreover, one can imagine filling the gap region with a functional nonlinear material and with the metal films acting as natural electrical contacts, creating a plasmonic phase or absorption modulator.

In this work we will give evidence of extreme nanofocusing through the use of a photoluminescent material in the gap with a three photon absorption process. Furthermore, by incorporating a nonlinear material into the gap, the high intensities gained through this nanofocusing process were utilized for nonlinear frequency conversion through both theoretical and experimental studies.

10346-41, Session 11

Fabrication and characterization of coupled ensembles of epitaxial quantum dots and metal nanoparticles supporting localized surface plasmons *(Invited Paper)*

Tigran A. Vartanyan, ITMO Univ. (Russian Federation); Vladimir Chaldyshev, Ioffe Institute (Russian Federation) and Saint-Petersburg State Polytechnical Univ. (Russian Federation); Nikita A. Toropov, Igor A. Gladskikh, Polina V. Gladskikh, ITMO Univ. (Russian Federation); Valeriy V. Preobrazhenskiy, Mikhail A. Putyato, Boris R. Semyagin, A.V. Rzhanov Institute of Semiconductor Physics (Russian Federation); Alexander Kosarev, Saint-Petersburg State Polytechnical Univ. (Russian Federation)

Epitaxial quantum dots (QDs) find numerous optoelectronic applications ranging from intermediate band solar cells to optical memory devices. Coupling of the epitaxial quantum dots to metal nanoparticles may improve their performance due to the field enhancement provided by the localized plasmon excitation. In this contribution we report on coupling an array of InAs quantum dots in the GaAs matrix to silver nanoparticles.

A stack of five layers of epitaxial InAs QDs separated by 10 nm thick GaAs barriers was grown by molecular beam epitaxy using Stranski-Krastanow mechanism. In the stacks the QDs were vertically self-aligned. The upper layer of QDs was capped by 3nm-GaAs/3nm-AlAs/4nm-GaAs layer sequence. Then, a thin silver layer was added via physical vapor deposition in a vacuum chamber at the residual pressure of 10 7 Torr. The equivalent thickness of the silver layer was set at 20 nm. Scanning electron microscopy reveals a dense labyrinth structure of silver deposits. After annealing at 200°C for two hours, isolated silver nanoparticles with broad size distribution in the range of 20 to 100 nm were formed above the layer of buried InAs quantum dots.

We studied interplay of the exciton resonance in InAs QDs and plasmon resonance in Ag nanoparticles. In particular, we observed more than two-fold enhancement of the exciton photoluminescence intensity from the InAs QDs when they were coupled to the silver nanoparticles. It seems to be due to the influence of the plasmon near fields on the radiative exciton recombination rate.

In-plane plasmonic antenna arrays resolve nanoscopic phase separation in model lipid membranes

Pamina Winkler, ICFO - Institut de Ciències Fotòniques (Spain); Raju Regmi, Institut Fresnel, Ctr. National de la Recherche Scientifique (France) and ICFO - Institut de Ciències Fotòniques (Spain) and Aix-Marseille Univ. (France); Valentin Flauraud, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Hervé Rigneault, Institut Fresnel, Ctr. National de la Recherche Scientifique (France) and Aix-Marseille Univ. (France); Jürgen Brugger, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Jérôme Wenger, Institut Fresnel, Ctr. National de la Recherche Scientifique (France) and Ctr. National de la Recherche Scientifique (France); María F. Garcia-Parajo, ICFO - Institut de Ciències Fotòniques (Spain) and

Institució Catalana de Recerca i Estudis Avançats (Spain)

Resolving the various interactions of lipids and proteins in the plasma membrane of living cells with high spatiotemporal resolution is of upmost interest [1]. Here we introduce an innovative design of plasmonic nanogap antennas to monitor single-molecule events on model biological membranes at physiological relevant concentrations by means of fluorescence correlation spectroscopy. Our design involves the fabrication of in-plane plasmonic nanogap antennas arrays embedded in nanometric-size boxes to provide full surface accessibility of the hotspot-confined region. Using these antennas we recently reported fluorescence enhancement factors of 104-105 times on individual molecules diffusing in solution, together with nanoscale detection volumes in the zeptoliter range [2]. In principle, the planarity of these antennas should enable similar studies on biological membranes without unwanted membrane curvature effects.

To show their applicability, we recorded the diffusion of individual molecules inserted in multi-component lipid bilayers as a simple mimetic system that recapitulates some of the most important features of cell membranes. We prepared membranes of different compositions: saturated phospholipids, sphingolipids and cholesterol and used antennas of different gap sizes (10-45 nm). The diffusion of individual molecules on membranes consisting of phospholipids and/or in a mixture with sphingolipids resulted Brownian, confirming homogenous lipid distribution. Interestingly, the strong confinement of antennas revealed the formation of transient (<1ms lifetime) nanoscopic domains of ~11 nm in size upon cholesterol addition. These results indicate that in-plane antennas represent a highly promising non-invasive tool to investigate the nanoscale dynamic organization of biological membranes and its impact in biological function.

UV fluorescence modification by aluminum bowtie nanoantennas

Emmanuel Lotubai, Yunshan Wang, Steve Blair, The Univ. of Utah (United States)

UV plasmonic nanostructures have applications in enabling label free native fluorescence biosensing and enhancing efficiency of UV light emitting diode. Aluminum nanostructures such as nanoaperture, bulleye aperture, dipole antenna have been shown to modify emission properties of UV fluorescence molecules. However, these structures demonstrate small radiative enhancement and total decay rate enhancement factors (less than 10x), which hinders the application of UV plasmonic structures. In this paper, we report FDTD simulation results on excitation and emission enhancement factors of a pair of aluminum bowtie antenna in ultraviolet region. The structure was chosen because they exhibit larger LDOS (local density of states) than aforementioned geometries based on calculations. The sizes and apex angles of bowtie antennas pairs are varied to determine the optimal geometries. Our results show that increasing the size of the antennas red shifts the excitation and emission resonance peak and increases the resonance peak intensity. Increasing the apex angles (20 degree to 60 degree) slightly blue shifts the excitation and emission peak and increase the peak intensity. Thus the optimal geometry is a pair of small bowtie (radius 20nm) with apex angle 60 degrees. The gap of bowtie antennas was kept constant. The highest radiative enhancement we can achieve is 25x (~340nm) and highest total decay rate enhancement is 100x, which is higher than previously studied geometries, but still 10 times lower than the limit predicted by LDOS. Those results can be used to make better antennas for UV fluorescence modification.

10346-44, Session 11

UV plasmonic enhancement through three dimensional nano-cavity antenna array in aluminum

Jieying Mao, Yunshan Wang, Steve Blair, The Univ. of Utah (United States)

Metallic nanostructure can enhance fluorescence through excited surface plasmons which increase the local field as well as improve its quantum efficiency. When coupling to cavity resonance with proper gap dimension, gap hot spots can be generated to interact with fluorescence at their excitation/emission region in UV.

Recently, A new SER substrate architecture has been demonstrated and investigated to greatly enhance immunoassay's fluorescence and detection sensitivity in visible and infrared region.[5,6] In this work, two distinct plasmonic structure of 3D resonant cavity nanoantenna has been studied and its plasmonic response has been scaled down to the UV regime through finite-difference-time-domain (FDTD) method. Two different strategies for antenna fabrication will be conducted to obtain D-coupled Dots-on-Pillar Antenna array (D2PA) through Focus Ion Beam (FIB) and Cap-Hole Pair Antenna array (CHPA) through nanosphere template lithography (NTL). With proper optimization of the structures, D2PA and CHPA square array with 280nm pitch have achieved distinct enhancement at fluorophore emission wavelength ~350nm and excitation wavelength ~280nm simultaneously. Maximum field enhancement can reach 20 and 65 fold in the gap of D2PA and CHPA when light incident from substrate, which is expected to greatly enhance fluorescent quantum efficiency that will be confirmed in fluorescence lifetime measurement.?

10346-46, Session 11

Optical bistability and optical response of an infrared quantum dot hybridized to VO2 nanoparticle

Ali Hatef, Nipissing Univ. (Canada); Naser Zamani, Department of Physics, College of Sciences, Shiraz University, 71946-84795, Iran (Iran, Islamic Republic of); Hamid Nadgaran, Department of Physics (Iran, Islamic Republic of); Alireza Keshavarz, Department of Physics, Shiraz University of Technology (Iran, Islamic Republic of)

Vanadium dioxide (VO2) features a semiconductor to metal phase change characteristic below and above a critical temperature that leads to an abrupt change in the particle's optical properties. These VO2 optical variations lead to alter this martial from a relatively transparent semiconductor to an opaque metal in the infrared region. Recently, VO2-based nanoparticles have been synthesised with a variety of different chemical and physical techniques where the value of critical temperature can be decreased to room temperature. In this work, we theoretically show that a hybrid system consisting of semiconductor quantum dot (SQD) and vanadium dioxide nanoparticle (VO2NP) can support the coherent coupling of exciton-polaritons and exciton-plasmon polaritons in the semiconductor and metal phases of the VO2NP, respectively. In our calculations the VO2NP phase transition is modelled with a filling fraction, representing the fraction of the VO2NP in the metallic phase. Our results show that detuning an infrared CW laser around the SQD resonance frequency results in the enhancement or suppression of the SQD's linear absorption for different values of the filling fraction. We also demonstrate that the strong coupling between SQD and VO2NP can result in optical bistability of the SQD absorption where the switch-up threshold for optical bistability can be strongly controlled by filling fraction without changing the structure of the hybrid system. These results suggest that such a process allows a SQD-VO2NP to act as coherent nanoantenna, offering novel ways in order to monitor local temperature variation at the nanoscale.

Topological features of plasmon polaritons *(Invited Paper)*

Meir Orenstein, Technion-Israel Institute of Technology (Israel)

Plasmon Polariton and similar fields of nanostructures, although reduced to two dimensions compared to light propagating in the bulk - can carry topological features that may be crucial for light matter interactions, We will discuss the surface plasmon polariton topological - non local characteristics, showing and measuring a different type of "plasmonic" modes' manifold, discussing the topological nature of perfect lensing, and show in real time how to generate and manipulate high order topologicalyl charged plasmons.

10346-48, Session 12

Excitation of dark modes in plasmonic clusters by focused cylindrical vector beams

Tian-Song Deng, John A. Parker, Nolan Shepherd, Norbert F. Scherer, The Univ. of Chicago (United States)

Control of the spatial polarization of light allows tailoring the electromagnetic response of plasmonic nanostructures. In this work, we show that focused cylindrical vector beams (CVBs) can be used to efficiently excite dark plasmon modes in highly symmetric gold nanoparticle (AuNP) dimers. Specifically, we use single particle spectroscopy and FDTD simulations to study the response of AuNP dimers excited by linearly (LP), azimuthally (AP), and radially (RP) polarized beams. Under LP excitation, the resonances correspond to in-phase coupling of the dipolar moments of the particles, with dipolar moments parallel or perpendicular to the dimer axis. These resonances are known as bright modes, as they can easily couple to light. By contrast, the field distribution of focused AP or RP beams indicates that the fields acting on the AuNPs is primarily perpendicular or parallel to the dimer's axis, but with opposite directions at each particle. Therefore, the resonances here are out of plane coupling of dipolar moments, or so called "dark modes". In addition, multipolar expansion of the fields associated with each scattering spectrum shows that the resonances excited by LP beams are dominated by electric dipole modes. By contrast, CVB excitation causes new modes, such as magnetic dipole and electric quadrupole modes, to be driven and that they even dominate the scattering spectra. This work opens new opportunities for spectroscopic investigation of dark modes and Fano resonances in plasmonic nanostructures, which are difficult or impossible to be excited by conventionally polarized light.

10346-49, Session 12

Suppression of infrared absorption in nanostructured metals by controlling Faraday inductance and electron path length

Sang Eon Han, Samuel M. Clark, The Univ. of New Mexico (United States)

Nanostructured metals have been intensively studied for optical applications over the past few decades. However, the intrinsic loss of metals has limited the optical performance of the metal nanostructures in diverse applications. In particular, light concentration in metals by surface plasmons or other resonances causes substantial absorption in metals. Moreover, if the device operates over a broad band as in many photovoltaic devices, metal absorption needs to be controlled over the whole spectrum of interest and this poses a significant scientific and engineering challenge. Here, we avoid plasmonic excitations for low loss in infrared optoelectronics and investigate methods to further suppress loss in nanostructured metals. We demonstrate that parasitic absorption in metal nanostructures can be significantly reduced over a broad band by increasing the Faraday inductance and the electron path length. Surprisingly, we find that nanostructured metals, when cleverly designed, can behave almost like a vacuum with a negligible optical loss in the infrared region. For an example structure, the loss is reduced in comparison to flat films by more than an order of magnitude over most of the very broad spectrum between short and long wavelength infrared. For a photodetector structure, the fraction of absorption in the photoactive material increases by two orders of magnitude and the photoresponsivity increases by 15 times because of the selective suppression of metal absorption. Further, we investigate how the physics of loss suppression can be realized in 2-dimensionally patterned metal nanostructures. In this case, we increase the electron path length by using serpentine nanostructures. These nanostructured metals become transparent with optical loss of less than 7% in the infrared even at a large metal area fraction of 30%. The loss suppression effect in the serpentine structures far exceeds that in metal grid structures or straight wire arrays. These findings could benefit many metal-based applications that require low loss such as photovoltaics, photoconductive detectors, solar selective surfaces, infrared-transparent defrosting windows, and other metamaterials.

This talk is based on the following papers:

10346-50, Session 12

Magneto-plasmonic properties of metal nanostructures as novel functional nanomaterials for bio and gas sensing

Roberto Rella, Istituto per la Microelettronica e Microsistemi (Italy)

Metallic nanostructures supporting Localized Surface Plasmon Resonances (LSPR) are characterized by their unique ability to control and manipulate light at the nanoscale. In this work we demonstrate that gold nanostructures can exhibit magneto-optic activity in the presence of modulated magnetic field of low intensity at room temperature in transversal configuration (T-MOKE). The MO response derives from a torque in the electrical polarizability of the gold nanoparticles in resonance condition due to an external magnetic field. In this condition the resonance is modulated out of the plane of the sample and a switch-off of the plasmonic hot-spots takes place and can be monitored by measuring the intensity of the reflected light in Kretschmann configuration. In order to validate our experimental results and obtain further insight of the physical mechanism underlying these effects, numerical simulations, based on Finite Element Method (FEM) techniques, have been performed. The optical and magneto-optical properties of the investigated gold nano-particles were theoretically analysed confirming the experimental outcomes. Finally, the MO signal was used as a new transducing signal for refractive index sensing in liquid phase. An increase of sensitivity and limit of detection was registered with respect to traditional plasmonic sensors, giving proof of concept of the potential biosensing applications of this sensing mechanism

10346-51, Session 13

Functional multi-layered composite metasurfaces *(Invited Paper)*

Yehiam Prior, Euclides Almeida, Weizmann Institute of Science (Israel); Ori Avayu, Tal Ellenbogen, Tel Aviv Univ. (Israel)

Recent years have shown major advances in light manipulation capabilities offered by metasurfaces. Different configurations of metasurfaces were studied, based on metallic inclusions or all-dielectric, working in transmission or in reflection [1]. Some of these metasurfaces function differently at different polarizations or different frequencies, but the degree of functional multiplexing in a single metasurfaces was rather limited. Here [2] we use a configuration of vertically stacked metasurfaces where each layer is constructed from a different optimal building block, e.g. different inclusion material and geometry, and is designed to perform a different functionality. This scalable approach allows us to demonstrate experimentally functional spectral multiplexing of visible light. We specifically show an aberration corrected metasurface-based triplet lens for RGB colors in the visible, integrated elements for STED microscopy, and elements with anomalous dispersive focusing.

In our design, the nanoparticles dimensions and inter-particle spacing were chosen in such a way to cover the entire visible spectrum, with minimal crosstalk between the layers. Metasurface based Fresnel lens elements, composed of different disc-shaped nanoparticles of gold, silver and aluminum were optimized for working at wavelengths of 650 nm, 550 nm, and 450 nm, respectively, and full RGB achromatic operation was demonstrated. As a further demonstration of functional element, a two-layer STED element was designed - consisting of one layer silver lens, focusing green light at 1 mm, and a second spirally shaped gold lens layer, creating a red vortex beam at the same focal spot.

The potential of the stacked architecture for realizing complex and multifunctional metasurface-based optical components will be discussed.

Light tunable fano resonnance in metal-dielectric multilayer structures

Zouheir Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

High-Q optical Fano resonances realized in a variety of plasmonic nanostructures and metamaterials are very much promising for the development of new potent photonic devices, such as optical sensors and switches. One of the key issues in the development is to establish ways to effctively modulate the Fano resonance by external perturbations. Dynamic tuning of the Fano resonance applying the mechanical stress and electric filds has already been demonstrated.I will discuss another way of tuning, i.e., photo-tuning of the Fano resonance. We used a simple metal-dielectric multilayer structure that exhibits a sharp Fano resonance originating from coupling between a surface plasmon polariton mode and a planar waveguide mode. Using a dielectric waveguide doped with azo dye molecules that undergo photoisomerization, we succeeded in shifting the Fano resonance thorough photo-modulation of the propagation constant of the waveguide mode. The present work demonstrates the feasibility of phototuning of the Fano resonance and opens a new avenue towards potential applications of the Fano resonance.

10346-53, Session 13

Plasmonic nano-shaping and nano-manipulation *(Invited Paper)*

Keiji Sasaki, Masaki Ide, Shutaro Ishida, Kyosuke Sakai, Hokkaido Univ. (Japan)

We clarified that multipolar plasmons of metal nano-disks can be selectively excited by circularly-polarized optical vortex beams. The orbital and spin angular momenta are transferred from Laguerre-Gaussian (LG)-mode photons to localized surface plasmons. Unfortunately, the mode volume of this plasmonic nanodisk resonator is sub-micrometer dimension that is restricted by the diffraction limit of the surface plasmon wave. In order to realize single-nanometer-sized cavities, we design the tailored plasmonic structure consisting of metal multimer surrounding a nano-gap. This metal structure makes it possible to localize the optical vortex field into the gap space with conserving the orbital and spin angular momenta. We discuss on the relations between the degrees of freedom in the multimer structures and the transferable angular momenta. The transfer of orbital angular momentum from nano-vortex photons to molecules or nanoparticles induces rotational radiation pressure, i.e., optical torque, which induces nano-vortex flow of molecules/particles and may lead to chiral structuring of molecule/particle assemblies. We experimentally demonstrate rotational manipulation of a 100-nm polymer bead with a gold nano-prism trimer structure. The plasmonic structure is illuminated with a circularly polarized beam of a near-infrared laser, so that the nano-sized field with the angular momenta is formed within the gap. The result shows orbital rotational motion of the particle with 25-nm diameter. We will also show detailed analyses of the rotational motions and their relations to the chirality of the plasmonic fields.

Nonlinear optics based on hybrid 2D semiconductor-plasmonic metasurfaces *(Invited Paper)*

Shangjr Gwo, National Tsing Hua Univ. (Taiwan); Jinwei Shi, National Tsing Hua Univ. (Taiwan) and Beijing Normal Univ. (China); Wei-Yun Liang, National Chiao Tung Univ. (Taiwan); Yanrong Wang, National Tsing Hua Univ. (Taiwan) and Beijing Normal Univ. (China); Soniya S. Robert, Chun-An Chen, Cheng-Tse Chou, National Tsing Hua Univ. (Taiwan); Hyeyoung Ahn, National Chiao Tung Univ. (Taiwan); Yi-Hsien Lee, National Tsing Hua Univ. (Taiwan)

Plasmonic metasurfaces consist of two-dimensional (2D) arrays of plasmonic nanoresonators (plasmonic “meta-atoms” or “meta-molecules”), which exhibit collective and tunable surface plasmon polariton (SPP) resonance controlled by electromagnetic near-field coupling between meta-atoms or meta-molecules. These man-made surfaces can produce a range of unique optical properties unattainable with natural materials. However, the intrinsic lossy nature of plasmonic materials limits their potential uses. The recent discovery of transition metal dichalcogenide (TMDC; MX2, M = Mo, W and X = S, Se, etc.) monolayers as promising 2D semiconductor materials for novel photonic applications offer an interesting hybrid scenario, alternative to pure plasmonic approaches. It is well known that the fundamental optical excitation of 2D semiconductor monolayers is based on excitons (bound pairs of electron–hole) owning to the remarkably large exciton binding energies in monolayer TMDCs, making them relevant even at room temperature. Therefore, the realization of hybrid 2D semiconductor–plasmonic metasurface systems lies in the ability to control and manipulate the light–matter interactions, especially those between SPPs and excitons. In this talk, I will focus on the emerging applications of plasmonic metasurfaces with precisely engineered properties for nonlinear optics using monolayers of TMDCs as the nonlinear media.

Optical transition and amplification of organic phosphor coupling with graphene plasmon

Seokho Kim, INHA Univ. (Korea, Republic of); Sunjong Lee, Korea Institute of Industrial Technology (Korea, Republic of); Dong Hyuk Park, INHA Univ. (Korea, Republic of); Bo-Hyun Kim, DGIST (Korea, Republic of)

Light-matter interactions in two dimensional (2D) materials have given new momentum to nano optoelectronics since the observation of localized surface plasmons interacting with the excitons. Graphene, a typical metallic

2D crystal with high optical absorbance, can provide surface plasmon effects to proximate molecules as nanostructured metals do. The spontaneous emission rate can be enhanced by the coupling of plasmonic modes with the emission frequencies of organic molecules. However, most experimental and theoretical studies report graphene plasmonics in the terahertz to mid-infrared range. Here, we demonstrate the optical transition and significant amplification of singlet emission from phosphoric molecule on a graphene substrate, with simultaneous enhancement of triplet emission in the visible regime. The spectroscopic investigations ascribe these phenomena to the coupling of graphene plasmonic modes with molecular transient dipole. The modulation of emission channel and quantum efficiency is achieved by specifically controlling the organic molecular surface density on graphene. The single layer graphene is the most efficient substrate for plasmon coupling, however, remarkable strong PL intensity is achieved by forming multi-stacks of the organic molecule-graphene hybrid layer. This work suggests a novel route for the manipulation of organic molecular emissions using graphene plasmonics, and can be applied in developing photonic devices with high quantum efficiency.

Modification of UV surface plasmon resonances in aluminum hole-arrays with graphene

Yunshan Wang, Sourangsu Banerji, Jieying Mao, Sara Arezoomandan, Berardi Sensale-Rodriguez, Steve Blair, The Univ. of Utah (United States)

Active optical devices enabled by plasmon resonances have gained increasing interest during recent years. Tunable UV devices can enable enhanced functionalities such as multiplexed sensing, wavelength-tunable light emission, and so on. Interestingly, in the UV range, graphene shows an abnormal optical absorption due to pi-plasmon resonance, which can be tuned by electric bias or chemical doping. Here we report our studies on the interaction of graphene pi-plasmons with the surface plasmon resonance on Al hole-arrays. Hole periodicities of 240, 280, 320 nm are employed. Transmittance though the Al hole-array was measured before and after graphene transfer. Two important features are noticed across all the measured samples: (i) the longer-wavelength resonant dip, which has its origin on SPRs in the Al/substrate interface, is not altered when adding graphene. This is a result of the placement of the graphene layer being on top of the Al film. On the other hand, (ii) the short-wavelength resonant dips, which are associated with SPRs at the top-interface, do red-shift when graphene is added. This is a result of interaction of graphene pi-plasmon with Al SPR. Moreover, it is observed that a maxima occurs in the 280 nm to 310 nm wavelength range (i.e. 4.3 to 4.0 eV). This is attributed to an enhanced graphene optical conductivity owed to pi-plasmons. This maxima is red-shifted from the UV peak in pristine graphene because our graphene has a large unintentional doping during the transfer process.

Resonant coupling between molecular vibrations and localized surface plasmon resonance of faceted metal oxide nanocrystals

Ajay Singh, Los Alamos National Lab. (United States); Delia J. Milliron, The Univ. of Texas at Austin (United States)

Colloidally synthesized doped metal oxide nanocrystals has recently got great scientific attention for their ability to manipulate the localized surface plasmon resonance (LSPR) by varying their composition. Due to highly variable carrier concentration in these material, it enables plasmon frequency over entire infrared region and has facilitated a new class of tunable plasmonic materials with potential applications in the fields of photocatalysis, sensors, smart windows and surface enhanced Infrared absorption spectroscopy (SEIRA). In particular, SIERA exploits the signal enhancement to increase the sensitivity of spectroscopic feature exerted by the plasmon resonance of nanostrucrtured/nanocrystal thin films. To date, most of the studies based on plasmon- molecular vibration coupling have been focused on the plasmonic metal nanocrystal. Here, we will present the doped Indium Oxide as prototypical material. Dopant driven nanocrystal shape evolution and thereby plasmon property of colloidally synthesized octahedron , cubo-octaherdron and cubic will be emphasized. We will further describe the size dependent plasmon property of doped Indium Oxide, map the near field enhancement property of single cubic nanocrystals via EELS and quantify both far field and near field plasmon property via COMSOL electromagnetic simulations. Furthermore, we show how C-H molecular bonds (2800-3200 cm-1) couples to periodic film doped Indium Oxide nanocrystal both experimentally and computationally. This development of metal oxide plasmonic platform for molecular sensing could lead to easy to make, electrically tunable surface enhanced infrared absorption spectroscopy substrates.

10346-58, Session 14

Symbiotic plasmonic behavior of bimetallic Ag-Co nanoparticles in the conductive regime

Abhinav Malasi, Jigxuan Ge, Ritesh Sachan, Humaira Taz, Mikayla Ehrsam, The Univ. of Tennessee Knoxville (United States); Jesse Goodwin, Webb School of Knoxville (United States); Gerd Duscher, The Univ. of Tennessee Knoxville (United States); Hernando Garcia, Southern Illinois Univ. Edwardsville (United States); Ramki Kalyanaraman, The Univ. of Tennessee Knoxville (United States)

The interaction between plasmonic nanostructures in the conductive (i.e. touching) and non-conductive regimes has lead to identifying new types of resonances as well as new functionalities. Conductive regime nanoparticles made from combinations of plasmonic metals with non-plasmonic metals such as Au-Ag, Au-Pd and Au-Co have been explored for applications in sensing, catalysis and magneto-optics. Here we show that the interaction of Ag-Co in the conductive regime shows a novel symbiotic plasmonic behavior. Ag-Co nanoparticles with a segregated microstructure were prepared by pulsed laser dewetting of bilayer films on optically transparent substrates as well as on electron transparent carbon membranes. Electron energy loss spectroscopy (EELS) investigations in a TEM showed that the Co region contained ferroplasmons, i.e. strong localized surface plasmons, which are not present in pure Co. Similar ferroplasmonic behavior was also evidenced in bimetals of Ag-Fe and Ag-Ni, though with markedly different intensities compared to Ag-Co. Far field spectroscopy from a collection of nanoparticles revealed that the plasmon bandwidth from Ag-Co can be equal to or larger than pure Ag of comparable volumes. By performing a volume dependent study using Ag triangles prepared by nanosphere lithography we determined that the radiative damping in Ag could be reduced by the contact with Co. Consequently bimetallic nanoparticles can show comparable or better plasmonic quantum efficiencies than pure Ag. In addition, since Ag in the bimetal is galvanically stabilized by Co, this bimetal has many promising attributes as a new plasmonic material, including more stable extraordinary optical transmission devices.

Directional and enhanced emission from a fluorescent nano-diamond

Guowei Lu, Peking Univ. (China)

We demonstrated experimentally unidirectional enhanced emission of a fluorescent nanodiamond coupled to a gold nanorod which was assembled via atomic force microscope nanomanipulation. The emission patterns can be controlled by adjusting the configurations, i.e., the gold nanorod orientation and separation with respect to the nanodiamond. Numerical

simulation results reveal that the unidirectional emission can be ascribed to the interference between the electromagnetic fields produced by the dipole like source and the out-of-phase dipole induced in the gold nanorod. The proposed hybrid nanostructures remarkably exhibit highly unidirectional emission even when the emitter is positioned up to 50 nm away from the nanorod antenna and present a broad working spectral bandwidth of ~ 200 nm.

Broadband enhancement of infrared absorption using Ag nanocrystals

Jae Hong Park, National Nanofab Ctr. (Korea, Republic of)

High performance microbolometers are widely sought for thermal imaging applications. In order to increase the performance limits of microbolometers, the responsivity of the device to broadband infrared (IR) radiation needs to be improved. In this work, we report a simple, quick, and costeffective approach to modestly enhance the broadband IR response of the device by evaporating Ag nanocrystals onto the light entrance surface of the device. When irradiated with IR light, strong fields are built up within the gaps between adjacent Ag nanocrystals. These fields resistively generate heat in the nanocrystals and underlying substrate, which is transduced into an electrical signal via a resistive sensing element in the device. Through this method, we are able to enhance the IR absorption over a broadband spectrum and improve the responsivity of the device by 11%. including electrodes of secondary batteries, fuel cells, solar cells, and energy harvesters, biological devices including biochips, biomimetic or biosimilar structured devices, and mechanical devices including micro- or nano-scale sensors and actuators.

Resonance modes in unbalanced Mach-Zehnder interferometers embedded in plasmonic waveguides

Shun Kamada, Toshihiro Okamoto, Masanobu Haraguchi, Tokushima Univ. (Japan)

Plasmonic waveguides (PWGs) are widely proposed for compact components of integrated circuits. We proposed an unbalanced Mach-Zehnder interferometer (MZI) for optical modulators or sensors devises by using Metal/Insulator/Metal (MIM) PWGs. Transmission spectra of the MZI were calculated by Finite difference time domain (FDTD) method. MIM PWGs of numerical simulation model is comprised of Ag/PMMA/Ag. Thickness of PMMA is 100nm. Incident light that has polarization of perpendicular to PWGs is irradiated for excite the gap plasmon mode.

We observed oscillation of transmission and transmission dips in calculated transmission spectra of an unbalanced MZI. To confirm the mechanism of the oscillation, analytical solution was calculated at an unbalanced MZI that has different path length. The numerical structures of oscillation of transmission and analytical solution have been found to be in good agreement. Therefore, oscillation of transmission is due to different path length of an unbalanced MZI. And we also calculated the field distributions of the MZI with incident light of continuous wave at dip wavelength. As a result, standing wave was observed at each airs of MZI. Those transmission dips are due to resonance in unbalanced MZI. Standing wave was appeared when wavelength of the gap plasmon mode is equal to the integral multiple of PWG length of resonance area. Therefore, an unbalanced MZI serves as a ring resonator.

In this study, it is found that an unbalanced MZI by MIM PWGs is appeared transmission properties as a ring resonator and a MZI.

Nano-metallic-planar-apex metamaterials

Dong Wei, Qing Tong, Yu Lei, Huazhong Univ. of Science and Technology (China); Zhaowei Xin, Huazhong Univ. of Science and Technology (China); Xinyu Zhang, Haiwei Wang, Changsheng Xie, Huazhong Univ. of Science and Technology (China)

We present the results of numerical simulations and preliminary experiments to investigate the nano-focusing effect of incident light based on the surface plasmon polaritons (SPPs) over the nano-metallic-planar-apex metamaterials (NMPAM). The NMPAM are prepared by electron-beam lithography(EBL) and a set of nanoscale fabrication tools. The NMPAM can be used to remarkably enhance the strength of the surface evanescent and thus lead to a remarkable excitation of several SPP modes on the nano-metal-film surface. The interaction of different SPPs will result in a unique near-field optical properties for imaging and optical storage, because incident beams can focus light into a nano-size point and thus enhance the light power greatly. The energy flow and electromagnetic field distribution is calculated by finite-difference time-domain (FDTD) method. The nano-spot position and intensity is experimentally shown based on careful controlling the arrangement of apexes. In our experiments, we fabricate a 10?10 array by EBL, and then the scanning near-field optical microscopy(SNOM) is used to observe the optical power distribution in nano-scale at the air-metal interface in infrared region. We find that the incident light can be focused into ~100nm-scale and consequently enhance the light power up to several times than before common focusing method. The principle of nano-focusing based on nano-planar-apex is theoretically explained. The NMPAM can be utilized for coupling with infrared photosensitive pixels to enhance the incident light converging so as to improve signal to noise ratio of infrared detection.

Flow-through nanohole array based sensor implemented on a smartphone

Juan Gomez, Univ. Nacional Autónoma de México (Mexico); Srijit Nair, Queen's Univ. (Canada); Gabriel Ascanio, Univ. Nacional Autónoma de México (Mexico); Carlos Escobedo, Queen's Univ. (Canada)

Mobile communications have massively populated the consumer electronics market over the past few years and it is now ubiquitous, providing a timeless opportunity for the development of smartphone-based technologies as point-of-care (POC) diagnosis tools.1 The expectation for a fully integrated smartphone-based sensor that enables applications such as environmental monitoring, explosive detection and biomedical analysis has increased among the scientific community in the past few years.2, 3 The commercialization forecast for smartphone-based sensing technologies is very promising, but reliable, miniature and cost-effective sensing platforms that can adapt to portable electronics in still under development. In this work, we present an integrated sensing platform based on flow-through metallic nanohole arrays. The nanohole arrays have 260 nm in diameter and 520 nm in pitch, fabricated using Focused Ion Beam (FIB) lithography. The nanohole arrays are integrated with a microfluidic chip that is used to deliver analytes to the sensing surface. An LED from a smartphone serves as light source to excite surface plasmons and the signal is recorded via a spectrometer and a CCD module. The sensing abilities of the integrated sensing platform is demonstrated for the detection of (i) changes in bulk refractive index (RI), (ii) real-time monitoring of monolayer self-assembly formation and (iii) real-time biosensing of a protein.

Excitation of plasmonic waveguide modes using principles of holography

Anton I. Ignatov, All-Russia Research Institute of Automatics (Russian Federation); Alexander M. Merzlikin, All-Russia Research Institute of Automatics (Russian Federation) and Institute for Theoretical and Applied Electromagnetics (Russian Federation)

One of methods for excitation of plasmonic surface waves and modes of plasmonic waveguides is using of periodic gratings on a metal surface or in dielectric parts of plasmonic waveguides. For particular examples of dielectric-loaded plasmonic waveguides, principles of holography were employed for development of such gratings to make the gratings more efficient and more compact. Holograms in the form of spatial modulations of refractive index of the dielectric of waveguides were theoretically analyzed. The modulations were determined by spatial distribution of intensity of the sum of exciting light beam (incident on a waveguide from free space) and excited wave (plasmonic mode of a waveguide). It was shown that such holographic gratings may have considerably higher (to several times) efficiency of coupling of the exciting light into plasmonic waves compared to the efficiency of usual strictly periodic one-dimensional gratings with optimized parameters. The advantage of holographic gratings over one-dimensional periodic gratings is most pronounced in the cases when intensity distributions of either exciting or excited waves are not uniform of when phase fronts of the waves are strongly curved in the area of a hologram. The suggested holographic method of excitation of plasmonic waveguide modes is rather universal. We expect this may be used for development of tapers with gratings to effectively excite plasmonic modes in dielectric-loaded waveguides with subwavelength aperture and for other types of plasmonic waveguides.

Using split ring resonators to generate nanoscale hotspot for heat assisted magnetic recording

Anurup Datta, Xianfan Xu, Purdue Univ. (United States)

In this work, we explore the use of a split-ring resonator (SRR) type of nanostructure for the purpose of generating a nanoscale hot spot. Subwavelength focusing of light has a wide range of potential applications, one of which is heat-assisted magnetic recording (HAMR), considered to be one of the next generation data storage technologies that can address the potential challenges of increasing the areal data storage density. A typical HAMR system consists of a plasmonic nanostructure also called as near field transducer (NFT) which helps in focusing light down to a sub diffraction volume and locally heat the recording medium to temporarily decrease its coercivity during the write cycle.

In the past we have studied extensively various types of nanostructures including bowtie antenna, C-shaped antenna, and E-shaped antenna for NFT in HAMR. SRR offers another possibility as an NFT. In addition to Mie resonance peaks, SRR has been shown to possess LC-circuit type of resonance in the infrared and optical frequency range. These resonance modes, when coupled with localized surface plasmons, can be utilized to design a hot spot near the gap of the SRR structure. The relation between the geometric dimensions of the SRR NFT and the different resonance peaks is established and the coupling efficiency of the incident radiation to the storage medium is computed. The performance of an SRR NFT is compared with other types of plasmonic NFTs. We believe this work provides an insight into the design of plasmonic nanostructures which can be of significance to the development of HAMR technology.

Surface plasmons on periodically corrugated surface

Eugene Chubchev, Igor Nechepurenko, Dukhov Research Institute of Automatics (Russian Federation); Alexey P. Vinogradov, Dukhov Research Institute of Automatics (Russian Federation) and Moscow Institute of Physics and Technology (Russian Federation) and Institute for Theoretical and Applied Electromagnetics (Russian Federation); Alexander A. Lisyansky, Queens College (United States) and The Graduate Ctr. (United States)

We have shown that there is a specific kind of strongly localized surface plasmon modes that exist only on periodically corrugated surface. These modes exist in the frequency range where the sum of the real parts of permittivities of metal and adjacent dielectric is positive. This frequency range is prohibited for conventional surface plasmon polaritons in case of flat metal surface. The reason why these modes arise is the surface-shape resonances [1] of single surface defect on flat surface. If such defects are periodiacally distributed on the surface than interaction among them leads to formation of nanoparticle chain waveguide [2, 3]. If the distance between defects is much smaller than free space wavelengths the eigenmodes of this chain waveguide are strongly localized.

Universal characterization of plasmons satellites in photoemission from nanostructures

Sandra de Vega, ICFO - Institut de Ciències Fotòniques (Spain); F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain)

Our understanding of the electronic structure of material surfaces has greatly relied on photoemission spectroscopy [1]. Photoelectrons additionally constitute an excellent source of information on optical modes, which are excited by Coulomb interaction with both the electron and the hole that is left behind [2]. In particular, plasmons have been extensively observed as satellite features in the emission spectra from planar surfaces [3]. Here, we explore the potential of plasmon satellites to render information on these excitations when photoelectrons are emitted from nanostructured materials.

Our study relies on a quantum-mechanical treatment of the plasmons and a semiclassical description of their interaction with the electron and the hole. We identify two interaction parameters that allow us to obtain universal multiple-plasmon probability distributions: the hole-plasmon and the transient electron-plasmon coupling coefficients. We further investigate characteristic values of those parameters for metallic spheres and graphene nanoislands. Our results support the ability of photoelectrons to resolve plasmons in these structures.

Ultrafast transient dynamics of optical loss mitigation in aggregated gain-plasmon hybrid systems

Alireza Rahimi Rashed, Bilkent Univ. (Turkey); Mohamed El Kabbash, Case Western Reserve Univ. (United States); Betul Kucukoz, Ankara Üniv. (Turkey); Quang Nnguyen, Case Western Reserve Univ. (United States); Ahmet Karatay, Halime Gul Yaglioglu, Ankara Üniv. (Turkey); Giuseppe Strangi, Case Western Reserve Univ. (United States) and Univ. della Calabria (Italy); Ekmel Ozbay, Humeyra Caglayan, Bilkent Univ. (Turkey)

The extraordinary properties of the plasmonic systems arise from the confining of the electromagnetic wave beyond the diffraction limit, as a result of surface plasmons. However, oscillating plasmons can be damped due to electron scattering events. One of the most successful approaches to compensate the optical losses, while maintaining the electromagnetic sub-wavelength confinement, is to incorporate gain material in plasmonic systems. In this work, we report on systematic and detailed study utilizing transient pump-probe absorption spectroscopy on hybrid systems consisted of the aggregates of core-shell quantum dots (QDs) and Au nanoparticles (NPs). Our study provides a clear understanding of the ultrafast gain-plasmon dynamics to control optical losses in plasmonic nanostructures, paving the way towards further promising scientific research aimed to enable their practical applications. We highlight that generating hot electrons in plasmonic NPs contribute to the transient differential absorption spectrum under optical excitation and is of great significance. The results suggest modifying the way of analyzing the transient absorption spectra of loss mitigated systems. Furthermore, a frequency pulling like effect of the transient bleach signal towards the emission maximum of the gain material is reported as an evidence of loss mitigation process. Additionally, we study the implications of the coupling strength between the electron oscillation frequency and the phonon modes of aggregated NPs on loss mitigation efficiency of gain-plasmon hybrid systems, based on the observed TA properties. Finally, we investigated the transient kinetics of all systems and showed that hybrid gain-plasmon systems have unique decay kinetics.

10346-87, Session PWed

Bright off-axis directional light harvesting with plasmonic corrugations

Alireza Rahimi Rashed, Bilkent Univ. (Turkey); Hamed Sattari, Ecole Polytechnique Fédérale de Lausanne (Switzerland) and Bilkent Univ. (Turkey); Ekmel Ozbay, Humeyra Caglayan, Bilkent Univ. (Turkey)

Enhancing the photon collection efficiency and narrowing the emission directivity of sub-wavelength diffracted light sources are two critical aspects for their practical applications. These features can be attained by creating symmetric or asymmetric periodic corrugations on the exit side of a single aperture in a metallic substrate. In this approach the emitted light of nano-emitter is coupled into the antenna plasmonic modes, resulting in the emission rate enhancement and the far field radiation in the oriented direction. Here, we propose a new design of bulls-eye antenna by introducing a metallic sub-plate and dielectric layer below conventional structure. Our proposed design provides high degree of directionality and out-coupled far field intensity of the emitted light from florescence sources as compared to conventional designs. The parameters are optimized for the emission peak of diamond NV centers. In our model, we have considered diamond NV centers to be doped to PMMA and placed inside the central cavity. We have optimized the design by considering the underlying physics of a dielectric layer sandwiched between metal layers. Proposed bulls-eye configuration provides higher out-coupled intensity efficiency even better than double side corrugated antenna. Moreover, we have studied trends for steering the radiated beam over the plate of the antenna. We have introduced a modification on the design of our proposed structure, with considerable off-axis beaming angle retaining high out-coupled light intensity. Our model shows that by introducing optimal asymmetries to grooves and ridges of the structure we can achieve high degree two dimensional off-axial steering angle.

Handheld highly selective plasmonic chem/biosensor using engineered binding proteins for extreme conformational changes

Derek J. Kosciolek, Ajay V. Sonar, Clarkson Univ. (United States); Lori A. Lepak, Phoebus Optoelectronics, LLC (United States); Peter Schnatz, The City College of New York (United States); Igor Bendoym, Phoebus Optoelectronics, LLC (United States); Mia C. Brown, The City Univ. of New York (United States); Ronald L. Koder, The City College of New York (United States); David T. Crouse, Phoebus Optoelectronics, LLC (United States)

We develop and fabricate a handheld, portable, highly selective and sensitive chem/biosensor that has potential applications in both airborne and water-based environmental sensing. The device relies on a plasmonic chip of subwavelength-scale periodic gold pillars engineered to resonate in the near infrared. The chip is functionalized with a novel class of proteins that exhibit extremely large conformational changes upon binding to a specific target analyte. The subsequent change in local refractive index near the surface of the gold is one to two orders of magnitude greater than current conventional methods, which produces a readily measurable 5 to 10 percent difference in light transmission. This allows us to forgo traditional, bulky tabletop setups in favor of a compact form factor. Both theoretical and measured changes in refractive index of the protein are presented here, as well as numerical and experimental results of the functionalized plasmonic chip. We then integrate these components into a fully stand-alone module, with discussions on the optical train, temperature tuning of the laser diode to obtain the plasmonic chip's spectral response, and methods to introduce airborne analytes onto the functionalized chip. While we present data on heme as the analyte, the functionalized protein can be engineered to pair with a wide variety of analytes with minimal alterations to the plasmonic chip or device design. Such flexibility allows for this device to potentially meet the needs of first responders and health care professionals in a multitude of scenarios.

10346-89, Session PWed

Ultrafast room temperature dynamic modulation of spontaneous emission in plasmonic nano-cavities

Mohamed El Kabbash, Case Western Reserve Univ. (United States); Ermanno Miele, National Univ. of Singapore (Singapore); Ahmad K. Fumani, Northwestern Univ. (United States); Michael Wolf, Elisha Haber, Jesse Berezovsky, Case Western Reserve Univ. (United States); Francesco De Angelis, Istituto Italiano di Tecnologia (Italy); Giuseppe Strangi, Case Western Reserve Univ. (United States)

The spontaneous emission (SE) of an emitter can be modified by changing its electromagnetic environment. Particularly, embedding an emitter in a high Q cavity e.g. photonic crystal, or small modal volume cavity, e.g. plasmonic nanocavity (PNC) increases its SE rate due to the Purcell effect. However, dynamically modifying the SE rate is challenging due to the ultrafast lifetime properties of emitters of ~ 1ns. Here we show, for the first time, that by using PNCs we can dynamically modify the SE rate at room temperature. Our approach relies on compensating the plasmonic optical

losses via resonantly coupled gain which dynamically modify the PNC Q factor.

Compensating plasmonic optical losses shares the same physics of enhancing the SE rate of an emitter coupled to a PNC. Both phenomena rely on non-radiative resonant energy transfer between the gain (donor) and plasmonic nanostructure (acceptor). In our work, we embedded quantum dots in an out of plane PNC and showed that by changing the gain excitation power we control the SE rate. Exciting more gain compensate more plasmonic losses, i.e. increases the Q factor of the PNC which increases the SE rate. The loss compensation of a single PNC was experimentally demonstrated by pump-probe confocal scattering spectroscopy. Very recently, modifying the SE rate was shown in photonic crystals at cryogenic temperatures using complicated photonic devices. The simplicity of our approach opens the route for further utilization of plasmonics in cavity quantum electrodynamics applications, quantum information applications and nano-scale optical communication sources.

Dislocated double-layered metal gratings: an efficient unidirectional coupler/ beamsplitter

Yang Shen, Wenjie Liu, XiaoYi She, Chongjun Jin, Sun Yat-Sen Univ. (China)

Surface plasmon polaritons (SPPs) show great promise in providing an ultracompact platform for integrated photonic circuits. However, challenges remain in easily and efficiently coupling light into and subsequently routing SPPs. We propose theoretically and demonstrate experimentally a one-dimensional dislocated double-layered metal grating (DDMG) structure, which operates as a unidirectional coupler capable of launching surface plasmon polaritons in a desired direction under normal illumination. The experimental results demonstrate a coupling efficiency of 36% and a contrast ratio of 43[1]. Moreover, we theoretically propose and experimentally demonstrate a switchable unidirectional coupler/ beamsplitter which can simultaneously perform both tasks using a two-dimensional version of DDMG[2]. The core of device is a 3?3 um2 periodic array of slanted gold 'mushrooms' (SGMA) composed of angled dielectric pillars with gold caps extruding from a periodic array of perforations in a gold film. The unidirectional coupling results from the interference of the in-plane guided modes scattered by the pair of dislocated gold gratings, while the output channel is determined by the polarization of the incident beam. This device, in combination with dynamic polarization modulation techniques, has the potential to serve as a router or switch in plasmonic integrated circuits.

Plasmonic Fano resonances in novel nanostructure consisting of two rings with different diameter

Maojin Yun, Tongtong Liu, Qingdao Univ. (China)

In this paper a novel metallic nano-structure consisting of two rings with different diameter is proposed to generate intense plasmonic Fano Resonances (FRs). In this nano-structures, the FRs is explained by the interference between spectrally overlapping narrow subradiant (dark) and broad superradiant (bright) plasmonic modes and is simulated by COMSOL Multiphysics based on Finite Element Method. The simulations shows that dipolar resonance only occur in the small-diameter ring as a bright plasmon mode, other than the large-diameter ring.- It can be found that the resonant wavelength will be red-shift with the change of the radius of rings. Such structure will have many potential applications in the field of chemical and biological sensors in the future.

Infrared detector based on cross-shape nano-antenna

Maojin Yun, Weipeng Hu, Qingdao Univ. (China)

In this paper the cross-shape nano-antenna composed of a cross metal film and a dielectric film in which the cross-metal film is deposited on the dielectric film is proposed and theoretically analyzed. It is found that this structure can effectively confine and dramatically enhance electromagnetic radiation. Meanwhile a infrared detector based on the cross-shape nano-antenna is presented and numerically analyzed with Finite Element Method (FEM) with wide-angle for infrared frequencies. The simulation shows that the design offers several times enhancement in absorption compared the performance of cross-shape nano-antenna detector with a bulk metal layer or nano-trip antennas, and is less affected by the incident angle and the resonance wavelength can be tuned by utilizing coupled different sizes. This design provides many practical potential applications for high flexible infrared detectors.

Polarizing filter based on anisotropic absorption of graphene ribbons with varying width

Maojin Yun, Peng Sun, Qingdao Univ. (China)

In this paper, we theoretically demonstrate a polarizing filter consisted of graphene ribbon arrays with varying width placed on the top surface of dielectric and a metal reflector rested at the bottom of the structure. It is found that proper ribbon width, which corresponds to resonant frequency of graphene plasmons, is a crucial factor that can significantly influence the absorption effect. The results of fullwave numerical simulations indicate that total absorption of more than 90% for TE polarization and approaching to 1% for TM polarization can be achieved at normal incidence in the infrared range. Therefore, this characteristic can be applied into polarizing filter by adjusting the coupling effect between the graphene ribbon arrays. Such structure will be beneficial to the manufacture of infrared nanophotonic devices for optical filtering and selective absorption.

Plasmonic waveguides based and optical logic gate

Sonia Tomer, Nishant Shankhwar, Yogita Kalra, Ravindra K. Sinha, Delhi Technological Univ. (India)

In this paper, a design of plasmonic waveguides based optical AND gate has been proposed. Various designs of Photonic crystal based optical logic gates have already been envisioned and proposed during the past decade, in which, wavelength of operation is comparable to the geometrical parameters. On the contrary, the proposed structure consists of plasmonic waveguides whose thickness is much smaller than the wavelength of operation. This may pave the way for large scale integration for the development of all optical circuits for optical computing systems. Moreover, the proposed design is simple and easy to fabricate using techniques like thin-film technology and lithography.The thickness of the waveguides is 50 nm and chosen wavelength of operation is 650 nm. The waveguides used are actually Insulator-Metal-Insulator structures in which metal region is made of silver and insulator is a dielectric material of permittivity ? = 4 . The data for refractive index of silver has been taken from Palik (1999). The design has been numerically analyzed in COMSOL Multiphysics® and the truth table for AND gate has been verified.

Tunable sub-10nm metal gap by manipulating PDMS substrate

Wenjie Liu, Yang Shen, Chongjun Jin, Sun Yat-Sen Univ. (China)

Manipulating light in sub-10-nm or subnanometer metal nanogaps is crucial to study the strong interaction between electromagnetic waves and matters. However, the fabrication of metallic nanogaps with precisely controlled size and high-throughput still remains a challenge.?In this work, taking advantage of the shrink effect of the PDMS, we developed a feasible and cost-effective method to mechanically tune the metal gap distance as well as the property of localized surface plasmon resonances (LSPR). Large tunable range from 140 nm to sub-10-nm or even 0 nm gap distance were achieved, transmission spectra show a remarkable red shift of the dipole resonance with narrowing gap. Importantly, a universal scaling law between the gap distance in nanoscale and the stretching amount of PDMS substrate in macroscopic scale were demonstrated experimentally and theoretically. The results reveal that, tuning of the gap distance in nanoscale region can be linearly transferred to the tuning of the PDMS length in macroscopic scale and the resonant wavelength which depended strongly on the gap distance could be easily tuned by the applied strain. We also developed an analytical method to explain a universal scaling law between the gap distance in nanoscale and the stretching amount of PDMS substrate in macroscopic scale.

Polarization-independent multi-peak plasmonic absorber

Igor Leonardo Gomes de Souza, Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil)

The effect of selective absorption of the spectrum of a metal-dielectric grating structure is studied. We propose a selective metamaterial absorber (MMs) of independent polarization spectrum based on a diffraction grating with trapezoidal geometry for the frequencies of the visible spectrum (400-700nm). Quasi-unit absorption with polarization independence is observed under normal incidence with three absorption peaks (blue, green and red). The understanding of a perfect selective absorption mechanism is illustrated by investigating the electric and magnetic field distributions at each resonant wavelength. The manufacturing tolerance of the device is also analyzed by varying the geometric parameters of the diffraction absorber grid.

Quasi-normal mode expansion of the interaction between light and dispersive nano-objects: a theoretical platform for nanoplasmonics

Mathias Perrin, Ctr. National de la Recherche Scientifique (France) and Univ. Bordeaux 1 (France)

One tough task in nanophotonic is to carry heavy numerical simulations – typically Finite Element Methods, or Finite Difference in Time Domain –, in order to compute some key physical quantities (absorption and extinction cross sections, Purcell factor), for different excitation parameters (wavelength, polarization, ...).

To overcome this problem, the Quasi – Normal Mode (QNM) expansion seems promising both in quantum and classical physics, and has received much attention in recent years. Indeed, the QNMs of the device under study need to be computed only once. Then, if excitation is changed (wavelength, polarization, ...) only the expansion coefficients have to be recalculated, and this is done quickly, using an analytic expression even for dispersive and dissipative systems.

In the present work, we derive a corrected QNM expansion that removes the hypothesis of weakly dispersive materials implicitly used in previous works [1]. This leads to more accurate predictions in the near IR range, as an Eigen-energy correction now appears in the expansion [2] and permits a better description going farther from the pole frequency. This analytic formulation has been extended to several non-orthogonal QNMs without using the complex concept of PML integration.

At the conference, we will discuss the interest of this method in topical problems of nanophotonics (Quantum plasmonics, Nonlinear Plasmonics, Bio sensing).

Plasmon-driven design of bimetallic catalysts with nanoscale resolution

Evgenia Kontoleta, Lai-Hung Lai, Erik C. Garnett, FOM Institute for Atomic and Molecular Physics (Netherlands)

It is well-known that plasmonic nanostructures have resonances that depend strongly on the particle shape and size. Here we use optical simulations and single particle experiments to show that the location of optical field “hot spots” corresponding to such localized resonances can be controlled by the illumination wavelength and polarization. We show that the optical field concentration can drive local chemical reactions with nanometer-level spatial control even using a uniform illumination source. As a first test platform we use gold nanotriangles with controllable edge length and thickness. We see that Pt can be photodeposited selectively on the triangle corners or edges depending on the illumination conditions. We investigate the three possible mechanisms leading to such localized deposition: local heating, local field enhancement and local hot electron generation. The gold nanotriangles were excited at their plasmon resonance frequency in a photoelectrochemical cell with variable bias to control the solution electrochemical potential. We verify plasmon-driven reduction of chloroplatinic acid to platinum nanoparticles only under illumination and investigate the bias-dependent deposition rate to determine the energy of these hot carriers for various illumination conditions and sample dimensions. We also study the deposition rate with and without electron and hole acceptors adjacent to the Au nanotriangles, which provides further evidence for a hot-electron mechanism. Our approach provides fundamental insights into hot-electron reactions and opens up a new synthetic pathway for hierarchical nanostructures with both simple synthesis and high spatial control. Such highly controlled nanostructures could find applications in single-molecule spectroscopy, photoelectrochemical water splitting and CO_2 reduction.

Polarization dependent second harmonic generations of equilateral triangular Au nanorods at localized surface plasmon resonances

Atsushi Sugita, Hirofumi Yogo, Atsushi Ono, Yoshimasa Kawata, Shizuoka Univ. (Japan)

Nonlinear plasmonics, the technologies of mixing multiple photons in localized surface plasmon (LSP) enhanced fields, have drawn great attentions. Most of the previous studies about the nonlinear plasmonics employed centrosymmetric metal nanoparticles, such as nanospheres, nanorods, or nanodisks, and they were forbidden for electric dipolar even-order nonlinear susceptibilities. However, the resultant nonlinearities were pretty small. In the present study, the second-order nonlinear optics were investigated for noncentro-symmetric equilateral triangular Au nanoprisms at the LSP resonances.

The model systems consisted of the Au nanotriangles arrayed two-dimensionally on the SiO2 substrates. The geometry of the system was C3v point symmetry. The scattering spectrum demonstrated that the linear optics of the systems were isotropic. The second-order nonlinearities were examined by the polarized second harmonic generation (SHG) spectroscopies. There were six robes in the polar plot of the SHG signals against the excitation light polarizations. The SHG intensities were the highest at the excitation light polarizations vertical to the edges of the triangles, while they were the lowest at the polarizations parallel to the edges.

The anisotropy in the polarized SHG signals were not reproduced with the second-order nonlinear susceptibility tensors imposed on the C3v point symmetry and it was explained by taking account of the fourth-order nonlinearities. The first two photons induced the electrostrictions and the other two were converted into the SHG waves on the transiently deformed nanoprism. The photo-induced anisotropies were dependent on the polarization directions, which resulted in the anisotropy in the polarized SHG signals against the excitation polarization.

Theoretical analysis of near-field distribution by point dipole source located on metallic surface

Changhoon Park, Jae W. Hahn, Yonsei Univ. (Korea, Republic of)

Conceptual and experimental demonstration of extraordinary transmission in subwavelength hole arrays perforated on metallic film attracts much interests in plasmonics. For the physics of single hole, near-field distribution by single hole is mainly composed of surface plasmon polaritons(SPPs) and diffracted fields. Diffracted field is called creeping wave or quasi-cylindrical wave in 1D object and it has asymptotic attenuation rate with respect to distance from aperture. However, theoretical derivation of diffracted field in 2D object is not investigated well. For the 2D aperture on metallic film, light from 2D aperture can be replaced with light from point dipole source due to excitation of local plasmon. Thus, near-field distribution by 2D aperture is replaced with field distribution from point dipole source. In this paper, we investigate near-field distribution based on SPPs and diffracted fields or quasi-spherical waves(QSWs) in 2D aperture. For obtaining characteristics of QSW and SPP, we solved Sommerfeld type integral for the case of horizontal electric dipole source and obtained closed-form solution for SPP and QSW. In the process of derivation, we used the modified steepest descent method described in literature to consider impact of SPP pole. With the closed-form solution for point dipole source, we investigate decay characteristics of near-field by point dipole source and we found that QSW asymptotically falls off as x-q where q ranges from 1 to 2. We expect that our closed-form solution is helpful to design plasmonic device such as sensor, lithography, etc.

Broadband coherent perfect absorber based on symmetric layered thin films using indium tin oxide in epsilon-near-zero wavelength regime

Tae Young Kim, Seoyoung Kim, Wonyoung Kim, Minsuk Kim, INHA Univ. (Korea, Republic of); Young Chul Jun, Ulsan National Institute of Science and Technology (Korea, Republic of); Chang Kwon Hwangbo, INHA Univ. (Korea, Republic of)

Coherent perfect absorption (CPA) is an optical phenomenon occurring in an absorbing thin film or in a subwavelength periodic structure by the interaction of two counter-propagating coherent waves; Incident light is trapped in a cavity, bouncing back and forth, until it is completely absorbed. In this study, we propose a new broadband CPA scheme based on epsilon-near-zero (ENZ) multilayer films. Using the admittance matching method, we designed a symmetric three-layer CPA device of [ZnSe / ITO-2 (9.93 nm) / ITO-1 (14.66 nm) / ITO-2 / ZnSe] using the different ENZ wavelengths of ITO thin films; The incident light is 1550 nm wavelength at a 45o incident angle and two media are prisms of ZnSe. This configuration was chosen to realize near infrared (NIR) broadband CPA while keeping the structure as simple as possible. The output irradiances in two exit media show a broadband CPA phenomenon in the wavelength region of 1442 nm ~ 1576 nm; It is much broader than the single-layer CPA. At CPA, the transverse magnetic field profile of the symmetric-ENZ-ITO-multilayer CPA was simulated using the finite-difference time domain (FDTD) method; When two input fields are incident at CPA, complete constructive interference patterns appear in the ENZ ITO films and there are not any transmitted and reflected waves in both incident and substrate media. Our design for ENZ thin film CPA devices can be used in optical switches, modulators, filters, sensors and thermal emitters.

Design of dielectric to plasmonic waveguide power transfer couplers

Emanuela Paranhos Lima, Univ. Federal da Bahia (Brazil) and Co. de Eletricidade do Estado do Bahia (Brazil); Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil)

Efficient directional couplers composed by parallel dielectric and metallic waveguides have been analyzed in details. The results show that an efficient power conversion of optical dielectric modes to long range plasmonic ones is possible in such devices. Low insertion losses in conjunction with short coupling length as well as a broadband operation can be obtained under certain conditions. This kind of couplers has potential applications for the design of photonic integrated circuits and for signal routing between dielectric and plasmonic waveguides.

Polarization independent asymmetric light absorption in plasmonic nanostructure

Davi Franco Rego, Univ. Federal da Bahia (Brazil) and Instituto Federal da Bahia (Brazil); Igor Leonardo Gomes de Souza, Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil)

The directional dependency of the optical coefficients, such as absorbance and reflectance, of a periodic hole plasmonic structure is numerically simulated and investigated. The tridimensional structure, which is composed of a metallic thin layer on a semiconductor matrix, is polarization independent and exhibits wide angle tolerance. It is found that the optical coefficients of the simulated structure have strong dependency to the radii of the holes due to cavity modes resonance and surface plasmon resonance. Simulations were carried out using gold and silver, varying the holes radii ranging from 40 to 70nm, as well as its depth, from 30 to 60nm of the metallic thin layer and from 100 to 200nm of the semiconductor matrix. A maximum contrast ratio of a unit was obtained for a broadband over above 100nm with 10-fold contrast in absorbance peak asymmetry. The resonant modes excited in the structure and excitation of surface plasmon polaritons in the metallic side illumination favors absorption, which explains the asymmetric behavior. We also investigate the structure's fabrication sensitivity by randomizing the generation of center of the holes in a supercell as well as the incident illumination angle dependency. These findings are significant for a diverse range of applications, ranging from optical integrated circuits to solar and thermovoltaics energy harvesting

Strong terahertz wave coupling to plasmons in grating-grate GaN HEMT arrays

Hugo Condori, Ashish Chanana, The Univ. of Utah (United States); Jimy Encomendero, Mingda Zhu, Cornell Univ. (United States); Yu Cao, IQE (United States); Ajay Nahata, The Univ. of Utah (United States); Huili Grace Xing, Cornell Univ. (United States); Berardi Sensale-Rodriguez, The Univ. of Utah (United States)

Electron plasma wave based devices have attracted significant attention during recent years for terahertz generation, detection and amplification. Efficient coupling of external terahertz radiation into and out of plasmons in a semiconductor hetero-structure is essential for the performance of such devices. Here, we report on mechanisms leading to an enhanced terahertz to electron plasma wave coupling in periodic grating-gate structures. This is achieved via the addition of source and drain (S/D) contacts as theoretically proposed by Popov [APL 89(12), 2006], which can properly synchronize electron plasma waves excited across each unit-cell when placed in close proximity to the gate fingers.

The analyzed hetero-structures consist of a 4.5um thick AlN buffer layer, followed by a 200nm GaN layer and a 20nm AlGaN barrier, which are grown on Si(111). A 2DEG is formed at the AlGaN/GaN interface. After definition of the S/D contacts and gate fingers in a periodic pattern, the back-side of the sample is etched employing DRIE so to get rid of the substrate. The resulting samples are ultra-thin membranes (thickness ~5um) and thus do not exhibit any substrate-related effects. The fabricated devices show a geometrically-defined resonance at 0.56 THz (77K), which is in close agreement with predictions from electromagnetic simulations (HFSS). Moreover, samples with S/D contacts show significantly stronger resonant responses when compared to structures without. Overall, our results demonstrate a simple way in which to enhance the electromagnetic coupling and thus improve the performance in electron plasma wave based devices.

Surface plasmon-polaritons in graphene: antiferromagnet structure

Igor V. Bychkov, Dmitry A. Kuzmin, Chelyabinsk State Univ. (Russian Federation) and South Ural State Univ. (Russian Federation); Valentin A. Tolkachev, Ivan Y. Biryukov, Chelyabinsk State Univ. (Russian Federation); Vladimir G. Shavrov, Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation)

Nowadays, in plasmonics great researchers attention is paid to investigation of graphene-based nanostructures and perspectives of its applications in data processing and storage devices. In our recent works we have considered some graphene-containing structures. Some interesting results on speckle-pattern rotation in graphene-coated optical fibers, surface plasmon manipulation by magnetic field in the planar gyrotropic waveguide formed by two graphene layers, plasmonically induced magnetic field and Faraday rotation of high order modes in graphene-covered nanowires have been obtained.

In this work surface plasmon-polaritons in dielectric – graphene – antiferromagnet structure is investigated. We assume that dielectric is non-dispersive one, antiferromagnet is centrosymmetric few-sublattice magnet (of rhombic symmetry) with exchange spin excitations of electroactive type. Eigen frequencies of exchange modes correspond to infrared and visible spectrum ranges (for example, YBa2Cu3O6+x, ?-Fe2O3). Frequency-dependence of graphene conductivity is taken into account.

Calculations are carried out in assumption of decaying length of surface electromagnetic wave is much greater than the lattice constant and phenomenological method may be used. Properties of the structure are depending on dielectric permittivity tensor of antiferromagnet and graphene conductivity.

Different propagation directions of electromagnetic wave with respect to antiferromagnet crystal orientation are considered. Dispersion equations and conditions of excitation of TM- and TE- waves and components of electromagnetic field are obtained. It is shown, that TE- waves, which are non-existing without graphene, may propagates in the structure when some relations between parameters of mediums are satisfied in frequency ranges of exchange modes of antiferromagnet.

3D multifocal metalens

Bo-Han Chen, National Taiwan Univ. (Taiwan); Pin Chieh Wu, Cheng Hung Chu, Academia Sinica (Taiwan); Mu-Ku Chen, Wei-Yi Tsai, Jia-Wern Chen, Tsung Lin Chung, National Taiwan Univ. (Taiwan); Din Ping Tsai, Academia Sinica (Taiwan)

Optical metasurface has attracted wide attentions because of its ability on the control of electromagnetic wave properties such as phase, amplitude as well as polarization in a subwavelength resolution. This characteristic profit the metasurfaces developing flat optical components like color filter, planar metalens, meta-hologram, polarimetry and so on. Take metalens as an example, the impinging light is converging into a single spot through 2ϖ phase modulation along a metasurface interface. Beside the compact dimension, integrated functionality is also possible in metalens that provides an additional dimension for designing devices. Although several lectures have demonstrated spatial functionalities like off-axis focus and multispectral lenses that are impossible via traditional optical components, the generalization of converging metalens in a three dimension scheme is still missing.

In this work, we present a design principle for a multifocal metalens in which the focal point can be designed at arbitrary position on a sphere at free space. To realize metalenses working in the visible light, gallium nitride (GaN) is implemented as the material composition. The results show that the non-coplanar focal points can be realized at will for three wavelengths corresponding to red, green and blue colour. Furthermore, a metalens which is able to focus three colours simultaneously at different positions is also achieved by integrating three components into a single meta-device. This study provides a promising way for the development of a variety of applications like miniature optical systems, multispectral camera and CMOS image sensor, just named a few.

Intrinsic exciton-plasmon coupling at polar surfaces of ZnO in the epsilon-near-zero region

Munise Cobet, Johannes Kepler Univ. Linz (Austria); Markus R. Wagner, Axel Hoffmann, Technische Univ. Berlin (Germany)

High resolution ellipsometry of the complex dielectric function of polar ZnO surfaces are presented which show the existence of an additional propagation mode in the interface formed by an 1s-exciton-free layer (dead layer) at the Zn-terminated surface and the 2D-electron accumulation zone of the n-type material . This natural "intrinsic" layer formation fulfills ATR-like conditions for simple reflection geometries in a certain frequency window so that no prism is required. In the energy range around the longitudinal B-exciton, where epsilon is near zero, enhanced exciton-plasmon coupling generated by the p-polarized light mimics a negative effective refractive index and non-linearities comparable with metamaterials.

In order to verify the conclusions, calculations of the optical response are performed, which theoretically show the effect of a Drude-like thin surface layer on a semiconductor with exciton-polaritons. Results of this simulations are rather high carrier concentration and strong localization.

Wideangle plasmonic filter for visible light applications

Igor Leonardo Gomes de Souza, Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil); Davi Franco Rego, Univ. Federal da Bahia (Brazil) and Instituto Federal da Bahia (Brazil)

We proposed and designed angle insensitive color filter based in metal/dielectric multilayers structures for red electromagnetic radiation (620-750nm). The thickness of the dielectric in the structure is calculated according to the physical theory and the omnidirectional resonance occurs when the reflection phase shift cancels the propagation displacement. The thickness of the metal is chosen analyzing a transmission properties in an interval of thicknesses previously described in the literature. We obtain analytically a highly stable filter with a transmission peak greater than 70% in approximately 634nm. This device can keep the same perceived transmitted color when the incidence angle changes from 0° to 50°, especially for TM polarized light.

Optics of multiple grooves in metal: transition from high scattering to strong absorption

Enok J. H. Skjølstrup, Thomas M. Sondergaard, Thomas G. Pedersen, Kjeld Pedersen, Aalborg Univ. (Denmark)

This paper studies theoretically how the optics of multiple grooves in a metal change as the number of grooves is increased gradually from a single groove to infinitely many arranged in a periodic array. In the case of a single groove the out-of-plane scattering (OUP) cross section at resonance can significantly exceed the groove width. On the other hand a periodic array of identical grooves behaves radically different and is a near-perfect absorber at the same wavelength. When illuminating multiple grooves with a plane wave the OUP cross section is found to scale roughly linearly with the number of grooves and to significantly exceed the physical array width even for widths of many wavelengths. The normalized OUP cross section per groove even exceeds that of a single groove, which is explained as a consequence of surface plasmon polaritons generated at one groove being scattered out-of-the-plane by other grooves. In the case of illuminating instead with a Gaussian beam, and observing the limit as the incident beam narrows and is confined within the multiple-groove array, it is found that the total reflectance becomes very low and that there is practically no out-of-plane scattering. The well-known result for periodic arrays is thus recovered. All calculations were carried out using Greens function surface integral equation methods taking advantage of the periodic nature of the structures. Both rectangular and tapered grooves will be considered.

Analysis of near-field thermal energy transfer within nanoparticles

Anil Yuksel, Michael Cullinan, Edward T. Yu, Jayathi Y. Murthy, The Univ. of Texas at Austin (United States)

Nanoscale size effects bring additional near-field thermal considerations when heating under high laser power. In this paper, we apply a Finite Difference Frequency Domain method to nanoparticles in a bed with Gaussian and Log-normally distributed particles to understand near-field thermal radiation energy effect. The nanoparticles are generated by using Discrete Element Model in which certain number of particles are generated by defining a position and radius. The solid particles interacting with the neighbouring particles are to be distributed randomly into the bed domain with an initial velocity and a boundary condition, which creates the particle packing within a defined time range under gravitational and Van der Waals forces. Finite Difference Frequency Domain, which allows electromagnetic field distribution, is applied by solving the Maxwell's equations to obtain thermal properties such as effective absorption and extinction coefficient. We show that different particle distributions create different plasmonic effects in the bed domain which results in non-local heat transport. We calculate the surface plasmon effect due to the electromagnetic coupling between the nanoparticles and the dielectric medium under the different distributions. This analysis helps to understand how sintering quality can be enhanced by creating stronger laser-particle interactions for specific groups of nanoparticles.

Reducing back scattering of plasmonic scattering nanostructures for enhancing light absorption inside perovskite solar cells

Omar A. M. Abdelraouf, The American Univ. in Cairo (Egypt) and Ain Shams Univ. (Egypt); Ahmed Shaker, Ain Shams Univ. (Egypt); Nageh K. Allam, The American Univ. in Cairo (Egypt)

The efficiency of the organic perovskite solar cells has remarkable rapid increase in last decade, which make perovskite material a good candidate for cheap photovoltaic. Plasmonic scattering nanostructure could concentrate, scatter or absorb electric field at the nanometer scale.

Using these nanophotonic structures in perovskite solar cells, light absorption percentage inside active layer could be increased. For best performance using plasmonic nanostructures, we need to reduce light losses due to absorption inside metal. Also, we aim to scatter all light inside active layer and reduce backscatter light.

Herein, theoretically, we studied how to minimize backscattering effects of metallic nanostructures deposited on top perovskite active layer. Backscattering causes reflection of incident light and would reduce the amount of light inside active layer.

We studied the effect of using different silver nanostructure shapes like sphere, cone, cube, and cylindrical. Also, we examined changing dimensions of sphere radius from 50nm to 125nm, cone height, cube side length, and cylindrical radius from 50nm to 200nm.

Our results show that backscattering is highly depending on shape and dimension. So, after changing these parameters, we could suggest some shapes and appropriate dimensions with lowest value of backscattering over active perovskite wavelength.

All calculations of this work built based on Mie theory. For verifying our results, we start by modeling silver sphere in air, which gave excellent matching with Mie theory results. All models are done using COMSOL a three-dimensional, finite element method simulation tool.

Finally, using suggested nanostructures, efficiency of perovskite solar cells could be enhanced.

10346-112, Session PWed

Second harmonic generation from metal-dielectric-semiconductor nanoresonator

Anatoly Khomenko, Paulina Segovia Olvera, Pamela Mastranzo-Ortega, Elena I. Chaikina, Ctr. de Investigación Científica y de Educación Superior de Ensenada B.C. (Mexico)

In this work numerically and experimentally studied second harmonic generation (SHG) and field enhancements of two-dimensional periodical structures based on a metal nanostrips separated from semiconductor block by a small dielectric gaps. The numerical study has been conducted using the commercially available finite element software Comsol Multiphysics.

Field enhancement effects on the metal and semiconductor surface were analyzed at different incident angles of pump light. We show that by varying the gap size, dielectric constant of gap material and metal strip width the optimal wavelength for SHG can be tuned over a wide spectral range.

The numerical results were used to optimize the configuration of experimental samples, which were fabricated by electron beam lithography method. Each sample sized 1?1 mm2 consists of grating of gold strips deposited on an oxidized silicon surface. The thickness of the naturally grown oxide was measured as 2 nm.

We performed the measurements of second harmonic diffraction efficiency and its dependence on the state of polarization of the pump beam with the different period of Au strips. As a pump source a mode locked Ti:Sapphire laser delivering pulses at 83.3 MHz repetition rate and temporal FWHM 140 fs was used in the experiments. The experimental results are in good agreement with the numerical data and demonstrate up to two-order increase in SH diffraction efficiency from the Si-surface after deposition of Au-strips.

SPP-assisted sub-wavelength reflection-type THz imaging with THz time-domain spectrometer

Senfeng Lai, Yanghui Wu, Wen Wu, Wenhua Gu, Nanjing Univ. of Science and Technology (China)

THz imaging has become a hot research topic in recent years, thanks to its merits of non-contact, strong penetration, immunity to hostile environments, and nondestructive detection. However, its spatial resolution is limited by the relatively long wavelength, so the location and measurement precision can only reach the level of the imaging wavelength, which has become a severe limitation of THz imaging. A simple way using surface plasmon polaritons (SPPs) to improve the location and measurement precision of THz by one order of magnitude was proposed in this manuscript, which can also realize subwavelength THz imaging.

10346-114, Session PWed

Orientational imaging of single plasmonic nanocube using dark-field hyperspectral imaging

Manas R. Gartia, Nishir S. Mehta, Georgios Veronis, Amirreza Mahigir, Louisiana State Univ. (United States)

Knowing the orientation of plasmonic nanostructures is important for catalyst, biosensors for DNA, protein detections, hotspot of surface enhanced Raman spectroscopy (SERS), and fluorescence resonant energy transfer (FRET) experiments. However, due to diffraction limit, it is challenging to obtain the exact orientation of the nanostructure using standard optical microscope. Hyperspectral Imaging Microscopy is a state-of-the-art visualization technology that combines modern optics with hyperspectral imaging and computer system to provide the identification and quantitative spectral analysis of nano- and microscale structures.

In this work, initially we use transmitted dark field imaging technique to locate single nanoparticle on a glass substrate. Then we employ hyperspectral imaging technique at the same spot to investigate orientation of single nanoparticle. No special tagging or staining of nanoparticle has been done, as more likely required in traditional microscopy techniques. Different orientations have been identified by carefully understanding and calibrating shift in spectral response from each different orientations of similar sized nanoparticles. Wavelengths recorded are between 300 nm to 900 nm.

Validation of the experimentally obtained results with finite difference time domain (FDTD) electrodynamics calculations and electron microscopy techniques allows us to confirm the correctness of our orientation assignments. The combination of high resolution nanometer-scale imaging techniques and the modern numerical modeling capacities thus enables a meaningful advance in our knowledge of manipulating and fabricating shaped nanostructures.

This work will advance our understanding of the behavior of small nanoparticle clusters useful for sensing, nanomedicine, and surface sciences.

Exceptional points in hybridized plasmonic systems

Ashok Kodigala, Thomas Lepetit, Boubacar Kante, Univ. of California, San Diego (United States)

Plasmonics and its applications have garnered ample attention over the years. These applications range from chemical and biological sensors to enhanced photovoltaics.We design for the first time 3D plasmonic structures with exceptional point (EP) singularities. Exceptional Points (EPs) are singularities of open systems where at least two complex eigenmodes coalesce. They manifest themselves by the simultaneous degeneracy of both resonant frequencies and linewidths. These points are highly sensitive to external perturbations as even a tiny variation will lift the degeneracy and cause splitting of both resonant frequencies and linewidths. These results make it possible to envision a highly sensitive molecular sensor.

Investigation of electron and ion beam exposures on a new HfO2 based hybrid resist

Paolo Ponzellini, Istituto Italiano di Tecnologia (Italy); Gioia Della Giustina, Univ. degli Studi di Padova (Italy); Matteo Ardini, Eugenio Calandrini, Francesco De Angelis, Istituto Italiano di Tecnologia (Italy); Denis Garoli, Univ. degli Studi di Padova (Italy)

During the recent years there was a growing interest in the application of nanostructured ceramic coatings. Several materials such as transition metals oxides: Hafnia Oxide (Hf2O3), Titania (TiO2), Zirconia (ZrO2), Alumina (Al2O3), Silica (SiO2), Indium Tin Oxide (ITO) and Lead Zirconate Titanate (PZT) can be applied in a wide variety of fields thanks to their chemical and thermal stability, mechanical resistance and advanced optical, structural and electrical properties. In order to extensively apply these materials in nanofabrication processes, it's of great interest to engineer the material in order to make it directly patternable. In fact, the traditional lithography and nanopatterning of inorganic films consists in complicated and time consuming processes. These comprises physical deposition onto a pre-patterned organic resist which is then removed by the lift-off process leaving the patterned structures. Among the different materials Hafnium dioxide (HfO2) is a well-known optical material due to its relatively high refractive index, high transparent from infrared (IR) to ultraviolet (UV) wavelength range, and low reflectivity in the visible and near IR regions. It has been used in several applications such as high-index optical coatings and as high -k gate dielectric in microelectronic next generation devices. Here we present the development of a negative tone sol-gel resist based on HfO2. Exposures under electron and ion beam have been investigated.

Efficient OAM generation at the nanoscale level by means of plasmonic vortex lens

Yuri Gorodetski, Ariel Univ. (Israel); Pierfrancesco Zilio, Paolo Ponzellini, Matteo Ardini, Xavier Zambrana-Puyalto, Andrea Jacassi, Eugenio Calandrini, Denis Garoli, Istituto Italiano di Tecnologia (Italy)

Structured light beams have been the subject of an intense work in the last years due to the numerous potential applications they may offer in several disparate technological and research fields. The possibility to produce and analyze singular optical beams at the micro and the nanoscale led to focus on the interaction of light with metallic nanostructures, resulting in Surface Plasmon Polaritons (SPPs) carrying angular momentum (AM).We will refer to these waves as Plasmonic Vortices (PVs). Such modes are generally surface confined helical electromagnetic distributions with a field singularity. The strength of the singularity, termed the topological charge of a vortex, is defined by the phase ramp acquired in one round trip about the singularity center. This charge is proportional to the AM carried by the field.

PVs can be generated by coupling AM-carrying beams to the plasmonic modes of metallic films using particular chiral grating couplers, which have been sometimes called plasmonic vortex lenses (PVLs). Several examples of these couplers have been presented so far. A feature common to most of them is the Archimede's spiral shaped grooves or slits milled in a noble metal film.

Here we theoretically and experimentally demonstrate an approach to the efficient PV coupling to the free space, by means of a single-layer PVL structure with a smoothed-cone tip at its center. We show that, by properly shaping the tip geometry, the PV excited by the spiral structure can be adiabatically coupled to the far-field mode, carrying well defined AM.

Ultrafast energy transfer between excitons and plasmons from weak to ultrastrong coupling regime

Sinan Balci, Turk Hava Kurumu Univ. (Turkey); Betul Kucukoz, Ankara Üniv. (Turkey); Osman Balci, Bilkent Univ. (Turkey); Ahmet Karatay, Ankara Üniv. (Turkey); Co?kun Kocaba?, Bilkent Univ. (Turkey); Halime Gul Yaglioglu, Ankara Üniv. (Turkey)

We investigate ultrafast energy transfer between excitons and plasmons in ensembles of core-shell type nanoparticles consisting of metal core covered with a concentric thin J-aggregate shell. The high electric field localization by the Ag nanoprisms and the high oscillator strength of the J-aggregate allow us to probe this interaction in the ultrastrong plasmon-exciton coupling regime. Transient absorption spectroscopy experiment revealed that the hybrid system shows half-plasmonic and half-excitonic properties. The tunability of the nanoprism plasmon resonance provides us a flexible platform to study the dynamics of the hybrid state in a broad range of wavelengths. Besides, we present a new method for the ?synthesis of plexcitonic nanoparticles to ?control the number of dye molecules self-assembled on Ag?-nanoprisms where, individual dye molecules? self-assemble into J-aggregates on Ag-nanoprisms. We observed a transition from weak coupling to the ultrastrong coupling regime. Ultrafast energy transfer of the hybrid system as a function of Rabi splitting energy revealed that the lifetime of the polariton states increases with the coupling strength and the upper polaritons are short-lived, whereas the lower polaritons are long-lived. Hybrid metal?organic nanoparticles presented in this study (i) have tunable Rabi splitting energies, (ii) are easy to prepare in large quantities in aqueous medium, (iii) can be uniformly assembled on solid substrates, (iv) have resonance frequencies in the visible spectrum, and (v) have small mode volume, thus making them an excellent model system for studying light?matter interaction at nanoscale dimensions from the weak to ultrastrong coupling regime.

10346-120, Session PWed

Experimentally quantifying losses of Fano resonances

Junhee Park, Ashok Kodigala, Abdoulaye Ndao, Boubacar Kante, Univ. of California, San Diego (United States)

A multilayered periodic array of coupled gold bars is experimentally shown to exhibit inversion between their hybridized modes in the near-infrared domain. Placing two bars hybridizes their individual plasmon modes. The resulting two fundamental modes of the system resemble symmetric (?+) and anti-symmetric (?-) modes investigated. Spatially displacing one of the bars with respect to the other can be used to modify the spectral position of these two fundamental modes even leading to resonance inversion contingent on near-field coupling. The multilayered nanostructures were fabricated by high resolution electron beam lithography (EBL), metal deposition and lift-off process on a glass substrate. SU-8 photoresist was planarized and the first layer of gold bars on the glass substrate are embedded in SU-8 which also serves as a dielectric spacer EBL, metal deposition, and lift-off steps for the second layer are carried out in a similar manner. The transmittance and reflectance spectra were acquired using a Fourier-transform infrared spectrometer (FTIR, Vertex 70, Bruker Inc.) system coupled with an optical microscope (Hyperion 2000) operated in the near infrared. The measured transmittance and reflectance spectra are normalized with a glass substrate with SU-8 spacer and with a gold mirror, respectively. Moreover, experimentally, the decay (radiation) rates of plasmonic modes are quantitatively estimated. This is of practical importance for sensing applications as it pertains and allows for loss engineering. The challenging fabrication and characterization of these multilayered structures are detailed. We highlight the importance of fabrication quality and its effect on device performance dependent on added losses.

10346-121, Session PWed

Photoluminescence of fullerene C60 thin film in plasmon coupled Au NPs monolayer, C60 film, Al film nanostructure

Oleg A. Yeshchenko, Viktor Kozachenko, Nataliya Berezovska, Yurii Liakhov, Taras Shevchenko National Univ. of Kyiv (Ukraine)

The optical properties of plasmon coupled Au NPs monolayer – C60 film – Al film nanostructure were studied in dependence of the fullerene film thickness varied in the range of 10 – 95 nm. Effects of the fullerene spacer thickness on plasmonic coupling of Au NPs with Al film were analyzed basing on the dependences of the intensity, wavelength and width of SPR extinction peak of Au NPs and the intensity of C60 PL on the fullerene film thickness.

The red shift, non-monotonic dependences with maxima of the intensity and width of SPR in Au NPs at the decrease of the spacer thickness were observed and considered as the result of thickness dependent plasmon coupling between Au NPs monolayer and Al film. The non-monotonic dependence with minimum of the PL intensity of C60 film on its thickness was also observed. The extrema of the thickness dependences of SPR extinction peak intensity and width and fullerene PL intensity occur at the same thickness value of 50 nm that allows to assume the same physical mechanism of such non-monotonic dependences. We assume that such mechanism is the excitation of the propagating SP-polaritons in Al film by the plasmonic near field waves from the Au NPs. The SP-polaritons excitation leads to additional radiative damping of SP oscillations in Au NPs. The increase of radiative damping causes the weakening of the plasmonic field of Au NPs in the gap between the Au NPs monolayer and Al film that leads to decrease of the fullerene PL intensity.

10346-122, Session PWed

Gold nanoparticle plasmon resonance in near-field coupled Au NPs monolayer / dielectric spacer / Al film nanostructure: tuning by variation of spacer thickness

Oleg A. Yeshchenko, Viktor Kozachenko, Yurii Liakhov, Taras Shevchenko National Univ. of Kyiv (Ukraine); Anatoliy O. Pinchuk, Univ. of Colorado at Colorado Springs (United States)

Effects of plasmonic coupling between the metal nanoparticles and thin metal film separated by thin dielectric film-spacer have been studied by means of the light extinction in three-layer planar Au NPs monolayer / dielectric (shellac) film / Al film nanostructure. An influence of coupling on the spectral characteristics of SPR extinction peak in Au NPs has been analyzed at spacer thickness varied in the range of 3 – 200 nm. The main observed features are strong red shift (160 nm), non-monotonical behavior of the magnitude and width of SPR at the decrease of the spacer thickness. An appearance of the intensive quadrupolar SPR peak has been observed at spacer thickness smaller than about 30 nm that is caused by the hybridization of dipolar and quadrupolar SPR modes in Au NPs in the presence of Al film. The appreciable enhancement (in 5.6 times) of light extinction by Au NPs monolayer in presence of Al film has been observed. It has been revealed that a certain value of dielectric spacer thickness (70 nm) exists at which such enhancement is maximal.

10346-123, Session PWed

Plasmonic detection of possible defects In multilayer nanohole array consisting of essential materials in simplified STT-RAM cell

Parinaz Sadri Moshkenani, Qiancheng Zhao, Mohammad Wahiduzzaman Khan, Ilya N. Krivorotov, Mikael Nilsson, Nader Bagherzadeh, Ozdal Boyraz, Univ. of California, Irvine (United States)

Plasmonic nanostructures are highly used for sensing purposes since they support plasmonic modes which make them highly sensitive to the refractive index change of their surrounding medium. Therefore, they can also be used to detect changes in optical properties of ultrathin layer films in a multilayer plasmonic structures. Here, we investigate the changes in optical properties of ultrathin films of macro structures such as STT-RAMs. Among the highest sensitive plasmonic structures, nanohole array has attracted many research interest because of its ease of fabrication, small footprint, and simplified optical alignment, and hence they are more suitable for defect detection in STT-RAM geometries. Moreover, the periodic nanohole pattern in the nanohole array structure makes it possible to couple the light to the surface plasmon polariton (SPP) mode supported by the structure. To assess the radiation damages and defects in STT-RAM cells we have designed a multilayer nanohole array based on the layers used in STT-RAM structure, consisting 4nm-Ta/2nm-CoFeB/2nm-MgO/1nm-CoFeB/5nm-Ta layers, all on a 300nm silver layer on top of a PEC boundary. The nanoholes go through all the layers and become closed by the PEC boundary on one side. The nanoholes are of 314nm depth, 350nm diameter, and 700nm period. Here, we consider the normal incidence of light and investigate zeroth-order reflection coefficient to observe the resonance. Our simulation results show that a 10% change in refractive index of the 2nm-thick MgO layer leads to about 123.2 GHz shift in SPP resonance in reflection pattern.

10346-59, Session 15

Self-assembly for plasmonic structures on large scale *(Invited Paper)*

Nobuyuki Takeyasu, Okayama Univ. (Japan) and RIKEN (Japan)

Metallic nano-structures exhibit plasmonic properties, which are different from bulk metals. For some practical applications, large amount of such structures are required over bulk scale. Self-assembly is a key platform for a large-scale fabrication of metallic nano/micro structures. However, the shape control is not easy even though their plasmonic properties are determined by their shapes. Here, I show different approaches for the shape controls of plasmonic structures with metallic atoms and nanoparticles (NPs), resulting silver nano-trees, gold NP dimers, and NP array. Silver fractal structures were formed through the assembly of silver atoms reduced from the silver ions in acetone/water solution under diffusion-limit condition. Gold NP dimers were formed through hydrophobic assembly, where hydrophobic point decorations were performed at the surface of each gold NP using Langmuir-Blodgett film. Over a wide area, NP array was formed using oil-in-water emulsion, which collected NPs dispersed in a solution and brought them into the oil/water interface through coalescence of oil droplets. I would like to show their applications to surface-enhanced Raman spectroscopy as well.

10346-60, Session 15

Plasmonic nanoparticle lithography

Zhenying Pan, Ye Feng Yu, Vytautas Valuckas, Guillaume G. Vienne, Arseniy I. Kuznetsov, A*STAR - Data Storage Institute (Singapore)

The fast development of nanoscience, especially in the field of nanoelectronics, nanophotonics and plasmonics, has shown a great demand for new nanofabrication techniques to fulfil diverse requirements. The nanolithographic methods, e.g conventional photolithography, focused electron beams lithography (EBL), and focus ion beams (FIB), all exhibit the capability for nanostructure fabrication but most of them inherently suffer from their nature, which limit the size of nanostructures, fabrication area, and throughput at reasonable costs. The limitations of these conventional lithographic techniques have motivated the development of alternative approaches such as micro-contact printing, scanning probe lithography and nanoimprinting lithography (NIL). In this paper, we propose a new alternative laser based approach which could satisfy the requirements of high resolution, fast processing speed for large area fabrication of sub-wavelength nanohole and nanoparticle arrays with feature size controllably varied from a few tens to a few hundreds nanometers. The technique, named as plasmonic nanoparticle lithography, effectively combines the laser induced transfer (LIT) [1, 2] and light-induced near-field nanomodification [3, 4] relying on the optical enhancement and thermal effect in near-field under spherical plasmonic nanoparticles. It allows producing ordered sub-wavelength nanohole arrays in a thin mask layer (e.g. Chromium film) upon laser exposure. Subsequent post-processing allows transferring the nanohole array into a desired substrate or converting it into an array of pillars made out of a desired material.

Electrohydrodynamic flow as a driving force for the directed chemical assembly of plasmonic meta-molecules

William Thrift, Regina Ragan, Mahsa Darvishzadeh-Varcheie, Filippo Capolino, Univ. of California, Irvine (United States)

Advances in understanding chemical and physical driving forces in self-assembly allow the fabrication of unique nanoarchitectures with subwavelength building blocks as the basis for plasmonic and metamaterial devices. Directed assembly of colloidal nanospheres has been shown as a

promising method for producing large area plasmonic metasurfaces. Still, self-assembly often faces significant challenges with fabrication precision, especially for metasurface applications. In this work, electrohydrodynamic (EHD) flow and chemical crosslinking are combined to form dense meta-molecules in the 2-dimensional plane of a working electrode immersed in Au nanosphere colloid solution. EHD provides a long range driving force to bring nanospheres together and crosslinking yields small, uniform gap spacings which yield strong light-matter interactions. This work represents a novel use of EHD flow for directed assembly to improve assembly kinetics with nanoparticles as small as 40nm. Selective chemical crosslinking is used to ensure selective deposition onto templates, reducing defects and nonspecific deposition. Circular meta-molecules are fabricated using directed assembly to produce strong magnetic resonances. We investigate the magnetic near field enhancements via dark field scattering spectroscopy assisted by full wave finite difference time domain simulations. Understanding long range (EHD flow) and short range (chemical crosslinking) driving forces provides the control for assembling colloidal nanoparticles in architectures for large area plasmonic metasurfaces as the basis of novel biosensing techniques and for achieving negative permeabilities at optical frequencies.

10346-63, Session 15

Large-scale nanofabrication of three-dimensional chiral nanostructures using a method combining nanospherical-lens lithography and hole mask lithography *(Invited Paper)*

Chang-Han Wang, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Jyun-De Wu, National Taiwan Univ. (Taiwan); Zhan-Hong Lin, Yi-Hsin Chien, Chi-Ching Liu, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Yang-Fang Chen, National Taiwan Univ. (Taiwan); Yun-Chorng Chang, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan)

Plasmonics is a research field that has been under intense researches during the last decade and many interesting and new research topics have been discovered. One of the new and hot research topics in Plasmonics is Chiral Plasmonics, which studies the different responses to incident light with different handedness. Although many new and novel findings in this topic have been reported so far, however, it is still limited to the available chiral nanostructures that can be fabricated. It is hard enough to fabricated planar nanostructures with chiral optical properties. It is even harder to fabricate three-dimensional chiral nanostructures using standard lithography processes.

In this study, we will demonstrate he fabrication of various three-dimensional chiral nanostructures using a method combining Nanospherical-Lens Lithography (NLL) and Hole Mask Lithography. NLL is a technique that uses polystyrene nanospheres to focus the incoming ultraviolet light and exposure the underlying photoresist (PR) layer. PR hole arrays form after developing. We subsequently covered the PR holes with oblique angle deposited Cr to form Cr metal holes. These holes are then used with Hole Mask Lithography for angled metal deposition. By the proposed procedures, we are able to fabricate chiral nanostructures that covers a large area with very high fabrication throughput.

In the final part of this study, we will also present theoretically and experimentally obtained results to demonstrate the optical properties of the fabricated nanostructures. The properties of the chiral structures are detailed investigated and we will propose several possible applications.

10346-64, Session 16

Ultrafast nonlinearities of semiconductor metasurfaces *(Invited Paper)*

Maxim R. Shcherbakov, M.V. Lomonosov Moscow SU (Russian Federation) and Cornell Univ. (United States)

Samples were fabricated using combinations of electron beam lithography, plasma-enhanced chemical vapor deposition of silicon, dry etching, molecular beam epitaxy of Al(x)Ga(1-x)As heterostructures, and wet oxidization of AlGaAs to AlGaO. Reflectance and transmittance spectra were measured using white light spectroscopy. Ultrafast transient traces were obtained using either single frequency pump-probe (Ti:Sap at 780 nm and 45 fs) or supercontinuum IR probe pumpr-probe. Experimental data are supported by fullwave simulations in either Lumerical FDTD or COMSOL Multiphysics.

10346-65, Session 16

Graphene-plasmon lenses for enhanced harmonic generation

José Ramón Martínez Saavedra, ICFO - Institut de Ciències Fotòniques (Spain); F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain)

Plasmons —the collective oscillations of electrons in metals— are one of the most promising phenomena for the design of photonic devices, thanks to its appealing properties such as strong field enhancement and energy concentration [1]. These capabilities make plasmonic materials the perfect ground for the enhancement of optical nonlinear effects, which typically require very high field intensities to be noticeable [2]. Among the plethora of plasmonic materials suitable for nonlinear effects, graphene arises as one of the most promising candidates, thanks to its active tunability properties and its linear dispersion relation, which makes it inherently nonlinear [3]. When the propagating plasmons exhibit long propagation distances, geometry can be exploited to accumulate them at focal hotspots, thus providing an additional mechanism for enhancing the nonlinear response.

In this work, we combine both the nonlinear properties of graphene and the geometrical nonlinear enhancement of a designated graphene structure to enhance harmonic generation to unprecedented limits. We analyze second- and third-order harmonic generation emission patterns from this device. We also perform a systematic study of its nonlinear properties as a function of the different material and geometrical parameters. We also explore the effect of different environments on the nonlinear effects, showing an enhancement of the second- and third-order responses of the lens. These results pave the way toward the realization of efficient, graphene-based nonlinear devices.

Nonlinear plasmonic sensing with nanographene

Renwen Yu, Joel D. Cox, ICFO - Institut de Ciències Fotòniques (Spain) and Barcelona Institute of Science and Technology (Spain); F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain) and Barcelona Institute of Science and Technology (Spain)

Plasmons provide excellent sensitivity to detect analyte molecules through their strong interaction with the dielectric environment. Plasmonic sensors based on noble metals are, however, limited by the spectral broadening of these excitations. Here we identify a new mechanism that reveals the presence of individual molecules through the radical changes that they produce in the plasmons of graphene nanoislands. An elementary charge or a weak permanent dipole carried by the molecule are shown to be sufficient to trigger observable modifications in the linear absorption spectra and the nonlinear response of the nanoislands. In particular, a strong second-harmonic signal, forbidden by symmetry in the unexposed graphene nanostructure, emerges due to a redistribution of conduction electrons produced by interaction with the molecule. These results pave the way toward ultrasensitive nonlinear detection of dipolar molecules and molecular radicals that is made possible by the extraordinary optoelectronic properties of graphene.

10346-67, Session 16

Extreme nonlinear plasmonic phenomena in nanostructured graphene

Joel D. Cox, Andrea Marini, ICFO - Institut de Ciències Fotòniques (Spain); F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain)

The realization of efficient high-harmonic generation (HHG) in solid-state systems is anticipated to pave the way for compact ultraviolet and ultrafast light sources, and to provide fundamental insight into quantum many-body electron motion [1-3]. Here we argue that the large light intensity required for HHG to occur can be reached by exploiting localized plasmons in doped graphene nanostructures. In particular, we demonstrate that the synergistic combination of strong plasmonic near-field enhancement and a large intrinsic nonlinearity originating from the anharmonic charge-carrier dispersion of graphene result in efficient broadband high-harmonic generation within a single material [4]. We extract this conclusion from rigorous time-domain simulations using complementary nonperturbative approaches based on atomistic one-electron density matrix and massless Dirac-fermion Bloch-equation pictures, where the latter treatment is supplemented by a classical electromagnetic description of the plasmonic near-field enhancement produced by the illuminated nanostructure.

High harmonics are predicted to be emitted with unprecedentedly large intensity by tuning the incident light to the localized plasmon resonances of ribbons and finite islands, which in turn can be actively modulated via electrical gating. In contrast to HHG in atomic systems, we observe no cutoff in harmonic order, while a comparison of graphene plasmon-assisted HHG to recent measurements in solid-state systems suggests that the HHG yields from bulk semiconductors can be produced by graphene plasmons using 3-4 orders of magnitude lower pulse fluence. Our results support the strong potential of nanostructured graphene as a robust, electrically-tunable platform for HHG.

10346-68, Session 17

Ultrafast dynamics of plasmonic nanostructures *(Invited Paper)*

Stephan Link, Rice Univ. (United States)

Aluminum nanostructures support tunable surface plasmon resonances and have become an alternative to gold nanoparticles. While gold is the most-studied plasmonic material, aluminum has the advantage of high earth abundance and hence low cost. In addition to understanding the size and shape tunability of the plasmon resonance, the fundamental relaxation processes after photo-excitation must be understood to take full advantage of aluminum nanostructures in various applications including photocatalysis and photodetection. In this work, we investigate the energy relaxation after ultrafast pulsed excitation and the launching of acoustic vibrations in individual aluminum nanodisks with varying diameters using single-particle transient extinction spectroscopy. We find that the transient extinction signal can be assigned to a thermal relaxation of the photoexcited electrons and phonons. The ultrafast heating induced launching of in-plane acoustic vibrations reveal moderate binding to the glass substrate and are affected by the native aluminum oxide layer as demonstrated by theoretical calculations. We furthermore compare the behavior of aluminum nanodisks to that of similarly prepared and sized gold nanodisks.

10346-69, Session 17

Superresolution imaging of the local density of states in plasmon lattices

Ke Guo, FOM Institute for Atomic and Molecular Physics (Netherlands); Marc A. Verschuuren, Philips Research (Netherlands); Femius Koenderink, FOM Institute for Atomic and Molecular Physics (Netherlands)

Periodic plasmonic nanostructures have been found promising in controlling photoluminescence directivity and efficiency for a wide variety of applications. Because of the inhomogeneous spatial distribution of the photonic resonances of periodic plasmonic nanostructures, their influence on emission is strongly dependent on the position of emitters relative to the nanostructures. Therefore, mapping the local dependence of directivity, efficiency, and emission rate enhancements is key to understanding and optimizing the devices. We introduce a method of mapping the local enhancement of spontaneous emission rates of emitters coupled to periodic nanostructures based on stochastic superresolution imaging. As an example, we show superresolved measurements of the local density of states (LDOS) at 605 nm induced by a hexagonal lattice of aluminum nanoantennas with a spatial resolution of 40 nm. Comparison with electrodynamic simulations indicates that the variation of the decay rate of the emitters in the investigated sample is hardly influenced by the lattice modes and mainly governed by single-particle LDOS variations and nearest-neighbor interactions.

10346-70, Session 17

Necklace beams in engineered nonlinear media *(Invited Paper)*

Natalia M. Litchinitser, Jingbo Sun, Salih Z. Silahli, Wiktor T. Walasik, Univ. at Buffalo (United States); Eric G. Johnson, Clemson Univ. (United States)

Colloidal suspensions offer as a promising platform for engineering polarizibilities and realization of large and tunable nonlinearities. Previous studies of Gaussian beams propagation in various colloidal suspensions predicted in a number of remarkable optical phenomena and applications, including initiation and regulation of chemical reactions, sorting different species of nanoparticles and imaging through highly scattering media. As compared to the conventionally used Gaussian beams, optical vortices that are characterized by the doughnut-shaped intensity profile and a helical phase front offer even more degrees of freedom for, in particular, optical trapping or imaging applications. In our earlier work, we predicted, using the linear stability analysis and numerical simulations, that the perturbations with an orbital angular momentum of a particular charge will be amplified and lead to the formation of a necklace beam with a particular number of peaks, or "beads." Here, we performed detailed experimental studies of such necklace beam formation that show an excellent agreement with the analytical and numerical predictions. This work might bring about new possibilities for dynamic optical manipulation and transmission of light through scattering media as well as formation of complex optical patters in colloids.

10346-71, Session 17

Plasmonic toroidal excitation with engineering metamaterials *(Invited Paper)*

Pin Chieh Wu, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Hui-Hsin Hsiao, Chun Yen Liao, Tsung Lin Chung, Pei Ru Wu, National Taiwan Univ. (Taiwan); Vassili Savinov, Nikolay I. Zheludev, Univ. of Southampton (United Kingdom); Din Ping Tsai, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan)

Natural toroidal molecules, such as biomolecules and proteins, possess toroidal dipole moments that are hard to be detected, which leads to extensive studies of artificial toroidal materials. Recently, toroidal metamaterials have been widely investigated to enhance toroidal dipole moments while the other multipoles are eliminated due to the spacial symmetry. However, to effectively excite a toroidal dipole, a specific excitation method is necessary since a closed-loop of induced magnetic dipoles in a toroidal metamaterial weakly interact with the external wave. Moreover, most of generated toroidal dipole moments are either aligned vertically to the substrate surface or embedded in a dielectric, which is another constraint for further applications.

In this talk, we will show several cases on the plasmonic toroidal excitation by engineering the near-field coupling between metamaterials. The gain-assistant toroidal resonance is subsequently studied for realizing toroidal lasing spaser. In addition, a novel design for a toroidal metamaterial with multi-layered structures is also studied. Because the induced toroidal dipole moment is oscillating at the interface between metallic structure and free space, this design overcomes the challenge in detecting the scattering of the induced toroidal dipole and provides a possibility of coupling with other dipolar moments. Besides, the non-radiating anapole mode results from the destructive interference between toroidal and electric dipoles are realized through such proposed toroidal metamaterials. To our best knowledge, this is the first proof-of-concept demonstration of anapole mode though coupled plasmonic metamaterials which offers a promising way for the investigation of optical properties with complicated electromagnetic fields.

10346-72, Session 18

Catching light in-flight: reshaping nanosecond laser pulses using active metasurfaces *(Invited Paper)*

Gennady B. Shvets, Cornell Univ. (United States)

One of their most appealing features of graphene-integrated metasurfaces is their ability to change their optical properties on a nanosecond time scale. I will describe our experiments showing temporal reshaping of an optical pulse through its interaction with a metasurface evolving on the time scale of the pulse itself.

10346-73, Session 18

A three-dimensional negative index medium and a miniature surface plasmon polariton amplitude modulator *(Invited Paper)*

Ta-Jen Yen, National Tsing Hua Univ. (Taiwan); Chu-En Lin, National Chin-Yi Univ. of Technology (Taiwan); Chih-Jen Yu, Chang Gung Univ. (Taiwan); Tsung-Yu Huang, Ting-Tso Yeh, Cheng-Wei Chang, National Tsing Hua Univ. (Taiwan)

In this talk, I introduce two plasmonic devices. Firstly, we design and construct a three-dimensional (3D) negative index medium (NIM) composed of gold hemispherical shells to supplant an integration of a split-ring resonator and a discrete plasmonic wire for both negative permeability and permittivity at THz gap. With the proposed highly symmetric gold hemispherical shells, the negative index is preserved at multiple incident angles ranging from 0° to 85° for both TE and TM waves, which is further evidenced by negative phase flows in animated field distributions and outweighs conventional fishnet structures with operating frequency shifts when varying incident angles. Finally, the fabrication of the gold hemispherical shells is facilitated via standard UV lithographic and isotropic wet etching processes and characterized by -FTIR. The measurement results agree the simulated ones very well. Secondly, we present a miniature surface plasmon polariton amplitude modulator (SPPAM) by directing and interfering surface plasmon polaritons on a nanofabricated chip. Our results show that this SPPAM enables two kinds of modulations. The first kind of modulation is controlled by encoding angular-frequency difference from a Zeeman laser, with a beat frequency of 1.66 MHz; the second of modulation is validated by periodically varying the polarization states from a polarization generator, with rotation frequencies of 0.5-10k Hz. In addition, the normalized extinction ratio of our plasmonic structure reaches 100. Such miniaturized beat-frequency and polarization-controlled amplitude modulators open an avenue for the exploration of ultrasensitive nanosensors, nanocircuits, and other integrated nanophotonic devices.

10346-74, Session 18

Giant nonlinearity arising from the vertical split ring resonators *(Invited Paper)*

Hui-Hsin Hsiao, Hui Jun Wu, Research Ctr. for Applied Sciences - Academia Sinica (Taiwan); Tsung Lin Chung, Wei-Yi Tsai, Ren Jie Lin, Wei Hou Lee, National Taiwan Univ. (Taiwan); Din Ping Tsai, National Taiwan Univ. (Taiwan) and Research Ctr. for Applied Sciences - Academia Sinica (Taiwan)

Increasing the nonlinear optical response at nanometer length scale is a very important issue due to the wide applications in various disciplines such as information science, bio-medicine and quantum computation technology. Second harmonic generation (SHG) arising from the metal nanostructures has provide a very powerful tool in studying the surface and interface properties of these materials. The SHG from various kinds of asymmetric geometric configurations such as V and L shape structures, imperfect nano-spheres, metal/insulator/metal multilayer structures, and planar split ring resonators have been proposed. However, all the previous studies in plasmonic nonlinear optical behavior rely on the enhancement of the electric field and seldom considered the magnetic field effect.

In this work, we present a vertical split ring resonator (SRR) based metamaterial to generate SHG. By adopting such a novel structure, both the electric and magnetic field will be significantly enhanced due to the localized surface plasmon resonance, hence the generation of the second-harmonic and its re-emission into the far field are dramatically increased several orders comparing with that of the planar SRR. We simulated and fabricated the reflective type vertical SRR, and optimized the aspect ratio to maximize the SHG signal. We further systematically studied the nonlinear optical response in the vertical SRR dimers and trimers and found that the gap distance between two SRRs plays a very important role in the SHG intensity. This work paves a new way in increasing the nonlinear transition quantum efficiency and provides a new insight in designing new nonlinear sources.

10346-75, Session 18

Periodic metal nanoparticle arrays for large-area enhanced light-trapping

Yassine Ait-El-Aoud, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States) and Univ. of Massachusetts Lowell (United States); Alkim Akyurtlu, Univ. of Massachusetts Lowell (United States); Richard M. Osgood III, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States)

Due to the unique properties of the electromagnetic interactions of light with metal nanoparticles, these particles can exhibit large optical field enhancements, resulting in large enhancements in the absorption or scattering of the incoming light. Thin film solar cells based can greatly benefit from this phenomenon. In this work, we have examined the effect of incorporating large-scale periodic arrays of these nanoparticles, fabricated using advanced patterning techniques that can be scaled up to large areas,onto an hydrogenated amorphous silicon thin film to determine their effect on light scattering. Samples were fabricated using the popular self assembly process method: dip coating, combined with nanosphere lithography, polystyrene spheres with 500 nm, 400 nm, and 200 nm diameter. The optical measurements, including the forward and backward scattering, were collected using the 150 mm integrating sphere UV-Vis-NIR spectrophotometer.

Conference 10347: Optical Trapping and Optical Micromanipulation XIV

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Sunday - Thursday 6 –10 August 2017

Part of Proceedings of SPIE Vol. 10347 Optical Trapping and Optical Micromanipulation XIV

10347-1, Session 1

Machined multicore optical fibers for on-chip optical manipulation

Georgia Anastasiadi, Mark Leonard, Lynn Paterson, William N. MacPherson, Heriot-Watt Univ. (United Kingdom)

Optical Tweezing is a powerful technique enabling a variety of single cell experiments. However, tweezing experiments tend to be based on a high numerical aperture microscope objective to simultaneously deliver the tweezing light and image the sample, introducing restrictions in terms of system flexibility.The development of a single optical fibre-based probe, capable of manipulating microparticles under a variety of microscope objective lens, has been demonstrated. The working principle of the probe is based upon two crossed beams to create an intensity profile that can trap particles in the intersection. Forming these beams requires the light to exit the fibre at an angle to the fibre axis. To realize this, a cleaved multicore fibre is modified using Focused Ion Beam machining (FIB) to form the angled mirrors in two cores, such that the light coming out these cores is deflected and crosses at a point close to the fibre end. The effectiveness of this approach has been tested by trapping yeast cells of 5-10?m diameter for three different repeats of the design.

By using a multicore fibre instead of separate fibres glued together, results in simplified probe, suitable for use in a wider range of applications, including on-chip manipulation. The beam intensity profile of the probe has been simulated to predict the trapping area in the sample medium and compared with experimental results. Three dimensional manipulation of cells has been achieved and the trapping force has been estimated.

10347-2, Session 1

Revealing the micromechanics driving cellular division: optical manipulation of force bearing substructure in mitotic cells

Matthew D. Ono, Daryl Preece, Michelle L. Duquette, Univ. of California, San Diego (United States); Michael W. Berns, Univ. of California, San Diego (United States) and Beckman Laser Institute and Medical Clinic (United States)

Proper cellular division underlies the natural development and repair processes in living tissues. In the anaphase stage of division, a motility force separates genetic material in the form of chromosomes; failure to separate chromosomes can result in tumor development and birth defects. Current estimates of this motility force based on viscous drag do not reflect forces from direct measurements. As such a more complete understanding of cellular substructure is needed to reconcile measurement with theory. During anaphase, chromosomes can be understood as elastic bodies whose deformations reflect physical forces and strains. Anaphase chromosome elongation has widely been attributed to viscous drag. However, LaFountain et. al found a physical element connecting sister chromosome ends in crane-fly spermatocytes such that a tethering force elongates chromosomes. Laser microsurgery was used to deduce the mechanistic basis for chromosome elongation in mammalian PtK2 cells. In half of tested chromosomes, laser microsurgery directed between separating chromosome ends reduced elongation by ~7.5%, suggesting a source of chromosome strain independent of viscous drag. When laser microsurgery was used to cut chromosomes in transport, the kinetochore attached fragments continued normal poleward travel while half of end fragments travelled to the opposite pole and the remaining fragments either stagnated or segregated normally. For fragments traveling towards the opposite pole, laser microsurgery directed between chromosome ends always ceased cross-polar travel suggesting the laser severed a physical linkage responsible for transmitting force to the fragment. Optical trapping of cross-polar moving fragments places an upper bound on the tethering force of ~1.5 pN.

10347-3, Session 1

Assessment of influence of nano-particles on the red blood cell aggregation *(Invited Paper)*

Alexey P. Popov, Tatiana I. Avsievich, Alexander Bykov, Igor Meglinski, Univ. of Oulu (Finland)

The red blood cell (RBC) aggregation is an intrinsic property of blood, which influencing significantly the blood microcirculation with a great potential in clinical applications. The ultimate understanding of the fundamental mechanism of the cells adhesion is essential for further proper applications. Presently there are two hypotheses of the 'cross-bridges' and 'depletion layer' to describe the cells interaction while either is still to be experimentally proven. Current study is aiming to obtain the experimental evidence toward the cells interaction mechanism. Optical tweezers were used to measure the RBC adhesion forces and energies. The cells interaction was examined in different solutions, including plasma, serum and model solutions with dextran or proteins, and nano-particles. The experimental result shows that the cells adhesion forces get stronger as they are separated in all solutions except dextran. The adhesion energy is found to be increasing few times, while in dextran the adhesion force decreases as the cells are separated and corresponding adhesion energy is constant. The obtained results are clarifying the mechanism of the RBC adhesion, confirming the 'cross-bridge' migration model to describe properly the cells interaction.

10347-4, Session 1

Manipulating mutant bacterial cells by tug-of-war multi-trap tweezers

Josh Lamstein, San Francisco State Univ. (United States); Anna S. Bezryadina, Univ. of California, San Diego (United States) and San Francisco State Univ. (United States); Daryl Preece, Univ. of California, San Diego (United States); Joseph C. Chen, San Francisco State Univ. (United States); Zhigang Chen, San Francisco State Univ. (United States) and Nankai Univ. (China)

We design and demonstrate multi-trap tug-of-war (TOW) optical tweezers with object-adapted optical potentials for trapping and manipulating asymmetric particles and biological samples such as mutant bacterial cells. While dual TOW tweezers can effectively trap rod-shaped objects and even stretch them laterally, triangular TOW tweezers enable in-plane trapping of larger asymmetric objects which do not necessarily have mirror symmetry. When trapping with the dual TOW tweezers, we previously demonstrated that they are more stable than Gaussian beam-based dual traps, and the strong lateral pulling forces from the TOW optical tweezers can stretch and even break apart cellular clusters. Here we show multi-trap TOW (with 3 and 4 arms) optical tweezers can be employed to control and manipulate mutant Sinorhizobium meliloti bacterial cells, which are typically multi-pronged. We discuss the advantage of such TOW beam-based optical tweezers over traditional Gaussian beam-based holographic tweezers, and the potential applications of these TOW tweezers in studying cellular viscoelasticity, biomechanics, motility, and intercellular interactions.

10347-5, Session 1

Optical measurements of cell adhesion *(Invited Paper)*

Josef A. Käs, Steffen Grosser, Univ. Leipzig (Germany)

We demonstrate that the optical stretcher, a fully automated dual-beam laser trap for probing single-cell mechanics, can also be used to trap pairs of cells and manipulate them. More specifically, we can press cells against each other and tear them apart again, enabling us to measure cell adhesion/ dissociation dynamics.

We show that we can see differences in adhesion behaviour between cell lines and we see single-molecule dissociation processes. We calculate the forces which we exert on the cells, which are in the pN range.

This "optical micromanipulator" provides high-throughput adhesion measurements with about 50 cell pairs per hour, while allowing for full optical inspection of the cell dissociation process. The method can be combined with other characterization methods readily available in the stretcher such as fluorescence imaging and cell rheology evaluation.

10347-6, Session 1

Hydrodynamic stretching for analysing urological cancer cells

Yuri Belotti, Tianjun Huang, Stephen J. McKenna, Ghulam Nabi, David McGloin, Univ. of Dundee (United Kingdom)

Prostate cancer (PCa) is one of the most common types of cancer in the world, with especially high rates of incidence in the United States and Western Europe. The current diagnostic gold standards are controversial can lead to issues in diagnosis. Blood tests are commonly used to check the level of the prostate specific antigen (PSA), when in fact this antigen is organ-specific but not cancer-specific with the outcome that many unnecessary procedures with significant side effects are carried out. We therefore need new methods to improve clinical diagnostics in this area.

Here we outline how one might be able to distinguish between different cellular phenotypes using a label-free measurement technique based on the mechanical stiffness of a cell. Our technique makes use of microfluidic devices which can act as hydrodynamic stretchers, squashing cells in a very high-throughput manner. Here we demonstrate that we can correctly classify two different prostate cell lines, DU145 (cancerous) and PNT2 (healthy) with a high degree of confidence. Our system involves a very high speed camera (~300,000 frames per second) and bespoke image processing to classify cell roundness coupled with machine learning to classify the cells. We will contrast the current system with attempt to extract the same data using optical stretching techniques, and outline developments of the technique to extract dynamic deformation in a time-resolved manner.

10347-7, Session 2A

Coherent control of light transmission and focusing in strong scattering medium *(Invited Paper)*

Hui Cao, Yale Univ. (United States)

Strongly scattering media usually look opaque, even though the material has little absorption. Due to the diffusion of light, the average transmission varies as one over the thickness of the medium. It poses a severe limitation for biomedical imaging and telecommunication. We experimentally demonstrate that the total transmission through a multiple-scattering sample can be varied by one order of magnitude by shaping the incident wavefront of a monochromatic laser beam. Our theoretical analysis reveals that the mesoscopic correlations are essential to significantly modify the total transmission.

In recent years wavefront shaping has been widely used to focus light to wavelength-scale regions (speckles) inside or behind a turbid medium. Increasing the size of focal spot to contain many speckle grains is of great interest for several applications. We show with optical wavefront-shaping experiments that long-range correlations substantially increase the dynamic range of control over light transmitted onto larger target regions, when the number of targeted speckles inside the focal area exceeds the dimensionless conductance.

Finally, we study the optimal diffusive transmission of broadband or polychromatic light in a disordered medium. A single input wavefront can exhibit strongly enhanced total transmission across a bandwidth that is orders of magnitude broader than the spectral correlation width of the medium. This is attributed to the long-range spectral correlations in coherent diffusion.

10347-9, Session 2A

Gaussian vs. Bessel light-sheets: performance analysis in live large sample imaging *(Invited Paper)*

Michael P. MacDonald, Sascha L. Reidt, Ricardo B. C. Correia, Cornelis J. Weijer, Univ. of Dundee (United Kingdom)

Light-sheet microscopy was selected as the Nature Method of the Year 2014 and has become a fundamental imaging technique in modern biology. Conventional Gaussian light-sheets are inherently limited by the trade-off between the beam waist and its depth of field, resulting in a non-uniform excitation across the field of view. Lately, Bessel and Airy lightsheets have been proposed because of their larger depth of field and their stability towards on-axis obstructions.

Recent studies describe the advantages of using Bessel beams and report an improved image quality, for example when imaging Arabidopsis root or when imaging cellular dynamics. Lightsheet microscopy is particularly suited to imaging the in toto development of live large samples, and Bessel beams have been applied for imaging organs of transgenic zebrafish. However, for the study of large scale and coordinated cell movements in embryonic development a quantitative analysis of its performance is still missing.

In our paper, we describe a novel application to Bessel beam light-sheet microscopy on large, living and highly scattering chick embryos and its potential use in answering important biological questions regarding coordinated cell movements, cell ingression and cell shape changes. We show that whilst using Bessel illumination can be of significant help when imaging thicker samples due to the increased depth of field, there is little or no benefit for overcoming light scattering during gastrulation in chick embryos.

10347-10, Session 2A

3D microscopy with scattering media *(Invited Paper)*

Laura Waller, Univ. of California, Berkeley (United States)

This talk will describe new methods for computational 3D microscopy with coded illumination and detection systems that use simple hardware modifications combined with efficient computational algorithms.

10347-11, Session 2A

Sculptured light for control and measurement on microscales *(Invited Paper)*

Alexander B. Stilgoe, Anatolii V. Kashchuk, Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Dynamic manipulation (using beam shaping) of light is an important tool with wide ranging applications in image analysis and optical micro-manipulation. We use dynamic manipulation of incident and scattered light to determine the properties of both resting/naturally moving and optically trapped particles. The application of specialized beam modes and careful analysis of scattered light can extract particular information from the system to determine the fundamental properties of objects under investigation. With appropriate choice of detector, improved sensitivity and bandwidth is also possible. We will overview measurements of position, force and angular momentum transfer and current research developments.

Dynamic manipulation (beam shaping) of light is an important tool with wide ranging applications in image analysis and particle manipulation. The use of dynamic manipulation of light enables very extensive determination of the properties of optically trapped particles. The archetypal measurement of a trapped particle is to detect aggregate properties of the light that it scatters, such as the change in average scattering direction to measure optical forces. Total angular momentum transfer could also be measured as an aggregate property of the scattered light. We investigate the performance changes in measurements of the properties of objects using optical mode shaping and the filtering of sculptured light fields. We demonstrate that position measurement performance can be significantly increased when specific modes are optimized. Through the appropriate choice of filter and detector, measurements can be performed with both high-bandwidth and sensitivity. We demonstrate measurements using both liquid crystal spatial light modulators and digital micromirror devices and discuss a specific behavior in each experiment and their performance. We further discuss challenges that occur in development of these techniques as well as their use when applied in specific experiments and more broadly outline possible uses of the methods in practical applications. This presentation will give an overview of both past successes in measurement of position, force and angular momentum transfer as well as current research developments.

10347-12, Session 2B

High fidelity beam shaping for optical neuroscience

Wolfgang Losert, Mitchell Weikert, Samira Aghayee, Univ. of Maryland, College Park (United States)

Optical neuroscience has surged in recent years. Advances in fast fluorescent calcium indicators and optically addressable ion channel now allow for two-photon imaging and perturbations of neuronal activity. Since most meaningful neuronal activity involves firing of multiple neurons, beam shaping with Phase-only Spatial Light Modulators (SLM) is emerging as a powerful approach for photo-stimulation of selective neurons in the brain. The ability to form any desired illumination pattern and to modify the wavefront at high speeds is essential to trigger neuronal activity in meaningful ways. Since the wavefront is aimed at modulating brain activity, it is important to minimize imperfections in beam shaping, in particular speckles and non-uniformities in intensity. Here we present an optical arrangement that allows for the removal of the unmodulated light from the path at the Fourier plane. The proposed configuration is effective enough to eliminate the need for removing the unmodulated light in two-photon applications. We find that this modified beam path not only removes speckles, but also increases the uniformity of peak intensities.

10347-13, Session 2B

Probing mechanobiology with laser-induced shockwaves

Christopher Carmona, Daryl Preece, Veronica Gomez-Godinez, Linda Z. Shi, Michael W. Berns, Univ. of California, San Diego (United States)

Traumatic Brain Injury (TBI) occurs when an external force injures the brain. According to the Center of Disease Control and Prevention, TBI is a contributing factor to a third of all injury-related deaths in the United States. Those that survive TBI can face temporary or permanent effects that significantly impact thinking or memory, movement, sensation, or emotional functioning. While clinical outcomes of TBI can vary widely in severity, few mechanisms of neurodegeneration following TBI have been identified for treatment. We propose a model for studying TBI using laser-induced shockwaves (LISs). To further our understanding on the way that cells respond to shear stress, an optical system was developed that allows single cells to be studied in response to a sudden but short application of shear stress. This system can generate LISs at a specified time and location. The LIS exerts a shear stress between 0 - 50 kPa depending on the distance from the shockwave epicenter. Our system utilizes an optically-coupled force measurement component that allows for the visualization of shockwave dynamics. Here, the force measurement system is characterized by imaging stages of the approximately 40 ns period of violent expansion and collapse of microbubbles responsible for shockwave generation. Ultimately, this system's capacity to quantitatively study shockwave dynamics permits the study of the spatiotemporal details occurring in cells in response to shear stress. Thus, TBI can be further studied and subsequent results could reveal the molecular basis for neurodegeneration and potential therapeutic avenues for treatment.

10347-14, Session 2B

Printing hydrogel based living neural networks

Anna M. Linnenberger, Meadowlark Optics, Inc. (United States)

We investigate holographic optical tweezing combined with step-and-repeat projection micro-stereolithography for fine control of live cell positioning within a three-dimensional (3D) hydrogel microstructure. Samples are fabricated using NT2 cells, which have been pre-differentiated into NT2-N human neurons. A twisted nematic 256x256 pixel SLM is used to pattern the supporting hydrogel structures. Neurons are shown to grow along printed hydrogel channels, demonstrating that the structure can be used to pre-determine the path of cellular growth. Sample viability is assessed for a variety of hydrogel geometries. This work demonstrates biocompatibility of the printing method. The samples fabricated with this system are a useful model for future studies of neural circuit formation, neurological disease, cellular communication, plasticity, and repair mechanisms.

10347-15, Session 3A

Nanohole optical tweezers in hetergeneous mixture analysis

Reuven Gordon, Gurunatha K. Laxminarayana, Noa Hacohen, Timothy S. DeWolf, Univ. of Victoria (Canada)

Since 2012, we have been studying the use of double nanohole optical tweezers in the trapping of proteins and other nanoparticles. This talk will overview recent developments in using the platform to analyze heterogeneous samples, such as egg-white. We will also describe recent advances in the setup, including thermal control which has allowed for probing transitions in the dynamics of proteins. I will also overview our work on the analysis of acoustic Raman modes of proteins and quantitative comparison with elastic network models.

10347-16, Session 3A

Optical trapping and Raman spectroscopy of single nanostructures using standing-wave Raman tweezers

Mu-ying Wu, Lin He, Gui-hua Chen, Guang Yang, Dongguan Univ. of Technology (China); Yong-Qing Li, East Carolina Univ. (United States) and Dongguan Univ. of Technology (China)

Optical trapping integrated with spectroscopic techniques is attractive for manipulation and characterization of nanoscale structures, and opens up new possibilities for assembly and control of nanodevices and biomolecules. Optical tweezers integrated with Raman spectroscopy allows analyzing a single trapped micro-particle, but is generally less effective for individual nano-sized objects in the 10-100 nm range. The main challenge is the weak gradient force on nanoparticles that is insufficient to overcome the destabilizing effect of scattering force and Brownian motion. Here, we present standing-wave Raman tweezers for stable trapping and sensitive characterization of single isolated nanostructures with a low laser power by combining a standing-wave optical trap (SWOT) with confocal Raman spectroscopy. SWOT is formed by the interference of a tightly focused Gaussian beam with the reflected beam by a dichroic mirror. This scheme has stronger intensity gradients and balanced scattering forces, and thus is more stable and sensitive in measuring nanoparticles in liquid with 4-8 fold increase in the Raman signals. It can be used to analyze many nanoparticles that cannot be measured with single-beam Raman tweezers, including individual single-walled carbon nanotubes (SWCNT), graphene flakes, biological particles, polystyrene beads (100 nm), SERS-active metal nanoparticles, and high-refractive semiconductor nanoparticles with a low laser power of a few mW. This would enable sorting and characterization of specific SWCNTs and other nanoparticles based on their increased Raman fingerprints.

10347-17, Session 3A

Interfacial resistances and other thermal effects in plasmonic optical tweezers and their implications for nano-biomolecule manipulation

Steven Jones, Pawel Karpinski, Daniel Andrén, Mikael Käll, Chalmers Univ. of Technology (Sweden)

An emerging technique for the optical manipulation of nanoparticles is the method of plasmonic optical tweezers. This technique is particularly interesting for its potential applications in the study of small biomolecules such as proteins or DNA. Plasmonic optical tweezers utilize the plasmonic resonance of noble metal nanostructures to confine electric fields to deeply subwavelength length scales. Because of this extreme field confinement, the optical gradient forces generated are strong enough to stably trap sub 100 nm dielectric nanoparticles.

It is well known that these plasmonic structures also exhibit significant heat generation due to Ohmic resistance of the oscillating electrons. This heat generation is detrimental when attempting to study optically trapped bio-molecules, which are extremely sensitive to their thermal environment. Because of this conflict between the optical forces generated by plasmonic structures and the associated temperature increase, a detailed understanding of nanoscale thermal transport phenomena is crucial to designing plasmonic optical trapping systems for applications in bionanophotonics. In this work we utilize Raman scattering to directly observe the temperature of the plasmonic antennae; as well as Brownian motion analysis, and temperature dependent fluorescent techniques to determine the temperature of the surrounding environment and the nanoparticle itself. Interesting thermodynamic phenomena are investigated, such as the Kapitza resistance, which can cause discrete temperature discontinuities at the boundary between dissimilar materials. Combined with finite element method simulations this work provides a clearer understanding of the thermal environment experienced by optically trapped nanoparticles, and outlines strategies that can be employed to mitigate temperature increases allowing for these systems to be effectively utilized in the study of delicate bionanoparticles.

10347-18, Session 3A

Probing of biomolecular films with colloidal nanomotors

Hana Sipova, Lei Shao, Nils Odebo Länk, Mikael Käll, Chalmers Univ. of Technology (Sweden)

Advanced design of nanomaterials requires a large amount of control over the properties of nanoscale components, including nanostructured substrates as well as biomolecular components. While properties of solid-state nanostructures can be assessed with numerous imaging methods available, probing biomolecular ensembles is much more difficult to perform because of their small dimensions and high sensitivity to environmental changes. There is, therefore, a great need for nanoscopic probes to biomolecular layers in their native, aqueous environment.

Here we demonstrate an ultra-sensitive method for probing of thin biomolecular films with rotary nanomotors. Single-crystal gold nanorods are trapped in 2D against a glass surface in a laser focus and rotated extremely fast in aqueous solutions through optical torques dominated by plasmonic resonant scattering of circularly polarized light. The rotational dynamics of the nanorods is found to be highly dependent on the properties of adsorbed biomolecular layers, such as the length or conformation of adsorbed molecules. Moreover the localized heating in the vicinity of the nanomotors generated by light absorption is employed in manipulating temperature at the nanoscale and monitoring of the temperature-induced transitions of molecular films. By tracking of rotational dynamics of the nanorods in real time we can observe kinetics of biomolecular interactions and temperature-induced molecular transitions.

We believe, that the method developed based on rotary nanomotors could meet a wide range of applications in nanobiotechnology, such as design of new functional materials, investigation of fast temperature-induced molecular transitions, as well investigation of nanoscale properties of biomolecular films and ultra-sensitive biomolecular detection.

10347-19, Session 3A

Electrostrictive in-situ nanoparticle detection with coherent Rayleigh-Brillouin scattering *(Invited Paper)*

Alexandros Gerakis, Princeton Plasma Physics Lab. (United States); Mikhail N. Shneider, Princeton Univ. (United States); Yevgeny Raitses, Brentley C. Stratton, Princeton Plasma Physics Lab. (United States)

We report on the development and application of coherent Rayleigh-Brillouin scattering for the in situ detection of large molecules and nanoparticles. This four wave mixing diagnostic technique relies on the creation of an electrostrictive optical lattice in a medium due to the interaction between polarized particles and the intense electric field gradient created by the optical interference of two intense pulsed laser beams. Though this interaction, we can detect the temperature, pressure, relative density, polarizability and speed of sound of a gas and gas mixture. This diagnostic was already successfully demonstrated in atomic and molecular gaseous environments, where the different gas polarizabilities and pressures were successfully measured. We are currently conducting in situ measurements with large molecules and nanoparticles produced in an arc discharge, the results of which will be presented in this meeting.

10347-20, Session 3B

Reflective inverse diffusion method for dynamic compensation of small optical system perturbations

Kenneth W. Burgi, Michael Marciniak, Air Force Institute of Technology (United States)

Reflective inverse diffusion uses phase front modulation to refocus light after reflective scattering. A spatial light modulator (SLM) is used to shape the wave front of a HeNe laser at 632.8-nm wavelength to produce a converging phase front after reflection. The reflection matrix (RM), measured from rough-surface reflectors, contains the phase information of the light from each SLM segment to every segment in the observation plane. This phase information can be used to produce phase maps that can refocus light to any segment in the observation plane. Phase maps created from

an RM refocused light to a single segment in the observation plane with demonstrated enhancements up to 25 times over the background speckle. The measurement of an RM requires the optical system to be completely static. Small perturbations in the laboratory setup cause significant decreases in enhancement performance. We present a method for reflective inverse diffusion that improved enhancement performance by dynamically compensating for small perturbations in the optical system. A continuously optimized phase map is used to update a diffraction-based propagation model. This model then determines the proper phase map to produce a single focused spot or multiple foci at any location in the observation plane.

10347-21, Session 3B

Beam shaping by the transport-of-intensity equation

Soheil Mehrabkhani, Thomas Schneider, Technische Univ. Braunschweig (Germany)

In this paper, a novel unified approach for beam shaping based on a phase retrieval technique by the use of the transport-of- intensity equation is presented. In principle, an arbitrary target profile can be generated by an appropriate phase modification of the input profile. The necessary phase information can be calculated by the transport-of-intensity equation. The axial intensity derivative of the equation is a fundamental requirement for its solvability. Although it can be easily calculated for the near distance between input and target planes, the determination of the intensity derivative for a far distance still has been reminded an open problem. For a solution of this obstacle, an intensity distribution in an auxiliary plane at an infinitesimal distance from the input plane has been used. The new intensity distribution is obtained from the given intensity information in two planes and consequently, the desired intensity derivative can be calculated by the difference of the intensity values in the first and auxiliary plane. Finally, from the transport-of-intensity equation, the phase information might be achieved. Thus, the target profile can be reconstructed by the phase and intensity values in the input plane. To verify the validity of this approach, the reconstructed and original target profiles are compared based on the correlation method. For a practical implementation, a phase shaper can be used to generate the required phase distribution in the input plane.

10347-22, Session 3B

Optimal trapping beam for spherical micro-particles

Michael Mazilu, Univ. of St. Andrews (United Kingdom)

Scattering is one of the simplest light mater interactions possible. For spherical particles, this process can be described using the Lorenz-Mie theory, which makes use of vector spherical harmonic solutions of Maxwell's equations to represent the fields involved. Using these solutions it is possible to describe the light field scattered from microscopic spherical particles and thus represent the field around a scattering object as a function of the incident fields. These solutions also allow us to determine the optical momentum transfer to the scattering object. This can be calculated using Maxwell stress tensor. Here, we use this approach to calculate the quadratic relationship between the incident field and the optical forces acting on the scattering objects. This relationship defines also a set of orthogonal optical eigenmodes, which delivers a natural basis to describe momentum transfer in light-matter interactions. Using this natural description of the momentum transfer it is possible to define, for each numerical aperture, particle size or geometry the optimal trapping beam in 1, 2 or 3 dimensions. We present a study as a function of the particle parameter and conclude on the maximum achievable trapping stiffness enhancement factor as a function of these parameters.

10347-23, Session 3B

Multi-focus beam shaping of high power multimode lasers

Alexander V. Laskin, AdlOptica Optical Systems GmbH (Germany); Joerg Volpp, Bremer Institut für angewandte Strahltechnik GmbH (Germany); Vadim V. Laskin, AdlOptica Optical Systems GmbH (Germany); Aleksei B. Ostrun, ITMO Univ. (Russian Federation)

Beam shaping of powerful multimode fiber lasers, fiber coupled solid-state and diode lasers is of great importance for improvements of industrial laser applications. Welding, cladding with millimetre scale working spots benefit from "inverse-Gauss" intensity profiles; performance of thick metal sheet cutting, deep penetration welding can be enhanced when distributing the laser energy along the optical axis as more efficient usage of laser energy, higher edge quality and reduction of the heat affected zone can be achieved. Building of beam shaping optics for multimode lasers encounters physical limitations due to the low beam spatial coherence of multimode fiber coupled lasers resulting in big Beam Parameter Products (BPP) or M? values. The laser radiation emerging from a multimode fiber presents a mixture of wavefronts. The fiber end can be considered as a light source which optical properties are intermediate between a Lambertian source and a single mode laser beam. Imaging of the fiber end, using a collimator and a focusing objective, is a robust and widely used beam delivery approach. Beam shaping solutions are suggested in form of optics combining fiber end imaging and geometrical separation of focused spots either perpendicular to or along the optical axis. Thus, energy of high power lasers is distributed among multiple foci. In order to provide reliable operation with multi-kW lasers and avoid damages the optics are designed as refractive elements with smooth optical surfaces. The paper presents descriptions of multi-focus optics, intensity profile measurements of beam caustics and experimental results of welding technology improvement.

10347-24, Session 3B

Generation of arbitrary vector beams

Benjamin Perez-Garcia, Tecnológico de Monterrey (Mexico); Carlos López-Mariscal, Underwater Photonics (Mexico); Raul I. Hernandez-Aranda, Julio C. Gutiérrez-Vega, Tecnológico de Monterrey (Mexico)

Optical vector beams arise from point to point spatial variations of the electric component of an electromagnetic field over the transverse plane. In this work, we present a novel experimental technique to generate arbitrary vector beams, and provide sufficient evidence to validte their state of polarization. This technique takes advantage of the capability of a Spatial Light Modulator to simultaneously generate two components of an electromagnetic field by halving the screen of the device and subsequently recombining them in a Sagnac interferometer. Our experimental results show the versatility and robustness of this technique for the generation of vector beams.

10347-25, Session 4A

Single-cell and single-molecule biosensing with optical nanosensors *(Invited Paper)*

Qimin Quan, The Rowland Institute at Harvard (United States)

Fluorescence imaging provides a powerful approach to study fundamental life processes and has become an integral part of the toolbox for biologists. In this talk, I will present optical nanosensors as a new tool; and how we push it to the limit for the applications of translational medicine. Two examples will be given to represent two distinct architectures to solve medical problems at single molecule and single cell level, respectively. The

first example is a "lab-on-a-chip" device that can measure binding kinetics between two single molecules without fluorescent labeling. The second example is a "lab-on-a-tip" device that monitors protein expressions in single living cells over time. These nanosensor approaches, complementary to fluorescent imaging, will broaden our understanding of basic life processes at molecular level and will provide new ways for drug discovery and disease diagnostics.

10347-26, Session 4A

An ultra-fast EOD-based force-clamp detects rapid biomechanical transitions

Michael S. Woody, E. Michael Ostap, Yale E. Goldman, Pennsylvania Muscle Institute (United States)

We assembled an ultra-fast infrared optical trapping system to detect mechanical events that occur less than a millisecond after a ligand binds to its filamentous substrate, such as myosin undergoing its 5 – 10 nm working stroke after actin binding. The instrument is based on the concept of Capitanio et al. (Nat Meth 9, 1013–1019, 2012), in which a bead-actin-bead dumbbell is held in two force-clamped optical traps. An applied force from the traps causes the filament to move at a constant velocity as the force from hydrodynamic drag resists the applied load. When the ligand binds, the filament motion stops within 100 ?s as the applied force is transferred to the attachment. Subsequent translations signal active motions, such as the magnitude and timing of the motor's working stroke. In our instrument, the beads defining the dumbbell are held in independent force clamps utilizing a field-programmable gate array (FPGA) to update the beam positions at 250 kHz. We found that in our setup, the acousto-optical deflectors (AODs) steering the beams were unsuitable for this purpose due to a slightly non-linear response in the beam intensity and deflection angle, likely caused by low-amplitude standing acoustic waves in the deflectors. These aberrations caused instability in the force feedback loop leading to artefactual ~20 nm jumps in position. This type of AOD non-linearity has been reported to be absent in electro-optical deflectors (EODs) (Valentina et al. Opt Lett 33, 599–601, 2008). We demonstrate that EODs improve the performance of our instrument. Combining the superior beam-steering capability of the EODs, force acquisition via back-plane interferometry, and the dual high-speed FPGA-based feedback loops, we smoothly and precisely apply constant loads to study the dynamics of interactions between biological molecules such as actin and myosin.

10347-27, Session 4A

Jamming of a single DNA molecule during nanoscale 3D confinement with attractive self interactions

Douglas E. Smith, Nicholas A. Keller, Univ. of California, San Diego (United States)

We use optical tweezers to study viral DNA packaging, a model for studying the physics of charged polymers under tight 3D confinement. Single DNA molecules ~6600 nm in length are translocated into a ~50 nm-diameter phage phi29 capsid through a nanochannel by a molecular motor. Theories and simulations predicted that attractive DNA-self interactions mediated by +3 or +4 ions would facilitate faster packaging with less force resisting confinement. However our experiments found the opposite—packaging stalls at much lower densities than achieved in purely repulsive conditions. We present studies that suggest that packaging stalls because the DNA undergoes a nonequilibrium jamming transition of the type used describe colloidal and granular systems in soft-matter physics. An abrupt deceleration is observed before stalling, indicating that a transition in DNA conformation causes an abrupt increase in resistance. Experiments in which conditions are changed during packaging also show that the dynamics are history-dependent. Our findings suggest that the concept of a jamming transition can be applied to a single polymer molecule.

10347-28, Session 4A

Evanescent single-molecule biosensing with quantum limited precision

Nicolas P. Mauranyapin, Lars Madsen, Michael A. Taylor, Muhammad Waleed, Warwick P. Bowen, The Univ. of Queensland (Australia)

Evanescent optical biosensors that operate label-free and can resolve single molecules have applications ranging from clinical diagnostics, to environmental monitoring and the detection and manipulation of viruses, proteins and antibodies.

Here, we demonstrate an optical nanofibre-based approach to evanescent detection and tracking of unlabelled biomolecules that utilises a combination of heterodyne interferometry and dark field illumination. This greatly suppresses technical noise due to background scatter, vibrations and laser fluctuations that has limited previous experiments, allowing operation at the quantum noise limit to sensitivity introduced by the quantisation of light.

We apply our biosensor to the detection of single unlabelled biomolecules, an application that has not previously been demonstrated using a nanofibre sensor. We perform measurements on low concentration solution of BSA and anti-E.coli antibody. BSA, in particular, has a 3.5 nm radius, and is among the smallest biomolecules detected using plasmonic and cavity-enhanced techniques. By achieving quantum noise limited performance, we increase the information that is extracted per scattered photon and we achieve state-of-the-art sensitivity with optical intensities five orders of magnitude lower than has been possible previously. This opens the door to apply quantum correlated photons to enhance the precision of single molecule biosensors. Moreover, the reduction of intensity enables studies of molecules behaviour for an extended period of time and can lead to the understanding of biological phenomena at the single molecule level, such as cell membrane formation and molecular motor motion with high sensitivity, in real time.

10347-29, Session 4A

Trapping-assisted analysis of single particles using integrated nanopores *(Invited Paper)*

Holger Schmidt, Mahmud Rahman, Mark Harrington, Univ. of California, Santa Cruz (United States); Matthew A. Stott, Aaron R. Hawkins, Brigham Young Univ. (United States)

Nanopores are nanoscale openings in thin membranes that have shown the potential for advanced electrical detection of single molecules based on ionic current blockades resulting from individual particles translocating through the pore. This technology is a forerunner for next generation sequencing. However, nanopores can form the basis of more advanced integrated sensors that can respond to a multitude of different targets and can be integrated with other detection modalities. Recently, we have demonstrated the combined electro-optical detection of single viruses and single nucleic acids on optofluidic chips that incorporate solid-state nanopores [1-3]. Here, we discuss the addition of optical trapping to further increase the functionalities of these devices. Examples include the use of a loss-based dual beam trap [4,5] for increasing translocation rates, and the combination of feedback controlled particle gating into an optofluidic channel with a waveguide-based ABEL trap [6] for high-throughput single bioparticle analysis.

10347-30, Session 4A

Direct measurement of a nonequilibrium system entropy using a feedback trap *(Invited Paper)*

Momcilo Gavrilov, John Bechhoefer, Simon Fraser Univ. (Canada); Raphael Chetrite, Univ. de Nice Sophia Antipolis (France)

The entropy function for an equilibrium system has a Gibbs-Shannon form; however, there is a long, sometimes contentious debate as to whether the Gibbs-Shannon form applies to systems out of equilibrium. Here, we report the first direct measurement of the entropy function for a system out of equilibrium. In a feedback trap, we confine a silica bead immersed in water in a virtual double-well potential that models a two-state system capable of storing one bit of information. By measuring the average work to erase a controlled fraction of the information, we isolate directly the change in entropy in a nonequilibrium system and show its compatibility with the Gibbs-Shannon form.

10347-31, Session 4B

Programmable diffractive optic for multi-beam processing: applications and limitations

Patrick Gretzki, Arnold Gillner, Fraunhofer-Institut für Lasertechnik (Germany)

A wide range of materials can be processed with ultra-short laser pulses with minimal thermal stress. These processes are used for the specific ablation and surface structuring in many applications. Due to low productivity, a direct processing on an industrial scale is not economical, so these processes are limited to indirect procedures like the structuring of injections molds. The available average laser power for modern laser source can no longer be used efficiently, so new optical systems are needed. In this paper we will discuss the field of applications and limitations for multi-beam processing based on diffractive optics. Especially the utilization of spatial light modulators (SLMs) for dynamic beam shaping and division will be shown. The possibility for high quality beam splitting with a closed loop feedback system will be presented. For industrial applications the suitability of the system has been evaluated for high average laser powers and it could be confirmed, that the modulation properties of the SLM can be held constant with an adapted cooling system. In combination with a galvanometer scanner the optics can be used for applications like thin film structuring, drilling of sieves and filters. A detailed analysis of the bottleneck regarding processing speed for different applications shows, that with suitable laser sources the yield of current applications can be significantly increased.

10347-33, Session 4B

Vectorial field propagation through high NA objectives using polarized Gaussian beam decomposition

Norman Girma Worku, Herbert Gross, Friedrich-Schiller-Univ. Jena (Germany)

Scalar fields can be propagated through non-paraxial systems using the Gaussian beam decomposition method. However, for high NA objectives, this scalar treatment is not sufficient to correctly describe the electromagnetic fields inside the focal region due to high ray bendings, which result in a significant change in the polarization state of light. To model these vectorial effects, the Gaussian beam decomposition method has to be extended to include the polarization state of light. In this work we have combined it with three dimensional polarization ray tracing in order to propagate vectorial fields through high NA optical systems. During Gaussian beam decomposition, each individual beamlet has a polarization vector [Ex,Ey,Ez] associated with its central ray. Individual Gaussian beams are then propagated through the system using the complex ray tracing method. The effect of the optical system on the polarization state of each beam is computed by applying the three dimensional polarization ray tracing of the corresponding central rays. Finally the individual beams are superposed coherently in the plane of interest resulting in the complete vectorial field. We apply the proposed method to compute the vectorial field inside the focal region of a high NA microscope objective lens and compare our result to the Richards-Wolf integral method. We find that the Gaussian beam decomposition method overcomes serious limitations of algorithms relying on Fourier transforms, i.e. the field sampling requirements are less critical in high NA focusing and in the presence of large aberrations. However, sharp edges in the amplitude profile are difficult to handle as they should be replaced with smooth Gaussian edge.

10347-34, Session 4B

Fraunhofer and Fresnel diffraction pattern of a Mathieu-Gauss beam through rectangular aperture

Cristian Hernando Acevedo Cáceres, Yezid Torres Moreno, Univ. Industrial de Santander (Colombia); Angela M. Guzmán , CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

The Mathieu-Gauss beams are unique and exhibit remarkable behavior in a variety of 3D applications such as optical manipulation of matter. These beams are characterized by the ellipticity parameter q, and the integer m, which is termed the mode order or charge. In these beams the total orbital angular momentum l is distinct of the value of the parameter m, i.e. physically be stressed . In this work we analyze the diffraction pattern in the Fraunhofer and Fresnel regime of a Mathieu-Gauss beam through a rectangular aperture theoretically and experimentally. This work allow describe how the orbital angular momentum and the topological charge of a beam are different concepts but are equal them for field distributions with azimuthal symmetry.

10347-35, Session 4B

Arbitrary manipulation of micro-particles in three dimensions by steering of multiple orbital angular momentum modes

Ting Xie, Huihui Wang, Fei Yuan, Shengqian Chang, Peng Sun, Siman Zhang, Huaye Li, Zhenrong Zheng, Zhejiang Univ. (China)

Optical tweezers is an increasingly important technique for controlling

and probing particles since computer-generated holography (CGH) make steering of multiple traps individually possible. In addition, the dark focus of orbital angular momentum (OAM) beams is increasingly widely used in trapping reflecting, absorbing or low-dielectric-constant objects. In this paper, we present a method to create arbitrary three-dimensional configurations of orbital angular momentum modes to achieve manipulation of micro-particles. Compared with conventional optical tweezers, this method can steer mixed patterns of traps individually and randomly by producing three-dimensional structure of optical vortices. These optical traps we used was formed by a CGH generated complex phase mask, which has three components: 1) a helical phase mask to change the transverse phase structure, 2) a blazed grating phase mask to vary the propagation direction of the incident beams, and 3) a modulated grating phase mask to divert the focal plane from the planar configurations. The latter one ensure that we can form three-dimensional trapping patterns. The trap patterns can also be generated dynamically by holographic display system based on liquid crystal on silicon (LCoS). The experimental results show that the refresh frequency of reconfiguring achieves 24fps. Our method is effective and promise an exciting new opportunity to be used as a valuable non-contact manipulation tool in various applications.

10347-36, Session 4B

Propagation of transverse linear and orbital angular momenta of beam waves

Mikhail I. Charnotskii, Consultant (United States)

We show that for paraxial propagation of scalar waves classic electromagnetic theory definitions of transverse linear (TLM) and orbital angular (OAM) momenta of beam waves are simply related to the wave coherence function in the coherent wave case. This allows the extension of the TLM and OAM density concepts to the case of partially coherent waves when phase is indeterminate. We introduce a general class of Radial Irradiance-Angular Phase (RI-AP) waves that includes the Laguerre-Gaussian (LG) beams, and similar to LG beams has discrete OAM to power ratio, but have more complex phase shape than simple helices of LG beans. We show on several examples that there no direct connection between the intrinsic OAM and optical vorticity. Namely, neither the presence of the optical vortices is necessary for the intrinsic OAM, nor the presence of the optical vortices warrants the non-zero intrinsic OAM. We examine OAM for two classes of partially-coherent beam waves and show that the common, Schell-type coherence, does not add variety to the TLM and OAM in comparison to coherent waves. However, Twisted Gaussian beam has an intrinsic OAM with per unit power value that can be continuously changed by varying the twist parameters. This analysis suggests an intrinsic OAM creation method based on rotation of tilted Gaussian beam. Using the parabolic propagation equation for the coherence function, we show that both total TLM and OAM are conserved for the free space propagation, but not for propagation in inhomogeneous medium. In the presence of the random inhomogeneous medium the total TLM and OAM are conserved in average, but the OAM fluctuations grow with the propagation path. This growth appears to be slower for the beams with rotation-symmetric irradiance.

10347-37, Session 5

Angular momentum exchange between light and small particles

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

We present a few simple examples to illustrate certain fundamental properties of the EM field. Using elementary physical concepts, we explain the nature of interactions that involve exchanges of energy, linear momentum, and angular momentum between EM fields and material media. First, the radiation force experienced by a small, polarizable particle which has a predetermined dielectric susceptibility will be examined. The dielectric susceptibility of small spherical particles will be related to their refractive index (with proper accounting for the effects of radiation resistance). We describe the relation between the energy and orbital angular momentum of a cylindrical harmonic EM wave trapped inside a hollow cylindrical cavity, and explore the relations among the energy, linear momentum, and angular momentum picked up by a small particle under illumination by a cylindrical harmonic EM wave. In light of this analysis, it becomes clear why a small particle spins around its own axis when illuminated by a light beam that carries spin angular momentum, whereas the same particle tends to orbit around an axis of vorticity when exposed to a beam (such as a vector cylindrical harmonic) that possesses orbital angular momentum.

10347-38, Session 5

Hybrid entanglement for quantum communication and information applications

Isaac M. Nape, Bienvenu I. Ndagano, Univ. of the Witwatersrand (South Africa); Benjamin Perez-Garcia, Tecnológico de Monterrey (Mexico); Stirling Scholes, Melanie McLaren, Univ. of the Witwatersrand (South Africa); Raul I. Hernandez-Aranda, Tecnológico de Monterrey (Mexico); Filippus S. Roux, National Metrology Institute of South Africa (South Africa); Thomas Konrad, Univ. of KwaZulu-Natal (South Africa); Andrew Forbes, Univ. of the Witwatersrand (South Africa)

Combining the multiple degrees of freedom of photons has become topical in quantum communication and information processes. This provides advantages such as increasing the amount of information that is be packed into a photon or probing the wave-particle nature of light through path-polarisation entanglement. Here we present two experiments that show the advantages of using hybrid entanglement between orbital angular moment and polarisation. Firstly, we present results where high dimensional quantum key distribution with spatial modes that have non-separable polarisation-OAM DOF called vector modes. Secondly, we show that through OAM-polarisation entanglement, the traditional 'which-way' experiment can be performed without using the traditional physical path interference approach.

10347-39, Session 5

Dynamics of optically levitated microparticles in vacuum placed in 2D and 3D optical potentials possessing orbital angular momentum

Yoshihiko Arita, Michael Mazilu, Mingzhou Chen, Tom Vettenburg, Juan M. Auñón Garcia, Univ. of St. Andrews (United Kingdom); Ewan Wright, College of Optical Sciences, The Univ. of Arizona (United States); Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

We demonstrate the transfer of orbital angular momentum to optically levitated microparticles in vacuum. We prepare two-dimensional (2D) and three-dimensional (3D) optical potentials. In the 2D case the microparticle is placed within a Laguerre-Gaussian beam. We explore the particle dynamics as a function of the topological charge of the levitating beam. Our results reveal that there is a fundamental limit to the orbital angular momentum that may be transferred to a trapped particle, dependent upon the beam parameters and inertial forces present. Whilst a Laguerre-Gaussian beam scales in size with azimuthal index, recently we have created a "perfect" vortex beam whose radial intensity profile and radius are both independent of topological charge. As the Fourier transform of a perfect vortex yields a Bessel beam, imaging a perfect vortex, with its subsequent propagation thus realises a complex 3D optical field. In this scenario we load individual silica microparticles into this field and observe their trajectories. The optical gradient and scattering forces interplay with the inertial and gravitational forces acting on the trapped particle, including the rotational degrees of

freedom. As a result the trapped microparticle exhibits a complex 3D motion that includes a periodic orbital motion between the Bessel and the perfect vortex beam. We are able to determine the 3D optical potential in situ by tracking the particle. This first demonstration of trapping microparticles within a complex 3D optical potential in vacuum opens up new possibilities for fundamental studies in levitated optomechanics.

10347-40, Session 5

Highly birefringent, liquid-crystalline microspheres are tuneable rotational probes for optical tweezers

Avin Ramaiya, Basudev Roy, Erik Schäffer, Eberhard Karls Univ. Tübingen (Germany)

Birefringent particles serve as probes for rotation measurements using optical tweezers. However, current probes are often difficult to fabricate, have a limited size range, are unstable in aqueous solutions, or have a small birefringence. Here, we used spherical microspheres composed out of the liquid-crystal precursor RM257 that were solid at room temperature and stable in aqueous solutions. The microspheres were produced in wide range of different sizes by a standard precipitation protocol. For large microspheres, the liquid crystal was in the nematic state and had a very high birefringence. When trapped with circularly polarized optical tweezers, microspheres rotated. Interestingly, the rotation peak in the rotational power spectrum had a shape corresponding to a sum of Gaussian and a Lorentzian function. We attribute this shape to a combination of thermal fluctuations and inertial effects of entrained water. Furthermore, we measured the birefringence as a function of particle size and discovered a topological radial-bipolar phase transition at a diameter of about 500,nm. For microspheres with a diameter of 1.2,mum, we measured rotation rates exceeding 7,kHz in aqueous solutions using a laser power of 1.2,W in the laser focus. This high rotation rate corresponds to a Reynolds number of 0.08 implying that inertial effects start to be relevant for a microscopic system. Among others, the particles are useful to study the rotational motion of biological, molecular machines.

10347-41, Session 5

Elliptical orbits of microparticles driven by an evanescent field *(Invited Paper)*

Lulu Liu, Harvard School of Engineering and Applied Sciences (United States); Andrea Di Donato, Univ. Politecnica delle Marche (Italy)

We report the elliptical motion of microparticles driven by a periodic evanescent field. We have fully characterized this motion experimentally and created a theoretical model based on the dynamics of Mie-particles under influence of near field optical forces and surface-induced hydrodynamic effects. The agreement between our model and experiments is confirmed by a series of measurements at an unprecedented level of precision. Our method offers an alternative to structured-light optics for inducing orbital motion in microparticles, with the inherent advantage of easy integration into lab-on-a-chip devices.

10347-42, Session 5

Speckles of an optical vortex and a perfect optical vortex: a comparative morphological study

Cristian Hernando Acevedo Cáceres, Univ. Industrial de Santander (Colombia); Sergey Sukhov, Aristide Dogariu, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Optical vortex (OV) beams are electromagnetic waves with a helical wave front due to phase singularities, which are characterized by an integer topological charge related to the spatial distribution of their wavefront. The diameter of an optical vortex is related with its topological charge. This property causes difficulties to achieve a high spatial accuracy and high orbital angular momentum coupling optical vortices into a fiber. To solve these requirements, the concept the perfect optical vortex (POV) has been introduced as optical waves whose ring width size and average ring diameter (the arithmetic average of the inner and outer ring-diameters) are both independent of the topological charge. In this work we study theoretically and experimentally the speckle formation produced by scattering the OVs and POVs through a diffuser. It is found that the speckle size of the OVs decreases with the order of the topological charge in free space propagation and it do not have a appreciable cluster form. Also it is found that the speckle size of the POVs is independent of topological charge in free space propagation and the speckle size remains the same over a long propagation when a lens is placed at focal distance from the diffuser. In addition, we showed that the speckle grains generated by using the POVs form cluster with ringing correlation tails in the speckle intensity distribution. Finally, we proved experimentally that the Shannon entropy value is similar in the OVs and POVs speckle patterns.

10347-43, Session 6

Avoiding induced heating in temperature sensing by optical trapping

Patricia Haro-González, Paloma Rodriguez Sevilla, Univ. Autónoma de Madrid (Spain); Yuhaix Zhang, National Univ. of Singapore (Singapore); Francisco Sanz-Rodríguez, Francisco F. Jaque, José García Solé, Univ. Autónoma de Madrid (Spain); Xiaogang Liu, National Univ. of Singapore (Singapore); Daniel Jaque, Univ. Autónoma de Madrid (Spain)

The trap heating during optical manipulation is an important issue mainly when optical tweezers are applied in biological studies. Temperature increase at the laser focus could be produced either by medium (water) absorption of the trapping wavelength (980 nm) or by heating release of the trapped particle after trapping light absorption. This is not a negligible effect and, indeed, it has been the subject of study of a number of papers appearing in the field of optical trapping. In those cases, alternatives should be found to minimize this effect.

A control of the intra trap temperature could be performed by photothermal sensors, such as NaYF4:Er3+,Yb3+ upconverting particles. This thermometer allows for real time determination of the optical trap temperature. Two methods have been proposed to reduce the temperature loading due to medium absorption of the trapping wavelength or by the optically trapped particle itself: shift of the trapping wavelength out of the water absorption band, and use of time-modulated laser trapping beams. By using the mentioned thermometers, both approaches have been proved to reduce temperature heating at the trap position.

10347-44, Session 6

High-speed position and force measurements in optical tweezers

Anatolii V. Kashchuk, Alexander B. Stilgoe, Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Position measurements of the light spot are used in a large variety of applications: from laser guidance and beam alignment to atomic force microscopy and tracking of microparticles. It is also an important procedure in optical tweezers for most quantitative measurements. For example, we track the position of the trapped particle by calculating the centroid and determine the optical force by measuring the change in the momentum of the trapping beam. The existing detectors provide either

accurate measurements, like in duo-lateral photodetectors, or high-speed measurements, such as quadrant photodiodes. Here we propose a detection method for performing ultrafast accurate beam tracking at high bandwidth. The idea of the method is to use a filter with a linear transmittance in order to modulate the amplitude of the input beam in such a way that the transmitted intensity of the light is proportional to the displacement of the trapping beam. After the linear filter, the intensity of the beam is detected by a high-speed photodetector. As the task of finding the position of the centroid reduces to an intensity only measurement, it is possible to use smaller and faster photodetectors. By varying the gradient of the filter, we can also tune the sensitivity of our position detector. We compare the approach experimentally with both duo-lateral and quadrant detectors. We show that our method provides versatile and accurate measurements while ensuring high bandwidth in the measurement of the beam position and optical force.

10347-45, Session 6

Multi-modal microscopy platform including optical tweezers and the need to perform spherical wave vectors decompositions for optical force and signal intensity calculations *(Invited Paper)*

Carlos Lenz Cesar, Univ. Federal do Ceara (Brazil) and Instituto de Física “Gleb Wataghin” (Brazil); Wendel L. Moreira, Petrobras (Brazil); Antonio A. R. Neves, Univ. Federal do ABC (Brazil); André A. de Thomaz, Univ. Estadual de Campinas (Brazil); Diogo B. Almeida, Univ. of Michigan (United States); Adriana Fontes, Univ. Federal de Pernambuco (Brazil); Hernandes F. Carvalho, Vitor B. Pelegati, Univ. Estadual de Campinas (Brazil)

We will present the multi-modal photonic platform including Optical Tweezers, linear and non linear optics techniques in a single instrument to allow parallel information gathering during single cell processes. The platform includes the following techniques: multipoint Optical Tweezers; Laser cutting; multi/single photon fluorescence, Fluorescence Lifetime Imaging (FLIM); Förster Resonant Energy Transfer (FLIM-FRET); Fluorescence Correlation Spectroscopy (FCS); Raman; Second/Third Harmonic Generation (SHG/THG); Coherent AntiStokes Raman Scattering (CARS) and cascade CARS; Near field tip-enhancement and 1 and 2 photons Photoluminescence Excitation Spectroscopy (1-2 PLE). Next, we will discuss the issue of spherical wave vectors decomposition of any optical beam in the Fourier space without any approximation solving the problem of spherical Bessel functions cancellation in both sides of the expansion. This expansion is the necessary first step to perform optical forces, as well as optical signals intensities, of scattering/absorbing particles. The limit of Rayleigh regime is easily obtained.

10347-122, Session 6

Optical trapping of rare earth-doped nanorods using an optical fiber tweezers approach

Jochen Fick, Institut NÉEL (France); Godefroy Leménager, Maud Thiriet, Lahlil Khalid, Thierry Gacoin, Ecole Polytechnique (France); Francisco Valdivia-Valero, Gérard Colas des Francs, Univ. de Bourgogne (France)

$NaYF_4$:(Er,Yb,Gd) nanorods of different size were trapped using our original optical tweezers consisting of two fiber tips facing each other. Trapping properties were found to depended drastically on the actual particle size. Small rods were efficiently trapped whereas long rods were strongly attracted by the fiber tips and their stable trapping position was situated at the apex of one single fiber tip. In the case of the long particles the trapped particle modified the fiber tip emission properties and trapping of a second nanorod at distances of some microns from the first one is observed. These experimental results will be explained by numerical simulations using the exact Maxwell Stress Tensor approach.

10347-46, Session 7

Hybrid 3D optical and acoustic trapping *(Invited Paper)*

Monika Ritsch-Marte, Medizinische Univ. Innsbruck (Austria)

Optical trapping is a very precise and versatile method for the contactless manipulation of microscopic particles, but the rather weak optical forces pose some limitations on the size and number of particles that can be handled. Acoustic radiation forces induced by ultrasound in the MHz range offer alternative means for particle trapping, which are well suited for dealing with many or large particles, due to the much longer wavelength and lower energy density.

We present a hybrid setup comprising optical and acoustic trapping, by which the strengths of the individual methods can be united. As a particular feature we have implemented 3D acoustic trapping with independent control of the trapping strength in each direction. Optical trapping played a crucial role as a tool to characterize and optimize the acoustic forces when developing this device. It also helped to investigate experimental challenges due to the close contact of the objective lens with the device, which affects the acoustic resonances.

This device is designed to study the contactless formation and trapping of large cell clusters, while offering the ability to image and probe mechanical properties by optical forces on the single cell level.

10347-47, Session 7

Optically enhanced acoustophoresis

Michael P. MacDonald, Craig McDougall, Paul O’Mahoney, Univ. of Dundee (United Kingdom); Alan McGuinn, Nicholas A. Willoughby, Heriot-Watt Univ. (United Kingdom); Yongqiang Qiu, Univ. of Glasgow (United Kingdom); Christine E. M. Demore, Univ. of Toronto (Canada)

One of the most powerful tools available to a life scientist is the ability to use antibody labelling to achieve highly specific cell sorting. However, there are some applications where it is not possible to use labels for regulatory, cost or efficacy reasons. One such application is in cell therapy where the sorted cell product is to be introduced into a patient. Hence there is an unmet demand for scalable label free sorting methodologies capable of meeting the future needs of cell therapy bioprocessing.

Acoustic control of cells is well suited to handling large volumes of cells but does not have the specificity/selectivity available from optical manipulation. Here we present a method for enhancing the acoustophoretic effect through the use of the optical selection of particles in an acoustically confined analyte flow, combining the bulk handling abilities of acoustics with the specificity of optics.

Axially periodic dispersion of acoustically confined particles within a simple microcapillary, arising from the effects of the finite length of the capillary, are used to achieve acoustophoretic particle separation. This effect is by itself insufficient to lead to complete particle separation but, through the introduction of optical selection within the narrow acoustophoretic fractionation column, efficient and scalable sorting can be achieved. We will show examples of this hybrid sorting approach, which is particularly well suited to extracting rare-species from a flow, as will be needed for future cell therapy bioprocesses.

10347-48, Session 7

Simultaneous optical trapping and imaging in axial plane

Yansheng Liang, Ming Lei, Zhiliang Cao, Yue Wang, Shaohui Yan, Manman Li, Dan Dan, Yanan Cai, Zhaojun Wang, Baoli Yao, Xi'an Institute of Optics and Precision Mechanics, CAS (China)

Optical tweezers has demonstrated great success in widespread applications, such as in life science, atom cooling and fundamental physics. Since most existing optical tweezers systems use single objective lens for both trapping and imaging, the trapping and imaging planes are confined to the same focal plane. To track the trapped micro-particles along axial direction, different volumetric imaging and tracking techniques have been developed to extract the axial information from the 3D image stacks, but at the cost of complex measurement schemes and challenging calibration procedures [1]. Therefore, a direct visualization method of trapped objects is highly desirable in many studies. G. Thalhammer et al. [2] employed a right-angle prism to directly image the trapped particles in axial plane in 2011, but the method was limited in macro-trapping with low magnification. Here, we further advance this approach by implementing the prism into a tight-focusing holographic optical tweezers setup combined with fluorescent imaging. Simultaneous optical trapping and imaging in axial plane are demonstrated with several types of optical traps structured by spatial light modulator. We have successfully trapped 3 silica beads along axial direction with Gaussian traps array of 1?3, and axially aligned the silica beads like a chain with focused Bessel beam. Moreover, the trajectory of the transported micro-particle driven by an Airy beam has been obtained. The technique proposed here may provide a new angle of view in optical trapping and imaging, and promote the combination of optical trapping and microscopic imaging.

10347-49, Session 7

Optical vortex response to introduced phase objects

Mateusz M. Szatkowski, Agnieszka Popiolek-Masajada, Jan Masajada, Wroclaw Univ. of Science and Technology (Poland)

Optical Vortex Scanning Microscope (OVSM) uses focused laser beam with embedded optical vortex to scan the sample. The optical vortex can be moved inside the focused light spot by shifting the vortex lens (which generates optical vortex). This new scanning method was tested experimentally with simple phase micro-objects. It was shown that our system is sensitive to small phase disturbances which have an impact on both optical vortex position and phase profile. One of the challenges for the OVSM is finding the effective procedures for surface topography reconstruction. We proposed a new experimental setup to support the works focused on this problem. The Spatial Light Modulator (SLM) is used as an object generator. SLM allows to generate any phase disturbance with specified value and size, which can be easily introduced into the beam carrying optical vortex. Our system gives an opportunity to measure optical vortex response due to phase modifications introduced by the SLM as well as vortex sensitivity. We tested how object position, size, phase value affects phase distribution around vortex and position of vortex point inside the beam. Phase retrieval algorithm, noise analysis and results of experiments will be presented. These results show the way in which the OVSM should be developed.

10347-50, Session 8

Tutorial on optomechanics

James Millen, Univ. Wien (Austria)

In the last few years a remarkable field of study has emerged, in which we study the interaction of light with the mechanical motion of massive objects: optomechanics. With the introduction of an optical resonator, cavity optomechanical systems have been cooled to their motional ground state. This means that objects many microns in size have been observed exhibiting quantum behaviour.

Optomechanical systems can be used to coherently transduce quantum signals, or store them for long times, indicating that in the future they will be essential components in quantum networks. They also offer the potential for ultra-precise sensing, and the on-chip nature of many nanomechanical systems points the way to technological integration.

In this lecture I will introduce the basic mathematical structure of optomechanical systems, how they can be cooled, several detailed examples, and the major results from the field. I will also discuss the future implications, and the relevance to studying fundamental physics and the limits of quantum mechanics. There will be a particular focus on systems where the nanomechanical oscillator is levitated and isolated from the environment, due to its relevance to the Optical Trapping and Micromanipulation community.

10347-51, Session 9

Laser refrigeration of levitated nanocrystals

A. T. M. Anishur Rahman, Peter F. Barker, Univ. College London (United Kingdom)

Levitated optomechanics has seen significant progress over the last five years. While a considerable control over the centre-of-mass motion has been achieved, the internal temperature of levitated particles remains at best at room temperature. Here we report on the demonstration of internal cooling of levitated ytterbium doped yttrium lithium fluoride (Yb^{3+}: YLF) nanocrystals. Using anti-stokes laser refrigeration we demonstrate that trapped particles can be cooled from room temperature to 130 K. By controlling the amount of trapping power, and exploiting the interaction between polarised light and the particles natural birefringence, we demonstrate that the Yb^{+3}: YLF nanocrystals can be aligned along the direction of the trapping laser's electric field enhancing the refrigeration. We show that both the spectral emission from the levitated particle induced by the trapping laser and a modification to the damping rate of the particle in the trap, can be used to determine the temperature of the levitated particle.

10347-52, Session 9

Optical and magnetic measurements of a frequency-locked graphene nanoplatelet in a quadrupole ion trap

Joyce E. Coppock, Univ. of Maryland, College Park (United States); Pavel Nagornykh, The Univ. of Texas at Austin (United States); Jacob P. J. Murphy, Bruce E. Kane, Univ. of Maryland, College Park (United States)

Extremely sensitive force measurements can be performed on electrically charged nanoscale materials by levitating them in a quadrupole ion trap in high vacuum. In this talk, we discuss recent results[1] and ongoing investigations on the magnetic properties of a few-layer, micron-scale, rotating graphene nanoplatelet. To facilitate such measurements, we have developed a method of frequency-locking a nanoplatelet to a radio-frequency electric field, making use of the fact that the intrinsic electric dipole moment of the irregularly-shaped platelet couples to the applied electric field. The rotation frequency has been varied up to 100 MHz,

with higher frequencies expected to be possible. The particle's motion is detected optically, via the scattering of a low-power 532 nm laser.

We observe the dynamics of the frequency-locked platelet in response to applied magnetic fields. From frequency- and field-dependent measurements, we observe one magnetic moment arising from diamagnetism and another arising from the rapid rotation of the platelet, and we estimate their magnitudes and compare them to proposed theoretical properties of graphene. We determine a gyromagnetic ratio corresponding to the rotational moment, which is larger than would be expected for charge fixed to the outside of the platelet. We hypothesize that the excess magnitude of the gyromagnetic ratio may arise from the Barnett effect, in which a spinning object develops a magnetic moment even in the absence of net charge.

10347-53, Session 9

Optomechanics of a levitated helium drop *(Invited Paper)*

Florian Marquardt, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany)

Inside a levitated helium drop, one can have optical whispering gallery modes of very high finesse. These can couple to the vibrations of the drop surface. I will describe our theoretical predictions for both the case of Helium-4 (in its superfluid state), as well as Helium-3. In the latter case, there is an interesting additional coupling between vibrations and rotations which would eventually permit quantum non-demolition measurements of the drop's angular momentum.

10347-54, Session 9

Cooperative effects between color centers in diamond: applications to optical tweezers and optomechanics *(Invited Paper)*

Mathieu L. Juan, Institut für Quantenoptik und Quanteninformation (Austria)

Both an atom and a lump of dielectric material are polarizable objects that can be manipulated with optical light, a feature exploited separately in the fields of ultracold atoms and optical tweezers. In a recent experiment we have shown that the force from quantum emitters (Nitrogen-Vacancy colour centres, NVs) embedded in a dielectric nanosphere (nano-diamond) can be observed, even in liquid. Remarkably, the magnitude of this effect suggests that due to the large density of centres, cooperative effects between centres significantly contribute to the observed modification of the trapping strength. Along with experimental data, I will present the underlying mechanisms allowing for cooperative effects to be observed at room temperature and in the presence of large dephasing. This work enables the study of cooperativity in nanoscale solid-state systems and the use of atomic physics techniques in the field of nano-manipulation. In particular, by controlling such effects we envision various promising applications in the field optical tweezers where it may be possible to significantly enhance the optical forces acting on small nano-objects with embedded quantum emitters. In the context of optomechanics, we argue that it is experimentally feasible to have a scenario where the optical dipole force due to the embedded quantum emitters is stronger that the bulk dipole force acting on the dielectric host. This would allow to use repulsive optical potentials for dielectric nanospheres, by using the internal structure of the quantum emitters, to levitate them in evanescent fields analogously to what can be done with ultracold atoms.

10347-55, Session 9

Coherent control of single spins in optically levitated nanocrystals

Robert M. Pettit, Univ. of Rochester (United States); Levi P. Neukirch, Los Alamos National Lab. (United States); Yi Zhang, A. Nick Vamivakas, Univ. of Rochester (United States)

Nitrogen-vacancy (NV) centers in diamond provide a platform for room temperature spin manipulation, making them a strong candidate for inclusion in optical levitation experiments seeking to couple mechanical and spin degrees of freedom. Here, we report progress on the coherent manipulation of single NV center spins contained within optically levitated nanodiamond in a free-space optical dipole trap. The NV center spin is coherently manipulated at both atmospheric pressure and low vacuum, and while the trapping beam causes a reduction in the fluorescence emitted by the center, no reduction in the spin coherence is observed. Further, after an initial exposure to low vacuum, the nanodiamond remains at near room temperatures at all pressures and trapping powers considered in these experiments.

10347-56, Session 10

MilliKelvin cooling of the center of mass motion of a levitated nanoparticle

Nathanaël P. Bullier, Antonio Pontin, Peter F. Barker, Univ. College London (United Kingdom)

Many recent experiments have brought optomechanics one step closer for testing quantum mechanics at nanoscales and probing nonclassical motions. These breakthroughs include cooling oscillators to their quantum ground state [1], performing quantum non-demolition measurements [2] and measuring squeezed states of mechanical motion [3]. Levitated optomechanics has the advantages over previous experimental set-ups of providing greater isolation, higher mechanical Q factor and longer coherence times [4]. We use a hybrid electro-optical trap to levitate silica nanoparticles in a Fabry-Pérot cavity [5]. The Paul trap provides a deep potential that enables trapping at lower pressures. Once trapped, the particle can then be localized in an optical well. The optomechanical interaction between the trapped particle and the cavity field can currently be used to cool the centre-of-mass motion to milli-Kelvin temperatures [6]. To date these measured temperatures have been limited by technical noise in our system. We report on our latest measurements that implement a low noise homodyne detection scheme which probes the motion of the particle near the ground state.

Optical trapping and control of nanospheres inside hollow core photonic crystal fibers

David Grass, Nikolai Kiesel, Univ. Wien (Austria); Daniel R. Ladiges, John E. Sader, The Univ. of Melbourne (Australia); Markus Aspelmeyer, Univ. Wien (Austria)

We report a hollow core photonic crystal fiber based optical conveyor belt for levitated nano-particles in vacuum. An optical read-out allows monitoring the three-dimensional motion of the particle over the entire fiber length and is used for radiation pressure based feedback cooling. Besides the target application of controlled and clean delivery of nano-particles into ultra-high vacuum for levitated optomechanical systems we utilize read-out and feedback cooling to investigate the local pressure along the fiber when a pressure gradient is applied. We compare the measurements with predictions from a direct simulating Monte Carlo method of the nonlinear Boltzmann equation.

10347-58, Session 10

Developing optomechanical inertial sensors using whispering gallery mode resonances *(Invited Paper)*

Ying Lia Li, Peter F. Barker, Univ. College London (United Kingdom)

Experiments in cavity optomechanics readily obtain measurements of displacement and force with unprecedented sensitivity, and many now approach or surpass quantum limits. In the work presented here, the optomechanical coupling between a whispering gallery mode (WGM) optical resonance and the centre-of-mass mechanical motion of the WGM cavity itself is exploited for inertial sensing. This system is shown to detect micro-g accelerations (g=9.81 ms^(-2)), with prospects towards obtaining quantum limited sensing. The development of an automated, portable prototype is described and results from field testing will be presented.

10347-59, Session 10

Rotational optomechanics with levitated nanorods

Stefan Kuhn, Univ. Wien (Austria); Benjamin A. Stickler, Univ. Duisburg-Essen (Germany); Alon Kosloff, Fernando Patolsky, Tel Aviv Univ. (Israel); Klaus Hornberger, Univ. Duisburg-Essen (Germany); Markus Arndt, James Millen, Univ. Wien (Austria)

Optical control over nano-mechanical structures has become a valuable tool for tests of fundamental physics and force sensing applications. In order to achieve optimal performance of such devices, their dissipation to the environment needs to be minimized. Levitating nanoparticles in external fields is a possible solution which opened up the growing field of levitated optomechanics. Here we extend this work to the rotational degrees of freedom of optically levitated silicon nanorods[1]. We track and manipulate their linear and rotational motion by exploiting the polarization of two counter-propagating, focussed laser beams. This allows us to gain full control over the ro-translational dynamics of the rod. We will discuss the prospects of our levitated system for sensing applications as well as for realising rotational optomechanics and cavity cooling [2,3] which may be an important step towards high-mass matter-wave interference experiments with nanoparticles.

10347-60, Session 11

Translational and rotational motion of Janus particles trapped in optical tweezers *(Invited Paper)*

Honglian Guo, South China Univ. of Technology (United States); Jing Liu, Institute of Physics, Chinese Academy of Sciences (China); Baoqin Chen, South China Univ. of Technology (China)

We study the rotation behavior of gold-coated Janus colloidal particle in optical traps. The Janus particle is observed to stably rotate in the optical trap. Both the direction and the rate of rotation can be experimentally controlled. Numerical calculations reveal that the rotation is the result of spontaneous symmetry breaking induced by the uneven curvature of the coating patterns on the Janus particle. In addition, we report the cyclic round-trip motion of Janus particles in static line optical tweezers . Both experiment and simulation show that this cyclic translational and rotational motion is a consequence of the collective action of the gold-face orientation dependent scattering optical force, the gradient optical force, and the spontaneous symmetry breaking induced optical torque in di?erent regions of the line optical tweezers. This study indicates a novel way to construct large quantities of fully functional motors for nano- or microdevices.

10347-61, Session 11

Maximum likelihood estimation in optical tweezers-based force sensing

Robert Meissner, Cornelia Denz, Westfälische Wilhelms-Univ. Münster (Germany)

Quantitative estimation of optical forces with artificial microprobes in optical tweezers is typically used to determine micro-rheological and biomechanical properties of living cells in both viscous and viscoelastic media. In viscous media, force calibration is performed by fitting the measured power spectrum density of Brownian motion of a microprobe with a Lorentzian function yielding friction coefficient and a so-called corner frequency, the latter being the ratio of the friction coefficient and the trap stiffness. Thus, the desired trap stiffness is directly obtained. Theoretical requirements of calibration are demanding, and a variety of error sources such as aliasing, drift or parameter bias have been treated. However, there is an increasing demand in fitting sparse or low signal-to-noise data as they represent the typical situation in biophysical analysis of cells.

In our contribution, we focus on the influence of user-biased initial conditions, i.e. frequency range or averaging techniques employed in biophysical settings. These conditions control the amount of data and noise included in fitting. By comparing state-of-the-art least squares estimation (LSE) with a novel approach based on maximum likelihood estimation (MLE), we show numerically that MLE is more robust than LSE, especially when the corner frequency is close to the Nyquist frequency or when noise limits the available range of frequencies. We observe a biased corner frequency of LSE when frequency ranges and number of averages change. We compare features of LSE and MLE, and demonstrate how MLE increases the applicability of optical tweezers for in vitro and in vivo biometrology.

10347-62, Session 11

Dynamics of a driven two-particle system coupled by hydrodynamic interactions in optical tweezers

Shuvojit Paul, Indian Institute of Science Education and Research Kolkata (India); Abhrajit Laskar, Ronojoy Adhikari, Institute of Mathematical Sciences (India); Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

A single trapped mesoscopic particle in optical tweezers in a viscous fluid behaves as an overdamped harmonic oscillator subjected to stochastic forces arising from thermal fluctuations in the fluid. The large viscosity of the fluid damps out the inertial response of the particle entirely, so that even if it is driven by an external sinusoidal force, no motional resonance is observed. However, if two particles are trapped at separations comparable to their radii, the near-field hydrodynamic interactions lead to unexpected effects. Here, we measure the amplitude and phase response of a weakly trapped particle (probe) to the hydrodynamically mediated forcing from a nearby strongly trapped particle driven at a fixed frequency. The amplitude response shows a clear resonance as a function of the driving frequency of the strongly trapped particle, while the phase behavior emulates the velocity response to the driving force in damped driven harmonic oscillators – which is expected since the colloidal particles in our case are dissipatively coupled. We validate our experimental results by analytically solving the hydrodynamically coupled equations of motion of the two particles and obtain good matches between theory and experiment. The amplitude response of the probe is a sensitive function of the fluid viscosity suggesting the use of this setup for two-point microrheology. Indeed, we are able to measure the viscosity of different glyecerol-water solutions with good accuracy using our technique. Our technique can now be extended to study near-field hydrodynamic effects in viscoelastic fluids where the retarded hydrodynamic interactions will produce surprising responses.

10347-63, Session 11

Optically driven colloidal microscopic Taylor-Couette cell

Antonio Ortiz-Ambriz, Pietro Tierno, Univ. de Barcelona (Spain)

We present an optically driven colloidal microscopic rheometer based on the recent work of Williams et al. [1]. With optical tweezers, we create a colloidal corral that confines a highly packed system of particles. In addition, we introduce an inner triplet of superparamagnetic particles which we can drive by applying an in plane rotating magnetic field. The interplay between magnetic and optical forces allows us to experimentally build a two dimensional Taylor-Couette cell, in which the outer wall and inner wall move independently of each other. Such a system can be used to explore the rheological properties of confined colloidal suspensions at a microscopic scale. The small scale of this rheometer allows us to explore how deformations in the structure lead to shear thinning, and how the coexistence of ordering phases leads to depinning transitions. Despite the discrete nature of the system, we observe local instabilities in the response of the layers' flow to the applied shear, which is a characteristic of shear banding in larger systems. Besides the rheological phenomena, we believe that these type of experiments can be useful to develop the understanding of non-equilibrium many body systems.

Optical torques on upconverting particles for intracellular microrheometry

Paloma Rodriguez Sevilla, Univ. Autónoma de Madrid (Spain); Yuhai Zhang, National Univ. of Singapore (Singapore); Nuno de Sousa, Manuel I. Marqués, Francisco Sanz-Rodríguez, Daniel Jaque, Univ. Autónoma de Madrid (Spain); Xiaogang Liu, National Univ. of Singapore (Singapore); Patricia Haro-González, Univ. Autónoma de Madrid (Spain)

Upconverting particles (UCPs) are a new class of optical nanomaterials that are able to convert infrared excitation into visible light output, a unique attribute that has been exploited in a large variety of research fields ranging from energy harvesting to biomedicine. Their starring role has been further boosted by the recent demonstration of their three dimensional control and tracking by single beam infrared optical traps. Such possibility has opened the door for exciting new applications and, at the same time, it has raised new fundamental questions regarding light-matter interactions at the nanoscale.

We have demonstrate that, once a single UCP is incorporated into an optical trap, particle dynamics cannot be only described in terms of optical forces, since optical torques (OTQs) need to be considered. We have demonstrated that OTQs are responsible of the stable orientation of the UCP inside the trap. The combination of single-particle polarized spectroscopy and numerical simulations has evidenced the dominant role of magnetic dipole torques.

Moreover, numerical calculations and experimental data allowed us to use rotation dynamics of a optically trapped single UCP for environmental sensing. In particular, we have shown for the first time that cytoplasm viscosity could be measured by using the rotation time and thermal fluctuations of an intracellular optically trapped UCP.

Our study constitutes a groundbreaking contribution within the emerging areas of optical manipulation and bioapplications of UCPs. Furthermore, the dominant role of OTQs as well as the potential use of rotation dynamics for intracellular studies will be of great interest for the large scientific community working on particles as remote biosensors.

10347-65, Session 11

Optical measurements of nanoparticle vibrations for fluid mechanics on the nanoscale

Matthew A. Pelton, Univ. of Maryland, Baltimore County (United States)

Optical measurements of acoustic oscillations in metal nanoparticles provide a sensitive probe into the mechanical properties of materials at GHz frequencies and nanometer length scales. In these experiments, an incident pump laser heats the nanoparticles, leading to their expansion and the excitation of mechanical vibrations. The vibrations produce oscillations in the plasmon resonance frequency of the nanoparticles, which are monitored by measuring the change in transmission through the sample of a second, probe laser pulse. By making these measurements on a highly monodisperse sample of bipyramidal gold nanoparticles, we were able to determine both the frequency and the decay rate of the vibrations. Measurements on nanoparticles in different solvents made it possible to determine the portion of damping and the vibrational frequency shift that are due to coupling to the surrounding liquid environment. Viscous damping could account for results at low viscosities, but significant discrepancies were observed for higher viscosities. The discrepancies were ultimately resolved by accounting for the viscoelastic nature of the surrounding liquids. For more viscous liquids, relaxation times are higher, and thus more of the vibrational energy is stored as elastic energy in the surrounding liquid. This reduces damping, and the restoring force provided by the stored energy increases the vibrational frequency, the opposite of what would occur for an ordinary

Newtonian fluid. These measurements demonstrate that metal nanoparticles can serve as nanoscale rheometers, with the picosecond response times required to reveal viscoelastic effects in conventional liquids.

10347-66, Session 11

Absolute temperature measurements in optical tweezers by synchronized position and force measurement

Anatolii V. Kashchuk, Alexander B. Stilgoe, Timo A. Nieminen, Halina H. Rubinsztein-Dunlop, The Univ. of Queensland (Australia)

Optical tweezers as a tool for contactless manipulation of the micro- and nanoparticles are widely used to apply and measure forces in biological systems. Precise temperature measurements are crucial for biological objects, such as bacteria or cells, as they are highly sensitive to the heating effects. It is also an important parameter for calibrating an optical trap for force measurements.

It is difficult to measure the exact temperature of a trapped object. Temperature can be obtained from viscosity measurements as it is a temperature dependent parameter. A particle is tracked by a CMOS camera and the optical force is determined directly by measuring the change of the momentum of the laser beam. We shift the trapped particle from the equilibrium position by moving the stage. The Stokes drag forces the particle out of the focal spot and balances the optical force. The temperature can be obtained using known data of the viscosity of water or by measuring the viscosity of the bulk liquid with other methods. In this proposed method we combine viscosity measurements with optical force detection and measure a temperature in the optical trap with 0.2K precision.

The absolute nature of the force detection method makes it suitable for measuring optical forces in a non-linear region of the optical trap and in various environments with known viscosity-temperature dependency, increasing the signal-to-noise ratio and expanding the applicability of the temperature measurements. The proposed method does not require a precalibration of the force detector and, therefore, can be used for temperature independent calibration.

10347-67, Session 12

Flow through oil nanothreads *(Invited Paper)*

Colin Bain, Alex Hargreaves, Joshua Bull, Durham Univ. (United Kingdom); Buddhapriya Chakrabarti, Sheffleld Univ. (United Kingdom)

The oil-water interfacial tension in emulsions of heptane/AOT/brine are reduced to ultralow values (< 10 micronewtons/m) by control of the salinity and temperature. Under these conditions, the dimensionless ratio of the force constant of an optical trap to the interfacial tension is O(1) so optical tweezers can be used to deform oil droplets. We have shown previously (Soft Matter 7, 2517 (2011)) that if an oil drop is pulled apart with a pair of tweezers, the two daughter droplets remain attached by an invisible oil thread of nanometric thickness. Optical pressure induced on the trapped droplets can be used to pump oil through the nanothreads. In this paper we will show how the bending rigidity stabilises the nanothreads and that the spontaneous curvature results in stable nanothreads on only one side of the phase inversion point. Flow through the nanothreads is analysed in the slender approximation for fixed radius by matching a parabolic flow profile within the thread to the solution for flow past a rigid cylinder. The internal flow accounts for a minor part of the mass transport between two droplets: most of the volumetric flow arises from motion of the whole thread. Relaxing the assumption of fixed radius in order to balance the normal stresses results in a singularity in the thread radius, placing an upper limit on the length of the thread through which oil can be pumped at a given flow rate.

10347-68, Session 12

Development of a Bessel-beam-based optical guide of aerosolized nanoparticles for femtosecond x-ray diffractive imaging

Andrei V. Rode, Woei Ming Lee, The Australian National Univ. (Australia); Salah Awel, Xiaoyan Sun, Daniel Horke, Ctr. for Free-Electron Laser Science (Germany); Richard A. Kirian, Arizona State Univ. (United States); Jochen Ku?pper, Henry N. Chapman, Ctr. for Free-Electron Laser Science (Germany)

The manipulation of airborne particles by light driven by photophoretic forces arise from uneven thermal gradient imposed upon a particle. In this work, we constructed a funnel-shaped hollow-core laser beam that can stably utilised these thermal gradients and controllably manipulate graphite particles over different heights based on their masses. By measuring the trapped particles of different mass at different heights inside the optical funnel, we show a direct relationship of the force that acted on the particles at each position in the laser beam. This allows for calibration, and prediction of the trajectories of objects in the optical funnel depending on laser intensity, size and air pressure.

Furthermore, we combined a spatial light modulator (SLM) and an electrically tunable lens to construct a variable-divergence aberration-free vortex beam to facilitate the dynamic and stable axial and azimuthal positioning of optically levitated micrometer-size particles under normal atmospheric pressure. In addition, modulation of the beam divergence with a predicted oscillatory movement and resulted particle move into a different equilibrium position provides a measure of the mass of a single, isolated particle. Such touch-free positioning could potentially be useful in guiding biomolecules at the focus of an x-ray free electron laser, for the recording of its structure in femtosecond coherent diffractive imaging experiments. The driving signal of oscillatory motion can potentially be phase-locked to an external timing signal enabling synchronization of particle delivery into the x-ray focus with XFEL pulse train.

10347-69, Session 12

Optical fabrication and trapping of superconducting nanoparticles in superfluid helium

Masaaki Ashida, Yosuke Minowa, Osaka Univ. (Japan); Mitsutaka Kumakura, Univ. of Fukui (Japan); Yuta Takahashi, Fusakazu Matsushima, Yoshiki Moriwaki, Univ. of Toyama (Japan)

Laser ablation in liquids provides us a unique opportunity to fabricate novel nano-materials. Among chemically inactive liquids, superfluid helium having extremely low temperature, negligibly small viscosity, huge thermal conductivity, and high transparency in visible region generates an ideal cryogenic space for the fabrication of nano-materials and the optical manipulation of their motion. Recently, we successfully fabricated nano- and micro-particles by the laser ablation in superfluid helium with a nanosecond Nd:YAG laser. Surprisingly, we found single-crystalline microspheres of semiconductors, such as ZnO, CdSe, etc., with high sphericity and their efficient lasing of whispering gallery modes. [Scientific Reports 4, 5186 (2014).] Here we applied this method to metals, such as indium and rhenium. At low temperature these metals show superconductivity, of which dependence on the size has attracted much attention for a long time. To select superconducting particles, we utilized perfect diamagnetism caused by Meissner effect. Namely, we designed a magnetic trap with two permanent magnets for the superconducting particles. Thus we fabricated and trapped a single or several superconducting particles after the laser ablation in superfluid helium, and then we measured the temperature dependence of the trapping force by changing the temperature of liquid helium and examined the size dependence of the superconductivity.

10347-70, Session 13

Thermodynamics of radiation pressure and photon momentum

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

Theoretical analyses of radiation pressure and photon momentum in the past 150 years have focused almost exclusively on classical and/or quantum theories of electrodynamics. In these analyses, Maxwell's equations, the properties of polarizable and/or magnetizable material media, and the stress tensors of Maxwell, Abraham, Minkowski, Chu, and Einstein-Laub have typically played prominent roles. Each stress tensor has subsequently been manipulated to yield its own expressions for the electromagnetic force, torque, energy, and linear as well as angular momentum densities of the electromagnetic field. We will present an alternative view of radiation pressure from the perspective of classical thermodynamics, invoking the properties of blackbody radiation in conjunction with gas-filled cavities that contain electromagnetic energy in thermal equilibrium with the container. In this type of analysis, Planck's quantum hypothesis, Einstein's A and B coefficients, the entropy of the gas, and the spectral distribution of the trapped radiation play the central roles.

10347-71, Session 13

Thermophoretic levitation of generic objects

Cheng Chin, Frankie Fung, Benjamin Foster, Mykhaylo Usatyuk, B. J. DeSalvo, Anita Gaj, The Univ. of Chicago (United States)

The levitation machine we demonstrate is based on pure thermophoretic force. At the center of a vacuum chamber is a 1-cm gap between a warm copper plate at room temperature and a stainless steel bucket filled with liquid nitrogen at T= 77?K. In the presence of a large temperature gradient, particles are levitated and trapped near the mid-plane between the top and bottom plates. A careful tuning of the pressure ensures the levitation force is stronger than gravity below the particle and weaker than gravity above the particle. Horizontal stability is provided by a inward radial heat flow toward the trap center. Such three-dimentional trapping stability offered by our system overcomes the Earnshaw's theorem for a static temperature field. We conducted quantitative comparison between the levitation force and the theoretical calculations. A good agreement with two theoretical models is concluded. We will report our system design, the performance of the levitation and address on future potential to levitation macroscopic objects.

10347-72, Session 13

Hopping hither and thither-examining Kramer's law and stochastic resonance with a levitated nanoparticle *(Invited Paper)*

Jan Gieseler, Harvard Univ. (United States) and ICFO - Institut de Ciències Fotòniques (Spain); Francesco Ricci, ICFO - Institut de Ciències Fotòniques (Spain); Loic Rondin, ETH Zurich (Switzerland); Raúl A. Rica, ICFO - Institut de Ciències Fotòniques (Spain); Marko Spasenovic, ICFO - Institut de Ciències Fotòniques (Spain) and Univ. of Belgrade (Serbia); Christoph Dellago, Univ. Wien (Austria); Lukas Novotny, ETH Zurich (Switzerland); Romain Quidant, ICFO - Institut de Ciències Fotòniques (Spain) and Institució Catalana de Recerca i Estudis Avançats (Spain)

Noise activated bistable systems are ubiquitous in nature since the dynamics of vastly different systems can be described by a fictitious particle hopping between two potential wells. Systems that fall into this class include quantum emitters, protein folding, phase transitions and neural signaling. Thus bistable systems play a prominent role in quantum and biophysics, chemistry and nanotechnology. However, given the complexity of the above mentioned systems, it does not surprise that results based on this model tend to be qualitative.

To gain further insight into the predictive power of theories based on noise activated dynamics in a double well potential, we investigate the bistable dynamics of an optically levitated particle in high vacuum with and without externally added noise. The high degree of control we have with this experimental platform allows us to tune and to calibrate all the system parameters. This allows us to compare our measurements quantitatively with the theoretical models.

We find excellent agreement with analytical models for the escape rate (Kramer's law) and the switching between the two potential wells and observe a clear signature of stochastic resonance. This demonstrates that a levitated nanoparticle in high vacuum is a versatile experimental platform for studying and simulating a wide range of stochastic processes and testing theoretical models and predictions.

10347-73, Session 13

A realization of an information machine with temporal correlations *(Invited Paper)*

Yael Roichman, Tamir Admon, Tel Aviv Univ. (Israel); Saar Rahav, Technion-Israel Institute of Technology (Israel)

We realize experimentally and in simulation an information machine which converts information to work. In our realization, a single particle is diffusing in a one dimensional channel. Fluid flow in the channel causes the particle to drift along one direction preferentially. A barrier placed at the end of the channel confines the particle to one side of the channel. If the fluid flow is weak in comparison to thermal forces, the particle is able to diffuse upstream, against the fluid flow, occasionally. During the machine's operation the particle is monitored continuously, each time it diffuses far enough upstream, away from the barrier, a feedback mechanism moves the barrier slightly closer to the particle, without acting on the particle or the fluid. Experimentally, this is realized using a low refractive index colloidal particle diffusing in a microfluidic channel and the barrier is made of a repelling laser beam. The particle is tracked using video microscopy, and holographic optical tweezers are used to control the barrier position. In a quasi-static mode of operation of the amount of used information is easily calculated through the Shannon entropy of uncorrelated steps. However, at faster rates of operation temporal correlations arise and their full characterization is required for assessment of the information used to operate the machine. We develop a scheme to calculate information at steady-state operation based on measured temporal correlations. We use this calculation to characterize the output power and efficiency of our information machine as a function of feedback cycle time.

Particle trapped by a non-conservative force under Brownian motion

Jack Ng, Hong Kong Baptist Univ. (Hong Kong, China);

Yongyin Cao, Hong Kong Baptist Univ. (Hong Kong, China) and Harbin Institute of Technology (China); Xiao Li, Hong Kong Baptist Univ. (Hong Kong, China); Che TIng Chan, Hong Kong Univ. of Science and Technology (Hong Kong, China)

A particle trapped by light typically also undergoes Brownian motion. This problem can be solved by solving the Langevin equation. We analytically and numerically solved the Langevin equation for a generalized harmonic oscillator with non-conservative forces, which governs the motion of an optically trapped particle under Brownian motion. It is shown that with non-conservative forces, equipartition theorem is no longer held because the non-conservative optical force keeps pumping energy into the system. However the equipartition theorem is still approximately valid in a heavily damped environment like water. The role of the parity-time symmetry and other symmetries in the stability of the optically trapping will also be discussed.

Short-time Brownian motion *(Invited Paper)*

Mark G. Raizen, The Univ. of Texas at Austin (United States)

Brownian motion has been the benchmark for classical transport in a disordered system for many years, and is characterized by diffusion. In 1907, Albert Einstein predicted that particle motion should be ballistic on very short time scales, rather than diffusive. Einstein concluded that this instantaneous velocity would be impossible to measure in practice, a prediction that held for over 100 years.

We report experiments with micron-sized beads held in optical tweezers. We developed novel methods for fast, shot-noise limited detection of laser-beam deflection. Using this system, we have resolved the instantaneous velocity of a Brownian particle in air and in liquid [1,2,3]. We use the velocity measurements to test the energy equipartition theorem. In liquid, we observe complex effects such as memory loss, and an anti-correlated thermal force. This work opens the possibility of studying the microscopic origins of dissipation due to viscosity of the fluid, and the onset of the arrow of time.

High bandwidth optical tracking of micro/nanoparticles

Muhammad Waleed, Lars Madsen, Catxere Andrade Casacio, Michael A. Taylor, Nicolas P. Mauranyapin, Warwick P. Bowen, Queensland Quantum Optics Lab. (Australia)

Since Einstein's explanation of Brownian motion of particles in the fluid in 1907, hydrodynamic interactions between particles and fluid have been studied extensively. For this purpose, optical tweezers is the fastest available tool to measure the displacement fluctuation of an optically trapped particle. In optical tweezers, the particle is trapped using a tightly focused laser beam. The particle scatters light both in even and odd modes of Gaussian beam and usually its position is detected by detecting both modes. Using this standard detection scheme, a major breakthrough appeared in 2011, where particle position was tracked at MHz speed which led to the observation of particle diffusion transition from normal to the ballistic Brownian motion. However, high power photodetectors are required to track particles in MHz regime.

In this work, we take a different approach to the high power detection problem. The information about the particle displacement is primarily in the odd spatial modes, while the trapping field is in the even spatial mode. Hence we can reduce the intensity without reducing the information by filtering out the even spatial modes. We perform the filtering using a split waveplate, which turns all the odd modes even, and a single mode fiber, which only transmits the first even mode (TEM00). This spatial mode filter detection would allow high power optical trapping and high bandwidth detection of particles without requiring high power photodetectors. This high-bandwidth optical tweezers system will be useful to better understand the fluid dynamics especially in biological fluids that are occurring at very short times scales (< microseconds).

Manipulating single and multiple biomolecules with dynamic temperature fields

Tobias Thalheim, Univ. Leipzig (Germany); Katrin Günther, TU Dresden (Germany); Michael Mertig, TU Dresden (Germany) and Kurt-Schwabe-Institut für Mess- und Sensortechnik e.V. (Germany); Frank Cichos, Univ. Leipzig (Germany)

One of the challenges of single molecule experiments in solution is the ability to trap and manipulate one or even multiple molecules against the erratic Brownian motion. Brownian fluctuations are fueled by thermal energy and increase in strength with increasing temperature. Therefore, it is at first glance counterintuitive to confine Brownian fluctuations with the help of elevated temperatures. In thermal non-equilibrium, however, temperature gradients induce thermo-phoretic and thermo-osmotic drifts, which provide our means for single particle and single molecule manipulation in solution.

We describe experiments which use optically heated metal nanostructures and metal films to create dynamical temperature profiles in solution. These temperature fields induce thermo-phoretic drift fields that act as effective potentials for objects suspended in liquids. As compared to their optical tweezers counterparts, thermophoretic trapping is force free. Combined with optical feedback mechanisms, such effective potentials can be shaped almost arbitrarily to store and manipulate single molecules. The inhomogeneous nature of the generated temperature fields further allows a trapping of a well defined number of molecules for interaction studies and the compression of conformational fluctuations of macromolecules. Dynamic reshaping of the virtual effective trapping potentials also provides access to fundamental principles of non-equilibrium statistical mechanics in thermal non-equilibrium such as the Jarzynski relation.

Diffracted optical vortices by an angular aperture

Angela M. Guzmán , Univ. Nacional de Colombia (Colombia); Paula López, Jesús Herman Mendoza Castro, Zayda Paola Reyes Quijano, Yezid Torres Moreno, Univ. Industrial de Santander (Colombia)

The measurement of the topological charge of laser beams with orbital angular momentum (OAM) is key to deciphering information encoded in several AOM channels. Current techniques useful for that purpose are interferometry, diffraction through triangular apertures [1], diffraction through pentagonal apertures, and azimuthal and radial decomposition [2].

A less explored issue is the effect of diffraction of OAM beams through circular sectors. Jack et al. [3] studied the angular diffraction of Gaussian beams (whose OAM is zero) through a circular sector. By means of a Fourier transform of the truncated Gaussian they showed that the orbital angular momentum spectra of the transmitted beam has a sinc-shaped envelope centered at zero orbital angular momentum, the width of which increases as

the central angle of the circular sector decreases.

We analyze here the spectra of a laser beam with integer OAM that has been diffracted by a circular sector. We present results for circular sectors of different central angles. For a circular ϖ-sector, we also study the influence of the transmittance in the OAM spectra of the transmitted beam, using intensity attenuators consisting of nanometric thin films of titanium oxide with different thicknesses.

We use a spatial light modulator to generate the incoming OAM beam [1] and measure the evolution of the intensity profile of the diffracted beam as it propagates away from the circular sector. The spectra of the diffracted OAM beams are shown numerically and experimentally to have a sinc-shaped envelope centered at the OAM value of the incoming OAM wave.

Angle-dependent rotation of calcite in elliptically polarized light

Catherine M. Herne, Natalie A. Cartwright, Matthew T. Cattani, State Univ. of New York at New Paltz (United States)

Calcite crystals trapped in an elliptically polarized laser field exhibit intriguing rotational motion. In this presentation, we show measurements of the angle-dependent motion, and discuss how the motion of birefringent calcite can be used to develop a reliable and efficient process for determining the polarization ellipticity and orientation of a laser mode. The crystals experience torque in two ways: from the transfer of spin angular momentum (SAM) from the circular polarization component of the light, and from a torque due to the linear polarization component of the light that acts to line up the optic axis of the crystal with the polarization axis of the light. These torques alternatingly compete and amplify each other, creating an oscillating rotational crystal speed. We model the behavior as a rigid body in an angle-dependent torque. We experimentally demonstrate the dependence of the rotational speed on the angular orientation of the crystal by placing the crystals in a sample solution in our trapping region, and observe their behavior under different polarization modes. Measurements are made by acquiring information simultaneously from a quadrant photodiode collecting the light after passing through the sample region, and by imaging the crystal motion onto a camera. We finish by illustrating how to use this model to predict the ellipticity of a laser mode from rotational motion of birefringent crystals.

Uncovering the radial modes of vortex beams

Bereneice Sephton, Council for Scientific and Industrial Research (South Africa) and Univ. of the Witwatersrand (South Africa); Angela Dudley, Council for Scientific and Industrial Research (South Africa); Andrew Forbes, Univ. of the Witwatersrand (South Africa)

Beams carrying orbital angular momentum (OAM) are ubiquitous in many experiments carried out today and cover a wide range of research, from surface micro-structure processing to optical tweezers and communications. It follows that these beams are a significant factor in the outcome of these research areas. They are often generated through the use of phase-only modulation with elements such as spatial light modulators and q-plates due to the simplicity of the approach. Interesting consequences result from this generation principal which include the introduction of radial modes as they propagate. We experimentally demonstrate how this effects the distribution of power where a notable decrease in the desired fundamental mode power occurs with higher OAM beams in addition to an expansion in the power across these radial modes. This research additionally affirms their mathematical description as the recently introduced Hyper-Geometric Gaussian beams.

Progress on optical trapping assay to measure DNA folding pathways in sperm

Ashley R. Carter, Luka Devenica, Amherst College (United States)

DNA undergoes a dramatic condensation in sperm nuclei. During this condensation, the DNA rapidly folds into a series of toroids when protamine proteins replace histone proteins. Measuring the mechanics and folding pathway for this incredible condensation is an important goal. Here, we report on progress to use an in vitro, optical trapping assay to measure the DNA folding dynamics for this process. In this assay, a single DNA molecule with its associated histone proteins is attached to a cover slip and to an optically trapped bead. Movement of the trapped bead applies a force on the DNA, stretching it to a particular DNA extension. When protamine is added the extension changes, allowing us to measure the preliminary folding dynamics for the process.

Investigation on unwinding motion of papillomavirus, E1 helicase with force spectroscopy

Sihwa Joo, Korea Research Institute of Bioscience and Biotechnology (Korea, Republic of); Seung-Jae Lee, Seoul National Univ. (Korea, Republic of); Bong Hyun Chung, Korea Research Institute of Bioscience and Biotechnology (Korea, Republic of); Arne Stenlund, Cold Spring Harbor Lab. (United States); Mina Lee, Korea Research Institute of Standards and Science (Korea, Republic of); Tai Hwan Ha, Korea Research Institute of Bioscience and Biotechnology (Korea, Republic of)

Like other viruses, papillomavirus replicates its genetic information using its own helicase, E1. Especially at the early stage of infection of papillomavirus, multiple copy of the viral episome by E1 is related to the success of infection. Therefore, E1 has been studied as one of the anti-viral drug targets. In addition, E1 belonging to the SFIII family is the representative helicase to study eukaryotic replication system with SV40, large T-antigen helicase. Recently, single-molecule force spectroscopies have been in the spotlight for manipulating biomolecules and mimicking in vivo environment existing tension and torque. Therefore, magnetic tweezers is a robust tool to study enzymes like helicase interacting with DNA. E1 is the mono-hexameric DNA helicase. It is known to be assembled into a hexameric form and unwind the DNA strand in the 3' to 5' direction when ATP is present. However, it is controversial whether E1 grips single strand or both strands when E1 is the active form, and it is unrevealed for the unwinding motion of E1 particularly on the long range DNA scale. Therefore, we studied dynamic motion of E1 with the hairpin constructs under tension by magnetic tweezers on various DNA length scales.

Photoionization of water molecules by a train of attosecond pulses assisted by a near-infrared laser: delay and polarization control

Lara Martini, Diego I. R. Boll, Omar A. Fojón, Consejo Nacional de Investigaciones Científicas y Técnicas (Argentina)

Basic reactions involving water molecules are essential to understand the interaction between radiation and the biological tissue because living cells are composed mostly by water. Therefore, the knowledge of ionization of the latter is crucial in many domains of Biology and Physics. So, we study theoretically the photoionization of water molecules by extreme ultraviolet attopulse trains assisted by lasers in the near-infrared range. We use a separable Coulomb-Volkov model in which the temporal evolution of the system can be divided into three stages allowing spatial and temporal separation for the Coulomb and Volkov final state wavefunctions. First, we analyze photoelectron angular distributions for di?erent delays between the attopulse train and the assistant laser field. The water molecule bound states are represented using the Moccia's monocentric wavefunctions. We compare our results for water and Ne atoms as they belong to the same isoelectronic series. Moreover, we contrast our calculations with previous theoretical and experimental work for Ar atoms due to the similarities of the orbitals involved in the reaction. Second, we study the effect of varying the relative orientations of the attopulse and laser field polarizations and we compare our predictions with other theories and experiments. We expect these studies contribute to the improvement of polarization experiments and the development of the attopulse trains and assistant laser fields technologies. Finally, we hope our work promote progress on the control of the chemical reactivity of water molecules since this could be useful in different fields such as radiobiology and medical physics.

A single-molecule study of mutual relation between the vaccinia virus E3L protein and Z-DNA by magnetic tweezers

Mina Lee, Korea Research Institute of Standards and Science (Korea, Republic of); Sihwa Joo, Bong Hyun Chung, Korea Research Institute of Bioscience and Biotechnology (Korea, Republic of)

The vaccinia virus E3L protein plays an important role in viral infection to the host and suppression of the host immune response. It contains a dsRNA binding domain and a Z-DNA binding domain at its C-terminal and N-terminal regions, respectively. Z-DNA binding motif is known to be crucial for viral pathogenesis. Since sequences capable of forming Z-DNA are frequently found in promoter region of genes and Z-DNA formation alters the transcription activity, it is likely that E3L modulates the host gene expression by binding to Z-DNA and, thus, affecting its dynamics and stability. However, the effect of E3L on the properties of Z-DNA has not been studied well yet. To address this, we used magnetic tweezers which can apply torsion and tension to biomolecules. Negative supercoiling by magnetic tweezers generated Z-DNA in physiological condition. The dynamics of Z-DNA in the presence of E3L was monitored at various tensions and torsions. Interestingly, we found that superhelical density onset for Z-DNA formation was lowered by E3L. It indicates that E3L facilitates Z-DNA formation, probably by capturing transiently formed Z-DNA. Our result suggests that E3L might alter metabolic pathway of the host genome by pushing conformational bias to Z-DNA.

Super-resolution plasmonic tweezers utilizing optical nonlinearity

Masayuki Hoshina, Nobuhiko Yokoshi, Hajime Ishihara, Osaka Prefecture Univ. (Japan)

As the laser technology advances, the targets of the laser manipulation have been shifting to nanoscale objects. One of the effective schemes to manipulate nanoparticles (NPs) such as single molecules is plasmonic tweezers, which utilizes localized surface plasmon resonance. If we create an array of metallic structures with many nanogaps (hot spots), it might be possible to trap NPs changing a trapping spot one by one with moving a laser beam. However, it will be difficult to choose a particular hot spot in the array because a number of spots are included in the beam cross-section though each spot is strongly localized beyond the diffraction limit. In order to overcome this limitation, we propose a super-resolution trapping scheme, where NPs are trapped only at a selected hot spot among multi spots in the beam cross-section.

We theoretically evaluate the radiation force exerted on a NP on the periodic metallic array assuming that the metallic array is irradiated concurrently with Gaussian and Laguerre Gaussian (LG) beams. We demonstrate that the NP is trapped only in a hot spot located at the beam center and at all the other spots covered by both the Gaussian and LG beams, NPs are repelled from the spots due to the resonant optical nonlinearity. This scheme is based on the principle similar to the stimulated emission depletion (STED) microscopy. The realization of the proposed super-resolution plasmonic tweezers will open a new avenue to develop a novel reaction field of single molecules.

Manipulation of micro-bubbles in water by CW laser

Peter P. Maksimyak, Oleg V. Angelsky, Andrew P. Maksimyak, Elena I. Kurek, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Gas and vapor bubbles of nano- and micrometric sizes in aqueous solutions are interesting for many fundamental and applied research problems: thermodynamic studies of liquid superheating and phase transitions in nano-scale, microhydraulic and micromachinery manipulation, microoptics, diverse biomedical applications including the cell investigations, precise drug delivery and therapy

In this work we demonstrate a simple scheme for generation of microbubbles and their ensembles in water suspension containing colloidal light-absorbing nanoparticles (diluted suspension of the black ink for jet printers) based on the suspension heating by the moderately focused beam of the near-IR laser. The bubbles are formed around the ink particles due to the superheated water evaporation; however, the great number of closely situated heating centers (particles) provides macroscopic collective effects of the inhomogeneous temperature distribution which can be suitably regulated by the incident laser power. As a result, we demonstrate the possibility of controllable growth of bubbles up to sub-millimeter size. Under special heating regimes, based of the special temporal variation of the incident laser power, generation of spatially-ordered systems of bubbles with controllable size distribution is shown. The bubbles obtained and their ensembles show high stability and can exist long time provided that the illumination conditions are maintained. Their spatial localization is fixed within the bright spot, and the bubbles can be transported over the liquid volume together with the focal region of the beam.

Microbubble trapping in inverted optical tweezers

Thomas J. Smart, Univ. College London (United Kingdom); Mehmet B. Ünlü, Bogaziçi Univ. (Turkey); Philip H. Jones, Univ. College London (United Kingdom)

Microbubble-enhanced ultrasound-induced sonoporation increases the permeability of cell membranes to bioactive materials. Since the cell membrane typically acts as an impenetrable barrier to water-soluble molecules, this enhanced uptake has clear implications for drug delivery and gene therapy. In order to better understand the role of microbubbles in sonoporation or to be able to develop efficient theranostic applications for microbubbles, it is crucial to have a means of manipulating and observing individual bubbles.

We have developed an inverted microscope optical tweezers for trapping and manipulation of microscopic gas bubbles. Trapping is achieved by a time-averaged optical trap using a rapidly-scanning Gaussian laser beam. Unlike holographic optical tweezers for microbubbles that employ a Laguerre-Gaussian beam, in this configuration the backwards-directed optical gradient force is sufficient to confine a microbubble against both the optical scattering force and the microbubble buoyancy. We have calibrated the optical trapping forces for microbubbles with a range of sizes, and determined the scanning trap configuration that produces the strongest confinement. These results are compared with a ray optics calculation of optical trapping force on microbubbles. Our system also includes a real-time "point-and-click" user interface for interactive selection, capture and isolation of individual microbubbles from a polydisperse population with optimal trap stiffness.

Controllable rotation of microsphere chain in dual-beam fiber-optic trap with transverse offset

Xinlin Chen, Guangzong Xiao, Xiang Han, Wei Xiong, Hui Luo, Kaiyong Yang, National Univ. of Defense Technology (China)

Controllable rotation of the trapped microscopic objects has traditionally been thought of one of the most valuable optical manipulation techniques. The controllable rotation of a microsphere chain is achieved by the dual-beam fiber-optic trap with transverse offset. The experimental device is made up of a PDMS chip housing two counter-propagating fibers across a microfluidic flow channel. Each fiber is coupled with different laser diode source to avoid the generation of coherent interference, both operating at a wavelength of 980 nm. Each fiber is attached to a translation stage to adjust the transverse offset distance. The polystyrene microspheres with diameter of 10 μm are chosen as the trapped particles. The microfluidic flow channel of the device was flushed with the polystyrene microspheres solution by the mechanical fluid pump. At the beginning, the two fibers were strictly aligned to each other. Five microspheres were captured as a chain parallel to the axis of the fibers. When introducing a transverse offset to the counter-propagating fibers by adjusting the translation stages, the microsphere chain was observed to rotating in the trap center. When the offset distance was set as 9 μm, the rotation frequency was estimated to be 0.9Hz. Experiment shows that the rotation speed increases with the offset distance. the rotation speed could be accurately controlled by adjusting the translation stages. A comprehensive analysis has been presented of the characteristics of the rotation. The functionality of rotated chain could be extended to applications requiring microfluidic mixing or to improving the reaction speed in a localized environment, and is generally applicable to biological and medical research.

Analysis of acceleration sensing in a dual-beam fiber-optic trap

Wei Xiong, Guangzong Xiao, Xiang Han, Xinlin Chen, Hui Luo, Kaiyong Yang, National Univ. of Defense Technology (China)

Optical fiber trapping is a technique utilized for manipulating micron-sized dielectric particles such as microspheres and biological cells. A dual-beam fiber-optic trap is designed to measure the acceleration in this article, which is created by the beams emerging from two coaxially aligned optical fibers. Acceleration of the system results in microparticle displacement along the sensitive axis, which is subsequently measured by optical detection to provide an acceleration measurement. We have analyzed the amplitude-frequency characteristics of the acceleration sensing system. The detection bandwidths of the system with the trapped polystyrene particles in various medium are discussed. Influences of thermal noise, detecting noise and laser noise act on the system are then analyzed. The acceleration sensing bandwidth is demonstrated to be dependent on the viscosity coefficient of the medium. The bandwidth is 1 kHz with the particle trapped in air atmosphere. And that is reduced to 1 Hz when the particle is in water. The computed results show that thermal noise (~1mg/√Hz) is the main factor that affects the acceleration-sensing ability. That can be reduced by lowering temperature and changing a low-viscosity medium. A limited sensitivity of several ?g/√Hz can be achieved when the thermal noise is ignored. Thus a low-noise and high-bandwidth acceleration sensing system based on dual-beam fiber-optic trap will be achieved with the particle in a vacuum environment.

Pancharatnam-Berry phase optical elements fabricated by 3D printing for shaping terahertz beams

Arturo I. Hernandez-Serrano, Enrique Castro-Camus, Centro de Investigaciones en Óptica, A.C. (Mexico); Dorilian Lopez-Mago, Tecnológico de Monterrey (Mexico)

The design, fabrication and characterization of space-variant Pancharatnam-Berry phase optical elements (PBOEs) is presented for the terahertz regime (THz). These PBOEs are made out of polystyrene and were fabricated by commercially available three-dimensional printers, providing a simple and inexpensive solution for the generation of THz vector beams. The polarization structure was characterized by using a THz time-domain imaging system. These devices can find applications in future THz technologies and provide new tools for the study of polarization morphologies.

10347-113, Session PWed

Analysis of the geometric phase produced by homogeneous and inhomogeneous Jones matrices for applications in space-variant polarized beams

Arturo A. Canales-Benavides, Dorilian Lopez-Mago, Raul I. Hernandez-Aranda, Julio C. Gutiérrez-Vega, Tecnológico de Monterrey (Mexico)

If light travels a set of anisotropic elements, it acquires a dynamic and a geometric phase. The former is produced by the optical path length and the latter by the evolution of the polarization state on the Poincaré sphere. Here, we provide a practical formulation to evaluate both type of phases for any polarization state entering an optical system characterized by a Jones matrix. By employing an automated and robust interferometric experiment,

we observe characteristic behaviors depending on whether the system is homogeneous, with orthogonal eigenpolarizations, or inhomogeneous, with nonorthogonal eigenpolarizations. The results apply either for classical or quantum states of light and can be used for the design of Pancharatnam-Berry phase optical elements.

10347-114, Session PWed

Formation of optical energy flows using the biaxial crystal

Peter P. Maksimyak, Oleg V. Angelsky, Andrew P. Maksimyak, Elena I. Kurek, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Separate particles of micro- or nano-scale or the ensembles of such particles merged into complex (inhomogeneous in intensity, polarization and coherence) optical field can be used for detection and diagnostics of fine effects, viz. the presence of internal energy flows at such fields determined by various factors. This problem is among topical ones at the epoch of moving from micro-optics to nano-optics.

Optical fields with rich structure of the internal energy flows we using a biaxial crystal. Propagation of a slightly divergent (conical) light beam with prescribed linear polarization generates a complicated optical field with spatially inhomogeneous distributions of the intensity, phase and polarization, that is accompanied by the intricate pattern of the transverse energy flows. Such fields offer a variety of possibilities for microparticles' trapping and control, for example:

a) the intensity minima (maxima) form natural traps for absorbing (dielectric) particles due to the gradient forces;

b) phase singularities associated with the amplitude zeros are coupled with the vortex-like orbital flows able to induce the rotation of the particles trapped;

c) both the orbital and spin flows can induce directional motion of particles in the transverse plane;

d) the spin angular momentum density of the field may induce controllable spinning motion of particles depending on their position within the beam cross section;

e) the output field pattern can be easily modified via the controllable input and output polarization, which provides suitable means for fine spatial positioning of the trapped particles.

Optical trapping with femtosecond laser pulses

Arijit K. De, Indian Institute of Science Education and Research Mohali (India); Anita Devi, Shaina Dhamija, Indian Institute of Science Education & Research Mohali (India)

Our group were the first to propose repetitive instantaneous trapping [1] and nonlinear optical effects [2] for trapping of nanoparticles. We also extended this work to Ray optics limit [3] and to arbitrary size limit (using generalized Lorentz-Mie theorem) [4, 5]. Using a home-built versatile femtosecond laser tweezer set-up, we also carried out experiments the results of which will be presented along with a discussion on the underlying theory.

Sorting and measurement of single gold nanoparticles in an optofluidic chip

Yuzhi Shi, Xiong Sha, Lip Ket Chin, Nanyang Technological Univ. (Singapore); Jiuhui Wu, Tianning Chen, Xi'an Jiaotong Univ. (China); Ai Qun Liu, Nanyang Technological Univ. (Singapore)

Gold nanoparticles have sparked strong interest owing to their unique optical and chemical properties. Their size-dependent refractive index and plasmon resonance are widely used for optical sorting, biomedicine and chemical sensing. However, there are only few examples of optical separation of different gold nanoparticles. Only separating 100-200 nm gold nanoparticles using wavelength selected resonance of the extinction spectrum has been demonstrated. This paper reports an optofluidic chip for sorting single gold nanoparticles using loosely overdamped optical potential wells, which are created by building optical and fluidic barriers. It is the first demonstration of sorting single nanoparticles with diameters ranging from 60 to 100 nm in a quasi-Bessel beam with an optical trapping stiffness from 10?10 to 10?9 N/m. The nanoparticles oscillate in the loosely overdamped potential wells with a displacement amplitude of 3–7 ?m in the microchannel. The sizes and refractive indices of the nanoparticles can be determined from their trapping positions using Drude and Mie theory, with a resolution of 0.35 nm µm?1 for the diameter, 0.0034 µm?1 and 0.0017 µm?1 for the real and imaginary parts of the refractive index, respectively. Here we experimentally demonstrate the sorting of bacteria and protozoa on the optofluidic chip. The chip has high potential for the sorting and characterisation of nanoparticles in biomedical applications such as tumour targeting, drug delivery and intracellular imaging.

Parallel alignment of bacteria using near-field optical force array for cell sorting

Haitao Zhao, Yi Zhang, Lip Ket Chin, Peng Huat Yap, Nanyang Technological Univ. (Singapore); Kuan Wang, Academia Sinica (Taiwan); Wee Ser, Ai Qun Liu, Nanyang Technological Univ. (Singapore)

This paper presents a near-field approach to align multiple rod-shaped bacteria in parallel. The conventional optical tweezer requires complex configurations, such as a dual-beam setup, to align a bacterium in-plane for direct observation, and also has limitations in parallel bacterial manipulation. In order to solve the problem, a near-field approach is proposed based on the interference pattern in silicon nano-waveguide arrays. This method is a promising toolbox for parallel single-cell analysis and is anticipated to benefit the research of single-cell biophysical characterization, cell-cell interaction, etc.

The waveguide array is composed of 101 silicon waveguides (width: 300 nm, height: 220 nm, gap: 200 nm). When a focused light (wavelength: 1550 nm, power: ~300 mW) is applied to the central waveguide, it is coupled evanescently to the adjacent waveguides and forms an interference pattern. The patterned optical field exerts two forces on the particle: a gradient force toward the surface and an overall scattering force toward the direction of light propagation. When a rod-shaped bacterium flows through the optical field, one end could be first trapped by the gradient force and then acts as an "anchor" on the surface. Thereafter, the bacterium is rotated both in the x-y plane by the scattering force to the equilibrium position, and in the x-z plane by the gradient force until contacting the surface. In the experiment, the Shigella bacteria is rotated 90 deg and aligned to horizontal direction in 9.4 s. Meanwhile, ~150 Shigella is trapped on the surface in 5 min and 86% is aligned with angle < 5 deg.

10347-118, Session PWed

Force tracing: a method to sculpt the optical force

Alireza Akbarzadeh, Foundation for Research and Technology-Hellas (Greece); Christophe Caloz, Ecole Polytechnique de Montréal (Canada)

One of the long-lasting controversies in the electrodynamics of light-matter interaction is the problem of optical momentum in a medium, which has engendered an enormous number of debates for more than a century. Aside from the prominent canonical controversy, optical force has played a crucial role in different applications such as optical trapping, optical microscopy, optical holograms, and optical tractor beams. In this presentation, we will briefly recapitulate the Abraham-Minkowski dilemma and the suggested expressions for the optical force in a medium. Then, we will describe how the fundamental connection between the energy and momentum conservation equations leads to the recently developed "force tracing" technique, which is basically a method to trace optical force fields along the trajectories of light rays. Furthermore, we will show that the force tracing technique not only significantly simplifies the conventional force computation procedure, but also offers the opportunity to sculpt the optical force in a reverse engineering approach. Accordingly, we will examine the validity of force tracing through several examples and illustrate that the Lorentz optical force density is directly proportional to the curvature of light rays. Moreover, based on the force-tracing method, we will demonstrate how graded-index lenses can be employed for interesting designs, which are offering versatile platforms for various sorts of optical manipulation such as optical sensing, space isolation, particle trapping. In this regard, we will go over the design procedures in detail and envision how optical force can lead to the formation of stable self-aligning systems made of graded-index devices.

10347-119, Session PWed

The total energy-momentum tensor for electromagnetic fields in a dielectric

Michael E. Crenshaw, U.S. Army Aviation & Missile Research, Development & Engineering Ctr. (United States)

Optically induced forces are under intensive investigation for micromanipulation and nanofabrication technology. A wide variety of physical principles have been applied to resolve issues related to momentums and optically induced forces for electromagnetic fields in dielectric media. Typically, one assumes some fundamental physical principle and the correctness of the results are affirmed by the fundamental nature of the principles that are used as the basis of the analyses. Although many well-founded theories have been advanced to resolve the physical issues, the theories are not all in agreement with each other and this leads to confusion and a lack of progress.

In a thermodynamically closed system, the total momentum, like the total energy, is a known quantity that is uniquely determined by temporal invariance. Then the construction of the unique total energy--momentum tensor resolves the Abraham--Minkowski controversy. Applying the four-divergence operator to the total energy—momentum tensor, one obtains conservation laws for the total energy and the total linear momentum. It is easily argued that the conservation law for the total energy, so obtained, cannot be incommensurate with the Poynting theorem that is systematically derived from the Maxwell field equations. It is also easily proven that the energy conservation law, derived from the four-divergence of the total energy--momentum tensor, is: 1) incommensurate with the Poynting theorem and 2) self-inconsistent because it's two non-zero terms depend on different powers of the refractive index. We discuss implications for resolution of the Abraham—Minkowski momentum controversy.

10347-79, Session 15

Probing chemical transformation in pL volume aerosol droplets

Anatolij Miloserdov, Calum P. F. Day, Antonia E. Carruthers, Newcastle Univ. (United Kingdom)

Aerosol droplets are a viable and exciting approach to probing chemical transformation and for use as chemical and environmental sensors. The nature of the air-liquid interface created through microscopic droplets existing in air can be exploited as micro-reactors to impose kinetic limitation and for fine control over reactions that require hazardous, expensive or reactive components.

Raman tweezing of aerosol is demonstrated as a route to quantify chemical and environmental change through measurement of single microscopic droplet dynamics and physical characteristics. Raman spectroscopy provides detailed insight into induced change in droplet chemistry and environment providing size, refractive index, composition, morphology, phase and mixing state information. Droplet solvent exchange mechanisms can be probed in situ through discrete control over the relative humidity of the localized environment where morphology dependent resonances provide insight into droplet physical characteristics. Aerosol equilibrated through uptake and transfer from water to heavy water is reversible and controllable allowing water diffusivity mechanisms in droplets to be studied through observation of OH and OD Raman stretches. Raman peaks arising due to the presence of solute can be exploited to extract temperature information through measurement of Stokes and anti-Stokes Raman. The relationship between these peaks are explored indicating reduced temperature as a result of the trapping laser and probe beams, and is dependent on chosen solvent.

10347-80, Session 15

Photoacoustic absorption spectroscopy of single optically trapped aerosol droplets

Ruth Signorell, Johannes Cremer, Paul Covert, ETH Zurich (Switzerland)

Within a narrow particle size distribution, the photoacoustic response from aerosols scales linearly with the particle number density. Yet, theoretical considerations indicate that particle heating and evaporation during the photoacoustic process could damp the measured response [1,2], which implies that it does not scale linearly with increases in the particle absorption cross-section that result from increases in the droplet size. To date, these effects of particle heating and evaporation upon the photoacoustic response have not been experimentally quantified.

We present the first measurements of the droplet-size-dependence of the photoacoustic response obtained from single optically-trapped aerosol droplets using our single-droplet photoacoustic spectrometer [3]. Measurements were made for a simple model system. As expected, our results show a significant nonlinearity between the magnitude of the photoacoustic signal and the absorption cross section calculated by Mie theory, especially for particles with a radius larger than 1 μm. This effect can be explained by local heat transfer processes at the surface of the particle.

The results give an experimental confirmation of the theoretical framework, improving confidence in photoacoustic absorption measurements of fine soot aerosols and opening up the possibility to correct photoacoustic field and laboratory measurements for the bias experienced when measuring the absorption of larger aerosol particles.

10347-81, Session 15

Optical trapping, pulling, and Raman spectroscopy of airborne absorbing particles based on negative photophoretic force

Gui-hua Chen, Lin He, Mu-ying Wu, Guang Yang, Dongguan Univ. of Technology (China); Yong-Qing Li, Dongguan Univ. of Technology (China) and East Carolina Univ. (United States)

Capture and characterization of small objects in air using lasers are attractive for the collection and analysis of atmospheric particles and biological aerosols. Optical pulling is the attraction of objects back to the light source by the use of optically induced “negative forces”. It is commonly expected that when illuminated by a light beam, a particle will be accelerated along the light propagation direction by radiation pressure. The idea of using laser beams to attract particles back to the light source is counterintuitive and has long been attractive to scientists. Here, we demonstrate that micron-sized absorbing particles can be optically pulled and manipulated towards the light source over a long distance in air with a collimated Gaussian laser beam based on negative photophoretic force. We also demonstrated that a variety of airborne absorbing particles can be pulled by this optical pipeline to the region where they are optically trapped with another focused Gaussian beam and their chemical compositions are characterized with Raman spectroscopy. The laser-induced photophoretic force is generated by the momentum transfer between the heating particles and surrounding gas molecules and can be several orders of magnitude larger than the radiation force and gravitation force. We found that micron-sized particles are pulled at a constant speed of 1-10 cm/s in the optical pulling pipeline and its speed can be controlled by changing the laser intensity. Optical pulling over large distances with lasers in combination with Raman spectroscopy opens up potential applications for the collection and identification of atmospheric particles.

10347-82, Session 15

Robust optical trapping and manipulation of absorbing particles in air by single dual-mode optical fiber-based tweezers

Souvik Sil, Tushar Kanti Saha, Ayan Banerjee, Indian Institute of Science Education and Research Kolkata (India)

Optical trapping of particles in air presents a challenge since the viscosity of air is extremely low so that the diffusivity of the particles is very high requiring steep confining potentials. Trapping with optical fibers should prove to be even tougher since fibers have much lower numerical aperture compared to microscope objectives, and additionally, single fibers are unable to trap particles in three dimensions using dipole forces. Photophoretic forces provide a solution towards trapping particles in air by virtue of their far stronger magnitude compared to dipole forces. In a vertical configuration trap, these forces easily balance gravity to provide stable axial trapping, and also generate a restoring force in the radial direction due to the spontaneous rotation of the trapped particle. Here, we develop a dual-mode single optical fiber based tweezers where mesoscopic absorbing particles can be trapped and manipulated employing photophoretic forces. We generate a superposition of Gaussian and Hermite-Gaussian beam modes from the optical fiber, by the simple innovation of coupling a lower wavelength laser into a commercial optical fiber designed to be single mode for a higher wavelength. The superposition mode is more effective in trapping and manipulation compared to the pure Gaussian mode, and we achieve robust trapping of the absorbing particles for hours with large manipulation velocities of 5 mm/s in the axial direction and 0.75 mm/s in the radial direction. The work has promising implications for trapping and spectroscopy of aerosols in air using simple single optical fiber-based traps.

10347-83, Session 15

A versatile system for optical manipulation experiments

Dag Hanstorp, Kelken Chang, Göteborgs Univ. (Sweden); Alvin Varghese, Cochin Univ. of Science & Technology (India); Ana Maria Gallego, Univ Nacional Autónoma de México (Mexico); Oscar K. Isaksson, Jonas Enger, Göteborgs Univ. (Sweden)

The development of a versatile experimental system for optical levitation will be presented. Microscopic liquid droplets are produced using a drop-on-demand dispenser based on piezo-driven inkjet printing technology. The vertically oriented dispenser releases the droplets towards a vertically focused 532 nm laser beam, where they are trapped. The size and position (in 3D) of trapped droplets are measured using two orthogonally placed high speed cameras, and the droplets charge is measured by recording its motion when an AC electric field is applied. Further, the charge can be altered by exposing the droplet to a radioactive source or UV light. Spectroscopic information of the trapped droplet is obtained by imaging the droplet on the entrance slit of a spectrometer. Raman spectra are obtained using the 532 nm trapping light, whereas laser induced fluorescence spectra are recorded by exciting the droplet using a cw Ti:Sa laser. Finally, the trapping cell can be evacuated, allowing investigations of droplet dynamics in vacuum and in control environments.

This system will be used to a variety of different applications. The set-up allows detailed studies of collisions of droplets, which will be used to investigate droplet coalescence for the application of rain drop formation in the atmosphere. Studies with the aim to investigate the spectroscopic signature of contaminants in droplets will be presented. Finally, the use of the system for didactic purposes as a means to demonstrate a variety of physical phenomena will be discussed.

10347-84, Session 16

Optical binding of two microparticles levitated in vacuum

Yoshihiko Arita, Univ. of St. Andrews (United Kingdom); Ewan Wright, College of Optical Sciences, The Univ. of Arizona (United States); Kishan Dholakia, Univ. of St. Andrews (United Kingdom)

Optical binding refers to an optically mediated inter-particle interaction that creates new equilibrium positions for closely spaced particles. Optical binding of mesoscopic particles levitated in vacuum can pave the way towards the realisation of a large scale quantum bound array in cavity-optomechanics. Recently we have demonstrated trapping and rotation of two mesoscopic particles in vacuum using a spatial-light-modulator-based approach to trap more than one particle, induce controlled rotation of individual particles, and mediate interparticle separation. By trapping and rotating two vaterite particles, we observe intensity modulation of the scattered light at the sum and difference frequencies with respect to the individual rotation rates. This first demonstration of optical interference between two microparticles in vacuum has lead to a platform to explore optical binding. Here we demonstrate for the first time optically bound two microparticles mediated by light scattering in vacuum. We investigate autocorrelations between the two normal modes of oscillation, which are determined by the centre-of-mass and the relative positions of the two-particle system. In situ determination of the optical restoring force acting on the bound particles are based on measurement of the oscillation frequencies of the autocorrelation functions of the two normal modes, thereby providing a powerful and original platform to explore multiparticle entanglement in cavity-optomechanics.

10347-86, Session 16

Towards large-scale optically bound nanoparticles

Fei Han, Zijie Yan, Clarkson Univ. (United States)

Optical matter is a unique class of materials formed by pure electrodynamic interactions of colloidal particles in an optical field, yet previous research on optical matter was almost limited to microparticle systems. Some recent experimental studies, including ours, have extended the boundary of optical matter into nanometer regime, but it remains a significant challenge to build large-scale optical matter with even more than 10 nanoparticles. Here we report our ongoing work on light-driven self-organization of plasmonic nanoparticles into mesoscale clusters and arrays. We use advanced laser beam shaping techniques and the significant electrodynamic interactions among strongly scattering Ag nanoparticles to stabilize the self-organization. By simultaneously controlling the intensity, phase and polarization of light, we can design and tailor the optical field to assemble stable optical matter with more nanoparticles, and reveal new structures arising from optical binding interactions.

10347-87, Session 16

Dynamics of optically bound knotted and chiral nanoparticles

Simon Hanna, Univ. of Bristol (United Kingdom); Stephen H. Simpson, Institute of Scientific Instruments of the ASCR, v.v.i. (Czech Republic)

We use computer simulations to explore the dynamical behaviour of optically bound assemblies of knotted and chiral nanoparticles. The knotted nanowire is not naturally occurring, but may be fabricated using two-photon polymerisation. Collections of such knots in circularly polarised counter-propagating plane waves form ordered arrays which rotate through interaction with the angular momentum of the beams. However, different types of behaviour are observed, depending on the size of the nanoparticles, their separation and the number of particles involved. Individual knotted or chiral particles will spin about their centres of mass while, at the same time, orbiting about each other. The sense of the spin and orbital motion (clockwise or anti-clockwise) can be the same or opposite in a given system, and can change with the sizes of the particles, which appears to be a consequence of the overlap between the particles and the intense regions of the optical field. Rotational synchronisation effects are also observed. Potential applications of the system as an optically-driven micro-machine are explored.

10347-88, Session 17

Nanoparticle size selection using near-field microphotonic array traps

Aravind Krishnan, Shao-Hua Wu, Michelle L. Povinelli, The Univ. of Southern California (United States)

Our experiments have used arrayed traps in the near field of a photonic crystal to selectively capture nanoparticles by size. The photonic crystal is designed to support a guided resonance mode, and the incident laser is tuned to the resonance wavelength. Each hole of the photonic crystal acts as a trapping site.

In this work, we use simulations of particle dynamics to determine the optimal experimental conditions for size selection. We include the effects of optical forces, fluid flow, and Brownian motion and explicitly track the trajectories of particles near an array of trapping sites. We study the effects of varying chamber height, flow rate, and particle concentration on size selectivity and trapping yield. We further present photonic crystal designs for selectively trapping smaller or larger particles out of mixed-particle solutions.

10347-89, Session 17

Particle trapping and hopping in an optofluidic lattice

Yuzhi Shi, Xiong Sha, Lip Ket Chin, Nanyang Technological Univ. (Singapore); Jiuhui Wu, Tianning Chen, Xi'an Jiaotong Univ. (China); Ai Qun Liu, Nanyang Technological Univ. (Singapore)

Particle jumping between optical potentials has attracted much attention owing to its extensive involvement in many physical and biological experiments. In some circumstances, particle jumping indicates escaping from the optical trap, which is an issue people are trying to avoid. Nevertheless, particle jumping can facilitate the individual trap in each laser spot in the optical lattice and enable sorting and delivery of nanoparticles. Particle hopping has not been seen in fluid because Fluidic drag force dramatically reduce the dwell time of particle or break the potential well. Here, we observe particle hopping in the microchannel by three reasons, e.g., particle collision or aggregation, light disturbing by pre-trapped particle and fake trapping position. We show that commonly ignored particle influence to the light could create a new isolated trapping position, where particle hops to the adjacent potential well. The hopping happens in an optofluidic fishnet which is comprised of discrete hotspots enabling 2D patterning of particles in the flow stream for the first time. We also achieve a 2D patterning of cryptosporidium in the microchannel. Our observed particle hopping in the flow stream completes the family of particle kinetics in potential wells and inspires new interests in the particle disturbed optical trapping. The 2D patterning of particles benefits the parallel study of biological samples in the flow stream and have potential on cell sorting and drug delivery.

10347-90, Session 17

Tracking Brownian particles in a standing-wave Bessel beam 2D optical trap

Keith D. Bonin, Chad McKell, Wake Forest Univ. (United States)

Optical traps are useful for manipulating small particles in fluid media. The motion of a particle in a fluid is determined by the viscoelastic properties that characterize the fluid as well as the proximity of nearby surfaces, especially in the case of microfluidics, where structural features are small. We have been working toward the goal of developing a method for loosely trapping particles in a plane, so that they can be readily tracked in a microscope, and stay in the imaging plane because of their 2D confinement. Our initial experiments, which we report here, use a standing wave optical trap formed by counter-propagating Bessel beams. A Bessel beam was chosen to produce a trapping region that is larger, with reduced center-zone diffraction, than a typical Gaussian beam. We will report on our initial characterization of the standing wave Bessel beam trap using latex sphere probes of 3 different diameters: 100, 200, and 300 nm. We will demonstrate that we can successfully trap such small particles in a 2D region, and track the motion of the beads within the 2D trap.

10347-91, Session 17

Dielectrophoretic focusing integrated pulsed laser activeted cell sorting

Xiongfeng Zhu, Yu-Chun Kung, Univ. of California, Los Angeles (United States); Ting-Hsiang Wu, NantWorks, LLC (United States); Michael A. Teitell, Pei-Yu E. Chiou, Univ. of California, Los Angeles (United States)

We present a pulsed laser activated cell sorter (PLACS) integrated with novel sheathless size-independent dielectrophoretic (DEP) focusing. Microfluidic fluorescence activated cell sorting (?FACS) systems aim to

provide a fully enclosed environment for sterile cell sorting and integration with upstream and downstream microfluidic modules. Among them, PLACS has shown a great potential in achieving comparable performance to commercial aerosol-based FACS (>90% purity at 25,000 cells sec?1). However conventional sheath flow focusing method suffers a severe sample dilution issue. Here we demonstrate a novel dielectrophoresis-integrated pulsed laser activated cell sorter (DEP-PLACS). It consists of a microfluidic channel with 3D electrodes laid out to provide a tunnel-shaped electric field profile along a 4cm-long channel for sheathlessly focusing microparticles/cells into a single stream in high-speed microfluidic flows. 10?m polystyrene beads can be focused at a particle speed up to 16 cm/s in high conductivity media (1 S/m). All focused particles pass through the fluorescence detection zone along the same streamline regardless of their sizes and types. Upon detection of target fluorescent particles, a nanosecond laser pulse is triggered and focused in a neighboring channel to generate a rapidly expanding cavitation bubble for precise sorting. DEP-PLACS has achieved a sorting purity of 91% for polystyrene beads at a throughput of 1,500 particle/sec.

10347-92, Session 17

Nanoparticle sorting in silicon waveguide arrays

Haitao Zhao, Yi Zhang, Lip Ket Chin, Peng Huat Yap, Nanyang Technological Univ. (Singapore); Kuan Wang, Academia Sinica (Taiwan); Wee Ser, Ai Qun Liu, Nanyang Technological Univ. (Singapore)

This paper presents a near-field approach to sort nanoparticles. The far-field approach, such as optical lattice, has difficulty in sorting nano-sized particles due to the large spot size limited by the diffraction barrier, while the conventional near-field approach generally has small light-particle interaction area and hence cannot manipulate nanoparticles massively. In order to avoid these drawbacks, a near-field approach is proposed based on the interference pattern in silicon waveguide arrays. This method has high potential in nanoparticle and biomolecule sorting.

The interference pattern is generated in waveguide arrays which are composed of 101 silicon nano-waveguides. When a focused light (? = 1550 nm, power = ~300 mW) is applied to the central waveguide, it is coupled to the adjacent waveguides and forms the interference pattern. The optical field will exert two forces on particles: the gradient force perpendicular to the waveguide surface and the scattering force along the light propagation. The vertical gradient force, induced by the evanescent wave, is large enough to trap both small and large particles onto the waveguide surface. Whereas the scattering force is only sufficient to push large particles toward the waveguide end. Therefore, the small and large particles can be separated efficiently. In the experiment, 300-nm and 500-nm polystyrene particles are separated as a demonstration. In a duration of 3 min, 93% of the 300-nm particles are trapped on the surface and move slightly near to the trapping position. Meanwhile, all the 500-nm particles are trapped and 85% of them are pushed to the waveguide end with an average lateral velocity of 7 ?m/s.

10347-93, Session 18

Optothermal assemblers and tweezers

(Invited Paper)

Yuebing Zheng, The Univ. of Texas at Austin (United States)

We exploit optothermal effects to realize versatile assembly and manipulation of colloidal particles and biological cells at low optical power and with simple optics. In this talk, I will present working principles and applications of the optothermal assemblers and tweezers that we have developed over the past three years. These include bubble-pen lithography, thermophoretic tweezers, reversible particle assembly, reversible particle printing, and colloidal lego.

10347-95, Session 18

Blue- and red-detuned laser trapping of individual dye-doped polystyrene particles

Tetsuhiro Kudo, National Chiao Tung Univ. (Taiwan); Hajime Ishihara, Osaka Prefecture Univ. (Japan); Hiroshi Masuhara, National Chiao Tung Univ. (Taiwan)

Optical trapping using the laser whose energy is resonant to electronic transition of the objects, leads to the manipulation of molecules, quantum dots, metal nanoparticles and various nanomaterials based on their quantum mechanical properties. Based on linear optical response theory with two-level model, it has been conventionally believed that attractive force is exerted on the object with the laser red-detuned from its electronic resonance peak, and the blue-detuned one induces the repulsive force.

However, there are experimental reports tell us blue-detuned laser can trap the dye molecules and nanoparticles efficiently. Motivated by these facts and in order to elucidate this contradiction, previously we proposed the nonlinear optical response theory of optical force with three-level system dyes, and we found blue-detuned laser provides the deeper optical potential compared with red-detuned one. Here, we experimentally demonstrate the resonance optical trapping of individual dye-doped polystyrene particles with the blue- and red-detuned lasers. We confirm that irradiation of blue-detuned laser can trap the particle much longer compared with that by red-one. The present study is very important step toward resonance optical trapping, and it will be possible to selectively trap the specific molecules, quantum dots and metal nanoparticles with tuning the wavelength of trapping laser.

10347-96, Session 19

A compact multi-trap optical tweezer system based on CD-ROM technologies

Thomas J. McMenamin, Woei Ming Lee, The Australian National Univ. (Australia)

Existing beam steering/shaping methods using acoustic optical deflectors, spatial light modulators and rapid scanning mirror has provided the ability to multiplex a single beam optical trap. This multiplexing ability offer users the ability to exert several trapping positions in the sample. However, these beam steering methods require extensive 4-f configurations. In this work, we demonstrate that a compact lens-scanning based system, based on an optical pickup unit (OPU), can be engineered to generate multiple optical traps. The crux of the technique is to alternate the pulsing of the compact laser diode at a rate synchronised with the oscillation of the objective lens, and compensating for the varied speed of the lens oscillation. By using this, we are also able to create a mixture of line and point trap geometries, and have these traps change position and shape over time as required by typical trapping experiments. The OPU used contains laser diode sources of multiple wavelengths (405nm, 650nm, 780nm) as well as a scanning objective lens of sufficient NA (0.65) for optical trapping. In addition, we constructed a compact darkfield system to visualise scattering light. The system has been demonstrated by experiments where microparticles and giant unilamellar vesicles (GUVs) have been optically trapped, moved and clearly imaged.

10347-97, Session 19

A biophotonics platform based on optical trapping of photonic membranes

Blair C. Kirkpatrick, Univ. of St. Andrews (United Kingdom); Tomá? ?i?már, Univ. of Dundee (United Kingdom); Kishan Dholakia, Andrea Di Falco, Univ. of St. Andrews (United Kingdom)

We present a biophotonics platform based on the optical manipulation of

photonic membranes via holographical tweezers. We review the fabrication and manipulation protocol which grants full six-degrees-of-freedom control over these membranes. This is despite the membranes having extreme aspect ratios, being 90 nm in thickness and 15 - 20 microns in side length.

The photonic properties of the trapped membranes can be tailored to very specific applications, by structuring their topology carefully. Our method merges the flexibility of photonic design of optical meta-surfaces with the advanced manipulation capability offered by holographic optical tweezers.

Here we demonstrate the validity of our approach, discussing the peculiar mechanical properties of trapped photonic membranes. Specifically, we focus on imaging and surface-enhanced Raman spectroscopy applications.

10347-98, Session 19

Photochemical tweezing of films of polymer

Zouheir Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

In this talk, I will discuss optical micro/nanomanipulation of films of photosensitive polymers in gradients of light Intensity. The polymers contain an azo dye molecule that undergo reversible photoisomerization, i.e. a molecular machine, and move in gradients of light intensity; a motion which is fuelled by a photochemical potential. The latter leads to a photochemical force that opposes the “classical” optical tweezing force, and the polymer moves away from the light into the dark.

10347-99, Session 19

Photonic arms, legs, and skin *(Invited Paper)*

Diederik S. Wiersma, LENS - Lab. Europeo di Spettroscopie Non-Lineari (Italy)

In this contribution we will report on a new adventure in the field of photonics, combining the optical control of photonic materials with that of true micro meter scale robotics. We will show how one can create complex photonic structures using polymers that respond to optical stimuli, and how this technology can be used to create moving elements, photonic skin, and even complete micro meter size robots that can walk and swim. using environment light as the only source of energy. The materials that we have developed to that end can also be used to realise tunable photonic components that respond to light and adapt their photonic response on the basis of the illumination conditions.

Conference 10348: Physical Chemistry of Semiconductor Materials and Interfaces XVI

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Sunday - Wednesday 6 –9 August 2017

Part of Proceedings of SPIE Vol. 10348 Physical Chemistry of Semiconductor Materials and Interfaces XVI

10348-1, Session 1

Electronic processes, morphologies, and structural-functional correlations in conjugated oligomers and polymers for OPV *(Invited Paper)*

Lin X. Chen, Northwestern Univ. (United States) and Argonne National Lab. (United States)

Conjugated polymers with charge transfer characters in a large extend are responsible for the recent advancement in organic photovoltaic (OPV) applications in bulk heterojunction (BHJ) devices. We have carried out collaborative studies on electronic processes and in-situ morphological development of these low bandgap polymers and small molecules using ultrafast optical spectroscopy and in-situ grazing incident X-ray scattering (GIXS). Conventional organic photovoltaic models, in which donor molecules are treated as anonymous electron sources and charge carrier diffusion channels, are challenged by near-infrared transient absorption results of low bandgap polymers indicating strong correlations between intramolecular donor dynamics in < 100 fs and corresponding device power conversion efficiencies. The other conventional model being challenged is the driving force for exciton splitting in the bulk heterojunction environment which has been described by the LUMO-LUMO energy off-set between conjugated polymer electron donor and fullerene derivative electron acceptor. Our study suggests the intramolecular charge transfer characters must be combined with local and global conformations of conjugated polymer chains to achieve the low band gap. Moreover, the morphology of the BHJ films is also investigated by in-situ GIWAS/GISAX methods including the effects of additives which suggest the interplays of the additives and the polymers in solution. The morphology of the heterojunction films has been correlated directly with the yield of the charge separation on time scales from femtosecond to microsecond. In addition, new photophysical studies are also carried out on a series of metal chelating conjugated polymers showing the capability and potential in photocatalytic hydrogen generation.

10348-2, Session 1

Nanoscale energetic mapping of bulk heterojunction solar cells

Sukumar Dey, Hanlin Hu, Weimin Zhang, Iain Macculloch, Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

The nanoscale organization and corresponding electronic properties of a photoactive donor-acceptor blend layers based on regioregular poly (3-hexylthiophene) (RR-P3HT) donor with fullerene and non-fullerene acceptors on Au(111) substrate has been studied using scanning tunneling microscopy and spectroscopy (STM/STS). Subsequent to annealing treatment, STM topography and dI/dV images are observed as a combination of phase-separated donor-rich, acceptor-rich, and mixed donor-acceptor domains. This technique permits to explore simultaneously the quantitative linkage between the nanoscale morphologies and corresponding local electronic properties. We determine the HOMO and LUMO-edges at the individual domains and interfacial band alignments of the donor-acceptor interface. We have observed a noteworthy deeper HOMO energy of RR-P3HT in mixed-region associated primarily with the degree of disorder-induced band gap widening of the polymer and donor:acceptor intermolecular interactions. Similarly, LUMO of the acceptor in the mixed region is also raised due to intermolecular interaction. These energetic difference in the mixed phase is likely to be responsible for the reduced recombination in bulk heterojunction (BHJ). Hence, this characterization provides nanoscale insight to the annealing-induced morphological organization and corresponding local electronic properties account for an impressive increase of the charge generation, transport and corresponding device performance of the BHJ solar cells.

10348-3, Session 1

Electronic structure and ion migration in lead-halide perovskites: a first-principles perspective *(Invited Paper)*

Leeor Kronik, Weizmann Institute of Science (Israel)

Power-conversion efficiencies of lead-halide perovskite (LHP) solar cells have rapidly improved and already well-surpassed 20%. This is impressive, especially because high-quality LHP crystals can be synthesized by relatively simple means, potentially offering new routes to cheaper high-efficiency cells. However, the microscopic origins and present limitations of the impressive photovoltaic and charge-transport properties of LHPs are far from being fully understood.

Here, I will briefly discuss the electronic-structure properties of LHPs based on a comparison between density functional theory (DFT) and direct and inverse photoemission spectroscopy (PES) and discuss how it is conducive to photovoltaic performance. I will then show, based on nudged-elastic band calculations, that ion migration may also play a key role, both positive and negative, in LHP properties in general and stability in particular.

10348-4, Session 2

In situ transient absorption of thin film formation *(Invited Paper)*

Cathy Y. Wong, Kelly S. Wilson, Univ. of Oregon (United States)

The electronic structure and exciton dynamics of solution deposited thin films are principal factors which determine the utility of a film for photovoltaic, transistor, or solid state lighting applications. These properties are typically measured in films after they have been prepared, but rarely during their preparation. Transient absorption spectroscopy can report on exciton dynamics by probing a sample at different delay times after a pump beam photogenerates a population of excitons. Transients are typically accumulated sequentially, with an individual differential absorption spectrum measured at each pump-probe delay time. This precludes the measurement of any system which changes during the collection period, which can span many minutes. In this work, we reveal the exciton dynamics of evolving chemical systems using a novel implementation of transient absorption whereby entire transients can be collected in a few laser shots. The exciton dynamics measured during the solution deposition of a thin film are validated by comparing the initial dynamics of the solution and the final dynamics of the dry film to traditional sequential transient absorption measurements. The dynamics during the film formation process will be presented for the first time. The information gained using this technique can be used to modify environmental parameters during the film formation process to enable the production of materials with tailored exciton dynamics.

10348-6, Session 2

Intra- and inter-molecular energy transfer in organic semiconductors: insights from nonadiabatic dynamics simulations *(Invited Paper)*

Sergei Tretiak, Los Alamos National Lab. (United States)

Using non-adiabatic excited-state dynamics simulations framework, we study ultrafast dynamics and exciton transport in several molecular systems. These simulations reveal an interplay of conformational vibrational

dynamics, internal conversion and energy transfer processes followed photoexcitation, which have specific spectroscopic signatures. For example, an efficient through-bond energy transfer occurs in the absence of spectral overlap between the donor and acceptor units being assisted by a transient delocalization of the wavefunction. Observed relationships between spatial extent/properties of electronic excitations and electronic functionalities allow us to understand excited state dynamics and energy transfer pathways in a number of organic molecular materials.

10348-7, Session 3

Optoelectronic properties of Ruddlseden-Popper phase halide perovskites *(Invited Paper)*

Adiitya D. Mohite, Los Alamos National Lab. (United States)

Understanding and controlling charge and energy flow in state-of-the-art semiconductor quantum-wells has enabled high-efficiency optoelectronic devices such as multijunction solar cells and light emission devices. Two-dimensional Ruddlesden-Popper perovskites are solution-processed quantum-wells wherein the bandgap can be tuned by varying the perovskite layer thickness, which modulates the effective electron-hole confinement. In my talk, I will describe new results on Ruddlesden-Popper phase perovskites based devices. In our first few attempts, we fabricated solar cells with efficiency approaching 13% as compared to the previous best of 4.5%. This phenomenal increase in efficiency is attributed to the near single-crystalline quality thin-films with a strongly preferential out-of-plane alignment of the inorganic perovskite component that facilitates efficient charge transport. Photovoltaic devices exhibit no hysteresis or degradation in performance under continuous operation and withstand an illumination intensity up to 4-Suns. Importantly, these devices with layered perovskites exhibit extraordinary, technologically relevant stability with no loss in performance with for ~2000 hours under humidity and 1-SUN full spectrum illumination. Finally, I will describe results on using these novel materials for light-emission applications and also discuss exciton dissociation mechanisms and how they vary with dielectric confinement.

10348-8, Session 3

Energy level alignment in hybrid perovskite solar cells *(Invited Paper)*

Philip Schulz, National Renewable Energy Lab. (United States)

The ongoing development of hybrid organic inorganic perovskite photovoltaics has revealed that the numerous interfaces in perovskite solar cells (PSC) play crucial roles for device efficiency and stability. Importantly, many critical interfacial properties are still poorly understood, a deficiency that often limits efforts to improve device performance. In this talk I will present our most recent results exploring the mechanisms by which transition metal oxide and carbon nanotube layers enable or suppress charge carrier extraction from the absorber.

We use photoemission spectroscopy and optical spectroscopy to probe the energetic alignment between a set of various lead halide based perovskite absorber films and different charge transport layers. We find that for comparable charge transport layers the energetic alignment can vary as a function of the halide composition in the perovskite which has further implications on the implementation in the device geometry. In one example, we show that ground state charge transfer between perovskite and transport material can lead to band bending in the transport layer such as a film of single-walled carbon nanotubes which is beneficial for charge transport away from the interface. Thus, we demonstrate, that integrated as a thin interlayer, carbon nanotubes can facilitate rapid charge carrier collection and thus improve PSC performance. In contrast to this observation, band bending induced in the perovskite film by the charge transport material such as high work function oxides can be detrimental for charge carrier collection and thus impede device functionality.

10348-9, Session 3

Colloidal APbX3 nanocrystals [A=Cs+, CH3NH3+, CH(NH2)2+] with bright photoluminescence spanning from ultraviolet to near-infrared spectral regions *(Invited Paper)*

Maksym V. Kovalenko, ETH Zurich (Switzerland)

Chemically synthesized inorganic nanocrystals (NCs) are considered to be promising building blocks for a broad spectrum of applications including electronic, thermoelectric, and photovoltaic devices. We have synthesized monodisperse colloidal nanocubes (4-15 nm edge lengths) of fully inorganic cesium lead halide perovskites (CsPbX3, X=Cl, Br, and I or mixed halide systems Cl/Br and Br/I) using inexpensive commercial precursors [1]. Their bandgap energies and emission spectra are readily tunable over the entire visible spectral region of 410-700 nm. The photoluminescence of CsPbX3 NCs is characterized by narrow emission line-widths of 12-42 nm, wide color gamut covering up to 140% of the NTSC color standard, high quantum yields of up to 90% and also low thresholds for stimulated emission [2]. Post-synthetic chemical transformations of colloidal NCs, such as ion-exchange reactions, provide an avenue to compositional fine tuning or to otherwise inaccessible materials and morphologies [3]. Similar synthesis methodologies are well suited also for hybrid perovskite nanocrystals based on methylammonium (MA) and formamidinium cations (FA): MAPbX3 [4], FAPbBr3 [5], Cs1-xFAxPbI3 and FAPbI3 [6]. In particular, Cs- and FA-based NCs (Figure below) are highly promising for luminescence downconversion (bright and narrow emission at 530 and 640 nm), for infrared light-emitting diodes and as precursors/inks for perovskite solar cells. In this talk, we will discuss the synthesis methodologies and optical properties of these novel APbX3 NCs.

High efficiency OLEDs enabled by molecular rotation *(Invited Paper)*

Dan Credgington, Univ. of Cambridge (United Kingdom)

Excitonic spin plays a crucial role in the design of organic light emitting diodes (OLEDs). The random spin statistics of recombining charge sets a limit of 25% on the fraction of singlet (spin-0) excitons formed by electrical excitation. Without efficient emission from triplet (spin-1) excitons, the same limit applies to the internal quantum efficiency (IQE) of fluorescent OLEDs. Phosphorescent OLEDs, utilising the heavy atom effect to render triplets emissive, and TADF OLEDs, based on thermally-assisted triplet-to-singlet up-conversion, are currently the most promising routes for triplet emission.

Here we demonstrate a different approach. The effective exchange energy in a family of linear copper and gold carbene metal amide compounds can be tuned via rotation about the metal-amide bond from positive to negative values. The energetic ordering of spin-states can therefore be inverted, enabling triplet-to-singlet down-conversion. The availability of degenerate states with high oscillator strength allows emission via triplets to occur on sub-microsecond timescales. Using such materials as emissive dopants in solution-processed OLEDs leads to extremely efficient devices with near 100% IQE (external quantum efficiencies >27%), and current efficiency, power efficiency and brightness comparable to or exceeding those of state-of-the-art vacuum-deposited OLEDs and quantum dot LEDs.

We describe the experimental and theoretical evidence for rotationally accessed spin-state inversion. Using time-resolved spectroscopy we show how the resulting emission depends strongly in the interplay between

rotational energetics, temperature, oscillator strength and the morphology of the emissive layer.

10348-11, Session 4

Determining charge carrier extraction in lead sulfide quantum dot near infrared photodetectors

Epimitheas Georgitzikis, IMEC (Belgium) and KU Leuven (Belgium); Pawel E. Malinowski, IMEC (Belgium); Mehedi Mamun, IMEC (Belgium) and Univ. Gent (Belgium); Oscar Enzing, IMEC (Belgium); Jorick Maes, Zeger Hens, Univ. Gent (Belgium); Paul Heremans, IMEC (Belgium) and KU Leuven (Belgium); David Cheyns, IMEC (Belgium)

Colloidal quantum dots (QDs) based on lead sulfide (PbS) have acquired scientific interest for infrared optoelectronic devices with potential bandgap tunability and ease of fabrication on arbitrary substrates. In this work, we show how device analysis data feed back into process optimization, towards the realization of high performance QD NIR photodetectors. Using the combination of transient PL, carrier transport and CV measurements we obtain the carrier density, lifetime and diffusion length in the layers. From the measured short diffusion length of the minority carriers, we deduce the need to achieve a wide depletion region to minimize recombination and thus enhance the carrier harvesting. Process optimization lead to a depletion region of more than 150 nm, resulting in high photon to carrier conversion. Furthermore, the complex index of refraction of all layers is characterized using ellipsometry and reflection/transmission, and these values are used as input for a transfer matrix method. Using the first interference peak, we show that a maximum EQE of 25% can be expected from optical modeling, a value that we almost reach experimentally (20%). Combining all of the above, we demonstrate 1450-nm photodetectors with dark current in the range of ?A and specific detectivity (D*) of 10^11 Jones.

10348-12, Session 4

Engineering hybrid interfaces in organic and perovskite optoelectronic devices *(Invited Paper)*

Yana Vaynzof, Heidelberg Univ. (Germany); Paul Hopkinson, Yunus Sevinchan, Carsten Hinzmann, Qingzhi An, Yvonne Hofstetter, Paul Fassl, David Backer-Koch, Ruprecht-Karls-Univ. Heidelberg (Germany); Osnat Magen, Technion-Israel Institute of Technology (Israel); Artem A. Bakulin, Imperial College London (United Kingdom); Nir Tessler, Technion-Israel Institute of Technology (Israel)

Hybrid interfaces such as organic/inorganic or inorganic/perovskite are commonly found in organic and perovskite optoelectronic devices. Many fundamental processes (e.g. charge separation, charge injection and extraction) take place at hybrid interfaces and have a significant impact on the device performance.

We will present three examples in which engineering of hybrid interface properties results in improvements in the device performance. In the case of hybrid organic-inorganic photovoltaic devices, we show that such improvements may be achieved by either organic or inorganic modifiers, or alternatively by introducing a dopant into the inorganic layer. These modifications result in an enhancement in the photo-induced charge separation efficiency, which is related to the density of the sub-bandgap states in the inorganic layer.

Next, we will demonstrate that interfacial sub-bandgap states at an inorganic/organic interface can influence charge injection in organic light-emitting diodes. By combining experimental results and modelling we show that not only the density, but especially the energetic position of these states determines the overall charge injection efficiency.

Finally, we will present how modifying both the bulk and interfacial properties of a metal oxide electron extraction layer can enhance the performance of perovskite solar cells. In this case, we find that surface modification by a self-assembled monolayer results in an improved perovskite film formation, while doping of the metal oxide improves its stoichiometry and as a result, enhances electron extraction.

10348-13, Session 4

Ion migration in organo lead halide perovskite based photovoltaic devices *(Invited Paper)*

Sven Huettner, Univ. Bayreuth (Germany)

The fundamental physics in organic-inorganic metal-halide perovskites, is still not sufficiently understood. Applied in photovoltaic devices, organolead halide based solar cells may suffer from hysteresis, that is the difference of the I-V curve during sweeping in two directions. This behaviour significantly influences the large-scale commercial application and seems to have its origin in ionic migration and directly affects stability and device performance. To investigate the mechanisms, we employ a combination of methods that help to identify the origin and effect of ion migration. We use electroabsorption spectroscopy, to explore the built-in potential, track the temperature dependent J-V behaviour and related current relaxation processes and perform X-ray photoemission spectroscopy experiments, showing the redistribution of iodine after applying a constant voltage. In addition, we carry out fluorescence microscopy under an electrical field which allows us to directly track the migration and accumulation of ions. This experiment allows to study the dynamic process of – in this case - iodide ions under an external electrical field and lets us estimate their mobility and diffusion constan. We associate the migration/accumulation of iodide ions with the modulation of interfacial barrier between perovskite and electrodes which gives rise to the shift of the built-in potential. We investigate the influence of PCBM on the migration of ions, which appears to be impeded by the presence of interdiffused PCBM molecules. Furthermore, photoluminescence microscopy gives access to interesting phenomena which are related to the presence of ions, such as blinking or long-term intensity changes in the emission signal.

10348-14, Session 4

Impact of band structure on recombination and efficiency in halide perovskite solar cells close to the radiative limit *(Invited Paper)*

Thomas Kirchartz, Uwe Rau, Forschungszentrum Jülich GmbH (Germany)

Some metal-halide perovskites have exceptionally good optoelectronic properties that make the materials attractive for applications in photovoltaics and other optoelectronic applications. Among the most remarkable properties are the extremely long charge-carrier lifetimes and high open-circuit voltages that are observed in thin films of CH3NH3PbI3. Recently, several explanations have been brought forward that connect the high lifetimes and Vocs with peculiar properties of the band structure of perovskites, in particular (i) the combination of a direct and an indirect band gap with a small energy offset and (ii) the low effective density of states. Here, we show how the direct-indirect combination of band gaps can indeed lead to longer lifetimes but the recombination rate, which is proportional to the ratio of the equilibrium carrier concentrations and the lifetime is likely to remain constant or constant. Therefore, the direct-indirect combination can explain good charge carrier collection but not high open-circuit voltages. This is different for the second feature of the band structure, namely the low effective density of states, which is combined with a high absorption coefficient. This is only possible of the matrix transition elements are high in perovskites. While for a given absorption coefficient, the effective density of states is irrelevant in the radiative limit at high mobilities, this is not the case if non-radiative recombination is present. This means, the high absorption at

low densities of states can indeed help the open-circuit voltage come closer to its radiative limit.

10348-54, Session 4

Heavy atom organic semiconductors *(Invited Paper)*

Dwight Seferos, Univ. of Toronto (Canada)

For over 7 years my group has been fascinated by how tellurium and selenium can influence the optoelectronic properties of conjugated electronic materials. Some of our work has focused on the development of conjugated polymers that self organize at the nanoscale by spontaneous phase-separation. We have been interested in conjuged block copolymers where each block contains a distinct heterocycle. These polymers are fundementally important for testing the limits of polymer phase separation. They are also useful in optoelectronic devices where nanoscale structure is important, such as solar cells. In this context we have developed selenophene-thiophene block copolymers and discovered that these copolymers undergo a significant amount of phase separation. This is surprising given the chemical similarity of the repeat units, however we have uncovered several properties, including crystal packing, that differ in these polyheterocycles. By increasing the compatibility of the selenophene and thiophene units and we observe co-crystallization in statistical copolymers. These statistical copolymers form nanowires and when fabricated into nanowire solar cells they operate with a greater efficiency than cells composed of homopolymer nanowires. We have also learned how to synthesize polymers and delocalized molecules based on tellurophene, and identified several unexpected properties in these materials including reversible binding of small molecules, and the ability to photo-reductively eliminate halogens. The synthesis, properties and optical applications of these materials will be discussed.

10348-15, Session 5

Mechanisms underlying emission quenching in conjugated polymers: the role of inter-chain interactions

Linda A. Peteanu, Eric C. Wu, Carnegie Mellon Univ. (United States); Matthew Y. Sfeir, Brookhaven National Lab. (United States)

Applications of conjugated polymers in photovoltaics and displays drive the need to understand how morphology and aggregation affect emission yields, spectra, and the facility with which charges are generated and migrate through the sample. It is known that solvent-polymer interactions in solution critically affect the properties of thin films formed when these solutions are evaporated onto substrates. Our work demonstrates that the propensity of conjugated oligomers and polymers to form emissive versus non-emissive aggregates in solution and in thin films is likewise governed by the solvent properties. Fluorescence correlation spectroscopy is used as a tool to identify both emissive and non-emissive species in dilute solutions while dynamic light scattering (DLS) is used to measure diffusion properties. In some solvents, such as toluene, conjugated materials form non-emissive aggregates even at picomolar concentrations. Under similar conditions, the same materials exhibit single-emitter properties in more polar solvents such as tetrahydrofuran (THF). These distinctions persist when the molecules are forcibly aggregated by addition of poor solvent and are correlated to variations in chain packing within the aggregate due to differences in their preferred conformation. Transient absorption spectroscopy is used to understand the impact of altering chain packing on the propensity for energy transfer and charge separation in the aggregated state and in films.

10348-16, Session 5

Intermolecular charge-transfer states for organic opto-electronics *(Invited Paper)*

Koen Vandewal, TU Dresden (Germany)

Intermolecular charge transfer (CT) states at the interface between electron-donating and electron-accepting (A) materials in organic thin films are characterized by absorption and emission bands within the optical gap of the interfacing materials. Depending on the used donor and acceptor materials, CT states can be very emissive, or generate free carriers at high yield. The former can result in rather efficient organic light emitting diodes, via thermally activated delayed fluorescence, while the latter property is exploited in organic photovoltaic devices and photodetectors. In this contribution, we will discuss the fundamental properties of CT states and link them to organic opto-electronic device performance. Furthermore, we introduce a new device concept, using an optical cavity resonance effect to boost CT absorption at photon energies below the optical gap of both donor and acceptor, enabling narrow-band, near infrared (NIR) photo-detection. This new type of photodetector can compete with standard organic photodetectors but extends their detection range to longer wavelengths.

10348-17, Session 5

Strategies for reducing energy loss and increasing efficiency of organic solar cells *(Invited Paper)*

Barry P. Rand, Princeton Univ. (United States)

Unique to the function of organic PVs are the creation of tightly bound excitons that can only be efficiently separated at a donor/acceptor (D/A) interface capable of providing the necessary energetic driving force for dissociation. At the D/A interface, the presence of charge transfer (CT) states, ground state complexes between the donor and acceptor materials, set the upper bound for the potential that can be extracted from a given D/A pair, but their role in photogeneration is not completely understood. Furthermore, the consequences of extreme levels of order in highly crystalline heterojunctions have not been conclusively determined.

We have recently been exploring organic semiconductor-based thin films that feature crystalline grains of up to 1 mm in extent. We have found that CT states from these films are highly delocalized, contributing to noticeably lower energy losses. Also, we have discovered that relative energies of CT states with respect to singlet and triplet energy levels are critical when considering devices that exploit multiple exciton processes such as singlet fission and its complement, triplet-triplet annihilation (or triplet fusion). We will discuss these aspects and their implications for more efficient organic solar cell function.

10348-18, Session 5

Optics and photo-physics of hybrid perovskites revealed via multi-scale modeling *(Invited Paper)*

Andrew M. Rappe, Liang Z. Tan, Univ. of Pennsylvania (United States); Fan Zheng, Lawrence Berkeley National Lab. (United States); Shi Liu, Carnegie Institution for Science (United States); Omer Yaffe, Weizmann Institute of Science (Israel); Yinsheng Guo, Louis E Brus, Columbia Univ. (United States); Jasmine P. H. Rivett, Felix Deschler, Univ. of Cambridge (United Kingdom); Maya Isarov, Efrat Lifshitz, Technion-Israel Institute of Technology (Israel)

The lead halide perovskites have recently demonstrated excellent photovoltaic power conversion efficiencies, but the physical explanation

underlying this success is still unknown. Part of the difficulty lies in the complex spatio-temporal fluctuations of the atomic structure and their interactions with carriers. In this talk, we show how the photo-physics of hybrid perovskites is understood in theory and manifested in experiments, focusing on the aspects of carrier relaxation, the nature of structural fluctuations, and the influence of spin-orbit effects. We show that a simple Debye-Waller picture is insufficient to describe the time-resolved nuclear response after photo excitation. Instead, the evolution of the pair distribution function indicates an activation of preferential sub-lattice motions over fully thermal motions, as supported by our molecular dynamics simulations and ultrafast electron diffraction experiments. We have examined the nature of structural fluctuations in DFT-MD simulations, finding that the organic molecules display significant displacive motion, and are not pure dipolar rotors.

The dynamics of electrons and holes is also very intricate. Our models of carrier relaxation, based on first-principles electron-phonon couplings, show that anisotropy is imprinted on the carrier distribution by polarized light. Time-resolved transient absorption experiments show that this anisotropy persists for several picoseconds, which is much longer than in other semiconductors. Spin-orbit coupling is predicted to affect carrier recombination rates, and affect the exciton splitting energies under a magnetic field. Our magneto-optical measurements on CsPbBr3 have shown how the Rashba effect results in non-linear Zeeman splitting of the excitons.

10348-19, Session 5

Understanding the device physics in polymer-based organic ratchets *(Invited Paper)*

Thuc-Quyen Nguyen, Univ. of California, Santa Barbara (United States)

Electronic ratchets, devices that can convert random AC signals into DC current, have been of great interest for years, in particular for applications in energy harvesting. In combination with an antenna, which absorbs electromagnetic waves from the environment and produces AC voltage at its terminals, electronic ratchets can be used to rectify AC signal into DC current that can be used to power small electronic devices. For many years, ratchets were not considered suitable for practical applications due to their complexity of fabrication, low output power, and, in some cases, their requirement of cryogenic operating temperatures. In this talk, I will discuss a simple ratchet device architecture that is able to transform random electrical noise signals to produce large DC currents at room temperature. Our ratchet has only three electrodes and can be fabricated via solution-processing methods and therefore has potential applications in low cost, flexible, and light-weight energy harvesting devices. It is possible to fabricate a working polymer ratchet using Scotch tape, pencil, and aluminum foil. The working mechanism of organic ratchets is based on the principle of a “charge pump”, which relies on the formation of rectifying junctions at metal/organic interfaces.

10348-20, Session 6

Field-induced exciton and CT-state dissociation probed by time-resolved luminescence quenching

Uli Lemmer, Karlsruhe Institute of Technology (Germany); Marina Gerhard, Philipps-Univ. Marburg (Germany); Andreas P. Arndt, Karlsruher Institut für Technologie (Germany); Martin Koch, Philipps-Univ. Marburg (Germany); Ian A. Howard, Karlsruher Institut für Technologie (Germany)

The microscopic mechanisms of exciton and charge-transfer-state dissociation in organic semiconductors play a major role for the efficiencies of organic solar cells [1]. One of the most direct experiments for probing the dynamics of these processes is luminescence quenching. Here, we present a comprehensive experimental and simulative study of the field and temperature dependence of the dissociation of singlet excitons in PTB7 and PC71BM, and from charge-transfer states generated across interfaces in PTB7/PC71BM bulk heterojunction solar cells. We deduce the relevant data from time-resolving the near infrared emission of the states from 10K to room temperature and for electric fields ranging from 0 to 2.5 MV/cm. To draw qualitative conclusions from our data, we use an analytical field-assisted hopping model in the presence of disorder [2]. We conclude that singlet excitons can be split by high fields, and that disorder plays a large role in broadening the critical threshold field for which singlet excitons are separated. Charge-transfer (CT) state dissociation can be induced by both field and temperature, and the data imply that a strong reduction of the Coulomb binding potential at the interface facilitates their separation. The observations provided herein of the field dependent separation of CT states as a function of temperature offer a rich dataset against which theoretical models of charge separation can be rigorously tested.

10348-21, Session 6

Structure and function of bilayer organic photovoltaics *(Invited Paper)*

Mark E. Thompson, Peter I. Djurovic, Piyumie Wickramasinghe, The Univ. of Southern California (United States)

The exciton is a critical part of each of the processes leading to photocurrents in Organic PhotoVoltaics (OPVs), and being able to control the location, lifetime and energy of the exciton is essential to achieving high efficiency. I will discuss our most recent work with both organic dyes, such as squaraines and dipyrrins for OPVs. This involves a careful materials design study that leads to both low energy absorption (into the nearIR) and the efficient use of multiple absorbers to efficiently harvest photons through the entire visible spectrum. In particular, I will discuss the structure of bilayer films with these red/NIR absorbers and the role that fullerene diffusion into the donor layers plays on the properties of the photovoltaics. I will also discuss a new approach to designing materials for OPVs that involves symmetry breaking charge transfer. These materials are symmetric molecules that spontaneously form an intramolecular charge transfer complex, with nearly complete one electron transfer from one part of the molecule to another. This intramolecular CT state readily forms a charge separated state at the D/A interface of the OPV. We have explored these materials as both donors and acceptors in OPVs and found that they give good performance and high Voc.

10348-22, Session 6

Correlating microscale luminescent, electronic, and photovoltaic heterogeneity in perovskite thin films and solar cells *(Invited Paper)*

Giles E. Eperon, Univ. of Washington (United States)

Whilst perovskite solar cells have demonstrated an unprecedentedly rapid rise in power conversion efficiencies to over 22%, they are still far off their theoretical maximums of >30%.[1] Recently, several reports have emerged demonstrating that there is significant heterogeneity in the microscale properties of perovskite films – some grains seem to be of higher material quality than others, and grain boundaries show high densities of non-radiative defects.[2,3] It has been suggested that this heterogeneity could limit the performance of solar cells made from these films. However, the exact relations between film heterogeneity and device performance are still unclear.

Here, I will discuss our latest advances in correlative microscopy on perovskite thin films and devices. We conduct high-resolution scanning confocal photoluminescence microscopy, scanning kelvin probe microscopy, conductive atomic force microscopy, and laser beam induced current and voltage mapping to understand the origin and effects of local heterogeneity in perovskites. We find that heterogeneity can stem from both the perovskite itself and the perovskite-contact interfaces, and we go on to elucidate the role and impact of this on device performance.

I will go on to discuss the roles of grain boundaries and passivation techniques on heterogeneity in films and devices. Based on our results we elucidate rational routes to pushing the performance of perovskite solar cells closer to the thermodynamic limits.

Charge-carrier conduction and recombination mechanisms in hybrid metal halide perovskites *(Invited Paper)*

Laura Herz, Univ. of Oxford (United Kingdom)

Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 21%. We discuss the fundamental photophysics that has enabled these materials to be such efficient light-harvesters and charge collectors. We demonstrate how parameters essential for photovoltaic operation are altered with perovskite composition [1], changes in electronic bandstructure [2,3] and dimensionality [4]. We further analyze distinct charge-carrier recombination and scattering mechanisms and their dependences on composition and temperature [2,3,5]. We use these insights to predict charge-carrier diffusion lengths and radiative efficiencies in the limit of ultra-low trap-related recombination and the presence of doping [6,7].

Linker-dependent singlet fission in tetracene dimers

Jimmy Joy, Nadezhda Korovina, Mark E. Thompson, Stephen E. Bradforth, The Univ. of Southern California (United States)

Singlet fission is a process of generating two triplet excitons from a single photon that has the potential to increase the theoretical maximum efficiency of a solar cell. The rate of singlet fission is dependent on the coupling between the singlet state [S1S0] and the correlated triplet pair [1(T1T1)] in a chromophore. A series of ethynyl-tetraceme dimers linked via a phenyl bridge have been synthesized with the chromophore units at ortho-, meta- and para- configurations. Such dimers allow the investigation of the contributions of through-space and through-bond coupling to the rate of singlet fission. Transient absorption spectroscopy has been used to observe the singlet state, the correlated triplet state and the separated triplet states in these dimers. The spectral deconvolution of the transient absorption data shows that the only the para-dimer forms separated triplets while the ortho-dimer only forms the correlated triplet pair while the meta-dimer does not undergo singlet fission.

10348-25, Session 7

Measuring the electronic structure of buried organic semiconductor interfaces *(Invited Paper)*

Aaron P Moon, Univ. of Texas at Austin (United States); Ravindra Pandey, Aaron K. Le, Jon A. Bender, Daniel E. Cotton, Sean T Roberts, The Univ. of Texas at Austin (United States)

A primary source of energy loss within semiconductor photovoltaics is charge carrier thermalization, wherein carriers produced by high-energy photons relax to the semiconductor's band edge, giving up their excess energy as heat. In commercial silicon photovoltaics, this process accounts for nearly 50% of the energy lost by these cells. One strategy to combat this loss is to use a material that undergoes singlet exciton fission (SF) to capture high energy photons. SF, a process that occurs in select organic semiconductors, generates two spin-triplet excitons from a singlet photo-generated spin-singlet excitation. These triplet excitons can each transfer to a silicon layer resulting in a reduction of thermalization losses. However, efforts to couple SF materials with silicon have largely been hindered by inefficient triplet energy transfer across their junction. Currently, the physical basis underlying this result is unclear, and may be tied to poor orbital overlap as well as band edge mismatch. Differentiating between these scenarios and others is central to the design of SF-based photovoltaics. Herein, we use electronic sum frequency generation (ESFG) to probe how the electronic structure of perylenediimides, a family of promising SF materials, is altered at buried interfaces. ESFG measurements of perylenediimide thin films suggest that strain relaxation within crystalline grains can lead to exciton energy shifts of ~150 meV, affecting both their ability to undergo SF near interfaces and transfer triplet excitons to silicon. Our measurements suggest careful control of the arrangement of SF-materials at a semiconductor interface is critical to effecting energy transfer between them.

10348-47, Session 7

Picosecond light-induced rotational disordering in the hybrid perovskites *(Invited Paper)*

Aaron M. Lindenberg, Stanford Univ. (United States) and SLAC National Accelerator Lab. (United States)

Femtosecond resolution electron scattering techniques are applied to resolve the first atomic-scale steps following absorption of a photon in the prototypical hybrid perovskite methylammonium lead iodide. Following above-gap photo-excitation, we directly resolve the transfer of energy from hot carriers to the lattice by recording changes in the root-mean-square atomic displacements, on ten picosecond time- scales. Measurements of the time-dependent pair distribution function show an unexpected broadening of the iodine-iodine correlation function while preserving the Pb-I distance. This indicates the formation of a rotationally-disordered halide octahedral structure developing on picosecond time-scales. This work shows the important role of light-induced structural deformations within the inorganic sublattice in elucidating the unique optoelectronic functionality exhibited by hybrid perovskites and provides new understanding of hot carrier - lattice interactions which fundamentally determine solar cell efficiencies.

10348-27, Session 8

Interface and defect engineering of core-shell quantum dots

Ajay Singh, Jennifer A. Hollingsworth, Los Alamos National Lab. (United States)

Colloidal quantum dots (CQDs) are attractive materials for lasers, displays and light-emitting applications due to their narrow and brighter spectral emission bandwidth, size-tunable bandgap and high-photoluminescence quantum yield (PLQY). However, these CQDs undergo inevitable degradation of their unique optical properties overtime due to their sensitive surface chemistry. To overcome these limitations, several approaches have recently been used such as over coating with an inorganic semiconductor shell of a wider band gap (core-shell hetrostructures), surface functionalization with new ligands or polymer coating and composites etc. In particular, core-shell heterostructured quantum dots with thick shell (so called "giant" quantum dots (g-QDs)) has shown higher PLQYs and improved photochemical stability than traditional thin-shelled or core only CQDs. The outstanding properties of g-QDs essentially depend on both the structure (defects, surface chemistry etc.) and the properties of interfacial layer (sharp or smoothen core/shell interface). These structural and interfaces properties of g-QDs are strongly influenced and can be tailored by the synthetic parameters. Here, we will present our recent results on understanding the behavior of interfacial layer and structural defects on the photophysical properties of g-QDs.

Highly luminescent nanocrystals of formamidinium tin iodide (FASnI3) *(Invited Paper)*

Maryna Bodnarchuk, EMPA (Switzerland); Sergii Yakunin, Maksym V. Kovalenko, ETH Zurich (Switzerland)

During recent years lead-halide perovskite semiconductors have shown great potential in the field of optoelectronics; in particular, in photovoltaics and as versatile photon sources [1]. This progress is deeply rooted into unique defect-tolerant photophysics of the compounds. Colloidal organic/inorganic lead halide perovskite nanocrystals (NCs) are intensely pursued as highly promising, low-cost light-emitting materials with wide color gamut. The latter arises from the narrow-band photoluminescence, covering the entire visible spectral region and characterized by very high quantum yields of up to 90% [2]. However, the use of toxic Pb limits their broad applications and commercialization. Since the toxicity of lead is of great concern in most countries, a nontoxic substitute for perovskite materials is eventually required. The Pb(II) could be replaced with Sn(II), which is in the same group in the periodic table. Such replacement of lead with tin has been demonstrated in bulk films, but not in colloidal nanocrystals. We have developed solution-phase synthesis of colloidal formamidinium tin iodide (FASnI3) NCs with nearly cubic and platelet shapes, exhibiting tunable emission peak between 720-900 nm and with high quantum yields of 50% and above [3]. Structural analysis indicates orthorhombic crystal structure for FASnI3 NCs, that is in agreement with literature findings for the bulk material. These NCs exhibit higher stability than their MA- or Cs-based analogues of the same size and morphology. We also find that facile oxidation of Sn(II) limits the durability of these materials. We will discuss possible mitigation strategies for improving the oxidative stability via polymer encapsulation.

10348-29, Session 8

The alkyl amines effect on the optical properties of inorganic perovskite quantum dot

Ya Zhu Yang, Shu-Ru Chung, National Formosa Univ. (Taiwan)

Perovskite quantum dots (QDs) is a new kind of optoelectronic materials in recent years. Compared with organic perovskite QDs (MAPbX3), inorganic perovskite QDs (CsPbX3) have a better stability. Inorganic perovskite QDs can be prepared at low temperature. Those novel QDs can be applied in solar cells, light-emitting diodes (LEDs), display, and biolables. Typical synthesis process to prepare CsPbX3 QDs is used oleic acid (OA) and cesium carbonate (Cs2CO3) to form Cs-oleate complex first. Moreover, the oleylamine (OLA) and octadecene (ODE) are used as capping agents. Cs-oleate complex then reacts with PbX2 to form CsPbX3 QDs (reacts for 5 s). As we know that the CsPbBr3 QDs emits green light, and its emission wavelength can be tuned by adding Cl- and I- ions to replace Br- ion. However, the reaction rate of CsPbX3 QDs is fast, and it is not easy to control the emission wavelength by particle size. In this study, we use the saturated alkyl amines with difference of carbon chain length such as dodecylamine (DDA), hexadecylamine (HDA), and octadecylamine (ODA) to prepare CsPbBr3 QDs. The result shows that the emission spectra for all samples range from 489 (ODA) to 514 nm (DDA), the full width at half-maximum (FWHM) is between 23 to 28 nm, the surface morphologies of all samples are nearly spherical, and the quantum yields (QYs) are higher up to 130 % (compared with R6G and the excitation wavelength is 450 nm). Based on emission spectra we can find that the emission peaks is fixed even under different excitation wavelength, imply that the particle size distribution of QDs is uniform. Moreover, the emission wavelength blue shifts with increasing carbon chain length of amines. The stability of alkyl amine-capped CsPbBr3 QDs is good, especially for DDA-capped sample. We also find that a small emission peak around 462 nm can be only observed for DDA-capped sample. Furthermore, this small peak also can be observed even prolong the reaction time to 10 min. The emission wavelengths of CsPbBr3 QDs can be controlled by carbon chain length of alkyl amines. The small FWHM and high QYs of CsPbBr3 QDs meaning that it is benefit to enhance the color gamut of display.

10348-30, Session 8

Colloidal perovskite nanocrystals: synthesis, optical properties, and applications *(Invited Paper)*

Alexander S. Urban, Ludwig-Maximilians-Univ. München (Germany)

Halide perovskites have emerged as an exciting material for photovoltaic and light-emitting applications due to their fascinating properties, including tunable optical band gaps, excellent absorption, and long charge carrier diffusion lengths. We review the current state of halide perovskite nanocrystals, focusing on our contributions to colloidal synthesis of hybrid and all-inorganic lead halide perovskites nanocrystals with controlled dimensionality, size and composition and on understanding their corresponding optical and electrical properties. We study the aspect of quantum-confinement and its effect on band-gap and exciton binding energies, quantum yield and photoluminescence decay rates. Based on the superb properties of the perovskite nanocrystals, we look at applicability, e.g. for amplified spontaneous emission (ASE), energy transfer and light-emitting devices.

Photonic nanopatterns in organo-metal halide perovskites by thermal nanoimprint lithography *(Invited Paper)*

Neda Pourdavoud, Andre Mayer, Si Wang, Bergische Univ. Wuppertal (Germany); Ting Hu, Jie Zhao, Bergische Univ. Wuppertal (Germany) and Nanchang Univ. (China); Kai Brinkmann, Ralf Heiderhoff, Bergische Univ. Wuppertal (Germany); André Marianovich, Wolfgang Kowalsky, Technische Univ. Braunschweig (Germany); Hella-Christin Scheer, Thomas J. Riedl, Bergische Univ. Wuppertal (Germany)

The recently re-discovered class of organometal-halide perovskites hold great promise for solar cells, LEDs and lasers.[1] Today, their potential has not been fully unlocked partially because of the lack of suitable nano-patterning techniques, which are mandatory to create resonator structures, waveguides etc. with a maximum level of precision directly into perovskite layers. Their chemical and thermal instability prevents the use of established wet-chemical patterning techniques.[2] In contrast to conventional inorganic semiconductors, crystal binding in these perovskites includes significant contributions of van der Waals interactions among the halide atoms and Hydrogen bonding.[3] The formation enthalpy per unit cell is only about 0.1eV in MAPbI3.[4] Here, we take advantage of the "soft-matter properties" of organo-metal halide perovskites and demonstrate that photonic nano-structures can be prepared by direct thermal nano-imprint lithography in MAPbI3 and MAPbBr3 at relatively low temperatures (<150°C). The resulting periodic patterns provide distributed feedback resonators, which afford lasing in MAPbI3 with ultra-low threshold levels on the order of 1 ?J/cm2.[5] Moreover, our results also state the first DFB lasers based on MAPbBr3. We will discuss the applicability of thermal imprinting for perovskite solar cells and LEDs.

Electron transfer and nonlinear activity in 2D semiconductors enhanced by nanoantenna through modeling and spectroscopy

Donald K. Roper, Gregory T. Forcherio, Mourad Benamara, Univ. of Arkansas (United States); Luigi Bonacina, Univ. de Genève (Switzerland); Jeremy R. Dunklin, Univ. of Arkansas (United States)

2D semiconductor heterostructures offer compelling new functionalities, e.g., gate tunability of p-n junction, valleytronics and anti-ambipolarity as well as unique optical, electronic and transport properties attributable to distinct atom-scale heterointerfaces. These features could enable atomically-thin flexible integrated circuits, field effect transistors and closed-loop resonators. However, present utility of 2D semiconductors is limited by difficulty in tuning their optoelectronic properties. This work examined nanoantenna (NA)-modulated electron transfer and nonlinear activity at heterointerfaces of monolayer (1L) transition metal dichalcogenides (TMD) exhibiting broken inversion symmetry. Heterostructures of 1LTMD and NA were self-assembled via exfoliation and dropcasting. Nanometer- and femtosecond-resolved electron energy loss spectroscopy (EELS) was used to simulate and measure low-energy NA plasmon modes, damping and electric near fields at heterointerfaces. Quantitated plasmon damping compared with computed inelastic population decay due to radiative and intraband mechanisms indicated electron injection through a Landau mechanism. Quantum efficiency of injection ranged from eight to over thirteen percent. Mid-bandgap edge states increased likelihood of nonlinear activity in exfoliated 1LTMD. A tunable femtosecond laser system for Hyper Rayleigh Scattering (HRS) was used to measure second order nonlinear coefficient of 1LTMD and NA-1LTMD heterostructure. A corollary novel computation method was used to validate measured values. Nonlinear susceptibilities for 1LTMD exceeding those of conventional materials by >102 pm/V with concomitant increases in second harmonic generation (SHG) intensity and two-photon absorption probability were investigated. Coordination of EELS and HRS offers a direct complementary measure of plasmon modes and damping, electric near-field and intrinsic nonlinear activity at high spatiotemporal resolution at heterointerfaces.

10348-33, Session 9

Organic micro-LEDs and cell-embedded lasers: new tools based on organic nanomaterials to advance physical understanding of biological systems *(Invited Paper)*

Malte C. Gather, Marcel Schubert, Anja Kämpf, Andrew Morton, Caroline Murawski, Klara C. R. Volckaert, Markus Karl, Nils M. Kronenberg, Philipp Liehm, Gareth B. Miles, Simon J. Powis, Stefan R. Pulver, Univ. of St. Andrews (United Kingdom)

The vast complexity of biological systems – even of single cells – poses enormous challenges for an in-depth understanding of their function and behaviour. In many cases, we simply lack the tools to observe the relevant processes or to perform deterministic experiments that reproducibly impose defined starting parameters, e.g. on a neuronal network. Here, we give two examples of microdevices that use organic nanomaterials to interface to biological systems. Organic micro-LEDs are used to optically control the behaviour of individual cells via optogenetic activation. We also show how organic microlasers can be embedded in live cells to facilitate long-term cell tracking.

10348-35, Session 9

Broadband excitation and nanoscale relaxation processes of excitons in monolayer MoS2 *(Invited Paper)*

Nicholas Borys, Lawrence Berkeley National Lab. (United States)

The tightly bound exciton complexes of monolayer MoS2 and other two-dimensional transition metal dichalcogenide semiconductors constitute an exciting class of electronic excitations for nanoscale optoelectronics. While it is tempting to assume that these states are analogous to excitons in conventional two-dimensional quantum wells, the atomically thin width, tunable many-body interactions and intricate band structure of monolayer MoS2 combine to produce a unique collection of unanticipated phenomena that defy such simplifications. Exploiting their strong light-matter interactions, a broad arsenal of near-field and conventional optical microscopy and spectroscopy tools has been used to explore and develop a better understanding of this rich suite of photoexcitations. Identified phenomena such as efficient broadband coupling, large renormalization of excitation energies and tunable relaxation dynamics set the stage for the incorporating monolayer MoS2 into a broad range of model optoelectronic systems where strong light-matter interactions and the precise control of energy transport are paramount. At microscopic to nanometer length scales, a striking diversity of photophysical behavior and distinct optoelectronic regions such as disordered peripheral edges, nanoscale charge puddles and defective grain boundaries are found in synthetic monolayer MoS2.

The spatially-dependent behavior, which can be traced to a combination of external stimuli, a complex interplay between excitons and defect states, as well as the temporal dynamics of the growth process, highlights the potential of using two-dimensional transition metal dichalcogenide semiconductors as a canvas in which specific excitonic functionalities can be patterned.

10348-36, Session 9

Strained relations: optical tuning of electronic dynamics in nanoparticle and molecular systems using ultrafast spectroscopy *(Invited Paper)*

Vanessa Huxter, The Univ. of Arizona (United States)

In colloidal metal and semiconductor nanoparticle systems, interface or surface strain can determine many of their optical and material properties including reactivity, catalytic activity and potential for energy and charge transfer. Strain can tune energy levels, raising and lowering the barriers to a variety of physical processes. The inherent strain in the material can be controlled synthetically by modifying the size or shape of the nanomaterial. We propose that strain can also be used as a dynamic, adjustable parameter. Using polarization controlled ultrafast electronic spectroscopy to selectively excite vibronic modes, we periodically enhance the interface strain. This enhancement has an optical readout in the oscillations that appear in the cross polarized anisotropy transient grating signal, providing a direct in-situ measurement of optically controlled strain. In semiconductor heterostructures, strain can be used to shift the relative separation of the levels and modify the rate of charge separation. In metal nanoparticles, the surface strain can be periodically enhanced, modulating their physical properties. Using strain as an adjustable parameter to control the optical properties of nanomaterials will provide new paths towards manufacturing robust, efficient solar cells and novel material systems. Moving from nanoparticle to molecular systems, I will also discuss ultrafast nonlinear spectroscopy measurements of new synthetic analogs of highly conserved natural light harvesting pigments. Relaxation in these tunable redox-active systems is driven by vibrational coupling and symmetry distortions, providing new pathways to controllable and efficient energy and charge transfer in artificial light harvesting systems.

10348-37, Session 10

Investigating ion migration via photoluminescence blinking in perovskite films

Gregory Tainter, Univ. of Cambridge (United Kingdom); Cheng Li, Univ. Bayreuth (Germany); Richard H. Friend, Hannah J. Joyce, Univ. of Cambridge (United Kingdom); Sven Huettner, Univ. Bayreuth (Germany); Felix Deschler, Univ. of Cambridge (United Kingdom)

Recent investigations have revealed spatial variation in photoluminescence (PL) emission of perovskite films. Other reports have found fluctuation in PL intensity in individual grains, i.e. blinking. Here we combine spatially, spectrally, and temporally resolved PL techniques to investigate the characteristic lifetime and emission energy of blinking grains within CH3NH3PbI3-XClX perovskite films. Histograms with millisecond resolution of PL intensity and energy variations are coupled with studies of the charge carrier lifetimes of blinking and non-blinking perovskite grains. These methods reveal a prolonged process, with the switching of increased to decreased emission intensity, and vice versa, taking up to tens of seconds. We investigate the influence on blinking activity of excitation density, while the difference between the influence of electrons and holes is investigated via the deposition of a film of phenyl-C61-butyric acid methyl ester (PCBM). We further investigate the influence of ion migration on blinking by applying an external voltage. The frequency of blinking events is found to be highly dependent upon excitation density. We investigate the scaling of PL intensity of a grain with ion concentration. We identify if the probability of a grain blinking is proportional to ion concentration or if blinking commences at a defined threshold value. These results give dynamic information on local ion migration between grains in perovskite films. From these results, the effect of migration and local over-abundance of ions on charge recombination is identified, which is a central question underlying the improvement of solar cell and LED performance.

10348-38, Session 10

Reversible laser induced amplified spontaneous emission from coexisting tetragonal and orthorhombic phases in hybrid lead halide perovskites *(Invited Paper)*

Anna Köhler, Univ. Bayreuth (Germany)

In the talk I will focus on the optical properties of lead halide perovskites and their dependence on the amount of excess PbI2. I shall first address that, at low temperature, it is possible to optically and reversibly induce a phase change from the orthorhomic to the tetragonal phase. By exploiting amplified spontaneous emission (ASE) from these phases, fully optical read-write-erase cycles can be conducted, as detailed in Adv. Optical Mater. 6 (2016) 917-928 . I shall then elaborate on how and why the photoluminescence features are modified in the presence of excess PbI2.

10348-39, Session 10

Excited state superposition in metal halide perovskites probed via two dimensional spectroscopy *(Invited Paper)*

Carlos Silva, Georgia Tech Research Institute (Canada)

Hybrid lead halide perovskites have emerged as promising materials for efficient opto-electronic technologies. Colloidal nanocrystals of these systems have shown remarkably high photoluminescence quantum yields, reaching upto 90% and have recently been proposed as inks to achieve high quality thin films [1]. Being virtually defect-free [2], these nanocrystals offer an ideal scenario to address some of the key issues in the photo-physical processes in these novel materials. Here, we use two dimensional phase modulation excitation spectroscopy to investigate coherent non-linear interactions in colloidal suspensions of CsPb(Br:I)3 nanocrystals. We observe a cross-peak close to the band-edge in the 2D spectrum within a population time of 50 fs, suggesting an evolution of coherent superposition of two distinct electronic states, that cannot be identified via conventional spectroscopies. Defects excluded, we attribute the presence of such a mixed-state to the weak but finite non-radiative decay channel for the primary photo-excitation. Such a superposition is quenched at higher excitation densities due to the presence of competing Auger interactions or via Coulomb screening by the high carrier density.

10348-40, Session 10

Solid-state organic/nanocrystal films for infrared/visible photon conversion via excitonics *(Invited Paper)*

Mark W. B. Wilson, Univ. of Toronto (Canada) and Massachusetts Institute of Technology (United States);

Lea Nienhaus, Mengfei Wu, Massachusetts Institute of Technology (United States); Daniel Congreve, The Rowland Institute at Harvard (United States) and Massachusetts Institute of Technology (United States); Vladimir Bulovic, Moungi G. Bawendi, Marc A. Baldo, Massachusetts Institute of Technology (United States)

The ability to efficiently interconvert low-intensity light between the visible and infrared would be an enabling technology—particularly for applications such as 3rd-generation photovoltaics, biological imaging, and cost-effective cameras in the short-wave infrared (SWIR; ?:1?3μm). Here, we present a novel approach using multi-excitonic interactions in nanostructured materials that could enhance existing silicon-based detectors. Specifically, we show that two excitonic materials—organic semi-conductors and colloidal nanocrystals—can be combined to create passive thin-film devices that achieve broadband, non-coherent down- or up-conversion between the SWIR and the visible.

To achieve upconversion, we synthetically tune the bandgap of PbS nanocrystals to absorb SWIR photons (?>1 μm), and funnel these excitations to an organic semiconductor (rubrene). Here, their energy is combined to create visible light. We achieve an upconversion efficiency of 1.2±0.2% with ?=808 nm excitation at 12 W/cm2. Further, we show that there is no fundamental barrier to efficient performance at a thousandth of this excitation intensity (less than natural sunlight!)

Our hybrid approach to achieve non-coherent upconversion may prove broadly applicable in solar and SWIR-detection applications, where effective molecular phosphors are lacking—indeed, quantum dots are ideal SWIR sensitizers, as their excitons are functionally spin-mixed at room temperature, and both their optical gap and ionization energy can be tuned via colloidal synthesis.

10348-41, Session 11

Effects of surface and interface traps on exciton and multi-exciton dynamics in core/shell quantum dots

Renato Bozio, Univ. degli Studi di Padova (Italy) and Consorzio Interuniversitario Nazionale per la Scienza e Tecnologia dei Materiali (Italy); Marcello Righetto, Alessandro Minotto, Univ. degli Studi di Padova (Italy)

Exciton interactions and dynamics are the most important factors determining the exceptional photophysical properties of semiconductor quantum dots (QDs). In particular, best performances have been obtained for ingeniously engineered core/shell QDs. We have studied two factors entering in the exciton decay dynamics with adverse effects for the luminescence efficiency: exciton trapping at surface and interface traps, non radiative Auger recombination in QDs carrying either net charges or multiple excitons.

In this work we present a detailed study into the optical absorption, fluorescence dynamics [1] and quantum yield [2], as well as ultrafast transient absorption properties of CdSe/CdS, CdSe/Cd0.5Zn0.5S, and CdSe/ZnS QDs as a function of shell thickness. It turns out that de-trapping processes play a pivotal role in determining steady state emission properties. By studying the excitation dependent photoluminescence quantum yields (PLQY) in different CdSe/CdxZn1-xS (x = 0, 0.5, 1) QDs, we demonstrate the different role played by hot and cold carrier trapping rates in determining fluorescence quantum yields. The complementary use of global and inversion analysis allows us to untangle the complex ultrafast transient absorption signals. Smoothing of interface potential, together with effective surface passivation, appear to be crucial factors in slowing down both Auger-based and exciton trapping recombination processes.

10348-42, Session 11

Ultrafast energy transfer in photosynthetic light harvesting *(Invited Paper)*

Gabriela Schlau-Cohen, John Ogren, Ashley Tong, Minjung Son, Massachusetts Institute of Technology (United States)

In photosynthetic light harvesting, absorbed energy migrates through a network of light-harvesting complexes to reach a dedicated location for conversion to chemical energy. This energy flow gives rise to a remarkable near unity quantum efficiency through a series of rapid energy transfer steps. We measure these ultrafast energy transfer dynamics within light-harvesting complexes in a near-native environment using transient absorption spectroscopy. We quantitatively compare the energy transfer dynamics within this near-native environment to those within the typical detergent-solubilized environment for light-harvesting complex 2 (LH2), the primary light-harvesting complex in purple bacteria. Through this comparison, we identify the energy transfer steps that change with the surrounding environment and those that are protected by the protein structure of the light-harvesting complex. Thus, we identify the effect of the surrounding membrane in driving energy flow.

10348-43, Session 11

Dopant-enhanced photoluminescence in solution processed semiconducting single crystals *(Invited Paper)*

Dmitry Y. Paraschuk, Olga D. Parashchuk, Vladislav G. Konstantinov, M.V. Lomonosov Moscow SU (Russian Federation); Oleg V. Borshchev, Nicolay M. Surin, Institute of Synthetic Polymeric Materials (Russian Federation); Sergey A. Ponomarenko, Institute of Synthetic Polymeric Materials (Russian Federation) and M.V. Lomonosov Moscow SU (Russian Federation); Artur A. Mannanov, M.V. Lomonosov Moscow SU (Russian Federation) and Zernike Institute for Advanced Materials (Netherlands); Maxim S. Pshenichnikov, Zernike Institute for Advanced Materials (Netherlands)

Organic optoelectronics needs materials combining high luminescence and efficient charge transport. Organic single crystals demonstrate the best charge transport properties in organics; however, tight molecular packing in them usually results in luminescence quenching. Here we report on enhancement of luminescent properties of solution-processed organic semiconducting single crystals via doping by molecular energy acceptors. As host and dopant molecules we synthesized thiophene-phenylene co-oligomers (TPCOs) of different lengths and used the longer TPCOs (with lower band gap) as dopant to the shorter ones (with higher band gap). We grew TPCO host single crystals doped by longer TPCOs in the concentration range 0.01–3% and studied their photophysics by steady-state and time-resolved photoluminescence (PL) spectroscopy. For the best host-dopant single crystals, the PL is maximal at the doping level ~1%, and all the PL comes from the dopant with the PL quantum yield corresponding to that of dilute dopant solution. As the mechanisms of host-dopant energy transfer, we modelled exciton diffusion and Förster resonant energy transfer using Monte-Carlo simulations. Our results demonstrate that doping of organic semiconducting single crystals by highly luminescent dopant is a promising route to high performance materials for organic optoelectronics.

10348-26, Session 12

Effect of crystal packing on the electronic properties of molecular crystals *(Invited Paper)*

Noa Marom, Carnegie Mellon Univ. (United States)

Molecular crystals have applications in nonlinear optics, organic electronics, and particularly in pharmaceuticals, as most drugs are marketed in the form of crystals of the pharmaceutically active ingredient. Molecular crystals are bound by dispersion (van der Waals) interactions, whose weak nature generates potential energy landscapes with many shallow minima that are close in energy. As a result, molecular crystals often exhibit polymorphism, the ability of the same molecule to crystallize in several structures. Crystal structure may profoundly influence the bioavailability, toxicity, manufacturability, and stability of drugs. In the context of technological applications, crystal structure affects the electronic and optical properties.

We perform large scale quantum mechanical simulations to predict the structure of molecular crystals and investigate the effect of crystal packing on their electronic and optical properties. The massively parallel genetic algorithm (GA) package, GAtor, relies on the evolutionary principle of survival of the fittest to find low-energy crystal structures of a given molecule. Dispersion-inclusive density functional theory (DFT) is used for structural relaxation and accurate energy evaluations. The structure generation package, Genarris, performs fast screening of randomly generated structures with a Harris approximation, whereby the molecular crystal density is constructed by replicating the single molecule density, which is calculated only once. Many-body perturbation theory, within the GW approximation and the Bethe-Salpeter equation (BSE), is then employed to describe properties derived from charged and neutral excitations.

For tricyano-1,4-dithiino[c]-isothiazole (TCS3), we propose a layered crystal structure, which is only 20 meV higher in energy than the observed cyclic dimer structure, and may exhibit a smaller gap, better transport properties, and broader optical absorption. For rubrene, we predict that a lesser known monoclinic crystal structure may exhibit higher singlet fission efficiency than the orthorhombic form, possibly rivaling that of pentacene. Thus, the electronic and optical properties of organic semiconductors may by optimized by modifying the crystal packing.

10348-44, Session 12

Nanostructural engineering towards high quality luminescent giant quantum dots

Amita Joshi, Ajay Singh, Jennifer A. Hollingsworth, Los Alamos National Lab. (United States)

The inorganic fluorophores such as quantum dots have application ranging from opto-electronics to cell imaging in biology. But this important aspect (optical) of the QDs has always been challenged by the surface or chemical environmental instabilities in bulk and at single particle level. To overcome the problems with these systems different approached have been used such as surface passivation with ligands, over coating with polymers, core-shell heterostructures etc. The core-shell semiconductor nanocrystals, called giant quantum dot (gQDs) nanocrystal with their wide-bandgap chalcogenides based core-shell structure have exhibited improved photo-physical properties. With decreased non-radiative recombination, suppressed blinking and enhanced photo-stability, the core-shell gQDs provided more opportunities for applications such as single particle tracking, active biolables and stable light emitting diodes. But still the chalcogenides based shell systems can undergo photo-oxidized and lead to emission loss and instability. Here, we will present our approach to overcome this problem by exploring the oxide based shell and polymer matrix, as they are more stable in case of photo-oxidation process and can greatly reduce the surface recombinations. The oxide shell and polymer matrix not only prevent the core oxidation but also maintain the structural integrity and act as a protective layer to prevent the leaching out of the cation or anion from the cores. By carefully choosing the oxide material for the over coating not only the optical properties of bare quantum dots and giant quantum dots were improved but also other undesirable results like nucleation of metal oxide nanocrystals was avoided.

10348-45, Session 12

Structural dynamics in lead-halide perovskites from first-principles molecular dynamics *(Invited Paper)*

David A. Egger, Weizmann Institute of Science (Israel) and Univ. Regensburg (Germany)

The optical and transport properties of lead-halide perovskites (LHPs) have been used as a basis for new solar cell technologies showing record improvements in efficiencies. In the search for the microscopic origins of this success, many recent studies suggest that structurally dynamic effects, going far beyond small harmonic vibrations, are active already at room temperature and standard operating conditions.

Here, I explore this issue in several different LHP materials using first-principles molecular dynamics based on density functional theory. In particular, I will focus on dynamic polar distortions and an assessment of optical phonons. I will also comment on the possible relevance of these phenomena for charge-carrier dynamics.

10348-46, Session 12

Nanoscale structure measurements for flexible electronics manufacturing *(Invited Paper)*

Dean M. DeLongchamp, National Institute of Standards and Technology (United States)

Flexible electronics is an emerging additive manufacturing method in which electronics are made using functional inks that are printed or coated. Organic photovoltaics (OPV) is a flexible electronics technology for making low-cost solar cell modules. Although OPV has significantly matured over the past few years, there remain significant challenges in moving from lab-scale devices to real manufacturing. We address this gap using a blade coating process as a prototype for slot-die coating and observing the structure of films in-situ as they dry. Our measurements include synchrotron-based X-ray scattering and a variety of optical methods.

I will highlight our studies of organic photovoltaic (OPV) systems deposited by blade coating, which can achieve up to 9.5 % power conversion efficiency (PCE). Our methods reveal a diversity of solidification mechanisms among OPV systems. Some are dominated by the nanoscale crystallization of the components, whereas others appear to be dominated by liquid-liquid phase separation. Examples of good performance can be found for systems that obey either mechanism. Systems that maintain high PCE in active layers thicker than greater than ≈200 nm, however, are rare. We describe one such system, in which the salient traits appear not to be the nanoscale shape and orientation of the domains, but rather the relatively pure phases and relatively strong diffraction of the polymer component. The results are extended to pilot-scale R2R coating by demonstrating nominally identical morphologies for both piece blade-coating and continuous-web, slot-die coating.

10348-50, Session PWed

Self-powered active acetylene gas sensing based on triboelectric nanogenerator by the semimetallic PEDOT:PSS hole transport layer

Gwiy-Sang Chung, Univ. of Ulsan (Korea, Republic of)

We report an enhanced triboelectric nanogenerator (TENG) based on the

contact-separation mode between a patterned film of polydimethylsiloxane (PDMS) with a semi-metallic elastomer of poly(3,4-ethylenedioxythiophen e):poly(styrenesulfonate) (PEDOT:PSS) and a nylon fiber film. The addition of ethylene glycol to the PEDOT:PSS film improves the functionality of the TENG significantly, yielding promising applicability in both indoor and outdoor (i.e., under sunlight) environments, with the maximum instantaneous power of 0.09 mW (indoors) and 0.2 mW (outdoors) for the load resistance of 3.8 M?. The device can also generate 11.2 V and 0.08 μA cm?2 in response to the forearm movement of a human. Additionally, by replacing the bare nylon fiber in the TENG design with a Ag@ZnO/nylon fiber film, a self-powered active sensor (triboelectric nanogenerator–based sensor; TENS) has been realized to detect acetylene (C2H2) gas. The TENS exhibits excellent sensitivity of 70.9% (indoors) and 89% (outdoors) to C2H2 gas of 1000 ppm concentration. The proposed approach for harvesting energy and sensing can be advantageous in practical applications and may stimulate new research that will enhance nanogenerators as well as wearable, self-powered active sensors.

Optical properties in Al2O3-Y2O3 dielectric ultrathin multilayer stacks grown by atomic layer deposition

Javier Lopez, Hugo Borbón, Roberto Machorro, Univ. Nacional Autónoma de México (Mexico); Nicola Nedev, Univ. Autónoma de Baja California (Mexico); Mario Farias, Hugo Tiznado, Gerardo Soto, Univ. Nacional Autónoma de México (Mexico)

Ultrathin multilayer stacks based on Al2O3-Y2O3 bilayers were prepared via thermal atomic layer deposition (ALD) in order to study the behavior of refractive index and optical bandgap energy as a function of Y2O3 thickness layer. Ttotal thickness (?100 nm), Refractive index n(?) and optical bandgap Eg, of each multilayer were studied via spectroscopic ellipsometry (SE). Cross-sectional mode scanning electron microscope (SEM) images allowed to verify the multilayer total thickness and confirmed the accuracy of the optical model used for SE measurements. From the Single effective oscillator model (MSEO), it found that Eg gradually decreases from 5.45 to 4.24 eV as the bilayer thickness increases. The Eg change is ?Eg= 1.2 eV for thickness variation between 2.1 to 13.3 nm. These results reveal that refractive index and optical bandgap can be modulated systematically as a function of bilayer thickness and open the possibility for this material to be exploited for developing opto-electronic devices in nanotechnology.

Chemical and charge transfer studies on interfaces of a conjugated polymer and ITO

Sam-Shajing Sun, Tanya S. David, Norfolk State Univ. (United States)

Conjugated oligomers and polymers are very attractive for potential future plastic electronic and opto-electronic device applications such as plastic photo detectors and solar cells, thermoelectric devices, field effect transistors, and light emitting diodes. Understanding and optimizing charge transport between an active polymer layer and conductive substrate is critical to the optimization of polymer based electronic and opto-electronic devices. This study focused on the design, synthesis, self-assembly, and electron transfers and transports of a phosphonic acid end-functionalized polyphenylenevinylene (PPV) that was covalently attached and self-assembled onto an Indium Tin Oxide (ITO) substrate. This study demonstrated how atomic force microscopy (AFM) can be an effective characterization technique in conjunction with conventional electron transfer methods, including cyclic voltammetry (CV), towards determining electron transfer rates in polymer and polymer/conductor interface systems. This study found that the electron transfer rates of covalently attached and self-assembled films were much faster than the spin coated films. The knowledge from this study can be very useful for designing potential polymer based electronic and opto-electronic thin film devices.

Spin-polarization effects upon light-Induced charge separation at BHJ interfaces

Oleg G. Poluektov, Jens Niklas, Argonne National Lab. (United States)

Organic Photovoltaic technology could provide sufficient energy to satisfy the global economic demands in the near future. Understanding the charge separation and electronic structure at a molecular level is crucial for improving the efficiency of OPV materials. In spite of the importance of this research a number of fundamental questions about how the organic bulk heterojunction cell enables efficient long-lived and long-range charge separation remain unanswered. Here we report on the relationship between efficiency of charge separation and spin-polarization phenomena. The detection of strong electron spin-polarization in the transient EPR spectra of organic photovoltaic materials points to the significance of electron spin dynamics and spin-quantum phenomena for the efficient charge separation in solar cells. Evidence for spin-dependent charge separation dynamics in OPV materials comes from the observation of spin-correlated radical pairs and triplet excitons generated by back recombination within primary CT-state. Important that spin-polarization in CT- and triplet-states can be detected only by transient EPR technique. The paper discusses possible pathways for spin-correlated radical pairs and triplet excitons formation. Correlation between manifestation of spin-polarization in radical pairs and triplets is reported. While the observation of the back recombination triplet indicates low charge separation efficiency, since back recombination competes with forward charge separation, there is no direct correlation with the OPV efficiency. One of the reason is that EPR experiments were done in the high magnetic field of the EPR spectrometer (versus the natural environment) where of singlet-triplet mixing is more efficient.

Development of a single-shot transient absorption technique: studying exciton dynamics in non-static systems

Kelly S. Wilson, Cathy Y. Wong, Univ. of Oregon (United States)

Single-shot transient absorption (ssTA) spectroscopy is a novel technique that is capable of measuring exciton dynamics of non-static systems, such as molecules as they undergo drying-mediated aggregation. This allows us to correlate evolving exciton dynamics with the progress of molecular aggregation, which, to our knowledge, has not yet been measureable. TA measures exciton dynamics using transients obtained by varying the time delay between a pump and probe pulse. Typically, these time delays are generated using a back-reflecting mirror mounted on a motorized translation stage; as a result, data collection requires a significant amount of time which limits measurements to systems that are static for the duration of the experiment. ssTA overcomes this restriction by employing cylindrically focused pump and probe pulses that enable us to spatially encode time delays, thus permitting collection of an entire transient in a single shot. A time delay range of ~50 ps, which is dependent on the beam profile and wavefront angle, has been successfully implemented. We present the design of our ssTA instrument, including time delay calibration. ssTA is demonstrated by measuring exciton dynamics during solution deposition of copper phthalocyanine dye into a thin film and comparing initial and final transients with traditional TA measurements. We also reveal, for the first time, how these dynamics change as molecules interact with each other during aggregation. This technique will tighten the feedback loop on the development of designer materials with target photophysical properties, such as singlet fission in electron donor materials.

Mechanism of fluorescent silicon nanoparticles

Woong Young So, Qi Li, Rongchao Jin, Linda A. Peteanu, Carnegie Mellon Univ. (United States)

Silicon (Si) is known to have an indirect bandgap transition, which means it has poor fluorescence properties. However, when engineered into sub-nm sized particles, Si nanoparticles become emissive due to quantum confinement. However, in unmodified Si particles, this effect is limited to generating red or near-infrared emission with low quantum yield. To resolve these limitations, surface-modification methods have successfully generated Si particles that emit in the blue, cyan, and green with quantum yields up to ~90%.[1,2] These modifications have also made the Si nanoparticles water-soluble, making them promising in biological applications. To date, the mechanism of emission in these species is still unclear although it has been speculated that charge transfer of SiON could be responsible. To investigate whether emission by these Si nanoparticles proceeds via a charge transfer mechanism, Stark spectroscopy is used. In this method, an external electric field is applied to the Si nanoparticles. Changes in the absorption and/or emission spectra due to the applied field can be taken as strong evidence for a charge transfer mechanism. From the results of Stark spectroscopy, Si nanoparticles are revealed to have ligand to metal charge transfer mechanism along with electric-field quenching, which is useful information for utilization into applications. Addition to the information found, a method of how to tune the emission maxima based on selection of ligands is prosed.

Depth profile interface analysis on full photonic devices

Yan Busby, Univ. of Namur (Belgium); Lucio Ciná, Sara Pescetelli, Aldo Di Carlo, Univ. degli Studi di Roma “Tor Vergata” (Italy); Jean-Jacques Pireaux, Laurent Houssiau, Univ. of Namur (Belgium)

To develop advanced spectroscopies allowing for three-dimensional analysis of hybrid interfaced materials stacks is both highly desirable and challenging. This contribution aims illustrating recent progress in this field by applying depth profile interface analysis on full photonic devices including solar cells and light-emitting devices. Interesting results have been recently obtained in the analysis of devices based on bulk heterojunctions (P3HT:PCBM) or organometal halide perovskite absorbers. In this approach, the device functionality was correlated to the depth-resolved elemental composition and chemistry of interfaces by combining quantitative chemical analysis with high-resolution X-ray photoelectron spectroscopy (XPS) and 3D molecular imaging with time-of-flight secondary ion mass spectrometry (ToF-SIMS). Materials erosion was performed with low-energy (< 1 keV) ion beams (Ar+ or Cs+) to preserve both the chemical information and the interface quality.

In conventional P3HT:PCBM solar cells, the heterojunction components distribution have been resolved the chemical analysis on S2p and O1s peaks, showing a strong PCBM segregation toward the top metal electrode.[1] In mixed halide perovskite absorbers, Cl segregation have been resolved.[2] In organolead halide perovskite solar cells, the interfaces quality, perovskite composition and top electrode metal diffusion was correlated to the perovskite deposition procedure and conversion environment.[3] In mesoscopic perovskite based LEDs, the device lifetime was correlated to the degradation of the hole-transporting material (HTM) and to the perovskite?HTM interface quality.[4] Recent results on graphene-based perovskite solar cells will be also discussed.

Growth method and mechanism formation of the InP nanostructured thin films

Orest Kvitsiani, Tinatin Laferashvili, Institute of Cybernetics (Georgia); Sch Lomithashvili, Georgian Technical Univ. (Georgia); Vladimer Mikelashvili, Institute of Cybernetics (Georgia) and Georgian Technical Univ. (Georgia)

InP is a direct bandgap semiconductor with bandgap width of 1.344 eV which gives strong near infrared emission; infrared photodetectors based on InP represent an important technology in the field of infrared detection. The nanostructured InP thin films exhibit unique properties, their emission wavelength can be tuned within the whole visible and near-infrared range by changing the size of nanocrystals (NCs).

An undoped n-type GaP wafers grown by the Czochralski method with the thickness of about 200-250 μm and the carrier concentration of

2?1016 - 4?1017 cm-3 were used in our experiments. The technology of electrochemical deposition of metallic thin films (20-25 nm thickness) on a semiconductor surface were used for fabrication of the In/GaP metal/semiconductor contacts with "near-ideal" photoelectric characteristics.

Dependence of the electric and photoelectric characteristics on the annealing temperature (100-350 0C) of In/GaP Schottky barrier was investigated. A new region of the strong photosensitivity in the 1.75-2.05 eV area was detected. The appearance of this region was attributed to the formation of a new nanostructured thin film on GaP surface, via the metal and semiconductor interaction.

Here we present new technology fabrication of InP nanostructured thin films, that differs from the Stranski-Krastanov growth mode, and from the formation of InP NCs by droplet epitaxy using molecular beam epitaxy, described in literature lately. The mechanism of the InP NCs formation on the GaP surface is discussed taking into account obtained experimental data and the publications.

Effects of plasmonic metal films on the emission properties of organic films

Sikandar Abbas, Linda A. Peteanu, Carnegie Mellon Univ. (United States)

There is a growing demand to improve the operational lifetime of electroluminescent devices utilizing conjugated polymers which are often deposited over metal electrodes. Photo-degradation of emissive organic layer is one factor that decreases the overall efficiency and longevity of these devices. Therefore, it is important to investigate the underlying photochemistry at metal-polymer interface. Here, effects of metal films on the emission properties of organic polymers are studied using Total Internal Reflection Fluorescence (TIRF) microscopy and Fluorescence Lifetime Imaging (FLIM). Poly(phenylene vinylene) (MEHPPV) is spun cast over gold films of varying thickness (2 nm to 8 nm). While 8 nm gold films completely quench the MEHPPV fluorescence, thinner gold films (~ 2 nm) cause minimal quenching. More surprisingly, MEHPPV exhibits a remarkable increase in photo-stability when deposited on gold films relative to that on glass, even in the presence of molecular oxygen and under continuous laser illumination. When the gold film is replaced with non-plasmonic metal film, this enhanced stability is not observed suggesting it is induced by interactions of the molecules with the surface plasmon of the gold films. The gold films are prepared by sputter coating process. If these films are kept under ambient conditions for ~ 4-5 hours, these metal films behave differently. The photostability effects are not observed when MEHPPV is deposited on these aged films. Experiments are underway to investigate the aging effects.

Ultrafast carrier dynamics in atomically thin 2D transition metal dichalcogenides

Felice Gesuele, Carlo Altucci, Pasqualino Maddalena, Univ. degli Studi di Napoli Federico II (Italy)

Two dimensional crystal are a new class of layered materials with novel and intriguing optical and electronic properties when reduced to single atomic layer. Several applications have been proposed in nanoelectronics, photodetection and photovoltaics; however the practical use of 2D crystals requires a detailed knowledge of the light matter interaction processes. As a consequence charge carrier dynamics is subject of intense studies in 2D crystals and requires ultrafast spectroscopies to be unveiled.

Here we employ hyperspectral ultrafast transient absorption spectroscopy based on supercontinuum probe: in this technique the samples are optically "pumped" using the femtosecond tunable pulse coming from an Optical Parametric Amplifier, and "probed" for changes in transmission with a "white light" laser-generated supercontinuum. We combine this technique with confocal microscopy in order to resolve the carrier dynamics with micron spatial resolution.

We prepare 2D crystals of transition metal dichalcogenides (MoS2 and WS2) by means of mechanical exfoliation (tape method) and characterize them by means of confocal microscopy, Atomic Force Microscopy, Raman and Photoluminescence spectroscopy to determine their number of layers, level of doping, presence of defects. We also compare results obtained with Chemical Vapor Deposition growth.

Transition Metal dichalcogenides are direct gap semiconductor, in the limit of single atomic layer. Our technique shows the presence of negative differential response (bleach) corresponding to the A and B exciton. Measured lifetimes are on the order of tens of picosecond for band-edge recombination mechanisms and depends on the pump fluence and, strongly, on the number of layers. Carrier dynamics in close proximity of flakes edges shows additional decay channel due to edge related defects and trap states.

Our results provide insights into the photophysics of these materials in view of their applications in optoelectronics and photovoltaics.

Science, engineering, and commercialization of flexible, printable 2D atomic materials and devices *(Invited Paper)*

Deji Akinwande, The Univ. of Texas at Austin (United States)

This talk will focus on the scientific progress, engineering achievements, and commercialization of flexible/printable atomically thin materials (graphene, TMDs, phosphorus, Xenes, etc.) and devices. A variety of advancements have been made in electronic, photonic, and passive devices over the past decade including the demonstration of 100GHz flexible transistors, discovery of novel switching properties, development of electronic tattoos, and understanding of interlayer coupling via high-pressure physics. In addition, nanomanufacturing advancements have enabled large-area materials which for the case of graphene has resulted in several commercial products. The talk will conclude with a perspective for the next decade of research.

Plasmon-enhanced photon emission and absorption in monolayer, two-dimensional semiconductors *(Invited Paper)*

Koray Aydin, Northwestern Univ. (United States)

Monolayer two-dimensional transition metal dichalcogenides (2D-TMDCs) have gained immense attention for their desirable transport properties and direct bandgap that have led to a plethora of studies on modern nanoelectronic and optoelectronic applications. These properties are known to occur exclusively in TMDCs when thinned down to one or few monolayers. However reduced dimensionality poses a significant challenge for photonics and optoelectronics applications due to poor light absorption and emission dictated by the volume of semiconductor material. Plasmonic nanostructures have been widely studied for enhancing light-matter interactions in wide variety of material systems resulting in increased emission and absorption properties. 2D Materials provide the ultimate lower limit in terms of material thickness, therefore investigation of plasmon/2D Material hybrid material systems with a specific aim to enhance light-matter interactions is essential for practical optoelectronic applications. In this talk, I will discuss increased photoluminescence emission from MoS2 using both periodic plasmonic nanodisc arrays as well as a single plasmonic optical antenna. I will also describe a method for understanding and identifying the contributions of excitation and emission field enhancements to the overall photoluminescence enhancement using a tapered gold antenna. Additionally, I will describe a systematic study in which we have demonstrated increased light absorption in a monolayer WS2 film.

10349-49, Session 1

Inkjet printed graphene-based field-effect transistors on flexible substrate

Mahmuda Akter Monne, Evarestus Enuka, Texas State Univ. (United States); Zhuo Wang, Chang'an Univ. (China); Maggie Y. Chen, Texas State Univ. (United States)

This paper presents the design and fabrication of inkjet printed graphene field-effect transistors (GFETs). The inkjet printed GFET is fabricated on a DuPont™ Kapton® FPC polyimide film with a thickness of 5 mill and dielectric constant of 3.9 by using a Fujifilm Dimatix DMP-2831 materials deposition system. A layer by layer 3D printing technique is deployed with initial printing of source and drain by silver nanoparticle ink. Then graphene active layer, doped with MoS2 monolayer/multilayer dispersion, is printed onto the surface of substrate covering the source and drain electrodes. Ion gel is adopted as the dielectric material due to the high dielectric constant. The dielectric layer is then covered with silver nanoparticle gate electrode. Characterization of GFET has been done at room temperature (25°C) using HP-4145B semiconductor parameter analyzer (Hewlett-Packard). The characterization result shows for a voltage sweep from -2 volts to 2 volts, the drain current changes from 949 nA to 32.3 μA and the GFET achieved an on/off ratio of 38:1, which is a milestone for inkjet printed flexible graphene transistor.

10349-4, Session 2

Correlated structural and optical properties of the MoTe2-WTe2 alloy system *(Invited Paper)*

Patrick Vora, George Mason Univ. (United States); Ryan Beams, National Institute of Standards and Technology (United States); Sean M. Oliver, Jaydeep Joshi, George Mason Univ. (United States); Sergiy Krylyuk, National Institute of Standards and Technology (United States) and Theiss Research (United States); Irina Kalish, Alina Bruma, National Institute of Standards and Technology (United States); Iris Stone, George Mason Univ. (United States); Arunima Singh, Francesca Tavazza, Stephan J. Stranick, Albert V. Davydov, National Institute of Standards and Technology (United States)

The structural polymorphism intrinsic to select transition metal dichalcogenides provides exciting opportunities for engineering novel devices. Of special interest are memory technologies that rely upon controlled changes in crystal phase, collectively known as phase change memories (PCMs). $MoTe_2$ is ideal for PCMs as the ground state energy difference between the hexagonal (2H, semiconducting) and monoclinic (1T', metallic) phases is minimal. This energy difference can be made arbitrarily small by substituting W for Mo on the metal sublattice, thus improving PCM performance. Therefore, understanding the properties of $Mo_{1-x}W_xTe_2$ alloys across the entire compositional range is vital for the technological application of these versatile materials.

We combine Raman spectroscopy with aberration-corrected scanning transmission electron microscopy and x-ray diffraction to explore the $MoTe_2$-WTe_2 alloy system. The results of these studies enable the construction of the complete alloy phase diagram, while polarization-resolved Raman measurements provide phonon mode and symmetry assignments for all compositions. Temperature-dependent Raman measurements indicate a transition from 1T'-$MoTe_2$ to a distorted orthorhombic phase (T_d) below 250 K and facilitate identification of the anharmonic contributions to the optical phonon modes in bulk $MoTe_2$

and Mo$_{1-x}W$_xTe_2$ alloys. We also identify a Raman-forbidden MoTe$_2$ mode that is activated by compositional disorder and find that the main WTe$_2$ Raman peak is asymmetric for x<1. This asymmetry is well-fit by the phonon confinement model and allows the determination of the phonon correlation length. Our work is foundational for future studies of Mo$_x$W${1-x}$Te$_2$ alloys and provides new insights into the impact of disorder in transition metal dichalcogenides.

10349-5, Session 2

Characterization of few-layer 1T' MoTe2 using polarization resolved Raman scattering and second harmonic generation *(Invited Paper)*

Ryan Beams, National Institute of Standards and Technology (United States); Luiz Gustavo Cancado, Univ. Federal de Minas Gerais (Brazil); Sergiy Krylyuk, Irina Kalish, Berc Kalanyan, Alina Bruma, National Institute of Standards and Technology (United States); Arunima Singh, Lawrence Berkeley National Lab. (United States); Kamal Choudhary, National Institute of Standards and Technology (United States); Patrick Vora, George Mason Univ. (United States); Francesca Tavazza, Albert V. Davydov, Stephan J. Stranick, National Institute of Standards and Technology (United States)

We study the crystal symmetry of few-layer MoTe2 in the metallic 1T' phase using polarization resolved Raman scattering and second harmonic generation (SHG). The bulk 1T' crystals were grown using chemical vapor transport and subsequently exfoliated onto an Si/SiO2 surface. Group theory analysis of the polarization dependence of the Raman scattering for crystals with various number of layers allowed for definitive assignment of the modes and resolves a discrepancy in the literature. The results were also compared to density-functional theory simulations. While bulk 1T' MoTe2 is known to be inversion symmetric, we find that the inversion symmetry is broken for crystals with even numbers of layers, resulting in a strong SHG signal comparable to other transition metal dichalcogenides. The layer-dependence and wavelength dependence of the nonlinear susceptibility was also measured. Finally, the measurements also determine the relationship between the crystal axes and the polarization-dependence of the SHG and Raman scattering, which now allows the anisotropy of polarized SHG or Raman signal to independently determine the crystal orientation.

10349-6, Session 2

Laser treated molybdenum disulfide nanosheets: towards engineering better 2D photodetectors

Moh Amer, Univ. of California, Los Angeles (United States) and King Abdulaziz City for Science and Technology (Saudi Arabia); Frank DelRio, National Institute of Standards and Technology (United States); Fadhel Alsaffar, Abdullah Alrasheed, King Abdulaziz City for Science and Technology (Saudi Arabia)

Transition Metals Dichalcogenide (TMDC) materials have attracted the scientific community due to their unique optical, mechanical, and electronic properties. Molybdenum disulfide (MoS2), an emerging 2D material, exhibit a tunable band gap that strongly depends on the numbers of layers, which makes MoS2 an attractive candidate for optoelectronic applications. However, recent reports have shown that engineering a monolayer using laser thinning can be an effective method without oxide formation, which can be a promising technique for various applications. Here, we investigate this laser thinning process using Raman spectroscopy, μ-XPS, and AFM measurements. Our results show that laser thinned multilayer MoS2 exhibit a large oxide on the surface of the nanosheet, contrary to previous reports. This oxide cannot be detected using μ-Raman spectroscopy. We also show that monolayer and bilayer MoS2 nanosheets exhibit distinctive phonon behavior compared to multilayer MoS2 nanosheets after prolonged laser treatments. This behavior is reflected on the steep intensity decrease for E2g mode, while the intensity of A1g mode slightly changes. This behavior can be interpreted as localized non-equilibrium temperature change due to the formation of anomalous particles on the surface of monolayer and bilayer MoS2 nanosheets. We show that these anomalous particles have a significant effect on the measured Raman properties of pristine monolayer and bilayer MoS2 nanosheets, unlike multilayer MoS2 nanosheets. Our results shed some light on the behavior of MoS2 nanosheets when laser treated for future photodetector applications.

10349-7, Session 3

Two-dimensional van der Waals materials based nonvolatile memory field-effect transistors

Do Kyung Hwang, Young Tack Lee, Won-Kook Choi, Min-Chul Park, Korea Institute of Science and Technology (Korea, Republic of)

Two-dimensional van der Waals (2D vdWs) materials are a class of new materials that can provide important resources for future electronics and materials sciences due to their unique physical properties. Molybdenum disulfide (MoS2) is one of the most promising n-type TMD semiconductors. Several research groups reported on MoS2 nanosheet based transistors that exhibit satisfactory carrier mobility values with high on/off current ratios. On the other hand, a newly discovered 2D vdWs material, called black phosphorous (BP), has generated considerable scientific and technological interest in the research community. 2D BP also has considerable potential for electronic and optoelectronic applications. This is evidenced by recent research on FETs, diodes, and photodetectors involving few-layered BP flakes.

Here, we report on a high performance MoS2 and BP nanosheet based nonvolatile memory transistors with a poly(vinylidenefluoride-trifluoroethylene) (P(VDF-TrFE)) ferroelectric top gate insulator. The MoS2 ferroelectric field-effect transistor (FeFET) shows a highest linear electron mobility value of 175 cm2/Vs with a high on/off current ratio more than 107, and a very clear memory window over 15 V. The program and erase dynamics and static retention properties are also well demonstrated. Our BP ferroelectric FETs (FeFETs) also exhibit a clear memory window of 15 V and a highest linear mobility value of 1159 cm2V-1s-1 with a 103 on/off current ratio at room temperature in ambient air. In order to explore advanced memory applications beyond unit memory devices, we implement two kinds of memory inverter circuits: a resistive-load inverter circuit and a CMOS inverter circuit combined with n-type MoS2.

10349-8, Session 3

Atomic layer deposition of tunable ZnO films for the application in resistive memory *(Invited Paper)*

10349-9, Session 3

Highly efficient strain energy harvester through electrochemical cointercalation into few layered graphene *(Invited Paper)*

Cary L. Pint, Nitin Muralidharan, Adam P. Cohn, Karl Zelik, Vanderbilt Univ. (United States)

Ambient human interactions are mechanical stimuli of low frequencies <1Hz; if efficiently captured could effectively power next generation smart wearable devices and sensors without ever requiring an external power supply. The best present day energy harvesting devices rely on low energy density piezoelectric materials which can only operate efficiently in moderate to high frequencies >10Hz. These limitations can be effectively overcome by taking advantage of the mechano-electrochemical coupling observed in high energy alkali metal electrodes used in traditional energy storage devices. Using two such identical electrodes separated by an electrolyte soaked separator, high energy alkali metal cations can be shuttled between them in response to ambient mechanical stimuli. Here we utilize the non-destructive, ultrafast co-intercalation chemistry of sodium ions into few layered graphene observed in the presence of glyme based solvents. Applying small bending motions which create tension in one electrode and compression in the other sets up a chemical potential gradient causing the migration of solvated sodium ions across the separator creating an electric current. The characteristic rapid ion insertion kinetics and the significantly high volume expansion of the multilayered graphene (~250%) observed during co-intercalation enables effective stress-voltage coupling of ~40 mV even at moderate bending radius of 20 mm at frequencies <0.1 Hz to >1 Hz thus significantly outperforming all known previous devices described in the literature. These results provide a design framework for developing efficient devices to harness energy from ambient human interactions such as exercising, walking, or running, which can be stored or used to power wearable technologies and sensing devices.

10349-10, Session 3

Interfacial dynamics during lateral epitaxy of one-dimensional (1D) nanocrystals over 2D membranes *(Invited Paper)*

Babak Nikoobakht, National Institute of Science and Technology (United States)

Interfacing mismatched low-dimensional materials is an important step in development of hybrid and complex heterostructures. At nanoscale size regimes, interfacial bonding strength and strain energy can very well define the structural integrity and physiochemical properties of semiconductor junctions changing fundamental properties such as distribution of electron-hole wave functions, carrier charge density, etc. Here, we present some of our results on structural behavior of 2D membranes and their overgrowth with laterally grown 1D nanocrystals. Based on the surface energy of 2D layered materials, we hypothesize different bonding scenarios between 1D and 2D nanocrystals. Using experimental results such as structural changes at the interfaces as well as electro-optical properties, we identify some of the interfacial forces involved, and discuss their significance in controlling the properties of the heterojunctions. We use the metal-catalyzed Surface-directed Vapor-Liquid-Solid (SVLS) process for the lateral growth of 1D nanocrystals

10349-11, Session 4

Superionic conductivity in low-dimensional polyborate nanocages *(Invited Paper)*

Vitalie Stavila, A. Alec Talin, Sandia National Labs. (United States); Terrence Udovic, National Institute of Standards and Technology (United States)

Low-dimensional anionic polyborate nanocages such as B12H122-, B10H102-, CB11H12-, and CB9H10-can enable high lithium and sodium conductivity in their corresponding salts. These solid-state materials display entropically driven order-disorder phase transitions with dramatic enhancements in conductivity (e.g., up to ~0.03 S cm-1 for NaCB9H10 at 297 K [1]). The increase in conductivity is due to a vacancy-rich cation sub-lattice, coupled with the high reorientational mobility of the quasi-spherical anionic nanocages (1-2 nm in size). This talk will focus on polyborate nanocage materials design strategies to achieve superionic conductivity at device-relevant temperatures. We will show examples of superionic-conducting phases near room-temperature, which can be further enhanced via doping and nanostructuring. Specifically, results of X-ray diffraction, quasielastic neutron scattering, differential scanning calorimetry, NMR, and AC impedance measurements on promising superionic materials will be presented. The possible relationship between the high reorientational mobilities of the anionic polyborate nanocages and the cationic conductivities will be discussed. Finally, an outlook on further improving the remarkable conductive properties of this class of materials will be presented, and the potential of superionic boron nanocages to meet the requirements of future all-solid-state energy storage devices.

The challenge of dimensional scaling of the non-volatile redox transistor to achieve ultrafast switching

Elliot Fuller, Francois Leonard, A. Alec Talin, Sandia National Labs. (United States)

The rapid performance gains and cost reductions derived from the downscaling of transistor dimensions have nearly come to a stop, signaling the end of Moore's Law. To address the need for novel logic and memory devices with vastly improved energy efficiency, we recently demonstrated a solid-state switch that uses facile ion insertion to modulate the electronic conductance of transition metal oxides. Our device, a non-volatile redox transistor (NVRT), achieves switching voltages as low as 5 mV. However, for the NVRT to be competitive with conventional or emerging electronic devices such as memristors it will have to achieve fast switching times on the order of 10s of nanoseconds or faster. In my presentation, I will describe our recent experimental and modeling efforts to understand how the NVRT, a solid-state electrochemical device, can be downsized to nanoscale dimensions and whether sufficiently fast switching times are possible using presently available materials.

10349-13, Session 4

Revealing interphases in all-solid-state batteries through time-of-flight secondary ion mass spectroscopy *(Invited Paper)*

Marina S. Leite, Univ. of Maryland, College Park (United States)

Mapping where Li preferentially accumulates during cycling in all-solid-state batteries can resolve critical open questions in the field, related to the undesired chemical reactions that causes capacity fade. Here, we implement time-of-flight secondary ion mass spectroscopy (ToF-SIMS) in oxygen free and controlled environment. We determine the spatial distribution of Li-ions in batteries formed by Si/LiPON/LiCoO2, an ideal model system. We directly map Li spatial distribution within all active layers of the batteries upon cycling. We deconvolute Li diffusion from the formation of a solid-electrolyte interphase (SEI) at the LiPON-LiCoO2 interface after the first lithiation step. ToF-SIMS can be applied to directly map Li in a variety of Li-ion energy storage systems, enabling the precise identification of the chemical reactions taking place during cycling, critical for the design of long-life and stable devices.

10349-14, Session 4

Reversible intercalation of lithium and sodium ions into layered and tunnel structured manganese oxides: one-dimensional versus two-dimensional diffusion

Bryan W. Byles, Ekaterina Pomerantseva, Drexel Univ. (United States)

Manganese oxides are attractive electrode materials due to their environmental friendliness, low cost, and high electrochemical activity. We study two different magnesium containing manganese oxides: the first is a material with layered buserite crystal structure (Mg-BUS) and open 2D ion diffusion pathways, and the second material is a tunnel structured phase with todorokite crystal structure (Mg-TOD) containing well-defined 1D diffusion pathways. The characteristic size of the square structural tunnels in Mg-TOD (the length of the tunnel wall) is ~9.6 Å, which is equal to the interlayer spacing in Mg-BUS crystal structure. Benefiting from the similar chemical composition and crystal structure dimensions of these two materials, we have studied the role of diffusion channel geometry in electrochemical reactions of reversible ion intercalation.

It was found that in both Li-ion and Na-ion batteries, the two materials have similar initial capacities of ~120 mAh/g. With continued cycling, the Mg-TOD maintained a greater amount of its initial capacity, indicating superior cycling stability. At a higher current rate, Mg-TOD maintains a higher capacity in a Li-ion battery, while in a Na-ion battery, Mg-BUS maintains a higher capacity, suggesting the layered structure allows for more facile diffusion of the larger and heavier Na+ ions. These results indicate that the tunnel walls, while impeding ion diffusion for the larger Na+ ions, provide structural stability during electrochemical cycling, a finding which can help guide the design of electrode materials for intercalation-based batteries.

10349-15, Session 4

The ion dependent change in the mechanism of charge storage of chemically preintercalated bilayered vanadium oxide electrodes

Mallory Clites, Ekaterina Pomerantseva, Drexel Univ. (United States)

Chemical pre-intercalation is a soft chemistry synthesis approach that allows insertion of inorganic ions into the interlayer space of layered battery electrode materials prior to electrochemical cycling. Previously, we have demonstrated that chemical pre-intercalation of Na+ ions into the structure of bilayered vanadium oxide (?-V2O5) results in record high initial capacities above 350 mAh g-1 in Na-ion cells. This performance is attributed to the expanded interlayer spacing and predefined diffusion pathways achieved by the insertion of charge-carrying ions. However, the effect of chemical pre-intercalation of ?-V2O5 has not been studied for other ion-based systems beyond sodium. In this work, we report the effect of the chemically preintercalated alkali ion size on the mechanism of charge storage of ?-MxV2O5 (M = Li, Na, K) in Li-ion, Na-ion, and K-ion batteries, respectively.

The interlayer spacing of the ?-MxV2O5 varied depending on inserted ion, with 11.1 Å achieved for Li-preintercalated ?-V2O5, 11.4 Å for Na-preintercalated ?-V2O5, and 9.6 Å for K-preintercalated ?-V2O5. Electrochemical performance of each material has been studied in its respective ion-based system (?-LixV2O5 in Li-ion cells, ?-NaxV2O5 in Na-ion cells, and ?-KxV2O5 in K-ion cells). All materials demonstrated high initial capacities above 200 mAh g-1. However, the mechanism of charge storage differed depending on the charge-carrying ion, with Li-ion and Na-ion cells demonstrating predominantly pseudocapacitive behavior and K-ion cells revealing diffusion limited intercalation processes. We will highlight how the size of chemically preintercalated, charge-carrying ions affects electrochemical properties and the mechanism of charge storage of the bilayered vanadium oxide electrodes.

10349-16, Session 4

Reversibility of water intercalation in potassium- and magnesium-intercalated Mxenes

Ilia N. Ivanov, Eric S. Muckley, Michael Naguib, Jagjit Nanda, Oak Ridge National Lab. (United States)

High electrical conductivity and high surface area of thermodynamically stable inorganic MXenes, two-dimensional layered carbide or nitrides materials showed promising performance in energy storage devices including Li- and Na- ion batteries and supercapacitors. We investigated the effect of water vapor intercalation in thin membrane of K+ and Mg2+ intercalated T3C2 MAxenes (Ti3C2-K and Ti3C2-Mg) using gravimetric technique and electrical resistance measurements.We demonstrate that Ti3C2-K and Ti3C2-Mg interact with water vapor differently, probably because of difference in size of intercalated cation (150 and 85 pm radium of K+ and Mg2+ ions respectively). Water remains partially trapped inside MAxenes layers even after prolong exposure of samples to vacuum on recovery stage. The recovery of Mxene resistive response in the vacuum on dehydration is an order of magnitude slower than the recovery time of the gravimetric response.

We used neutron total scattering experiments on hydrated MXenes and DFT-MD simulations of to develop a model of water interaction with Ti3C2-K and Ti3C2-Mg.

We show that Ti3C2-K and Ti3C2-Mg can be used as water vapor sensors in 0-85% relative humidity range, achieving detection thresholds of ~0.8%. This is comparable with the performance of metal oxides, graphene oxide and conjugated polymers based RH sensors.

10349-17, Session 4

Structural and optical studies of ZnO:Mn nanostructures

Arun Aravind, Univ. of Kerala (India); Jayaraj M. K., Cochin Univ. of Science & Technology (India)

ZnO has great potential in a wide range of applications such as microelectronics, optoelectronics and sensors. Hydrothermal method has proven to be an effective method for the growth of nanostructured materials. Dilute magnetic semiconductors (DMS) gained much more attention due to their wide applications in spintronics. A large number of research works is published after the theoretical prediction on the room temperature ferromagnetism (RTFM) in transition metals doped ZnO. Manganese doped ZnO nanostructures were prepared by hydrothermal method. An appropriate amount of ammonium hydroxide was added to the mixture of zinc acetate (0.3M - 1M) and manganese acetate (0.001M-0.1M) solution to adjust the pH value above 9. These solutions were transferred into Teflon lined stainless steel autoclave and maintained at various temperatures in the range of 100-200oC for 3 to 6 h under autogenous pressure. The formation of ZnO:Mn nanostructures were confirmed by scanning electron microscopy (SEM), x-ray diffraction (XRD), Raman scattering and EDAX analysis. Optical absorption studies confirms the red shift of ZnO:Mn nanostructures with TM doping. The broad green-yellow-orange photoluminescent emission from ZnO nanostructures originates from the oxygen vacancy or ZnO interstitial related defects. The presence of non-polar E2high and E2low Raman modes in nanostructures indicates that TM doping didn't change the wurtzite structure of ZnO.

Comparison of structural properties of iron nano-particles prepared by sol-gel method and spin coating technique

Sunil Dehipawala, Queensborough Community College

(United States); Pubudu Samarasekara, Univ. of Peradeniya (Sri Lanka); Harry D. Gafney, Queens College (United States)

Small scale magnets have very high technological importance today. Instead of traditional expensive methods, scientists are exploring new low cost methods to produce micro magnets. We synthesized thin film magnets containing iron and nickel oxides. Films were synthesized using sol-gel and spin coating methods. Several different precursor concentrations were tested to find out the ideal concentrations for stable thin films. Structural properties of iron particles were investigated using Mossbauer spectroscopy, X-ray absorption spectroscopy including Extended X-ray Absorption Spectroscopy, X ray Absorption Near Edge Structure, and pre-edge feature appears before the main absorption edge. The variation in oxidation state and other structural parameters were deduced. It appears the oxidation state of iron particles prepared by sol-gel method is very stable up to annealing temperatures of 6000C. The iron particles prepared by spin coating method exist in two different chemical environments with slightly different oxidation states.

Visible light irradiation-induced conductivity change for CVD-grown graphene on different substrates

Xiangdi Li, Xianming Liu, Yun Luo, Peng Zhang, Xiaohua Lei, Weimin Chen, Chongqing Univ. (China)

Transparent conductive films (TCFs) play important roles in applications such as touch panels, liquid crystal displays, solar cells, and organic light emitting diodes. Graphene with atomic scale thickness has been investigated widely as potential replacements for ITO in TCFs. The TCF should conduct electricity effectively under visible light irradiation. However, some previous works show that the conductivity of graphene may change. It is necessary to understand the stability of electrical properties of graphene electrodes under visible light irradiation.

This research examines the influence of lighting on the electrical properties of graphene on different substrates, including PET, glass and SiO2, which were the most widely used materials represent the flexible and rigid applications. The graphene sheets were prepared by CVD and subsequently transferred to the three different substrates. Samples were placed inside a vacuum chamber with optical windows. The resistances of graphene under periodic visible light irradiation were measured. Results show that the resistances for graphene samples on all substrates increased slowly under lighting, while decreased slowly as well after the light was switched off. The degree and pace of the change were different for graphene on different substrates, which were influenced as well by the illumination time, environment atmosphere and irradiation power. Graphene on flexible PET substrate is more stable than that on other substrates. Photo-desorption of small molecules on the graphene surface may be the main reason resulting in the graphene resistance increasing.

Hydrogen sensing properties based on self-assembly monolayer film of Pt/Pd core-shell nanocrystals

Gwiy-Sang Chung, Univ. of Ulsan (Korea, Republic of)

This report presents the synthesis of Pt/Pd core-shell nanocrystals and their monolayer distribution as a resistivity-type sensor that can be utilized for implementing a fast-response hydrogen (H2) sensor. Pd nanocubes with an average size of 40 nm were synthesized via a chemical route, subsequently, Pt/Pd core-shell nanocrystals as colloids were synthesized using these Pd nanocubes via a facile chemical route and were then carefully assembled on a SiO2/Si substrate using the self-assembly monolayer (SAM) technique. Three different Pt/Pd core-shell nanocrystals with varied Pt shell thicknesses were synthesized for the SAM process. The short diffusion length of Pt/Pd due to the thin Pt shell layer and the monolayer distribution of the Pt/Pd core-shell preferentially accelerated the adsorption-desorption of the H2 molecules on the sensing interface, resulting in a very quick response to H2 gas. At an optimum operating temperature of 150oC, the sensor showed a fast-response time of 6 sec, a maximum response of 3.6% to 1 vol% gas concentration, and a broad detection range of 0.001-4 vol% H2 concentrations. The aforementioned outcomes of the as-fabricated sensor demonstrate the possibility of implementing an efficient H2 sensor for safety applications.

10349-38, Session PWed

Formation properties of two-dimensional atomic layers for high-efficiency multi-layer-nanostructure smart packages

Sungwon Hwang, Kyung-Jin Yeum, Konkuk Univ. (Korea, Republic of)

Two dimensional (2-D) atomic layers have several advantages such as flexibility in choosing substrates, easy fabrication, large package area, minimum change of components, enhanced expiration date, and reduced defects by oxygen blocking structure for smart packages. The formation of 2-D atomic layers preventing oxygen penetration is crucial for enhancing the efficiency of multi-layer-nanostructures(MLNs). The nanostructures of two types of packages containing defect-free MLNs with atomic layer and defective thin film were determined by scanning electron microscopy and high-resolution transmission electron microscopy. The defective thin film has a porous structure, whereas the defect-free MLNs with atomic layer had a single crystal structure. These results suggest that the well-defined 2-dimensional atomic layer of MLNs can be utilized for the high- efficiency smart packages.

Molecular dynamics modeling and simulation on graphene nanoribbon trench for fullerene shuttle device

Jeong-Won Kang, Korea National Univ. of Transportation (Korea, Republic of)

The position controlling C60 fullerene encapsulated into a graphene-nanoribbon trench is investigated via classical molecular dynamics simulations. The graphene-nanoribbon trench can provide nanoscale empty spaces, and a C60 encapsulated therein can be considered as media for a nanoelectromechanical shuttle device. The classical molecular dynamics simulations presented here provide information on the potential application of a graphene-nanoribbon trench in a C60 shuttle device. Driving forces applied to C60 resulted in its motion toward the edges of the graphene-nanoribbon trench, the suction forces induced at both edges were balanced with the driving forces, and finally, the C60 fullerene gradually settled on the edges of the graphene-nanoribbon trench after several oscillations. The results of the present simulation suggest the importance of graphene-nanoribbon trenches encapsulating fullerenes in a wide range of applications in the field of nanotechnology.

The performance of quantum dots-based white light-emitting diodes

Kuan Lin Chen, Shu-Ru Chung, National Formosa Univ. (Taiwan)

Recently, the investigation of quantum dots (QDs) as a color converter for white light-emitting diodes (WLEDs) application has attracted a great deal of attention. Because that the narrow emission wavelength can be controlled by their particle sizes and compositions, which is facilitated to improve the color gamut of display as well as color rendering index (CRI) and the correlated color temperature of WLEDs. In a typical commercially available LCD display, the color gamut is approximately to 92 % of the National Television System Committee (NTSC). In order to enhance NTSC, the full width at half-maximum (FWHM) of color converter should be less than 30 nm. Therefore, the QDs are the best choice for display application due to the FWHM of QDs is less than 30 nm. In this study, the hot injection method with one-pot process is used to synthesis of colloidal ternary ZnCdSe green (G-) and red-emission (R-) QDs with a narrow emission wavelength around 530 and 613 nm. By controlling the complex reagents-steatic acid (SA) and lauric acid (LA), high performance of G- and R-QDs can be prepared. The quantum yields (QYs), particle sizes and FWHM for G- and R-QDs are 70, 30 %, 3.2 ± 0.5, 4.1 ± 0.5 nm and 25, 26 nm, respectively. In order to explore the performance of QDs-based WLEDs, mixing ratios effect between G-QD and R-QD are studied and the WLED is packed as conformal-type. Different ratios of G-QD and R-QD (10:1, 20:1 and 30:1) are mixed and fill up the 3020 SMD blue-InGaN LED. After that, UV curable gel is deposited on the top of QD layer to form WLED and named as LED-10, LED-20 and LED-30. The results show that the Commission International d'Eclairage (CIE) chromaticity coordinates, color rendering index (CRI), luminous efficacy of LED-10, LED-20 and LED-30 are (0.27, 0.21), 53, 1.9 lm/W, (0.29, 0.30), 72, 3.3 lm/W and (0.25, 0.34), 45, 6.8 lm/W, respectively. We can find that the positions of CIE can be controlled simply by adjusting the ratios of G- and R-QDs. Besides, the LED-20 device shows the high CRI, implying that it has great potential for application on backlight of display technology and solid-state lighting.

Layer-number-dependent optical properties and application for thickness determination in 2D graphene-like materials

Li Xiaoli, Wang Ying, Hebei Univ. (China)

2D graphene-like materials (2DMs) can be usually exfoliated from layered materials (LMs), which form strong chemical bonds in-plane but display weak van der Waals (vdW) bonding out-of-plane. The remarkable properties of 2DMs make them to be the ideal materials for promising applications in nanoelectronics and optoelectronics devices. However, the properties of 2DMs are highly related to their thickness, i.e., layer number (N), and thus the N determination of 2DM flakes is critical to cater to quality appraisals for the 2DM industrial products. Layer-number-dependent optical properties of 2DMs have been widely probed by several optical techniques, such as optical absorption, Raman spectroscopy, photoluminescence. The definite relations between the optical properties and N by different optical techniques can be demonstrated for rapid and accurate identification of the thickness or N of 2DM flakes. This paper will be expected to pave the ways to construct N-identification techniques of 2DM flakes based on optical techniques, benefit the whole 2DM community for fundamental study, practical applications and quality appraisal for industrial products.

10349-42, Session PWed

Carrier transfer in coupled quantum dot-quantum well hybrid structure

Ying Wang, Qinglin Guo, Suheng Zhang, Xiaoli Li, Baolai Liang, Shufang Wang, Guangsheng Fu, Hebei Univ. (China)

The carrier coupling and transfer in InAs QDs and In0.15Ga0.85As QW hybrid structures grown by molecular-beam epitaxy are investigated by using photoluminescence (PL) spectroscopy. The samples contains a layer of 1.8 ML self-assembled InAs QDs and a QW of 15 nm In0.15Ga0.85As separated by a GaAs spacer of 3 nm or 170 nm. At the low temperature of 10 K, PL spectra are measured as a function of laser excitation intensity in the range of 0.01 W/cm2 ~ 10000 W/cm2. As indicated by figure (a), the QW is strongly coupled with the QDs and carriers can transfer from the QW into InAs QDs though the 3 nm thin GaAs spacer, but not for the 170nm spacer sample. The strong carrier transfer enhance the carrier injection for QD ground states (GS) and subsequently lead to a coulomb effect in the 3 nm spacer sample, which enable the PL peak from the QD GS to display a blueshift while the laser excitation intensity is over 100 W/cm2. Further temperature-dependent PL measurements in figure (d) show that the integrated intensity of QD peak has almost no changes under 170 K for the coupled hybrid structure. However, a clear increase of QD PL integrated intensity is found for the uncoupled structure, likely due to carrier thermal excitation from QW to QDs. In summary of PL results, the coupled hybrid structure has a better PL performance than the uncoupled one in consideration of carrier collection efficiency, temperature stability, and exciton localization effect.

PECVD growth of high quality graphene on interdigital electrodes of MEMS supercapacitor

Azrul Azlan Hamzah, Hafzaliza E. Zainal Abidin, Mohd A. Mohamed, Burhanuddin Y. Majlis, Univ. Kebangsaan Malaysia (Malaysia)

MEMS supercapacitor with vertical graphene layers grown via Plasma Enhanced Chemical Vapor Deposition (PECVD) at different deposition times has been investigated in this work. Graphene attracts much attention in supercapacitor research due to its exceptional properties such as high electrical conductivity, good electrochemical stability and excellent mechanical behavior. The fabrication of direct growth graphene nanolayers on MEMS supercapacitor interdigital electrodes is achieved via several subsequent Plasma-Enhanced Chemical Vapor Deposition (PECVD) deposition, E-beam evaporation and spin coating processes. PECVD has been chosen in this work due to its high growth selectivity and excellent nanostructure patterning. PECVD graphene was grown at 1000°C at times ranging from 2 to 10 minutes, with 40 Watt power. All samples were analyzed using Raman spectroscopy, Field Emission Scanning Electron Microscope (FESEM) and Atomic Force Microscopy (AFM). Raman analysis shows that at growth time of 2 minutes, only D band and G band peaks appear. In absence of the 2D peak, amorphous carbon formation was confirmed. At growth time of 6 minutes, D band, G band and 2D band were detected. The ratio I2D/IG is 0.36 and the value of full width at half maximum (FWHM) is 52.57 cm-1, which confirmed that multilayer graphene was formed on the MEMS supercapacitor. High quality graphene layers has been deposited for growth time of 10 minutes, in which the Raman spectra exhibits I2D/IG value of 0.43. The value of FWHM is calculated to be 60.48 cm-1, indicating a highly structured graphene layers, useful for increasing the efficiency of MEMS supercapacitor.

10349-44, Session PWed

Enhanced performance in quantum dot light-emitting diodes by adopting interfacial layer on ZnO

Jinyoung Yun, Kukjin Lee, Hokyun Jang, Korea Univ. (Korea, Republic of); Jeonghun Kwak, The Univ. of Seoul (Korea, Republic of); Gyutae Kim, Korea Univ. (Korea, Republic of)

Since the first quantum dot (QD) light-emitting diodes (QLEDs) were introduced about two decades ago, QLEDs emerge as a next generation flat-panel display because of their unique optical characteristics such as the narrow spectral emission, easy control of the emission wavelength by changing their size and composition. However, the performance of QLEDs is still lacking compared with other light-emitting devices. Thus, more research in material synthesis, device design, and processes are required to improve the efficiency and lifetime. Balancing electrons and holes in QLEDs is one of the important factors to improve the performance. Particularly, using a metal oxide electron transport layer (ETL) and an organic hole transport layer (HTL) in QLEDs leads to severe imbalance of electrons and holes due to intrinsic difference of electrical properties between organic and inorganic materials. In this work, we introduce enhanced performance of inverted red-emitting QLEDs by adopting a non-conjugate polymer monolayer onto the ZnO ETL. The interfacial polymer layer can tune the work function of the metal oxide surface. Also, the device showed reduced leakage current and improved device performance compared to those without the interfacial layer. It means that electrons and holes were balanced well by controlling the electron injection into the QLEDs with the interfacial layer. The performance of the QLEDs and the analysis on charge balance will be presented.

10349-45, Session PWed

Synthesis and characterization of Au-MWCNT/PEDOT: PSS composite film for optoelectronic applications

Jasna Mannayil, Anjana R., Jayaraj M. K., Cochin Univ. of Science & Technology (India)

Recently, flexible organic optoelectronics have got great attention because of their light weight, mechanical flexibility and cost effective fabrication process. Conjugated polymers like PEDOT: PSS are widely used for the transparent electrode applications due to its chemical stability, high conductivity, flexibility and optical transparency in the visible region. Conductivity of the PEDOT: PSS polymer can be enhanced by adding organic solvents or conducting nano fillers like CNT, graphene, etc. Carbon nanotubes are good nano fillers to enhance the conductivity and mechanical strength of PEDOT: PSS composite film. In the present work, the effect of gold nano particles in PEDOT: PSS/CNT composite is studied. The conductivity enhancement in PEDOT: PSS/CNT thin films can be attributed to the formation of CNT network in the polymer matrix and conformational change of the PEDOT from benzoid to quinoid structure. Even though the conductivity was enhanced, the transparency of the composite thin films decreased with increase in CNT concentration. To overcome this problem, gold nano particles were attached to CNT walls via chemical route. Au-MWCNT/PEDOT: PSS composite films were prepared by spin coating method. TEM images confirmed the decoration of gold nano particles on CNT walls. Electrical and optical properties of the composite films were studied. This simple solution processed conducting films are suitable for optoelectronic applications

Photon-trapping micro/nanostructures for high linearity in ultra-fast photodiodes

Hilal Cansizoglu, Yang Gao, Cesar B. Perez, Soroush Ghandiparsi, Ekaterina Ponizovskaya Devine, Univ. of California, Davis (United States); Mehmet F. Cansizoglu, The Univ. of Texas Southwestern Medical Ctr. at Dallas (United States) and Univ. of California, Davis (United States); Toshishige Yamada, Univ. of California, Santa Cruz (United States); Aly Elrefaie, Shih-Yuan Wang, Saif M. Islam, Univ. of California, Davis (United States)

Photodetectors (PDs) in datacom and computer networks where the length of the links are a few meters only, need to handle higher than typical input power used in communication links. A thin absorption region can limit the maximum power handling capability of the high-speed PD, contributing to nonlinearity in the currents that can contribute to high order harmonic generations and degrade the signal-to-noise ratio. Nonlinearity is caused by a decrease in the electric field under intense illumination that reduces the carrier velocity due to a space-charge effect or an electric-field screening effect in a thin photo-absorption region. Photon-trapping micro/nanostructures can effectively bend the light in-plane to the direction of the PD surface and avoid current crowding in a PD. Consequently, the photocurrent per unit volume remains at a low level contributing to high linearity in the photocurrent. We present the effect of design and lattice patterns of micro/nanostructures on the linearity of ultra-fast silicon PDs designed for high speed multi gigabit data networks.

Highly efficient silicon photovoltaic using photon trapping micro/nano structures

Yang Gao, Hilal Cansizoglu, Ahmet Kaya, Ahmed S. Mayet, Soroush Ghandiparsi, Cesar B. Perez, Univ. of California, Davis (United States); Ekaterina Ponizovskaya Devine, W&WSens Devices, Inc. (United States); Toshishige Yamada, Univ. of California, Santa Cruz (United States); Aly Elrefaie, Shih-Yuan Wang, W&WSens Devices, Inc. (United States); Saif M. Islam, Univ. of California, Davis (United States)

Crystalline silicon (c-Si) remains the most commonly used material for photovoltaic (PV) cells in the current commercial solar cells market. However, current technology requires “thick” silicon due to the relative weak absorption of Si in the solar spectrum. We demonstrate several CMOS compatible fabrication techniques including dry etch, wet etch and their combination to create different photon trapping micro/nanostructures on very thin c-silicon surface for light harvesting of PVs. Both the simulation and experimental results show that these photon trapping structures are responsible for the enhancement of the visible light absorption which leads to improved efficiency of the PVs. Different designs of micro/nanostructures via different fabrication techniques are correlated with the efficiencies of the PVs. Our method can also drastically reduce the thickness of the c-Si PVs, and has great potential to reduce the cost, and lead to highly efficient and flexible PVs.

10349-48, Session PWed

InAs/GaAs quantum dot lasers monolithically grown on Si substrates

Mingchu Tang, Jiang Wu, Siming Chen, Mengya LIao, Alwyn Seeds, Huiyun Liu, Univ. College London (United Kingdom)

As a future driving force technology, Si photonics can improve the low-cost and high speed inter-chip communication by using optical transmission instead of electrical connection. However, Si based light-emitting sources have been considered as “holy grail” for silicon photonics due to bulk Si has in-direct bandgap. Using InAs/GaAs quantum dots (QDs) as active region in laser structure, could bring high performance light emitting sources on Si platform. The challenge of monolithic growth is that high density of threading dislocations will propagate into laser active region due to the lattice mismatch between GaAs and Si. In this paper, we have optimised the III-V buffer layer includes GaAs buffer layer and InGaAs/GaAs strained-layer superlattices (SLSs) defect filter layers (DFLs), which sufficiently reduce the density of threading dislocations.

The laser devices with optimised GaAs buffer layers and DFLs have been fabricated as broad-area laser with 50 μm ridge width without any facet coating. the maximum operation temperature is 75 °C under continuous-wave (CW) operation mode with threshold current density at 62.5 A/cm2 at room temperature. A 29.7% drop in power after 3,100 h is observed during the lifetime test. These results indicate that a reliable Si based laser device has been demonstrated, and has the capable to be integrated on Si opto-electronic integration circuits.

10349-50, Session PWed

Modified Richardson Dushman thermionic emission equation for metals and nano-materials

Olukunle Charles Olawole, Dilip K. De, Sunday O. Oyedepo, Covenant Univ. (Nigeria)

Ordinary Richardson Dushman equation fails to explain many experimental observations, of thermionic emission including temperature variation of work function in metals. Recently it has been shown that it does not fit very well either thermionic emission data from graphene and carbon nano-tube. In this paper we show that Modified Richardson Dushman (MRD) equation derived on the basis of temperature variation of Fermi levels, explains very well thermionic emission data from many materials, including temperature variations of work function, except for alkali metals. It is found that it not only explains thermionic emission data of graphene and carbon nano-tube better than ordinary Richardson Dushman (RD) equation but also explains some physical parameters such as effective thermionic mass, values of work function and its temperature variation which RD equation cannot.

10349-18, Session 5

2D emerging devices: from ordinary to extra-ordinary *(Keynote Presentation)*

Deji Akinwande, The Univ. of Texas at Austin (United States)

This talk will present our latest research advances on 2D nanomaterials towards greater scientific understanding and advanced engineering applications. In particular the talk will highlight our work on topological 2d materials, zero-power devices, wearable sensors, straintronics, and new topological semiconductor transistor concepts. Finally, recent commercial electronic products employing graphene and related materials will be featured.

10349-19, Session 5

Monolithic integration of III-V nanostructures for electronic and photonic applications *(Invited Paper)*

Benedikt Mayer, IBM Research - Zürich (Switzerland); Stephan Wirths, Svenja Mauthe, IBM Research - Zürich (Swaziland); Lukas Czornomaz, Heinz Schmid, Marilyne Sousa Petit, IBM Research - Zürich (Switzerland); Clarissa Convertino, IBM Research - Zürich (Swaziland); Yannick Baumgartner, IBM Research - Zürich (Switzerland); Heike Riel, IBM Research - Zürich (Swaziland); Kirsten E. Moselund, IBM Research - Zürich (Switzerland)

At IBM we have recently developed a novel III-V integration scheme, Template-Assisted-Selective-Epitaxy (TASE), where III-V material is grown directly on top of Si within oxide nanotubes or microcavities which control the geometry of nanostructures. This allows us to grow III-V material non-lattice matched on any crystalline orientation of Si, to grow arbitrary shapes as well as abrupt heterojunctions and to gain more flexibility in tuning of composition. In this talk applications for heterojunction tunnel FETs, MOSFETs as well as microcavity III-V lasers monolithically integrated on Si will be discussed along.

10349-20, Session 5

Self-aligned nanoscale processing solutions via selective atomic layer deposition of oxide, nitride, and metallic films *(Invited Paper)*

Necmi Biyikli, Utah State Univ. (United States); Ali Haider, Petro Deminskyi, Mehmet Yilmaz, Bilkent Univ. (Turkey)

Controlling the lateral dimensions of thin films by patterning is an essential requirement for microelectronics industry for continuous device miniaturization. Conventionally, thin film patterning is achieved by photolithography which includes several processing steps. During the atomic layer deposition (ALD) process, film nucleation is critically dependent on the surface chemistry of the substrate which makes it possible to achieve selective ALD (SALD) by chemically modifying the substrate surface. Local modification of substrate surface opens up possibilities to achieve lateral control over film growth in addition to robust thickness control during ALD process. SALD offers numerous advantages in nanoscale device fabrication such as reduction of the lithography steps required, elimination of complicated etching processes, and minimization of expensive and poisonous reagent use.

In this work, we report detailed investigation to select the most compatible inhibition layer among poly(methyl methacrylate) (PMMA), polyvinylpyrrolidone (PVP), and ICP-polymerized fluorocarbon layers for SALD of metal-oxide and metallic thin films. In addition, multi-layer graphene layers are explored as plasma-compatible inhibition layers for selective deposition of III-nitride materials. Extensive materials characterization efforts are carried out to correlate the ALD recipe parameters with the selective deposition performance. The robust albeit rather simple and straightforward technique presented in this work overcomes various challenges associated with previous methods of SALD and provides an alternative route towards nano-patterning particularly for the sub-10 nm technology nodes.

10349-21, Session 6

Triangle-lattice InGaN/GaN nanocolumn arrays exhibiting photonic crystal effect *(Invited Paper)*

Katsumi Kishino, Shunsuke Ishizawa, Yuzo Matsui, Jun Yoshida, Sophia Univ. (Japan); Ai Yanagihara, Sophia Univ. (Jordan)

GaN nanocolumns are extensively studied as promising nano-materials for high-performance visible emitters because of their dislocation filtering and strain relaxation effects. The size and position of nanocolumns were precisely controlled using Ti-mask selective-area growth (SAG) by RF-MBE, fabricating uniform arrays of pn-junction InGaN/GaN nanocolumns. The periodic arrangement in the nanocolumn arrays led to nanocolumn photonic crystal (PhC) effect. It is however, necessary to integrate a wave-guiding scheme in the nanocolumn system to activate efficiently the PhCs. In the experiment, triangle-lattice GaN nanocolumn arrays with the lattice constant from 280 to 350 nm were grown, followed by the growth of InGaN/GaN superlattice buffer, MQW, and p-type GaN cladding layers. In the upper region of pn-junction nanocolumns from SL to p-GaN, the nanocolumn diameter increased and introduced the increase in the equivalent refractive index, which acts to confine the optical field there. Thus, the optical mode propagated laterally, interacting with the nanocolumn PhC. The diffraction at the photonic band edge resulted in high-directional beam radiations from the nanocolumn system. The photonic band edge was systematically investigated for various nanocolumn arrays with L=280–250 nm. The experimental photonic band diagram for the triangular-lattice pn-junction InGaN/GaN nanocolumn array exhibited a clear photonic band edge.

10349-22, Session 6

Top-down etching of GaN nanostructures for optoelectronics and beyond *(Invited Paper)*

George T. Wang, Benjamin Leung, Sandia National Labs. (United States); Miao-Chan Tsai, Changyi Li, Ganesh Balakrishnan, The Univ. of New Mexico (United States)

Chemical etch processes for GaN materials and devices are significantly underdeveloped due to its apparent inertness to common wet etchants. To fully realize the potential of the III-nitrides in new opto-electronic devices, such as in optical nano- and microcavity lasers, more complete knowledge and development of techniques with anisotropic etching are needed. Here, we explore the etch characteristics of GaN using the general geometric principles of crystallographic dissolution processes to enable the prediction of facet-determined etch structures. We perform the first complete orientation-dependent etch rate measurements, clearly showing fast a-plane etch rate relative to m-plane, and use them to predict the faceting of pillar structures with good agreement with experiment. Finally, we use these developments in GaN wet etching to fabricate functional optical nanowire and microcavity structures, where faceting enables smooth sidewalls for a high quality cavity structure. Control over the lasing properties of nanowires fabricated using this method, including single-mode lasing, polarization control, wavelength tuning, and beam shaping, will also be highlighted.

This work was performed, in part, at the Center for Integrated Nanotechnologies, a U.S. Department of Energy, Office of Basic Energy Sciences user facility. Sandia National Laboratories is a multi-mission laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

10349-23, Session 6

Controlling reabsorption effect of Bi-color CdSe quantum dots-based white light-emitting diodes

Cyuan-Bin Siao, National Central Univ. (Taiwan); Shu-Ru Chung, National Formosa Univ. (Taiwan); Kuan-Wen Wang, National Central Univ. (Taiwan)

Because the traditional white light-emitting diode (WLED) composed of YAG: Ce phosphor shows low color quality due to lack of red color emission, the colloidal semiconductor quantum dots (QDs) have the potentials to be used in WLED as a down-converting component to replace incandescent lamps. Among various QDs, CdSe has been extensively studied because it possesses attractive characteristics such as high quantum yields (QYs), narrow emission spectral bandwidth, as well as size-tunable optical characteristics. However, in order to enhance the color rendering index (CRI) of WLED, blending materials with different emission wavelengths has been used frequently. Unfortunately, these procedures are complex and time-consuming, and the emission energy of smaller QDs can be reabsorbed by larger QDs, resulting in decreasing the excitation intensity in yellowish-green region. Therefore, in this study, in order to decrease the reabsorption effect and to simplify the procedures, we have demonstrated a facile thermal pyrolyzed route to prepare bi-color CdSe QDs with dual-wavelengths. The emission wavelengths, particle sizes, and QYs of QDs can be tuned from 537/595 to 537/602 nm, 2.59/3.92 to 2.59/4.01 nm, and 27 to 40 %, for GR1 to 3 samples, respectively when the amount of Se precursor is decreased from 1.5 to 0.75 mmol. Meanwhile, the area ratio of green to red (Ag/Ar) in fluorescence spectra is gradually increased, due to the increase in growth rate, decrease in nuclei formation in red emission. The GR1, GR2, and GR3 QDs are then encapsulated by convert types to form the LED, in which the QDs are deposited on the blue-emitting InGaN LED chip (?em = 450 nm). After encapsulation, the devices properties of Commission International d'Eclairage (CIE) chromaticity and Ag/Ar area ratio are (0.40, 0.24), 0.28/1, (0.40, 0.31), 0.52/1, and (0.40, 0.38), 1.02/1, respectively for GR1, GR2, and GR3. The results show that the green emission intensity are strongly reabsorbed by red emission, as the Ag/Ar area ratios are gradually increased and the CIE are dramatically shift to white light region, suggesting that the Se amount not only can tune the red emission intensity but also can decrease the reabsorption effect. Based on the above results, the GR3 is suitable to be applied for WLED against the reabsorption effect. Therefore, the GR3 QDs are further blended with different transparent acrylic-based UV resin (UV resin/QDs=15/85, 30/70, and 45/55) and the CIE, CRI, and luminous efficacy are (0.37, 0.36), 70, 2.85 lm/W, (0.35, 0.34), 73, 2.98 lm/W, and (0.29, 0.29), 70, 3.26 lm/W, respectively. As a result, by simply adjusting the concentration of Se precursor, QDs with dual-wavelengths can be prepared and the reabsorption effect can be avoided to show promising lighting properties for the application in WLED.

10349-24, Session 7

Semiconducting nanowires self-assembly towards solution processed electronics for sensing and RF applications *(Invited Paper)*

Maxim N. Shkunov, Marios Constantinou, Univ. of Surrey (United Kingdom); Sergiy Krylyuk, Theiss Research (United States); Grigorios-Panagiotis Rigas, Bobur Mirkhaydarov, Kaspar Snashall, Michael P. Hughes, Univ. of Surrey (United Kingdom); Brian A. Korgel, The Univ. of Texas at Austin (United States); Philippe Caroff, The Australian National Univ. (Australia)

Single crystalline inorganic nanowires (NWs) are exceptional semiconducting components for solution-processed, low-cost printed electronic devices. Their excellent charge-carrier mobility, high surface-to-volume ratio and solution processability make them ideal building blocks for flexible circuits, chemical/biological sensors and RF switch elements. The key challenge in nanowire printed electronics is the controllable deposition of nanowires with selected properties on pre-defined locations. NWs selective assembly based on their morphological and electrical properties remained mainly unexplored, with NWs being deposited as-synthesised, thus dramatically affecting the reproducibility and reliability of NW-based devices.

In this work we address the above challenge and demonstrate high quality solution processable nanowire assembly platform, targeting field-effect transistor for flexible electronics for chemical and biological sensor applications utilising Si nanowires, and RF switch devices for reconfigurable antennas with InAs nanowires. For reproducible printable NW FETs, we have developed a method for one-step nanowire positioning, alignment, purification and selection by using dielectrophoresis (DEP) and impedance spectroscopy to isolate the highest conductivity and lowest defect density Si nanowires at 5-20MHz DEP signal range. The method also provides ordered monolayer assembly of NWs with desired lengths and controlled number of NWs in the device channel area, ranging from a few NWs to hundreds per device.

Finally, functionalised Si NW FETs are developed with highly sensitive response to volatile organic compounds with sub-ppm detection level, with high prospects for both environmental monitoring and early stage cancer related diagnostics. Using the same methodology, very–low impedance InAs nanowire FETs are demonstrated for RF applications.

10349-25, Session 7

Fabrication of single crystalline stripe in Si and Ge film on rolled flexible glass substrate by UV cw micro-chevron laser beam *(Invited Paper)*

Wenchang Yeh, Shimane Univ. (Japan)

No Abstract Available.

10349-26, Session 7

Thermal transport and thermal management by silicon nanostructures *(Invited Paper)*

Jaeho Lee, Univ. of California, Irvine (United States)

Thermal transport in low-dimensional materials with dimensions scaling below the phonon mean free path and even close to the phonon wavelength poses significant challenges for thermal management of semiconductor devices. While phonons can display both wave-like and particle-like behaviors, the dominant mechanism for thermal conductivity reductions in silicon nanostructures remains unclear. The interpretation has been complicated by the coupled effects of phonon coherence, boundary scattering, backscattering, and contact resistance. Here, we isolate the wave-related coherence effects by comparing periodic and aperiodic silicon nanomeshes, and quantify the particle-related backscattering effect by comparing variable-pitch silicon nanomeshes. Based on the combination of thermal conductivity measurements and phonon ray-tracing simulations, we conclude phonon coherence is unimportant for thermal transport when periodicities are greater than the dominant wavelengths but smaller than inelastic mean free paths. We also show that phonon backscattering, as manifested in the classical size effect, is responsible for the thermal conductivity reduction in silicon nanomeshes. Based on the new understanding, we demonstrate a novel thermoelectric cooling design utilizing the unique thermal transport properties in silicon nanomeshes. Due to the strong anisotropy including the ultralow in-plane thermal conductivity and the high cross-plane thermal conductivity, the silicon nanomesh provides effective thermoelectric cooling performance even at a confined lateral space, which is unachievable by conventional isotropic materials. This work helps bridge the gap between fundamental materials research and device engineering and provides new pathways of utilizing low-dimensional materials and their unique properties for advancing breakthroughs in thermal management of semiconductor devices

10349-27, Session 7

Fabrication of effective photon trapping and light manipulating micro/nano structures

Yang Gao, Hilal Cansizoglu, Ahmet Kaya, Ahmed S. Mayet, Soroush Ghandiparsi, Cesar B. Perez, Univ. of California, Davis (United States); Ekaterina P. Devine, W&WSens Devices, Inc. (United States); Toshishige Yamada, Univ. of California, Santa Cruz (United States); Aly Elrefaie, Shih-Yuan Wang, W&WSens Devices, Inc. (United States); Saif M. Islam, Univ. of California, Davis (United States)

We present a CMOS compatible fabrication technique to create micro/nanostructures on silicon and germanium surfaces for effective photon trapping and enhanced absorption. We achieved more than 10 times absorption enhancement enabled by these photon trapping micro/nanostructures compared to bulk silicon and germanium counterparts. This method can lead to designing both highly efficient photovoltaics, ultra-fast photodetectors and highly sensitive photon counting devices with dramatically reduced device thickness. We also demonstrate that different fabrication techniques (dry etch, wet etch, and their combination) and different design/geometries of these micro/nanostructures can affect the ability and extent of the photon trapping and light manipulation in semiconductors. .

10349-28, Session 7

Extreme bandwidth and efficiency in silicon photodetectors using photon-manipulating micro/nanostructures

Hilal Cansizoglu, Yang Gao, Soroush Ghandiparsi, Ahmet Kaya, Cesar B. Perez, Ahmed S. Mayet, Ekaterina Ponizovskaya Devine, Univ. of California, Davis (United States); Mehmet F. Cansizoglu, The Univ. of Texas Southwestern Medical Ctr. at Dallas (United States) and Univ. of California, Davis (United States); Toshishige Yamada, Univ. of California, Santa Cruz (United States); Aly Elrefaie, Shih-Yuan Wang, Saif M. Islam, Univ. of California, Davis (United States)

Nanostructures allow broadband and near-unity optical absorption and contributed to high performance low-cost Si photovoltaic devices. Despite considerable research and tangible progress in the field of nanostructures enhanced solar cells, photodetectors (PDs) did not receive similar attention until the recent demonstration of a micro/nanohole integrated and CMOS-compatible Si PD that enables above 20 Gb/s data rate with 52% quantum efficiency (QE) at 850 nm. Integration of micro/nanoholes maximizes the QE by bending the light to efficiently couple to in-plane direction. Such Si PDs can be further designed to enhance the bandwidth (BW) of the PDs by reducing the device capacitance with etched holes in an axial pin junction. Here we present the ultimate limit of BW and QE of Si PDs with micro/nanoholes based on a combination of empirical evidence and device modeling. Higher than 50 Gb/s data rate with above 40% QE at 850 nm is conceivable in transceivers designed with such Si PDs that are integrated with photon trapping micro and nanostructures.

10349-29, Session 8

Every atom counts: solving the structure of ligand protected Au102 nanoparticles using electron microscopy and diffraction *(Invited Paper)*

Alina Bruma, National Institute of Standards and Technology (United States)

The Au102(p-MBA)44 nanoclusters recently became the subject of study in biolabeling analyses for site-specific covalent conjugation to viral surfaces, photodynamics and nanocatalysis. The single crystal X-ray method, which is one of the most direct and decisive analytical tools - has been applied with limited success in the case of ligand-protected Au nanoclusters. Using this technique, only a few species have been successfully crystallized and their structure unambiguously determined: Au25[SR]18, Au38[SR]24, Au102[SR]44 (where SR=thiol ligands). Other direct characterization techniques such as electron microscopy prove to be extremely cumbersome for these systems due to the electron beam induced irradiation. In this talk we report a technique for acquiring nanobeam (NBD) electron diffraction patterns acquired at millisecond rate, involving an ultralow electron dose, which can be used for nanoscale systems susceptible to electron beam damage. The acquired electron diffraction patterns show stability for several milliseconds, suggesting that they are the representative patterns and emphasize that the thiolate ligands on the surface of the nanoclusters are not damaged during the electron-beam interaction. We demonstrate that the method can be directly correlated with structural predictions previously obtained with the help of Density Functional Theory (DFT). The strength of this method demonstrated its ability to build a structural “atlas” in reciprocal space for nanoparticles and quantum dots whose structure cannot be otherwise determined using X-ray techniques.

10349-30, Session 8

Chroplasmonic and chiroexcitonic photonics *(Invited Paper)*

Wenchun Feng, Univ. of Michigan (United States); Chuanlai Xu, Jiangnan Univ. (China); Nicholas A. Kotov, Univ. of Michigan (United States)

Several types of plasmonic and excitonic nanoparticles (NPs) and their assemblies had been discovered over the last decade. The origin of the giant polarization rotation in chiroplasmonic systems will be elaborated. NP assemblies organized by DNA will be used to discern different geometries contributing to photon adsorption and emission. Chiroexcitonic systems will be considered using nanoscale helices from semiconductors. Preparation of nanoscale helices with near unity enantiomeric excess enabled elucidation of the effect of their geometry on the spectral position and intensity of the chiroptical bands. Applications of chiroplasmonic and chioexcitonic materials for biosensing and photonic devices will be demonstrated.

10349-31, Session 8

Broadband graphene optical modulator with 35 GHz speed and athermal performance

Yang Xia, Univ. of California, San Diego (United States); Hamed Dalir, Yuan Wang, Xiang Zhang, Univ. of California, Berkeley (United States)

Ultra-compact, wide-band and complementary metal-oxide semiconductor (CMOS)-compatible optical modulators with athermal high-speed operation are highly desirable in optical interconnection systems. However, conventional optical modulators usually suffer from the trade-off between footprint and optical bandwidth due to weak light-matter interaction. And the limited temperature stability constrains their application in modern optical interconnection systems. The tunable absorption in graphene is intrinsically wide band, high speed and temperature insensitive, with extremely strong light-matter interaction. In this work, we experimentally demonstrate a graphene optical modulator with 35 GHz modulation speed. This is achieved by placing the graphene layers in a planar structure and adjusting the interlayer distance so that the resistance and capacitance are both reduced. In addition, the modulation covers 1500-1640 nm bandwidth and exhibits speed stability in a wide range of temperatures (25-145 °C). Our results indicate the potential of the graphene modulator in advanced optical interconnection systems.

10349-32, Session 8

Silver film grain boundary pinning by ion bombardment decreases surface plasmon resonance absorption

David M. Fryauf, Juan J. Díaz León, Univ. of California, Santa Cruz (United States); Andrew C. Phillips, Univ. of California Observatories (United States); Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States)

Telescope mirrors based on highly reflective silver films must be protected from atmospheric corrosion with dielectric overlayers. Reflectivity is optimized when the silver surface is extremely smooth and uniform prior to dielectric overlayer deposition. Silver thin films were deposited on glass slides by electron beam evaporation using a custom deposition system at the University of California Observatories Astronomical Coatings Lab. The silver thin films were subsequently covered with a stack of dielectric films utilizing silicon nitride and titanium dioxide deposited by ion assisted electron beam evaporation to fabricate protected mirrors. In-situ argon ion bombardment was introduced after silver deposition prior to the deposition of dielectric films to assess its effects on the performance of the mirrors. Effectiveness of the ion bombardment was systematically studied for different holding time in vacuum, the time between the end of the silver thin film deposition and the start of the ion bombardment, related to the changes in the surface morphology of silver films and resulting reflectivity spectra. Reflectivity at wavelengths in the range of 350nm – 800nm was found to improve due to ion bombardment, which was qualitatively interpreted to result from decreased surface plasmon resonance coupling. The decrease in the coupling is explained by asserting that the ion bombardment slows down silver surface diffusion and pins grain boundaries, preventing post-deposition grain growth, forming smoother silver-dielectric interfaces.

10349-33, Session 8

Multi-physics simulation of monolithic tantalum oxide memristor-selector structures illustrating negative differential resistance

John F. Sevic, Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States)

Self-assembled niobium dioxide (NbO_2) thin-film selectors self-aligned to tantalum dioxide (TaO_2) memristive memory cells are studied by a multi-physics simulation of the mass transport equation coupled to the current continuity equation and heat equation. While a compact circuit model can resolve quasi-static negative differential resistance (NDR), a self-consistent coupled transport formulation provides a non-equilibrium picture of NbO_2-TaO_2 selector-memristor operation ab initio. By employing the drift-diffusion transport approximation, a finite element method is used to study dynamic electrothermal behavior of our experimentally obtained selector-memristor devices, showing bulk conditions exist favorable for electroformation of NbO_2 selector thin-films. Simulation results suggest Poole-Frenkel defects introduce negative differential resistance, in agreement with our measured results.

10349-34, Session 8

Study of thin film oxidation kinetics using a combination of simulations and advanced characterization

Juan J. Díaz León, David M. Fryauf, Nobuhiko P. Kobayashi, Univ. of California, Santa Cruz (United States)

No Abstract Available.

Conference 10350: Nanoimaging and Nanospectroscopy V

Sunday - Tuesday 6 –8 August 2017

Part of Proceedings of SPIE Vol. 10350 Nanoimaging and Nanospectroscopy V

10350-1, Session 1

Recent progress in the study of surface chemistry on various noble metal surfaces by ultrahigh vacuum tip-enhanced Raman spectroscopy *(Invited Paper)*

Nan Jiang, Univ. of Illinois at Chicago (United States)

Tip-Enhanced Raman Spectroscopy (TERS) affords the spatial resolution of traditional Scanning Probe Microscopy (SPM) while collecting the chemical information provided by RAMAN spectroscopy. This system, further aided by the benefits of Ultra-High Vacuum, is uniquely capable of obtaining surface data that would otherwise be unobtainable with less-specialized methods. Large polyatomic molecular adsorbates on various single crystal surface (Ag, Cu and Au) will be explored in this talk. By investigating substrate structures, superstructures, and the adsorption orientations obtained from vibrational modes, we extract novel surface-chemistry data at an unprecedented spatial (<1nm) and chemical resolution.

10350-2, Session 1

Tip-enhanced Raman scattering monitoring of a nanoscale pH at a solution/solid interface by chemically modified tip-enhanced Raman scattering tip *(Invited Paper)*

Prompong Pienpinijtham, Chulalongkorn Univ. (Thailand); Sanpon Vantasin, Yasutaka Kitahama, Kwansei Gakuin Univ. (Japan); Sanong Ekgasit, Chulalongkorn Univ. (Thailand); Yukihiro Ozaki, Kwansei Gakuin Univ. (Japan)

Thus far, TERS measurements have been carried out for dry samples, and relatively few studies have been reported for TERS measurements in solution/liquid systems due to a number of limitations including problems with laser focusing, sample preparation, the feedback system of SPM, and adsorbed contaminants on the TERS tip. In the present study, a TERS tip was chemically modified with pH sensitive molecules i.e., p-mercaptobenzoic acid (pMBA) and paminothiophenol (pATP), which have received much attention in pH/chemical probes using SERS techniques. In pMBA, a ?COOH group is converted to a ?COO? moiety when an acidic solution becomes alkaline. For pATP, in an alkaline solution, two pATP molecules react each other to form an azo (N=N) dimer, i.e., 4,4?dimercaptoazobenzene (DMAB), while a pATP molecule is stable in acidic environments.

We developed a nanoscale pH profile on a 4 ? 4 ?m2 area of NH2-anchored glass slide in an aqueous solution using chemically modified TERS. pMBA and pATP are bonded to the tip surface. A pH profile can be developed by a peak at 1422 cm?1 due to the ?COO? stretching vibration of pMBA and that at 1442 cm?1 due to the N=N stretching vibration due to the formation of 4,4?-dimercaptoazobenzene (DMAB) on the pATP-modified tip. The pMBA- and pATP-modified tip can be used to determine pH in the range of 7?9 and 1?2, respectively. This technique suggests a possibility for the pH sensing in wet biological samples.

10350-4, Session 1

Evaluation of probes for tip-enhanced Raman scattering by darkfield microspectroscopy and calculation

Yasutaka Kitahama, Shohei Uemura, Ryota Katayama, Kwansei Gakuin Univ. (Japan); Yuko S. Yamamoto, Kagawa Univ. (Japan); Toshiaki Suzuki, UNISOKU Co., Ltd. (Japan); Tamitake Itoh, National Institute of Advanced Industrial Science and Technology (Japan); Yukihiro Ozaki, Kwansei Gakuin Univ. (Japan)

Tip-enhanced Raman scattering (TERS) can be observed highly sensitive spectral image with high spatial resolution. However, it shows low reproducibility due to difference and change in optical properties of the metallic tips. For surface-enhanced Raman scattering (SERS), the spectra have been related with the scattering spectra due to localized surface plasmon resonance (LSPR) of the individual metallic nanostructures, which observed by a darkfield illumination, and the calculated electromagnetic (EM) field around the nanostructures. In the present study, we tried to relate TERS spectra with the LSPR spectra and the calculation in a similar way of SERS. By conventional darkfield illumination, LSPR scattering spectra at the apex of the tip were measured and were compared with the corresponding scanning electron microscope (SEM) images and TERS spectra. The LSPR peak from the apex with smaller curvature was red-shifted. By excitation using polarization parallel to the tip, the polarized LSPR peak was stronger than that by perpendicular polarization. Also in the case of TERS, the similar trend was observed. It was confirmed whether the vertical polarization to the sample plane (z-polarization) is effective or not by the polarized LSPR and TERS spectra. By excitation at different wavelengths, moreover, TERS enhancement factors were compared. In the calculation for TERS, the nanostructure like a monopole antenna was adopted, because the EM field is enhanced not at both sides, but at only apex. The dependence on taper and curvature of the tip were compared with the calculated results for the nanostructure like a conventional dipole antenna.

10350-18, Session 1

Hierarchical plasmonic metamaterials and metasurfaces for ultrasensitive, reproducible SERS *(Invited Paper)*

Dangyuan Lei, Jiyan Dai, The Hong Kong Polytechnic Univ. (Hong Kong, China)

In this talk I will present our recent research on the design and preparation of three-dimensional (3D) hierarchical metamaterials and two-dimensional (2D) hierarchical metasurfaces as novel SERS substrates with ultrahigh sensitivity and reproducibility. The former substrate consists of close-packed arrays of nanoholes and uniformly distributed mesopores over the bulk and the second comprised of sub-wavelength-sized conical nanopores and sub-5-nm nanogrooves. Both substrates employ a cascaded field enhancement mechanism, leading to the ultrahigh sensitivity, and have a (quasi)periodic arrangement of plasmonic near-field hot-spots, ensuring excellent structural and signal reproducibility. In particular, the latter substrate is highly mechanically flexible, allowing for extreme adaptability to complex working conditions such as build-in real-time monitoring of trace level molecules.

10350-5, Session 2

Wavefront correction for superresolution microscopy *(Invited Paper)*

Peter Kner, Kayvan F. Tehrani, Benjamin Thomas, Abhijit Marar, The Univ. of Georgia (United States)

Superresolution microscopy is rapidly becoming an essential tool in the biological sciences allowing imaging biological structure at length scales below 250 nm. Currently, superresolution microscopy has been applied successfully on single cells achieving resolutions of 100nm down to 20nm over a few microns of depth. When superresolution microscopy is applied in thicker samples the resolution rapidly degrades. Optical aberrations and scattering distort and reduce the point spread function causing different superresolution techniques to fail in different ways. I will discuss our work on combining structured illumination microscopy and stochastic optical reconstruction microscopy with adaptive optics to achieve sub-diffraction resolution in thick tissue.

10350-6, Session 2

Fluorescence scanning microscopy with SPAD array *(Invited Paper)*

Marco Castello, Giorgio Tortarolo, Istituto Italiano di Tecnologia (Italy); Mauro Buttafava, Federica A. Villa, Politecnico di Milano (Italy); Sami Koho, Alberto Diaspro, Istituto Italiano di Tecnologia (Italy); Alberto Tosi, Politecnico di Milano (Italy); Giuseppe Vicidomini, Istituto Italiano di Tecnologia (Italy)

In a typical fluorescence laser scanning microscope (i) an excitation laser beam is focused on a small (usually diffraction-limited) region of the sample, (ii) the fluorescence arising from the molecules located in this region is registered by a photodetector and (iii) the beam is sequentially scanned across the whole sample to reconstruct its (3D) image. Comparing to camera-based (wide-field) microscope systems, scanning systems have a limited temporal resolution (frames per second) and typically a reduced field-of-view. However, the fast photodetectors employed in laser-scanning microscopes make them extremely well suited for studying the molecular dynamics, with temporal resolution way beyond the possibilities of camera-based systems. In classical single element detectors, such as photomultiplier tubes (PMTs) or single photon avalanche diodes (SPADs), the temporal resolution spans from tens to hundreds picoseconds, giving access to information regarding molecular diffusion and photophysical dynamics. The single element detectors however lack in spatial information, as all the photons arriving from the excitation spot are accumulated into a single detector; by replacing the single element detector with a detector array it is possible exploit the photon positions to decipher spatial information about the position of the molecules within the excitation spot, thus refining the spatial resolution. High sensitivity bi-dimensional array of SPAD (SPAD array) detector is ideal for such a task, as it maintains the high temporal resolution of single element SPADs, while providing additional spatial information on the location of molecules within the excitation spot. Here we present a novel SPAD array optimized for fluorescence scanning microscopy. It consists of a 5?5-pixel array with 50 μm pixel size, 75 μm pixel pitch, < 200 ps temporal resolution and <1% pixel crosstalk. In the context of spatial resolution we demonstrate the integration of the SPAD array into a confocal scanning microscope obtaining the most straightforward implementation of image scanning microscopy. In the context of temporal resolution we show its potentiality for time-resolved microscopy/spectroscopy.

10350-7, Session 2

Tomographic STED microscopy

Jennifer-Rose Krüger, Laser-Lab. Göttingen e.V. (Germany); Jan Keller-Findeisen, Max-Planck-Institut für Biophysikalische Chemie (Germany); Claudia Geisler, Alexander Egner, Laser-Lab. Göttingen e.V. (Germany)

Far-field optical microscopy represents a well-established method in the life sciences. Due to diffraction, the resolution is limited to lambda/2 in the focal plane. This constraint can be surpassed by nanoscopic techniques. Amongst others, STED microscopy provides a resolution of up to 20 nm. By definition, resolution enhancement in STED microscopy is achieved by narrowing the effective fluorescent area. This reduction of detection volume depends on the factor of resolution enhancement and is directly linked to a decrease in fluorescence signal which limits the acquisition rate in many cases.

Here, we present a STED technique based on a rotating 1D depletion pattern. This novel STED variant can achieve a higher resolution for a given depletion light intensity as compared to the classical implementation. Furthermore, the overall fluorescence signal detected is higher than for conventional STED microscopy working at the same resolution. Consequently, not only identical super resolution conditions can be realized at lower depletion laser powers but also the acquisition can be sped up. Moreover, both aspects have the potential to drastically reduce photobleaching and sample damage.

10350-8, Session 2

Beam shaping for superresolution nonlinear lifetime and Raman microscopy

Ryan Beams, Stephan Stranick, National Institute of Standards and Technology (United States)

We experimentally and theoretically investigate various phase-masks for superresolution nonlinear microscopy. By applying a Toraldo-style phase-mask to the excitation beam, we can reduce the size of the center of the point-spread function at the expense of increasing the intensity of the side lobes. In order to utilize the central spot for imaging, the side lobes have to be suppressed. This can be accomplished by either engineering the collection volume to only collect the central spot or by exploiting the multiplicative nature of nonlinear microscopy. The first case has the advantage of being a general approach any signal. In the later case, the shape of the second beam is chosen such that it only overlaps with the central lobe. Therefore, by controlling the shape of both beams the nonlinear signal, such as coherent Raman processes, is only generated in the overlap region leading to an improved spatial resolution. To illustrate this technique, we use fluorescence lifetime imaging and coherent Raman scattering with a spatial resolution of ≈ ?/7. These results are compared to analytical calculations of the point-spread function from strongly focused fields.

10350-9, Session 3

Tip-enhanced Raman spectroscopy of semiconductor nanostructures *(Invited Paper)*

Edward T. Yu, The Univ. of Texas at Austin (United States)

Raman scattering can serve as a powerful probe of local bonding, strain, temperature, and other properties of molecular and solid-state materials via their influence on vibrational modes or optical phonons. Raman scattering interactions are typically very weak, however, making characterization of materials with high spatial resolution extremely challenging. We have used tip-enhanced Raman spectroscopy (TERS), in which optical excitation of plasmonic modes at the apex of a metal-coated scanning probe tip enables Raman scattering signals to be detected from nanoscale volumes with precise positional control, to characterize a variety of semiconductor nanostructures. In studies of Ge-SiGe core-shell nanowires, we measure

spatially resolved Raman spectra along the length of a tapered nanowire to demonstrate the ability to measure local strain distributions with nanoscale spatial resolution. In addition, we observe tip-induced shifts in Raman peaks associated with the interaction of optical phonon modes with inter-valence band carrier transitions, enabling local carrier distributions to be probed and interactions among plasmon, phonon, and carrier excitations to be elucidated. In tip-induced resonant Raman studies of single- and few-layer transition metal dichalcogenide materials, we observe large enhancements in Raman signal levels measured for MoS2 associated with excitation of plasmonic gap modes between an Au-coated probe tip and Au substrate onto which MoS2 has been transferred, and significant differences in Raman spectra for monolayer compared to bilayer MoS2. The origins of these differences in terms of strain, altered vibrational modes, and other factors will be discussed.

10350-10, Session 3

Enabling strain-sensing at the nanoscale with TERS *(Invited Paper)*

Erin Wood, Yanfei Yang, Will Gannett, Gordon A. Shaw, Randolph E. Elmquist, Mark Keller, Angela Hight Walker, National Institute of Standards and Technology (United States)

This talk will present three primary ideas: The first will be the use of test structures between laboratories and instrumentation as a tool to aid in understanding of the results from tip-enhanced Raman scattering (TERS) results. This test structure was designed to be used to help enable comparability between backscattering instrumentation, although it also is particularly useful for establishing the limitations of instrumentations. This test structure has been presented at a previous SPIE meeting, although we go into great detail of the data analysis, not the manufacturing process as previously presented. Secondly, we discuss advanced in tips including commercially available metal dielectric tips that have a broad-spectrum enhancement. Most of this talk, however, will focus on our work on graphene-based systems such as epitaxially-grown graphene on SiC, exfoliated graphene, and CVD graphene on copper. This work will focus on the use of TERS to both sense mechanically applied strain and expand our understanding of strain in 2-D materials. Finally our recent work on highly purity carbon nanotubes will be presented.

10350-11, Session 3

Multimodal tip-enhanced microscopy *(Invited Paper)*

Kai Braun, Anke Horneber, Dai Zhang, Alfred J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

Electromagnetic coupling between plasmonic resonances of two closely spaced metal particles can lead to a strongly enhanced optical near field in the gap between. It is the leading amplification mechanism for surface- and tip-enhanced Raman scattering (SERS/TERS) or enhanced molecular luminescence and has widespread applications in nanoplasmonics. Scanning near-field optical microscopes (SNOM) have the ability to correlate local optical properties with topography at the nanometer scale. Collecting correlated signals of photoluminescence (PL) and Raman as well as topography, tip-enhanced hyperspectral imaging is able to provide a thorough map of the chemical and morphology-related optical properties in multi-component material systems. Introducing new microscope functions offer us insights into various aspects, such as morphology related photophysical and photochemical processes.

Despite its attractive capabilities, developing a tip-enhanced near-field microscope providing reliable and reproducible performance is demanding. Stringent requirements have to be met, such as precise positioning of a nanometer-sized tip apex inside the laser focus, capability of maintaining the tip-sample distance with an accuracy of some angstroms and reproducibly locate the tested species with ultrahigh accuracy etc. In the last years great efforts have been made in our lab to develop stable, reproducible and reliable near-field optical microscopes, which largely meet the above requirements. They successfully demonstrated their capability in high-resolution optical imaging and spectral mapping, or using the tip as local probe for enhanced coupled fields. Furthermore we demonstrate the direct manipulation and measurement of surface properties via electrical charging or injection of charge carriers and ultrafast non-linear optical microscopy.

10350-12, Session 3

Reproducible plasmon nanofocusing on optimized plasmonic tip structure for optical nano-imaging

Takayuki Umakoshi, Misaki Tanaka, Osaka Univ. (Japan); Yuika Saito, Gakushuin Univ. (Japan); Prabhat Verma, Osaka Univ. (Japan)

Optical nano-imaging technique using plasmon nanofocusing has a great potential to achieve near-field measurements background-free from far-field incident laser, since plasmon nanofocusing enables to generate near-field light by propagating plasmon excited at a coupler far from the apex with adiabatically condensing its light energy. Since Raschke et al. reported plasmon nanofocusing on a metallic tip in 2007, increasing interest in this topic has been seen. In the most cases, metallic tips were fabricated through electrochemical etching, which produced gold conical tip. Practically, this is the only way reported so far to fabricate tips that works for plasmon nanofocusing.

In this work, making an important development in tip fabrication for the plasmon-nanofocusing-based near-field microscopy, we optimized configurations and fabrication processes of plasmonic tips for plasmon nanofocusing, so that 100% reproducible plasmon nanofocusing was achieved on fabricated tips. We first deposited an atomically smooth silver layer (thickness: 40 nm, roughness: less than 1 nm) on an oxidized silicon pyramidal tip through thermal evaporation. We then fabricated a grating by focused ion beam, whose structure was optimized by FDTD simulation. Through these optimizations, we observed light spots appeared at apexes of more than 20 fabricated tips with reproducibility of 100% by illuminating the grating with laser of 642 nm wavelength. Owing to such efficient plasmon nanofocusing, we have also proposed a completely new and unique broadband nano-imaging technique, the details of which as well as the details of tip fabrication tricks will be included in the presentation.

10350-13, Session 4

Imaging nanoscale nuclear architecture in cancer development *(Invited Paper)*

Yang Liu, Jianquan Xu, Hongqiang Ma, Univ. of Pittsburgh (United States); Wei Jiang, West China Second Univ. Hospital, Sichuan Univ. (China) and Univ. of Pittsburgh (United States)

Alteration in nuclear architecture remains one of the most striking abnormalities in cancer cells and remains the gold standard in cancer diagnosis. However, microscopically defined nuclear architecture in cancer often do not unambiguously distinguish early-stage aggressive cancers from benign lesions, or identify proper cancer patients who can benefit from treatment. Super-resolution fluorescence microscopy revolutionizes the file of light microscopy by overcoming the diffraction limit. We will present the use of single-molecule localization microscopy to investigate how nanoscale organization of nuclear architecture is altered at various stages of cancer development in cancer progression cell line models, animal models of carcinogenesis and human patients.

10350-14, Session 4

Multiple emitter fitting using reversible jump Markov chain Monte Carlo *(Invited Paper)*

Keith A. Lidke, The Univ. of New Mexico (United States)

In single molecule based super-resolution imaging, high labeling density or the desire for greater data collection speed can lead to clusters of overlapping PSFs in the raw super-resolution image data. Multi-emitter fitting algorithms can identify and localize the particles in those dense regions of the data. In this work, we improve upon the state-of-the art in multi-emitter fitting by employing Reversible Jump Markov Chain Monte Carlo (RJMCMC). Markov Chain Monte Carlo (MCMC) can be used to find the posterior distribution of a set of parameters, which in the multi-emitter fitting problem consists of the particle positions and intensities and a local background. RJMCMC takes this concept further and allows jumps between parameter spaces, in this case allowing the addition or subtraction of emitters in the model. We allow four mechanisms to make jumps between spaces of various models, called birth, death, merge and split. Birth (death) allows the addition (deletion) of an emitter anywhere in the sample. Split allows the possibility that an existing particle can be actually two or more neighboring particles. Merge allows the chance of two adjacent particles to join into a single particle. RJMCMC averages over the possible models, weighting them by their probabilities. This Bayesian approach also allows prior knowledge on intensity, background and particle density to be easily input in a principled manner. Although demonstrated here in 2D, the approach can be easily extended to analysis of 3D data with arbitrary PSFs.

10350-15, Session 4

An ultra-fast algorithm for high-density localization microscopy

Hongqiang Ma, Yang Liu, Univ. of Pittsburgh (United States)

High-density localization of multiple fluorescent emitters is a common strategy to improve the temporal resolution of super-resolution localization microscopy. In recent years, various high-density localization algorithms have been developed. Despite their rigorous mathematical model and the subsequent improvement in image resolution, they still suffer from high computing complexity and the resulting extremely low computation speed, thus limiting the application to either small dataset or expensive computer clusters. It is still impractical as a routine tool for a large dataset. With the recent advance of high-throughput localization microscopy with sCMOS cameras that can produce a huge amount of data in a short period of time, fast processing now becomes even more important. Here, we present a simple algebraic algorithm based on our previously developed method, gradient fitting, for fast and precise high-density localization of multiple overlapping fluorescent emitters. Through numerical simulation and biological experiments, we showed that our algorithm can yield comparable localization precision and recall rate as DAOSTORM in various densities and signal levels, but with much simpler computation complexity. After being implemented on a GPU device (NVidia GTX1080) for parallel computing, it can run over three orders of magnitude faster than DAOSTORM implemented on a high-end workstation.

Therefore, our method presents a possibility for online reconstruction of high-speed super-resolution imaging with high-density fluorescent emitters.

10350-16, Session 4

Single marker switching microscope with isotropic resolution over large axial range

Haugen Mittelstädt, Claudia Geisler, Alexander Egner, Laser-Lab. Göttingen e.V. (Germany)

Single marker switching (SMS) based nanoscopy techniques overcome the resolution limit by utilizing molecular switching events in conjunction with localization of sufficiently separated point-shaped emitters. The typically inferior axial resolution due to detection through a single objective lens can be improved by employing two opposing lenses for detection. Interference of the fluorescence signal then enables a resolution of better than 20 nm in all three spatial directions. However, the volume in which markers can be localized is restricted to thin optical layers around the focal plane of ~0.25 µm (iPALM [1]) or ~1 µm thickness (4Pi-SMS [2], W-4PiSMSN [3]), thereby necessitating scanning steps to image thicker structures.

Here, we present a 3D-SMS microscope based on the stereo view principle which clearly overcomes this axial restriction and makes detection point spread function modifications and delicate interference patterns obsolete. By simultaneously observing an emitter through four low numerical aperture (NA) lenses which are oriented in a tetrahedron-like shape, our microscope allows to acquire super-resolved 3D-images of an axially extended volume of several micrometer thickness without axial scanning. The image quality benefits from the significantly enhanced solid angle as compared to detection through a single standard high NA lens. Our system not only enables imaging within fluorescently labeled whole cells, but also permits to track individual fluorescent markers.

10350-3, Session 5

In-situ electrochemical tip-enhanced optical spectroscopy and imaging *(Invited Paper)*

Taka-aki Yano, Masahiko Hara, Tokyo Institute of Technology (Japan)

Tip-enhanced optical spectroscopy has been nowadays recognized as a powerful tool for nano-imaging and nano-analysis with a nanoscale spatial resolution far beyond the diffraction limit of light. In this study, we utilized a plasmonically-active metallic probe tip to apply DC voltage to sample surfaces through the tip, enabling us to locally initiate electrochemical reactions. Reversible oxidation and reduction reactions were observed with organic self-assembled monolayers, which was in-situ characterized through tip-enhanced Raman spectral changes. The tip-applied DC voltage was also utilized to measure local diffusion of lithium ions on a lithium-ion battery cathode.

10350-17, Session 5

Physical chemistry of Nanogap-Enhanced Raman Scattering (NERS) *(Invited Paper)*

Yung Doug Suh, Korea Research Institute of Chemical Technology (Korea, Republic of) and Sungkyunkwan Univ. (Korea, Republic of); Hyun Woo Kim, Korea Research Institute of Chemical Technology (Korea, Republic of)

Plasmonic coupling-based electromagnetic field localization and enhancement are becoming increasingly important in chemistry, nanoscience, materials science, physics, and engineering over the past decade, generating a number of new concepts and applications. Among the plasmonically coupled nanostructures, metal nanostructures with nanogaps have been of special interest due to their ultrastrong electromagnetic fields and controllable optical properties that can be useful for a variety of signal enhancements such as surface-enhanced Raman scattering (SERS). The Raman scattering process is highly inefficient, with a very small crosssection, and Raman signals are often poorly reproducible, meaning that very strong, controllable SERS is needed to obtain reliable Raman signals with metallic nanostructures and thus open up new avenues for a variety of Raman-based applications. More specifically, plasmonically coupled metallic nanostructures with ultrasmall (?1 nm or smaller) nanogaps can generate very strong and tunable electromagnetic fields that can generate strong SERS signals from Raman dyes in the gap, and plasmonic nanogap-enhanced

Raman scattering can be defined as Raman signal enhancement from plasmonic nanogap particles with ?1 nm gaps. However, these promising nanostructures with extraordinarily strong optical signals have shown limited use for practical applications, largely due to the lack of design principles, high-yield synthetic strategies with nanometer-level structural control and reproducibility, and systematic, reliable single-molecule/single-particle-level studies on their optical properties. All these are extremely important challenges because even small changes (<1 nm) in the structure of the coupled plasmonic nanogaps can significantly affect the plasmon mode and signal intensity. In this Account, we examine and summarize recent breakthroughs and advances in plasmonic nanogap-enhanced Raman scattering with metal nanogap particles with respect to the design and synthesis of plasmonic nanogap structures, as well as ultrasensitive and quantitative Raman signal detection using these structures. The applications and prospects of plasmonic nanogap particle-based SERS are also discussed. In particular, reliable synthetic and measurement strategies for plasmonically coupled nanostructures with ?1 nm gap, in which both the nanogap size and the position of a Raman-active molecule in the gap can be controlled with nanometer/sub-nanometer-level precision, can address important issues regarding the synthesis and optical properties of plasmonic nanostructures, including structural and signal reproducibility. Further, single-molecule/single-particle-level studies on the plasmonic properties of these nanogap structures revealed that these particles can generate ultrastrong, quantifiable Raman signals in a highly reproducible manner.

10350-19, Session 5

3D plasmonic architectures for ultrasensitive Raman spectroscopy *(Invited Paper)*

Manohar Chirumamilla, Aalborg Univ. (Denmark); Remo Proietti Zaccaria, Andrea Toma, Istituto Italiano di Tecnologia (Italy)

The fabrication of innovative plasmonic architectures supporting extremely large electric field enhancement has gained increasing attention over the last few years, especially for the detection of molecules in highly diluted liquids, and/or the spectral signature collection of single/few molecules concentrated in nanogaps. The application of the “hot-spot” concept, induced by localized surface plasmon resonances, has been successfully exploited for surface-enhanced infrared absorption and surface-enhanced Raman spectroscopy. Within this context, we have conceived and developed novel 3D plasmonic architectures, endowed with multiple tips and detached from the substrate by means of standing silicon pillars. By exploiting the localization and enhancement capabilities of the proposed configurations, we have investigated the Raman signal of different biomolecules, approaching the single/few units detection limit. Raman spectra have been observed for p-Aminothiophenol and Rhodamine-6G molecules under very low concentrations (below 1 fM) in order to statistically ensure only single/few molecules per hot-spot. Finally, we have shown how the 3D configurations can be recycled for multiple uses in a cost effective way, still preserving high reproducible SERS enhancement performances.

10350-20, Session 5

TiO2-enhanced Raman spectroscopy and its relevance to electromagnetic and chemical enhancements

Yusuke Tanaka, Taka-aki Yano, Masahiko Hara, Tokyo Institute of Technology (Japan)

Plasmonic nanoparticles have been commonly utilized for surface-enhanced Raman spectroscopy (SERS) because of the strong field enhancement effect. Here, we propose to utilize titanium dioxide (TiO2) nanoparticles as an alternative to plasmonic ones. Since TiO2 possesses a relatively high refractive index, TiO2 nanoparticles with diameters of 150-250 nm exhibit strong electromagnetic resonances in the visible region, enabling us to employ them as an efficient field enhancer for SERS. We performed dark-field spectroscopy of individual TiO2 nanoparticles with various diameters, and determined the optimal size of the nanoparticle providing the strongest enhancement of Raman scattering from sample molecules attached on the nanoparticle surface. More interestingly, the SERS spectrum was found to be significantly different from the neat spectrum in terms of peak position and peak-to-peak intensity ratio, indicating the chemical enhancement effect caused by interfacial charge-transfer transition between sample molecules and TiO2.

10350-21, Session 6

Nanometer resolution imaging and tracking of fluorescent molecules with minimal photon fluxes *(Invited Paper)*

Klaus Gwosch, Francisco Balzarotti, Yvan Eilers, Max-Planck-Institut für Biophysikalische Chemie (Germany); Arvid H. Gynnå, Uppsala Univ. (Sweden); Volker Westphal, Max-Planck-Institut für Biophysikalische Chemie (Germany); Fernando D. Stefani, Univ. de Buenos Aires (Argentina); Johan Elf, Uppsala Univ. (Sweden); Stefan W. Hell, Max-Planck-Institut für Biophysikalische Chemie (Germany)

We introduce MINFLUX, a concept for localizing photon emitters in space. By probing the emitter with a local intensity minimum of excitation light, MINFLUX minimizes the fluorescence photons needed for high localization precision. In our experiments, 22 times fewer fluorescence photons are required as compared to popular centroid localization. In superresolution microscopy,MINFLUXattained ~1-nanometer precision, resolvingmolecules only 6 nanometers apart. MINFLUX tracking of single fluorescent proteins increased the temporal resolution and the number of localizations per trace by a factor of 100, as demonstrated with diffusing 30S ribosomal subunits in living Escherichia coli. As conceptual limits have not been reached,we expect this localization modality to break new ground for observing the dynamics, distribution, and structure of macromolecules in living cells and beyond.

10350-22, Session 6

Angstrom resolution using Cryogenic Optical Localization in 3D (COLD) *(Invited Paper)*

Daniel Böning, Siegfried Weisenburger, Max Planck Institute for the Science of Light (Germany); Benjamin Schomburg, Karin Giller, Stefan Becker, Christian Griesinger, Max-Planck-Institut für Biophysikalische Chemie (Germany); Vahid Sandoghdar, Max Planck Institute for the Science of Light (Germany)

The significance of super-resolution microscopy beyond the diffraction barrier was honored by the Nobel Prize in Chemistry last year. One such popular method employs pinpointing the position of single fluorophores, whereby the center of the point-spread function can be determined with arbitrary localization precision depending on the available signal-to-noise ratio. At room temperature, the signal of a fluorophore is limited by photobleaching resulting in typical localization precisions on the order of ten nanometers. We have already demonstrated Angstrom localization precision made possible by the substantial enhancement of the molecular photostability at cryogenic temperatures. We also verified the feasibility of colocalization and cryogenic distance measurements by resolving two fluorophores on the backbone of a double-stranded DNA at nanometer separation.

Here, we present our results on resolving the positions of multiple fluorophores attached to proteins using cryogenic colocalization microscopy. By applying algorithms borrowed from cryogenic electron microscopy, we can reconstruct a three-dimensional density map for the positions of the fluorescent labels with a resolution of several Angstrom, yielding excellent agreement with the expected crystal structure (Figure 1). Our technique pushes optical resolution by nearly two orders of magnitude beyond the state-of-the-art conventional super-resolution microscopy. It allows us to gain structural information that might not be accessible via existing analytical methods such as x-ray scattering or magnetic resonance spectroscopy. We discuss the potential of the technique for further improvement and its important challenges.

10350-23, Session 6

High-speed localized plasmonic structure illumination microscopy for biological imaging

Anna S. Bezryadina, Junxiang Zhao, Joseph L. Ponsetto, Yang Xu, Univ. of California, San Diego (United States); Xiang Zhang, Univ. of California, Berkeley (United States); Zhaowei Liu, Univ. of California, San Diego (United States)

We developed localized plasmon structured illumination microscopy (LPSIM) for high-speed super-resolution imaging. This new plasmonic technique was applied to observe biological specimens' movement with video speed imaging, 50nm resolution and wide field of view at the same time. LPSIM method was based on controlled plasmonic excitations from laser on a periodic 2-D array of nano-discs as a structured illumination pattern to excite a fluorescently tagged biological sample and achieve 3 times resolution improvement over standard microscopy. The LPSIM sapphire substrates have hexagon lattice array of 60 nm silver discs with 150 nm pitch and PMMA layer on top to protect array from oxidation or damaging bio-sample. Since the localized plasmonic field provides strong near-field enhancement of fluorescence particles, the LPSIM imaging process requires lower illumination laser power and shorter exposure time, thus provides faster imaging speed and longer observation time.

Our LPSIM method is very easy to implement for biological samples by drop-casting prepared cells in a solution, pressing down slice of tissue, or directly growing sample on the substrates. We tested our super-resolution imaging performance by using microtubules, fluorescent beads, neuron cells, and human tissues. By taking sequence of images at high speed we could create a video and observe dynamic of movements over wide field of view. As of today the LPSIM has higher speed than STORM or PALM, better spatial resolution than other SIM methods, and broader field of view and lower laser damage than STED.

10350-24, Session 6

Nanoscale Photoacoustic Tomography (nPAT) for label-free super-resolution 3D imaging of red blood cells

Pratik Samant, Armando Hernandez, Shelby Conklin, Liangzhong Xiang, The Univ. of Oklahoma (United States)

Here we present a novel imaging technique, nanoscale photoacoustic tomography (nPAT) for label-free super-resolution imaging of in vivo samples in 3D. This imaging modality uses a focused ultrashort (~7ps) laser pulse durations in order to generate photoacoustic (PA) waves, which are then detected and used to construct an image. These PA waves are high frequency (~GHz) signals that cannot be detected by a typical ultrasound transducer. In order to maximize bandwidth and obtain high-resolution, we use a pump-probe detection method in order to detect signals in the GHz range. This allows us to achieve a theoretical resolution on the order of ~10nm in the axial direction. The calculated sensitivity of this system is ~25Pa of the photoacoustic wave. The amplitude of the generated PA signal is directly proportional to the concentration of the absorber, in our case hemoglobin. Therefore, we can generate 3D absorption coefficient maps of our sample by raster scanning at different points. We present in the letter the simulations and experimental work that we have done so far in making this imaging modality a reality.

10350-36, Session PMon

Turning Ag/PDA/CuO into a 3D glass microfiber as the SERS platform for monitoring the photoinduced surface catalytic coupling reaction of 4-nitrothiophenol to 4,4'-dimercaptoazobenzene

Gongchun He, Jyunde Chen, Pei-Ying Lin, Worasaung Klinthong, National Sun Yat-Sen Univ. (Taiwan); Shuchen Hsieh, National Sun Yat-Sen Univ. (Taiwan) and Kaohsiung Medical Univ. (Taiwan)

A silver/polydopamine/copper oxide film decorated glass microfiber (Ag/PDA/CuO@GMF) was successfully fabricated using a simple preparation method and served as a 3D SERS substrate. The electron was found to transfer from silver nanoparticles to CuO through PDA, which served as an electron donor, facilitating a strong improvement of the electromagnetic field, leading to the enhancement of SERS intensity. The enhancement factor of Ag/PDA/CuO@GMF was as high as 1.07?106, which is suitable for a single molecule detection. Furthermore, the Ag/PDA/CuO@GMF was applied to monitor the photoinduced surface catalytic coupling reaction for converting 4-nitrothiophenol (4-NTP) to 4,4'-dimercaptoazobenzene (DMAB) in situ. The metal–semiconductor nanocomposite, which combined Ag nanoparticles and CuO in Ag/PDA/CuO@GMF, exhibited the highest catalytic activity over the individual Ag or CuO as the SERS substrate. The pseudo first-order reaction kinetics with the reaction rate constant of 0.1679?0.0022 min-1 explained the conversion of 4-NTP to DMAB. Thus, CuO/PDA/Ag@GMF proved to be a promising SERS substrate for application in biosensing and catalyst fabrication.

10350-37, Session PMon

Three-dimensional nanoscale optical vortex profilometry

Bogdan V. Sokolenko, Dmitrii Poletaev, V.I. Vernadsky Crimean Federal Univ. (Russian Federation)

The geometry of surface can be analyzed with optical vortices due to the high sensitivity of singular beam phase to the small distortions of the wavefront. The interference of the reference beam and the Laguerre-Gaussian beam transmitted through the isotropic thin plate coated with a wedge-shaped layer of 500 nm thickness makes possible to analyze the rotation of the spiral phase, depending on the thickness of the applied layer, as well as a surface topology in reflected beam regime. Evaluation of phase sensitivity shows that the distinguishable spiral phase rotation occurs at the isotropic plate thicknesses equals to wavelength300. The overall resolution of vortex profilometer based on phase-shifted singular beam is determined by shift - retrievement algorithm and may exceed diffraction limits for lens systems.

10350-38, Session PMon

Dynamic modeling of AFM piezoelectric MC in liquid with various percentages of glycerin in the presence of rough surface in nanoscale

Alireza Habibnejad Korayem, Iran Univ. of Science and

Technology (Iran, Islamic Republic of)

One of the most useful applications of an AFM is imaging of biological ?particles in a liquid medium. The increase of the topography accuracy in a liquid ?medium requires accurate dynamic modeling of a Microcantilever (MC). This article ?investigates the accurate dynamic modeling of the non-uniform AFM piezoelectric ?MC with rectangular geometry in the amplitude mode in liquid medium for rough ?surfaces. To increase the accuracy of the modeling, the Modified couple stress ??(MCS) theory in the liquid medium according to the Timoshenko beam model has ?been used. Moreover, for solving equations, the differential quadrature (DQ) method ?has been used, because in comparison with the other methods it has a high speed in ?solving equations and it is accurate in the number of fewer elements. In addition, the ?accurate force modeling has been established by considering the shear forces caused ?by liquid on the sides of the piezoelectric MC by solving the Navier-Stokes ?equations, and by considering the hydrodynamic force, squeeze force and applied ?forces between the sample surface and the MC tip. The results illustrate that utilizing ?higher vibration modes effects on the quality of rough surface topography with the ?rectangular roughness in the liquid medium and increase the quality of surfaces ?topography in the tapping mode, especially in the second MC vibration mode. ?Moreover, it should be noted that the sensitivity of the MC vibration amplitude to ?the piezoelectric MC angle is higher in comparison with other investigated ?parameters.?

10350-25, Session 7

Hyperspectral mapping of optoelectronic properties at length scales that matter in 2D semiconductors *(Invited Paper)*

James P. Schuck, The Molecular Foundry (United States)

Transition metal dichalcogenide semiconductors such as monolayer MoS2 are atomically thin direct band gap semiconductors which host a compelling combination of crystalline order and tightly bound exciton complexes with intense light-matter interactions. I will discuss our efforts aimed at the nano-optical investigation of these materials, where we uncover new optoelectronic regions and spatially-varying features that were hidden in prior optical studies. In addition, hyperspectral photoluminescence-excitation (PLE) mapping of TMDCs is enabling us to directly probe excited state properties, revealing charge puddling, unexpectedly-large binding energies, "anomalous" high-energy absorption features, and the first direct determination of band-gap renormalization as a function of carrier density in MoS2. Directly quantifying the fundamental exciton properties and carrier-dependent renormalization effects is essential for developing exciton-based optoelectronic devices in monolayer TMDC semiconductors that capitalize on their remarkable ability to tune the underlying many-body interactions.

10350-26, Session 7

Efficient plasmonic tip for nano Raman microscopy *(Invited Paper)*

Atsushi Taguchi, Osaka Univ. (Japan)

Tip-enhanced Raman spectroscopy (TERS) is recently becoming indispensable as a nano-imaging technique for analyzing advanced nano-devices and nano-materials because it allows strong enhancement of weak Raman signals from the nanometric volume of a sample. However, consistent enhancement in TERS is still an issue, and scientists have been struggling to fabricate good tips for a reliable, strong and reproducible enhancement. Here, I show that discretely arranged metal nano-grains work as an efficient optical antenna with large scattering cross section [1]. TERS image of graphene and carbon nanotubes are shown with enhancement factor of 5,500 and spatial resolution of 14 nm. This finding will bring TERS to a new level, where it can be utilized with more confidence of large reproducible enhancement for those nano-sized samples that have extremely weak Raman scattering. [1] A. Taguchi, et al., Nanoscale 7, 17424 (2015).

10350-27, Session 7

Near-field visible light absorption imaging by Raman-nano-light source

Ryo Kato, Osaka Univ. (Japan); Yuika Saito, Gakushuin Univ. (Japan) and Osaka Univ. (Japan); Takayuki Umakoshi, Prabhat Verma, Osaka Univ. (Japan)

In aperture-less near-field scanning optical microscopy (NSOM), when the apex of a sharp silicon nano-tip is illuminated with an incident laser, a strong Raman signal of silicon (LO phonon mode) is created at the tip apex. This silicon Raman signal can be partially absorbed by the sample while passing through it when the nano-tip is placed on the sample. Since the silicon Raman light is highly confined at the only tip apex, this absorption occurs only in near-field. In terms of inherent optical properties of the sample, because the total amount of absorption is dependent on sample topography as well as absorption coefficient of the sample, it is required to remove the effect of sample thickness from absorption measurements to observe only absorption properties of the sample. For this purpose, we employed two excitation lasers with wavelengths of 488 nm and 594 nm. We took the absorbance ratio between two Raman signals of silicon excited by two different wavelengths, which allowed the contribution of sample topography to be neglected. To verify the success of this technique, we observed two types of carbon nanotubes (CNTs) that have different absorption properties (semiconducting and metallic CNTs). An absorbance ratio image (A613nm / A502nm) allowed us to distinguish the two kinds of CNTs clearly due to the difference of their absorption coefficients. The present results demonstrate the flexibility of aperture-less NSOM, not only for vibrational spectroscopies, such as tip- enhanced Raman spectroscopy, but also for electronic energy state analysis.

10350-28, Session 7

Sharply focused azimuthally polarized beam characterized by photoinduced force microscopy

Jinwei Zeng, Fei Huang, Caner Guclu, Mehdi Veysi, Hemantha K. Wickramasinghe, Filippo Capolino, Univ. of California, Irvine (United States)

A sharply focused azimuthally polarized beam (APB) presents a strong longitudinal magnetic field with a vanishing electric field at its beam axis, forming an effective magnetic dominant region at the vicinity. This magnetic dominance is extremely desirable in the proposed high-speed ultra-compact optical magnetic force manipulation and microscopy, where the interaction between matter and the magnetic field of light can be exclusively exploited. However, direct characterization of such beam is challenging due to its subwavelength features. Here we show for the first time a direct characterization on a sharply focused APB in nanoscale using the novel Photoinduced Force Microscopy (PIFM) technique, which simultaneously excites and detects incident beam in near-field. Comparing to the Scanning Near-field Optical Microscopy (SNOM) which has near-field excitation and far-field detection, PIFM boasts a much smaller background noise and a more robust system. Based on the measured force-map, we develop a theoretical model to retrieve the corresponding electric and magnetic field distribution, and correct the distortion caused by the imperfect probe-tip of the PIFM. This research pioneers the exploration in the experimental investigation on the sharply focused structured light, unveiling its potentials in a plethora of optoelectronics, chemical, or biomedical applications.

10350-29, Session 8

Improving axial resolution in nanoscopy with supercritical angle fluorescence emission *(Invited Paper)*

Nicolas Bourg, Clement Cabriel, Iván Coto Hernández, Institut des Sciences Moléculaires d'Orsay (France); Siddharth Sivankutty, Sandrine Lévêque-Fort, Guillaume Dupuis, Univ. Paris-Sud 11 (France); Emmanuel Fort, Institut Langevin (France); Sandrine Lévêque-Fort, Institut des Sciences Moléculaires d'Orsay (France)

We propose to take advantage of Supercritical Angle Fluorescence (SAF) emission, also called forbidden light, to extract axial information in super-resolution microscopy. When a fluorophore is located in the vicinity of the coverslip interface, its near-field component can become propagative and be emitted above the critical angle. As this SAF emission decreases exponentially with the fluorophore/interface distance, absolute nanometric axial position of each fluorescent emitter can be extracted. To take advantage of the axial information hold by SAF, only the detection of the microscope need to be modified. Different pupil engineering strategies can be implemented depending on the super-resolution approach. In combination with dSTORM, an absolute axial localization precision of 15 nm within an axial range of ~150 nm above the coverslip can be achieved, allowing to investigate adhesion structures. Associated to STED microscopy, membrane imaging specificity can achieved.

10350-30, Session 8

Development of integrated optical nanoscopy using photonic chips *(Invited Paper)*

Balpreet S. Ahluwalia, Øystein I. Helle, Jean-Claude Tinguely, David A. Coucheron, Marcel Lahrberg, Firehun Tsige Dullo, Cristina I. Øie, UiT The Arctic Univ. of Norway (Norway)

Photonic integrated circuits (PIC) reduce the footprint, cost and complexity of optical systems. PIC technology enables on-chip integration of several optical functions. The compatibility with standard optical fibre components enable high-speed light coupling into PICs. Advancement of PIC technology has revolutionized several optical systems, while optical nanoscopy using photonic-chip has not been explored. Here, we discuss the integrated platform and the optical functions necessary for developing chip-based nanoscopy. By retrofitting a standard microscope with appropriate photonic-chip we convert it into an advanced nanoscope. The development of chip-based optical nanoscopy would enable wide-penetration of cost-effective, miniaturized multi-modality optical nanoscopy.

10350-31, Session 8

Chip-based nanoscopy: towards integration and high-throughput imaging

David A. Coucheron, Øystein I. Helle, Christina I. Øie, Firehun Tsige Dullo, Balpreet S. Ahluwalia, UiT The Arctic Univ. of Norway (Norway)

The advent of optical nanoscopy has opened up new research possibilities in the field of life sciences. Although optical nanoscopy provides unprecedented resolution, it suffers from a low throughput. This poses a major limitation to applications requiring large screening, such as in pathology and pharmaceutical research. Here, we report high-throughput integrated optical nanoscopy based on a photonic chip. The photonic chips are used to generate, steer and deliver the illumination, while a standard microscope is used to collect the signal. The sample is placed directly on top of waveguide chip and is illuminated by the evanescent field generated at the top of the waveguide surface. Chip-based nanoscopy decouples illumination and collection optics, enabling high-throughput imaging. As the entire laser illumination is integrated, an array of waveguides can be employed to simultaneously illuminate large areas. Here we demonstrate the high-throughput capabilities of the chip-based nanoscopy through large field of view imaging.

For optical nanoscopy, high intensity in the evanescent field is preferred. This is achieved by fabricating thin (100-200 nm) waveguides made of high-refractive index contrast. The waveguide material is transparent in the visible light region (405-660 nm) for fluorescence imaging. Chip-based optical nanoscopy would enable widespread availability of affordable optical nanoscopes by retrofitting any standard fluorescence microscope with the photonic chip. The optical fibre-compatibility with the photonic chips enables light delivery with commercially available telecom optical devices, which may enhance the imaging speed.

10350-32, Session 9

Dynamics of surface plasmon polaritons and excitons in ultrastrong coupling regime *(Invited Paper)*

Remo Proietti Zaccaria, Istituto Italiano di Tecnologia (Italy) and Chinese Academy of Sciences (China); Hai Wang, Haiyu Wang, Hong-Bo Sun, Jilin Univ. (China); Andrea Toma, Istituto Italiano di Tecnologia (Italy)

The interaction of quantum emitters with surface plasmon polaritons (SPPs) has attracted tremendous attention due to the possibility of controlling light–matter interactions at the nanoscale [1-5]. Recently, with the introduction of photochromic molecules and organic semiconductors with inhomogeneous broadened absorption spectra, the light–matter interaction has entered a completely new regime, in which the Rabi splitting values are remarkably enhanced. In the so-called ultrastrong coupling regime, the Rabi splitting energy becomes an appreciable fraction of the exciton transition energy, which has been experimentally and theoretically observed in a variety of systems.

In the present work, ultrastrong exciton-plasmon coupling in squaraine dye filled gold nanoholes array is investigated both from a static and dynamic point of view. A Rabi splitting energy of 860 meV, corresponding to ?50% of the exciton transition energy, is observed in steady-state reflection measurements. Moreover, transient absorption experiments were performed to understand the dynamics of the ultrastrong coupled exciton-plasmon states. It is found that the lower hybrid band is characterized by a shorter lifetime than the uncoupled exciton states, phenomenon which can be attributed to the very strong radiative damping of SPPs modes.

Nanoplasmonic multiplexing of optical angular momentum from the visible to terahertz range *(Invited Paper)*

Min Gu, Haoran Ren, RMIT Univ. (Australia)

Similar to the other physical dimensions of light, such as time, space, polarization, wavelength, and intensity, optical angular momentum (AM) is another physically-orthogonal dimension of light. Owing to an unbounded set of orbital angular momentum (OAM) modes carried by helically-phased beams, the availability of using AM-carrying beams as information carrier to generate, transport and detect optical signals has recently been largely explored in both classical and quantum optical communications, suggesting that AM is indeed a promising candidate to dramatically boost the optical multiplexing capacity. However, the extrinsic nature of OAM modes restricts conventional OAM multiplexing to bulky phase sensitive elements, imposing a fundamental limit for realizing on-chip OAM multiplexing. Recently, we demonstrate an entirely-new concept of nanoplasmonic multiplexing of AM of light, which for the first time enables AM multiplexing to be carried out by an integrated device with six orders of magnitude reduced footprint as

compared to the conventional OAM detectors. We show that nanoring slit waveguides exhibit a distinctive outcoupling efficiency on tightly-confined plasmonic AM modes coupled from AM-carrying beams. More intriguingly, unlike the linear momentum sensitivity with a typical sharp resonance, the discovered AM mode-sorting sensitivity is nonresonant in nature, leading to an ultra-broadband AM multiplexing ranging from visible to terahertz wavelengths. This nanoplasmonic manipulation of AM of ultra-broadband light offers exciting avenues for future on-chip AM applications in highly-sensitive bio-imaging and bio-sensing, ultrahigh-bandwidth optical communications, ultrahigh-definition displays, and ultrahigh-capacity data storage.

10350-34, Session 9

Plasmon-enhanced light-matter interactions on nanoporous gold nanoparticles and arrays *(Invited Paper)*

Wei-Chuan Shih, Univ. of Houston (United States)

Light matter interaction can provide rich compositional information from various types of samples in a non-destructive fashion. Our laboratory has developed a broad range of opto-analytical spectroscopy, imaging, and sensing technologies with core innovations in nanomaterial, device, and instrumentation. In this talk, I will report our work in light-based sensing and imaging using various plasmon-enhanced light-matter interactions as contrast mechanisms, e.g, Raman, fluorescence, extinction, and near-infrared absorption. Over the past few decades, numerous studies have led to the current state of knowledge by largely attributing the enhancement to nanostructural “singularities”, e.g., small gaps and sharp protrusions on the order of 10 nm. However, most of these studies relied on advanced lithography or colloidal surface chemistry to produce nanostructural singularities, aka “hot spots”. Lithographic techniques such as focused ion beam is time-consuming and cost-prohibitive for scaling up. Colloidal surface chemistry produces assays that are challenging to translate into a “biochip”.

To overcome these issues, I will present our efforts in engineered nanostructures with high-density plasmonic hot spots and their use in chemical and biosensing – in some cases at the single molecule level. I will discuss their potential uses in biomedical and environmental applications, in particular, the potential translation into point-of-care, low-cost, distributed, and wearable devices. I will also discuss our early results of plasmon-enhanced nanoimaging and colorimetric detection by DotLens smartphone microscopy.

10350-35, Session 9

Planar plasmonic nano antennas explore membrane nanoscale heterogeneities in living cells

Raju Regmi, Institut Fresnel (France) and ICFO - Institut de Ciències Fotòniques (Spain); Pamina Winkler, ICFO - Institut de Ciències Fotòniques (Spain); Valentin Flauraud, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Kyra J. E. Borgman, Carlo Manzo, ICFO - Institut de Ciències Fotòniques (Spain); Jürgen Brugger, Ecole Polytechnique Fédérale de Lausanne (Switzerland); Hervé Rigneault, Jérôme Wenger, Institut Fresnel (France); María F. Garcia-Parajo, ICFO - Institut de Ciències Fotòniques (Spain)

The spatiotemporal architecture of the cell membrane and diffusion dynamics of its constituents (lipids and proteins) are critical for many cellular processes such as signaling, trafficking and cell adhesions. Sub-diffraction photonics based on plasmonics offer new opportunities to follow such events as they can confine electric fields in nanoscale hotspots with spatial dimensions comparable to single molecules (~5 nm). In this work, we propose in-plane plasmonic nanogap antenna arrays and study the diffusion characteristics of phosphoethanolamine (PE) and sphingomyelin (SM) in Chinese hamster ovary cells by incorporating fluorescent lipid analogs.

The enhanced electric fields in nanoscale probe areas yield a sub-diffraction spatial resolution ultimately making it possible to follow single molecule events at physiological expression levels. Fluorescence correlation spectroscopy and burst analysis of these events show free 2D Brownian diffusion for PE (with both confocal and nanogap antennas). However the diffusion dynamics of SM at the nanoscale indicates extremely heterogeneous behavior which was otherwise hidden in the confocal ensemble.

The findings presented here are crucial to understand the spatiotemporal and heterogeneous organization of live cell membranes at the nanoscale. In addition, the proposed technique is fully biocompatible and thus provides various opportunities in biophysics and live cell research.

Conference 10351: UV and Higher Energy Photonics: From Materials to Applications 2017

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Sunday - Monday 6 –7 August 2017

10351-1, Session 1

Research on AlGaN deep UV lasers and B-III-N alloys *(Invited Paper)*

Xiaohang Li, King Abdullah Univ. of Science and Technology (Saudi Arabia)

Deep-ultraviolet (DUV) emitters with wavelengths shorter than 280 nm have numerous applications such as high-density optical storage, disinfection, and biochemical identification. However, most of the commercially available DUV emitters including mercury lamps, quadrupled Nd:YAG lasers, and excimer lasers have limitations in many applications due to their large footprint, poor reliability, or toxicity. Recently, the III-N semiconductor-based UV light emitters have drawn great attention, as the AlInGaN direct bandgap covers the entire DUV range (200–280 nm), which can lead to efficient, compact, and reliable DUV emitters. Compared to other group-III-nitride wide bandgap ternary alloys, the BAlN alloy has not been studied extensively. A detailed understanding of BAlN-AN heteroepitaxy is motivated by achieving DUV light sources. Recently, theoretical and experimental studies have shown that boron-containing nitrides are promising for UV application. BAlN has a similar bandgap as AlN that does not vary significantly as a function of boron content, thereby being transparent to the UV spectrum. In addition, it has been shown that wurtzite BAlN layers with small amounts of boron incorporation (i.e. less than 5%) could introduce strong refractive index contrasts. Therefore, higher boron-content and high-quality wurtzite BAlN layers are desirable in UV distributed Bragg reflectors (DBRs). In this presentation, we will cover the latest progress regarding the DUV lasers and B(Al)N materials.

10351-2, Session 1

Challenges and breakthroughs in the development of AlGaN-based UVC lasers

Ramon Collazo, North Carolina State Univ. (United States); Ronny Kirste, Adroit Materials, Inc. (United States); Zlatko Sitar, North Carolina State Univ. (United States) and Adroit Materials, Inc. (United States)

Despite the rapid progress in III-nitride-based laser diodes, sub-300 nm UV semiconductors lasers have not been realized yet, mainly due to the lack of proper crystalline substrates and poor defect control in the wide bandgap semiconductors. Al-rich AlGaN alloys are the building blocks for these deep UV optoelectronics devices with the highest crystalline quality Al-rich AlGaN films obtained on AlN single crystal substrates. Furthermore, reduction in non-radiative centers and compensating point defect is required to achieve high IQE. Recently, UV LEDs emitting at 265 nm exceeding 80 mW, as well as low-threshold, optically pumped lasers emitting at wavelengths between 230–280 nm have been demonstrated. Nevertheless, issues related to the performance and further improvement of the heterostructure-based active regions as related to quantum efficiencies and emission polarization is desired. These issues to be discussed are classified in two main categories: (1) growth, crystallography and surface morphology control and (2) identification and control of point defects. In addition to this, results on electrically-pump laser structures will be discussed, showing the very near possibility of the first ever demonstration of deep UV semiconductor lasers. Such devices will find direct and immediate uses in health care, bio-defense and other commercial and defense applications. The use of light sources in the deep UV will lead to detection systems of different chemical and biological aerosols, providing for detection of a variety of pollutant agents among other effluents, in addition to help in increasing the availability of clean potable water through efficient UV disinfection.

10351-3, Session 1

Broadband ultraviolet light emitter based on GaN quantum dots on truncated pyramids

Jong-Hoi Cho, Seung-Hyuk Lim, Min Ho Jang, KAIST (Korea, Republic of); Samuel Matta, Julien Brault, Ctr. de Recherche sur l'Hétéro-Epitaxie et ses Applications (France); Yong-Hoon Cho, KAIST (Korea, Republic of)

Broadband ultraviolet (UV) light sources have been used for many applications such as UV curing, UV spectrophotometry and phototherapy. However, traditional UV light sources such as mercury-vapor lamps remain with some challenging issues. The mercury-vapor lamps are bulky systems and present environmental issues coming from the use of mercury. In this respect, UV light emitting diodes (LEDs) have been suggested to replace mercury-vapor lamps. Because of compact size, the phototherapy using UV LEDs can treat location of lesions without damage of adjacent normal skin. However, narrow spectrum range of conventional UV LEDs makes utilization limited since some applications such as UV spectrophotometry require a broad UV spectrum. Moreover, in AlxGa1-xN-based UV LEDs (x > ~0.25), UV light laterally propagates since the top of the valence band can be converted to crystal field split-off hole band. It has out-of-plane polarized light, which consequently has limited light extraction efficiency. In this study, we demonstrated broadband UV light source from UV-A to UV-C using GaN QDs on hexagonal truncated pyramids. Since the built-in electric fields and growth rates are different depending on regions such as (0001) polar facet, {101¯1} semipolar facets and its boundary, various UV emission wavelengths can be observed from each region, which leads to a broadband UV light source. In addition, most of the UV light source was emitted from GaN QDs, which have predominantly in-plane polarized light. This result presents a potential for solid-state based broadband light sources.

10351-4, Session 1

A design of energy detector for ArF excimer lasers

Zebin Feng, Academy of Opto-Electronics, CAS (China) and Univ. of Chinese Academy of Sciences (China); Xiaoquan Han, Yi Zhou, Lujun Bai, Academy of Opto-Electronics, CAS (China)

ArF excimer lasers with short wavelength and high photon energy are widely applied in the field of integrated circuit lithography, material processing, laser medicine, and so on. Excimer laser single pulse energy is a very important parameter in the application. In order to detect the single pulse energy on-line, one energy detector based on photodiode was designed. The signal processing circuit connected to the photodiode was designed so that the signal obtained by the photodiode was amplified and the pulse width was broadened. The amplified signal was acquired by a data acquisition card and stored in the computer for subsequent data processing. The peak of the pulse signal is used to characterize the single pulse energy of ArF excimer laser. In every condition of deferent pulse energy value levels, a series of data about laser pulses energy were acquired synchronously using the Ophir energy meter and the energy detector. A data set about the relationship between laser pulse energy and the peak of the pulse signal. Then, by using the data acquired, a model characterizing the functional relationship between the energy value and the peak value of the pulse was trained based on an algorithm of machine learning, Support Vector Regression (SVR). By using the model, the energy value can be obtained directly from the energy detector designed in this project. The result shows that the relative error between the energy obtained by the energy detector and by the Ophir energy meter is less than 3%.

10351-5, Session 1

Formation of p-type ZnO through cocktail implantation *(Invited Paper)*

Wei-Yen Woon, National Central Univ. (Taiwan)

We present a study on the. formation of p-type ZnO thin film through ion implantation. Group V dopants (N, P) with different ionic radii are implanted into chemical vapor deposition grown ZnO thin film on GaN/sapphire substrates prior to thermal activation. It is found that monodoped ZnO by N+ implantation results in n-type conductivity under thermal activation. Dual-doped ZnO film with a N: P ion implantation dose ratio of 4:1 is found to be p-type under certain thermal activation conditions. Higher p-type activation levels (1019 cm(-3)) under a. wider thermal activation range are found for the N/P dual-doped ZnO film co-implanted by additional oxygen ions. From high resolution x-ray diffraction and x-ray photoelectron spectroscopy it is concluded that the observed p-type conductivities are a result of the promoted formation of P-Zn-4N(O) complex defects via the. concurrent substitution of nitrogen at oxygen sites and phosphorus at zinc sites. The enhanced solubility and stability of acceptor defects in oxygen co-implanted dual-doped ZnO film are related to the reduction of oxygen vacancy defects at the surface. Our study demonstrates the prospect of the. formation of stable p-type ZnO film through co-implantation.

10351-6, Session 2

Performance stability of reflection-mode AlGaN photocathode under different preparation methods

Junju Zhang, Yijun Zhang, Nanjing Univ. of Science and Technology (China)

Solar-blind detectors have received widespread use in manufacturing and space detection due to their spectral response wavelength. The widebandgap semiconductor AlGaN could be an outstanding selector because of its physical and chemical stability, high solar rejection, and detectivity performance. In addition, the image intensifier and vacuum photodiode based on an AlGaN photocathode has the distinctive characteristics of low dark current and high sensitivity. Nevertheless, the performance stability of the AlGaN photocathode was rarely reported. It is known that the traditional activation method of the III-nitride photocathode is that the cesium(Cs) source is kept continuous and the oxygen(O) source is introduced periodically. To investigate the attenuation performance of the AlGaN photocathode, three samples with the same structures grown by metalorganic chemical vapor deposition were activated with three different activation methods, which are called Cs-only, Cs–O, and Cs–O–Cs activation, respectively. The spectral responses and attenuated photocurrents of the three AlGaN photocathodes were measured. The results show that the Cs–O activated AlGaN photocathode exhibits the lowest attenuation speed in the first few hours, and the attenuation speed of the Cs-only activated one is fastest. After attenuating for 90 min, the attenuation photocurrent curve of the Cs–O–Cs activated sample is coincident with that of the Cs–O activated one. The main factor affecting the photocurrent attenuation is related to Cs atoms desorbed from the photocathode surface.

10351-7, Session 2

FUV-DUV spectra of graphene, carbon nanotubes, and polymer nanocomposites

Kenta Kobashi, Kwansei Gakuin Univ. (Japan); Yusuke Morisawa, Kindai Univ. (Japan); Krzysztof Bec, Kwansei Gakuin Univ. (Japan); Ichiro Tanabe, Osaka Univ. (Japan); Masahiro Ehara, Institute for Molecular Science (Japan) and Kyoto Univ. (Japan); Harumi Sato, Kobe Univ. (Japan); Yukihiro Ozaki, Kwansei Gakuin Univ. (Japan)

The far-ultraviolet (FUV) region, which is the region of 120-300 nm, provides unique information about the electronic transitions and structure of a molecule. We have recently succeeded in measuring electronic spectra of graphene, carbon nanotubes, and polymer nanocomposites down to 150 nm using a newly developed attenuated total reflection (ATR)-UV spectrometer. The spectra of graphene show a thickness dependence. A thin graphene sample with the thickness of 1-2 nm shows a small peak near 155 nm. Single-wall carbon nanotubes with the thickness of 1-2 nm yields a similar peak. We investigate band assignments for these peaks including theoretical calculation. In the case of polymer nanocomposites a polymer gives rise to major peaks below 200 nm while nano carbon part does not show a peak in the whole region because the content of nanocarbon is very small compared with the polymer. We compared an FUV-DUV spectrum of PHB (poly(hydroxybutyrate))-graphene nanocomposites with that of PHB. A peak near 171 nm shows a longer wavelength shift by ca. 2 nm upon the formation of nanocomposites, indicating a change in electronic structure in the polymer. We investigate the cause of the shift by using quantum chemical calculations.

10351-8, Session 2

Extended polariton condensate of GaN microwire with whispering gallery mode at room temeperature

Hyun Gyu Song, Min Kwan Kim, Min-Sik Kwon, Sunghan Choi, Kie Yong Woo, Yong-Hoon Cho, KAIST (Korea, Republic of)

Exciton cavity polaritons (polaritons) are bosonic quasi-particles providing a unique semiconductor-state system for research of interacting condensate. Surviving temperature of polaritons is determined by Bohr radius and binding energy of exciton and phonon energy. Especially, the temperature upper limit for wide bandgap semiconductor like GaN is expected to be above room temperature (RT) due to large exciton binding energy and oscillator strength. Up to now , strain-induced potential fluctuation due to lattice misfit for two-dimensional cavity of GaN have prevented the construction of long-range off-diagonal term necessary for any quantum control. Especially as-grown GaN microwire could be free for lattice misfit due to strain bending and no observable dark spot. In addition, long- range off-diagonal term can be stable at RT because of reduced interaction with phonon result from large spatial overlap between exciton and photon. In this work, using a single hexagonal microwire grown by selective area method of metalorganic chemical vapor deposition, we show the condensates can propagate over microscopic distances from the excitation area because of no microscopic potential fluctuation, while preserving their spatial coherence at RT due to large Rabi splitting energy. The extension of the condensate is related to the repulsive local potential induced by excitons generated by off-resonance pumping within small excitation area. To our knowledge , the characteristics of RT extended polariton condensate of single GaN microwire systems remain unexplored until now. The single microwire structure with the manipulation of this local excitation provide a versatile method to control the extended state at RT.

10351-9, Session 2

Tunnel junctions based ultra-violet light emitting diodes *(Invited Paper)*

Siddharth Rajan, Yuewei Zhang, Jamal-Eddine Zane, Fatih Akyol, The Ohio State Univ. (United States)

We report on the design, demonstration and current status of tunnel junction-based UV LEDs. III-Nitride ultraviolet light emitting diodes (UV LEDs) are promising in various applications including sterilization, water purification and medical sensing. However, both the light extraction efficiency and electrical efficiency face fundamental challenges for the conventional UV LED structures. This stems from the poor p-type conductivity and high p-type contact resistance. Hole injection using interband tunneling provides an elegant solution to the fundamental issues of UV LEDs, and can resolve both the hole injection and light extraction issues that have been the primary problems for UV LEDs.

In this talk, we will discuss in detail the heterostructure and polarization engineering needed to realize efficient interbank tunneling in ultra-wide band gap devices. We will then outline some of the growth and fabrication challenges, and our approaches to overcome these. Finally, we will present our results on tunnel-injected UV LEDs that have enabled us to achieve efficient UV light emission in the UVA and UVB wavelength ranges with on-wafer efficiency comparable to state-of-the-art values [1,2,3].

10351-10, Session 3

Recent advances in metals for plasmonics applications in the UV range *(Invited Paper)*

Yael Gutiérrez, Francisco González, José M. Saiz, Rodrigo Alcaraz de la Osa, Univ. de Cantabria (Spain); Juan M. Sanz, Textil Santanderina SA (Spain) and Univ. de Cantabria (Spain); Dolores Ortiz, Univ. de Cantabria (Spain); Henry O. Everitt, U.S. Army Aviation and Missile Command (United States) and Duke Univ. (United States); Fernando Moreno, Univ. de Cantabria (Spain)

Extending plasmonics to the UV range is a hot topic due to the many challenges arising in fields such as biology, chemistry (photocatalysis) or spectroscopy techniques. A recent study considered several metals for this task by comparing their plasmonic performance (PP) to those of gold and silver in the visible. The main conclusion was that Mg, Al, Ga and Rh can be considered promising metals for UV-plasmonics. However, nanoparticles (NPs) made of Mg, Al and Ga suffer from the formation of a native oxide layer whose thickness strongly depends on the ambient conditions and that affects its plasmonic behavior. A more recent numerical study presented Rh as one of the most promising metals for UV-plasmonics not only for its good PP but also for its low tendency to oxidation. Moreover, the easy fabrication through chemical means of Rh NPs with sizes smaller down to 10 nm, and its potential for photocatalysis applications, makes this material very attractive for building plasmonic tools for the UV.

In this contribution, we will make an overview of our recent research in metals for UV plasmonics. We will pay special attention to our studies on the plasmonic properties of NPs made of Rh and two of the synthesized geometries: tripod stars and nanocubes. The role of shape, polarization of the incident radiation on the performance and generation of LSPRs in the UV will be explored as well as the possibility of generating hot spots with NPs aggregates located on flat substrates for applications in SERS experiments.

10351-11, Session 3

Reduction of plasmon damping in aluminum nanoparticles with rapid thermal annealing

Feifei Zhang, Julien Proust, Davy Gerard, Jérôme Plain, Jérôme Martin, Univ. de Technologie Troyes (France)

Aluminum is now widely regarded as a promising plasmonic material, especially in the ultraviolet spectrum. In this presentation, we propose rapid thermal annealing (RTA) as a simple method to significantly decrease the amount of intrinsic losses in aluminum nanoparticles. We study the structural and optical properties of aluminum nanodisks before and after RTA at different temperatures.

Our results unveil how RTA affects the plasmonic properties of Al nanoparticles through the competition between the reduction of the number of grain boundaries and oxidation. If RTA is performed below a threshold temperature of 400oC, oxidation is extremely weak and the plasmonic resonances sustained by Al nanodisks are blue shifted with a diminution of their full width at half maximum. This improvement is due to a diminution of the number of grain boundaries inside the metal core. Hence, RTA appears as a simple, cost-effective and up-scalable technique to improve the plasmonic properties of aluminum. In contrast, above the threshold temperature, oxidation becomes predominant, resulting in a detrimental effect on the plasmon resonance. This effect should be taken into account in any industrial process involving heated Al nanoparticles

10351-12, Session 3

Aluminum plasmonics for UV nanooptics *(Invited Paper)*

Jérôme Martin, Davy Gerard, Jérôme Plain, Dmitry Khlopin, Feifei Zhang, Julien Proust, Univ. de Technologie Troyes (France)

An electromagnetic field is able to produce a collective oscillation of free electrons at a metal surface. This allows light to be concentrated in volumes smaller than its wavelength. The resulting waves, called surface plasmons can be applied in various technological applications such as ultra-sensitive sensing, Surface Enhanced Raman Spectroscopy (SERS), or metal-enhanced fluorescence, to name a few. For several decades plasmonics has been almost exclusively studied in the visible region by using nanoparticles made of gold or silver as these noble metals support LSPR only in the visible and near-IR range. Nevertheless, emerging applications will require the extension of nano-plasmonics toward higher energies, in the UV range. Aluminum is one of the most appealing metal for pushing plasmonics up to ultraviolet energies. The subsequent applications in the field of nanooptics are various. This metal is therefore a highly promising material for commercial applications in the field of ultraviolet nano optics. As a consequence, aluminum (or UV) plasmonics has emerged quite recently. Aluminium plasmonics has been demonstrated efficient for numerous potential applications including non-linear optics, enhanced fluorescence, UV-SERS, optoelectronics (plasmonic assisted lasing, by coupling Al with wide bandgpap semiconduc-tors such as GaN), photocatalysis, structural colors and data storage. In this talk, we will discuss about the recent advances in aluminum plasmonics. Different preparation methods developed in the laboratory to obtain aluminum nanostructures will be presented with their optical and morphological characterizations. Both advantages and issues of aluminum as a plasmonic material will be part of the presentation.

10351-13, Session 4

Sample photodegradation and protection in UV resonance Raman spectroscopy

Yasuaki Kumamoto, Kyoto Prefectural Univ. of Medicine (Japan)

Raman spectroscopy enables a sensitive, label-free molecular analysis of a biological sample. Employing UV light for the Raman excitation allows tremendous scattering enhancement of molecules up to 108 due to the electronic resonance, as well as fluorescence-free spectral acquisition thanks to the wavelength separation of Raman scattering and fluorescence of a sample. In UV Raman spectroscopy, however, sample photodegradation often occurs due to absorption of the UV light by molecules in the sample. This is the serious limitation of the technique in biomedical sciences. Here we present three approaches for sample protection from UV-induced photodegradation. Trivalent ions of three lanthanide group elements, terbium, europium, and thulium, were added to a buffer solution immersing fixed cells so that molecular photodegradation of the cells during Raman measurement were significantly suppressed. Utilizing such protective effects

of lanthanide ions, I successfully achieved repetitive, twice higher signal-to-noise ratio UV Raman imaging of cells. The underlying mechanisms of the protection effect can be explained as energy relaxation of the excited molecules by the lanthanide ions. Removing oxygen from the sample environment also suppressed molecular photodegradation of the cells during UV measurement, by avoiding generation of reactive oxygen species around the excited molecules. Combination of these two techniques further suppressed the UV-induced photodegradation of the cellular molecules. Cooling the sample is the other approach for suppressing the molecular photodegradation under UV exposure, by decelerating the rates of photoreactions. The presented three techniques can extend applications of UV resonance Raman spectroscopy in biomedical sciences.

10351-14, Session 5

The role of light interference in the formation of laser-induced shallow pits from metal micro-particles on glass

Eyal Feigenbaum, Omer Malik, Alexander M. Rubenchik, Manyalibo J. Matthews, Lawrence Livermore National Lab. (United States)

In high power laser systems the presence of metal particulate contamination on the exit surface of silica glass was recently reported to result in sub-micron deep laser-induced shallow pits (LSPs), which appear in high densities and result in light scattering thus limiting the optics lifetime. In the LSP formation process the incident laser beam deposits heat into the skin depth of the metal particle, which in turn ejects a plasma plume towards the substrate surface, propelling the particle away from the substrate, and etching a LSP into it. We present here a model that predicts the laser-induced plasma pressure exerted on a surface-bound micron-scale metal spherical particle, resulting in the modification of the glass substrate under the particle by etching. The model starts with a full-wave FDTD electromagnetic simulation of the geometry which results in the absorption distribution in the metal particle, leading to the plasma emitted from the particle and to the projected plasma pressure on the surface. The model predications provide an explanation to the puzzling observed 'shoulder' signature in LSP profiles, as well as agreeing with other experimentally observed trends. The model highlights the significance of the interference of the incident light in the open cavity geometry formed between the micro-particle and the substrate in the resulting LSPs shape, and provides an understanding of the geometry dependence. These results contribute to the current understanding of laser-induced damage science and can enable high resolution controlled machining of silica surfaces using plasma etching jets.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-718628.

10351-15, Session 5

Changes in electronic states of molecules resulted from interactions in the condensed phase *(Invited Paper)*

Yusuke Morisawa, Nami Ueno, Kindai Univ. (Japan); Shin Tachibana, Kwansei Gakuin Univ. (Japan); Masahiro Ehara, Institute of Molecular Science (Japan); Yukihiro Ozaki, Kwansei Gakuin Univ. (Japan)

The wavelength region shorter than 200 nm, far-ultraviolet (FUV) region, is very rich in information about the electronic states and structure of a molecule. We have recently developed a totally new UV spectrometer based on attenuated total reflection (ATR) that enables us to measure spectra of liquid and solid samples in the 140–280 nm region. This paper shows the studies by the attenuated total reflection far-ultraviolet (ATR-FUV) spectroscopy. Intermolecular interactions between alkyl chains such as CH---HC should be reflected in the phase behavior of organic compounds. We measured the attenuated total reflectance spectra in the far-UV region (145–300 nm) of n-tetradecane (Tm = 5.9 °C) from 15 to -38 °C to determine its temperature dependency. With decreasing temperature, the absorption band at 153 nm in the liquid phase becomes weaker and new bands appear at around 200 and 230 nm. These results suggest that an unusually compressed structure might be generated at the surface at low temperatures, and this phase change, which is reversible, is responsible for the unusual absorption observed in the ATR-FUV spectra. We have also investigated composite polymer electrolytes (CPE). ATR-FUV spectra of CPEs composed of Poly(ethylene oxide) (PEO) and Li salt were observed and its variation of anions for the CPEs are studied.

10351-16, Session 5

A measurement validated model for an infrared laser induced filament damage formation in fused silica glass

Eyal Feigenbaum, Ted A. Laurence, Lawrence Livermore National Lab. (United States)

Here we measure and develop a model for filament formation in silica glass especially suitable for picosecond laser pulses, which is simplified with respect to the model for ultrashort pulses and enables the derivation of closed form expressions. This is critical for high power laser systems where the beam has to be directed through optics, e.g., thin debris shields. The experimental measurements of filamentation damage in fused silica induced by infrared ps pulses laser will be detailed. An analytical model adjusted to picosecond pulse-lengths is derived, resulting in expressions for the expected field intensities and carrier densities in the filament, and thus also the energy loss. The analytical expressions are validated with split-step beam-propagation-method numerical simulations, and compared to the experimental data. We have found that simulations and calculations of the propagation of high intensity laser beams through fused silica are able to capture the essential effects and features of experiments with ps pulses of 1053 nm. An upper limit of approximately 5 TW/cm^2 for the propagation intensity in the filament is found. For 1-5 ps pulses the beam decays and is dissipated rapidly off the front surface, while for longer pulses a filament of finite length is formed, followed for some cases by a second filament after a longer distance. Further cases and details of the model and measurements will be discussed.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-718742.

10351-17, Session 6

Multiphoton ultraviolet excitation allows label free ratiometric imaging of neurotransmitters *(Invited Paper)*

Sudipta Maiti, Tata Institute of Fundamental Research (India)

Multiphoton ultraviolet excitation provides unprecedented access to the naïve fluorescence of physiological chromophores. This has been exploited to image neurotransmitters, e.g. serotonin and dopamine in live cells. Here we extend the technique to perform ratiometric imaging of neurotransmitters in live neurons. Ratiometric imaging provides quantitative measure of the change of concentrations of cellular analytes, but is usually achievable for only a few analytes using specially designed reporter molecules added externally. Here we describe a label free ratiometric imaging technique for direct detection of changes in intra-vesicular serotonin concentration. At higher concentrations of serotonin, there appears a growing longer wavelength tail with an isoemissive point at 376 nm due to formation of oligomers. So we split the emission signal into two channels to determine the intra-vesicular concentration of serotonin using multi-photon microscopy. We first generate a calibration curve and show that our technique is sensitive to alterations in the range of ~ 10-150 mM of serotonin. As a proof of principle study, we then show an increase in

intra-vesicular serotonin concentration upon addition of external serotonin. In brief, our label free ratiometric imaging technique can be utilized to investigate conditions affecting vesicular serotonin packaging and content.

10351-18, Session 6

Enhanced thermoelectrical properties of new doped conjugated polymers

Jiae Lee, Han Young Woo, Korea Univ. (Korea, Republic of)

Thermoelectric (TE) materials have attracted growing attention due to their potential to convert vast amounts of waste heat directly into electricity, therefore reducing the dependence on fossil fuel. Because of mechanical flexibility, solution processability, and low thermal conductivity, organic thermoelectric materials are of great interest.1 For improving thermoelectric properties, enhanced electrical properties are required by chemical doping of conjugated polymers.The electrical conductivity can be also modulated by carrier mobility from morphology changes.

In this contribution, we synthesized two kinds of p-type thermoelectric polymers based on cyclopentadithiophene (CDT) and benzothiadiazole (BT) moieties with different solubilizing side chains. To increase the chain planarity, dialkylmethylene substituents were attached (CPDTSBT) at 4 position of CDT via double bond where the first carbon (next to the main backbone) in the side chain is sp2 hybridized and located in the same plane of the main chain. For comparison, the bis(ethylhexyl) substituted polymer was also prepared (CPDTBT). The film morphology, i.e., interchain ordering and orientation was investigated by Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS) and the electrical conductivity was measured by 4 point probe with changing the concentration of dopant (tris(pentafluorophenyl) borane).In the UV-vis spectra, the increase of the polaronic peak in the range of 800 to 1100 nm was observed with increasing concentration of dopant. Furthermore,by adjusting the amount of dopant, the electrical conductivity was increased up by 6 orders of magnitude and the resulting power factor up to 6.15?W/mK2 was measured. CPDTSBT shows the higher crystalline morphology, electrical conductivity and the resulting power factor, compared to CPDTBT. Finally, it will be discussed in detail how the molecular structure and morphology can affect the electrical and thermoelectrical properties.

DNA methylation detection using nano bowtie antenna enhanced Raman spectroscopy *(Invited Paper)*

Shuang Fang Lim, Ling Li, Robert E. Riehn, Hans D. Hallen, North Carolina State Univ. (United States)

We show that methylated-DNA (m-DNA) can be distinguished from non-methylated (n-DNA) with bowtie enhanced Raman spectra. Raman energies in both DNA samples are found at 1324, 1407 (weak), 1473, and 1567 cm-1. The primary differences are two additional Raman peaks in the 1200 – 1700 cm-1 band with methylation: one at 1239 cm-1 and the other at 1639 cm-1. We also show distinct Raman peaks attributed to the state of the m-DNA. A comparison between dried/denatured and liquid state m-DNA, show a general broadening of the larger lines and a transfer of spectral weight from the ~1470 cm-1 vibration to the two higher energy lines of the dried m-DNA. We attribute the new peaks to DNA denaturing under high salt conditions.

10351-20, Session PMon

Smartphone incorporated on-site crude oil analyzer based on CMOS image sensor

Sangwoo Oh, Korea Research Institute of Ships and Ocean Engineering (Korea, Republic of); Kiyoung Ann, Dongmin Seo, Sanghoon Shin, Euijin Han, Korea Univ. (Korea, Republic of); Moonjin Lee, Korea Research Institute of Ships and Ocean Engineering (Korea, Republic of); Sungkyu Seo, Korea Univ. (Korea, Republic of)

Crude oil is a mixture composed of various hydrocarbons such as saturated hydrocarbons, unsaturated hydrocarbons, resins, and asphaltenes. Among them, the unsaturated hydrocarbons consist of alkenes, alkynes, and aromatic hydrocarbons, and the aromatic hydrocarbons contain chemicals with one or more benzene rings, which emit fluorescence upon receiving an ultraviolet light. Conventional instrument for detecting the emitted fluorescence from the crude oil usually utilize an expensive light source, e.g., halogen lamp, and an expensive detector, e.g., photomultiplier tube (PMT), to measure the intensity of the emitted fluorescence and to quantify the crude oil concentration. While this established instrument can provide high sensitivity with a high-end detector, i.e., PMT, this relatively expensive, bulky, and single pixel detector has many limitations to be widely accepted in on-site instruments. To address this issue, we propose a crude oil fluorescence analyzer composed of low-cost and compact optoelectronic elements, i.e., light emitting device (LED) for light source and complementary metal oxide semiconductor (CMOS) image sensor for detector. Since this device employs multi-million pixels of CMOS image sensor, it can minimize the fluorescent noise by selective data collection, enabling low concentration (~ 1 ppb) crude oil fluorescence detection as an on-site platform. Furthermore, the proposed device also improves the user convenience by integrating a remote system that enables operation and analysis on a smartphone. This low-cost, compact, and highly sensitive crude oil fluorescence analyzer holds great promise in many applications requiring fluorescence detection and quantification.

Real-time label-free detection and sizing of protein molecules using a deep UV microfluidic platform

Pavankumar Challa, Quentin Peter, Maya A. Wright, Yuewen Zhang, Jacqueline A. Carozza, Tuomas P. J. Knowles, Univ. of Cambridge (United Kingdom)

Optical detection has become a convenient and scalable approach to read out information from microfluidic systems. For the study of many key biomolecules, including peptides and proteins, that have low fluorescence at visible wavelengths, however, this approach typically requires the labelling of the species of interest with extrinsic fluorphores to enhance the optical signals obtained, a process which can be time-consuming, requires purification steps, and has the propensity to perturb the behaviour of the systems under study due to interactions with the labels themselves. As such, the exploitation of the intrinsic fluorescence of protein molecules in the deep UV is an attractive path to allow the study of unlabelled biomolecules, yet deep UV detection has to date required the use of coherent sources with frequency multipliers and devices fabricated out of materials that are incompatible with widely used soft-lithography techniques. Here, we develop a deep UV-LED platform that allows the visualisation in real time of unlabelled proteins within microfluidic channels fabricated into PDMS doped with carbon nanoparticles using soft-lithography. Using this platform, we demonstrate intrinsic fluorescence detection of proteins at nanomolar concentrations on chip and combine detection with micron-scale diffusional sizing to measure the sizes of proteins in solution in a label free manner by exploiting a microfluidic co-flow geometry. These results open up the possibilities for routine use of label-free measurements of a key class of biomolecules in lab-on-chip devices.

10351-22, Session PMon

Probing Li-ion transport at carbon anode/solid electrolyte interfaces using in operando SEM

Alexander Yulaev, National Institute of Standards and Technology (United States) and UMD (United States); Vladimir Oleshko, Paul Haney, National Institute of Standards and Technology (United States); A. Alec Talin, Sandia National Laboratories (United States); Marina S. Leite, Univ. of Maryland, College Park (United States); Andrei Kolmakov, National Institute of Standards and Technology (United States)

Today all-solid-state lithium-ion batteries (SSLIBs) offer a promising alternative basis to substitute liquid counterparts in many industrial applications owing to their high specific energy and power densities, improved cycle life, and reduced safety risks of a thermal runaway. Despite all advantages mentioned above, the dearth of techniques enabling spatially resolved characterization of ionic transport at battery interfaces remains a key challenge to understand the interplay between their structure and performance during operation. Here, we implement scanning electron microscopy (SEM) in conjunction with Auger electron spectroscopy (AES) to probe Li-ion transport at the anode-solid electrolyte interface in operando conditions. We fabricate a model SSLIB sample made of $LiCoO_2$ cathode, LiPON electrolyte, and (i) ultra-thin amorphous carbon or (ii) single-layer graphene anodes. Altering the charging current and oxidizing conditions at the amorphous carbon anode, we observe the variation in Li plating morphology between in-plane and out-of-plane growth behavior. We experimentally quantify the nucleation density of Li deposits as a function of current during cycling under UHV conditions and confirm the observed dependence using a 2D nucleation/growth model. In addition, AES data reveal that battery cycling leads to appreciable capacity losses even under UHV conditions. Finally, using graphene as an electron transparent anode, we directly probe the lithium transport at the anode-electrolyte interface. We foresee that our findings will shed light on details of Li-ion battery transport inhomogeneity and help elucidate a risk-free parameter space.

Conference 10352: Biosensing and Nanomedicine X

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Sunday - Monday 6 –7 August 2017

10352-1, Session 1

Upconverting nanoparticles as optical sensors of nano- to micro- Newton forces

Alice Lay, Derek S. Wang, Michael D. Wisser, Yang Zhao, Randy D. Mehlenbacher, Yu Lin, Stanford Univ. (United States); Holger Fehlauer, Stanford School of Medicine (United States); Michael Krieg, Wendy L. Mao, Miriam B. Goodman, Jennifer A. Dionne, Stanford Univ. (United States)

Nearly all diseases trace back to improper mechanotransduction, but few sensors have the nanoscopic size and stable signal to measure these sub-microNewton forces in vivo. We investigate sub-25nm lanthanide-doped nanoparticles (NPs) as optical force sensors, which provide several biocompatible features: sharp emission peaks in upconversion (UC) and photoluminescence (PL), high signal-to-noise by virtue of near infrared illumination in UC, and photostability. To increase force sensitivity, we introduce d-metal doping; the d-metal energetically couples to the lanthanides with an efficiency that varies with pressure. Using a diamond anvil cell and atomic force microscopy to probe nanoNewton to microNewton forces, we perform force-dependent spectroscopy on NaYF4: Er3+,Yb3+ nanoparticles doped with 0% to 5% Mn2+. We find that color, quantitatively defined as the red-to-green emission ratio, varies linearly with force and is highly dependent on crystal structure. Namely in UC, cubic-phase NPs change from orange to red, while optimized hexagonal-phase NPs change from yellow-green to green. These color responses are not only reproducible over several compression and release cycles, but provide stable signal for over 24 hours. Compared to current mechanobiology tools, these optical force sensors provide nanoscopic size, large dynamic range (i.e. nN to N), and a ratiometric signal (i.e. color) that is robust to systematic errors. To demonstrate in vivo imaging capabilities, we feed water-soluble NPs (5mg/mL concentration) to C. elegans. Using two-photon confocal microscopy, we image the NPs along the digestive tract, correspond their color to force, and quantify mechanical processes within key anatomical features like the pharynx and grinder.

10352-2, Session 1

Plasmonic active rotary nanomotors for tunable biochemical release, removal, and microfluidic manipulation *(Invited Paper)*

Donglei Fan, The Univ. of Texas at Austin (United States)

In this talk, we will discuss our recent progress on design, assembling and operation of an innovative type of rotary nanomotors made from micro/nanoscale building blocks, such as nanowires, nanodisks, nanodots, and microrods. Arrays of nanomotors can be efficiently assembled and rotated with controlled angle, chirality and speed to 18,000 rpm, the same level of that of jet engine. The nanomotors are one of the smallest rotary Nanoelectromechanical System (NEMS) Devices, having all dimensions less than 1 ¬m. They can operate for 80 hours over 1.1 million cycles. The micro/nanomotors are further equipped with plasmonic sensing components. The motorized sensors can readily realize tunable biochemical release and its real time monitoring, enhanced chemical removal, and microfluidic manipulation. This work can inspire a new concept of robotized nanosensors that offer unprecedented precision and control for research in single cell stimulation, cell-cell communication, and system biology.

10352-3, Session 1

Plasmonic biosensors for resource-limited settings *(Invited Paper)*

Srikanth Singamaneni, Washington Univ. in St. Louis (United States)

Plasmonics is expected to make a tremendous impact in the field of life sciences, with applications in bioimaging, biosensing, targeted delivery and externally-triggered locoregional therapy. Plasmonic biosensors are considered to be highly promising for the development of simple, portable, sensitive, on-chip biodiagnostics for resource-limited settings such as at-home care, rural clinics, developing countries with low and moderate incomes and battle-field. While there has been a tremendous progress in the rational design of nanotransducers with high sensitivity and the development of hand-held read-out devices, the translation of these biosensors to resource-limited settings is hindered by the poor thermal, chemical, and environmental stability of the biorecogntion elements. "Cold-chain", which is employed in the affluent parts of the world for reagent transport, storage, and handling, is expensive (capital cost of freezers, recurring cost of liquid nitrogen), environmentally unfriendly, and simply not feasible in resource-limited settings where electricity and refrigeration are not reliable or even available. Degradation of the sensitive reagents and biodiagnostic chips outside the cold-chain, compromises analytical validity, preventing accurate and timely diagnosis. We will present a novel class of plasmonic biosensors that rely artificial antibodies or peptide recognition elements with excellent thermal and chemical stability. In addition, we have recently introduced silk and metal-organic frameworks as protective coatings to stabilize natural antibodies bound to nanotransducers against thermal denaturation and loss of biorecognition. This multi-pronged approach overcomes the poor stability of existing plasmonic biosensors and takes them closer to real-world applications in resource-limited settings.

10352-4, Session 1

Novel approaches towards practical applications of CMOS-compatible integrated surface enhanced Raman scattering sensors

Cuong Nguyen, William Thrift, Qiancheng Zhao, Mahsa Darvishzadeh-Varcheie, Arunima Bhattacharjee, Allon I. Hochbaum, Filippo Capolino, Ozdal Boyraz, Regina Ragan, Univ. of California, Irvine (United States)

Quick diagnosis via the ability to monitor bacterial metabolic activity over time would allow physicians to make informed decisions regarding patient treatment at an unprecedented level; unfortunately, the bottom line in healthcare is often cost. Thus our Surface enhanced Raman Scattering (SERS) platform is being developed as a low-cost biosensing system to provide new tools for metabolomics to positively impact healthcare. Here, the fabrication of an integrated device composed of silicon nitride trench waveguides, microfluidic channels, and self-assembled Au nanoantennas will be presented. Nanofabrication of SERS sensors with reproducible response over device-relevant areas is achieved by utilizing electrohydrodynamic flow as driving force in colloidal assembly. Au nanoentannas assembled on waveguides enhance the nonlinear refractive index by approximately 10-fold to be 7.1x10-19m2/W. An average SERS enhancement factor of 1.4x109 and signal standard deviation of 10% over 1mm2 area are obtained for the known analyte benzenethiol using excitation wavelength of 785 nm. Uniform 1nm interparticle spacing allows for parts-per-billion detection limits of bacterial metabolites. When using SERS surfaces for pyocyanin, a metabolite released by pseudomonas aeruginosa (PA) during biofilm formation, 100 parts-per-trillion detection limit and 1 part-per-billion quantification limit are achieved in pure gradients. Furthermore, in vitro detection of pyocyanin

in microfluidic channels was quantified during PA biofilm formation down to 10 parts-per-billion and correlated with biofilm growth stages using fluorescence imaging. When untreated bacteria-free supernatant is used as samples, SERS sensors were able to detect pyocyanin after 2 hours of growth, compared to 8 hours for UV-Visible spectroscopy.

10352-5, Session 2

Exploring plasmonic nanoantenna arrays as a platform for biosensing *(Invited Paper)*

Kimani C. Toussaint Jr., Univ. of Illinois at Urbana-Champaign (United States)

In recent years, the PROBE Lab at the University of Illinois at Urbana-Champaign has made significant developments in plasmonic nanoantenna technology by more closely exploring the rich parameter space associated with these structures including geometry and material composition, as well as the optical excitation conditions. Indeed, plasmonic nanoantennas are attractive for a variety of potential applications in nanotechnology, biology, and photonics due to their ability to tightly confine and strongly enhance optical fields. This talk will discuss our work with arrays of Au bowtie nanoantennas (BNAs) with an emphasis on how their field enhancement properties could be harnessed for particle manipulation and sensing. We also present our work with pillar-supported BNAs (pBNAs) and discuss their potential for sensing applications, particularly when adapted for responses in the near-IR. The talk will conclude with a brief discussion of some of the future work pursued by the PROBE lab, including adapting BNAs for lab-on-a-chip applications.

10352-6, Session 2

Real-time label-free detection and sizing of protein molecules using a deep UV microfluidic platform

Pavankumar Challa, Quentin Peter, Maya A. Wright, Yuewen Zhang, Jacqueline A. Carozza, Tuomas P. J. Knowles, Univ. of Cambridge (United Kingdom)

Optical detection has become a convenient and scalable approach to read out information from microfluidic systems. For the study of many key biomolecules, including peptides and proteins, that have low fluorescence at visible wavelengths, however, this approach typically requires the labelling of the species of interest with extrinsic fluorphores to enhance the optical signals obtained, a process which can be time-consuming, requires purification steps, and has the propensity to perturb the behaviour of the systems under study due to interactions with the labels themselves. As such, the exploitation of the intrinsic fluorescence of protein molecules in the deep UV is an attractive path to allow the study of unlabelled biomolecules, yet deep UV detection has to date required the use of coherent sources with frequency multipliers and devices fabricated out of materials that are incompatible with widely used soft-lithography techniques. Here, we develop a deep UV-LED platform that allows the visualisation in real time of unlabelled proteins within microfluidic channels fabricated into PDMS doped with carbon nanoparticles using soft-lithography. Using this platform, we demonstrate intrinsic fluorescence detection of proteins at nanomolar concentrations on chip and combine detection with micron-scale diffusional sizing to measure the sizes of proteins in solution in a label free manner by exploiting a microfluidic co-flow geometry. These results open up the possibilities for routine use of label-free measurements of a key class of biomolecules in lab-on-chip devices.

10352-9, Session 3

An automatic holographic adaptive phoropter *(Keynote Presentation)*

Gholam A. Peyman, Nasser N. Peyghambarian, Jim Schwiegerling, Babak Amirsolaimani, College of Optical Sciences, The Univ. of Arizona (United States)

Phoropters are the most common instrument used to detect refractive errors. During a refractive exam, lenses are flipped in front of the patient who looks at the eye chart and tries to read the symbols. The procedure is fully dependent on the cooperation of the patient to read the eye chart and provides only a subjective measurement of visual acuity and can at best provide a rough estimate of the patient's vision. Phoropters are difficult to use for mass screenings requiring a skilled examiner, and it is hard to screen young children and the elderly etc.

We have developed a simplified, lightweight automatic phoropter that can measure the optical error of the eye objectively without requiring the patient's input. The automatic holographic adaptive phoropter is based on a Shack-Hartmann wave front sensor and three computer-controlled fluidic lenses for each channel of a binocular system. The fluidic lens system is designed to be able to provide power and astigmatic corrections over a large range of corrections without the need for verbal feedback from the patient in less than a minute.

10352-10, Session 3

Simultaneous multimodal ophthalmic imaging with spectrally encoded scanning laser ophthalmoscopy and optical coherence tomography at 400 kHz *(Invited Paper)*

Mohamed T. El-Haddad, Ivan Bozic, Joseph D. Malone, Jianwei D. Li, Amber M. Arquitola, Shriji N. Patel, Karen M. Joos, Yuankai K. Tao, Vanderbilt Univ. (United States)

Multimodal ophthalmic imaging systems that combine concurrent scanning laser ophthalmoscopy (SLO) and optical coherence tomography (OCT) have demonstrated utility for aiming, tracking and compensation of bulk motion, and mosaicking. However, these systems suffer from added cost and complexity because both modalities often require separate sources, scanners, optics, and electronics. Here, we demonstrate a novel approach for swept-source spectrally-encoded SLO and OCT (SS-SESLO-OCT) for simultaneous imaging in vivo. A 200 kHz Axsun wavelength-swept laser was buffered to achieve a line-rate of 400 kHz. Buffered output was shared between SESLO, OCT, and 1.2 GHz linear-in-wavenumber clock. The detected signals were digitized on a dual-channel AlazarTech card with 4 GS/s maximum sampling rate. SESLO and OCT shared the imaging optics and the fast-axis scanner, which guaranteed inherently co-registered fields-of-view. In vivo performance was demonstrated by imaging the cornea and the retina of a healthy volunteer. Additionally, aiming with live SESLO display enabled mosaicking of ultrawide-field retinal images (>90o). Imaging was performed at 200 frames-per-second with >2 GPix/s throughput, enabling three-dimensional motion tracking with high spatial and temporal resolutions. Finally, A modular scan-head was designed and rapidly-prototyped, that can be coupled to ophthalmic surgical microscope-integrated and slit-lamp imaging optics for intraoperative guidance or clinical diagnostics. Our design reduces the complexity, cost, and maintenance required for clinical translation of these technologies. We believe SS-SESLO-OCT may benefit intraoperative imaging by allowing for real-time surgical feedback, instrument tracking, and overlays of computationally extracted biomarkers of disease, and slit-lamp imaging by enabling aiming, image registration, and multi-field mosaicking.

10352-11, Session 3

Multiplexed surface-enhanced Raman immunoimaging in vivo with gold nanoantennas

Rizia Bardhan, Yu-Chuan Ou, Joseph Webb, Vanderbilt Univ. (United States)

The upregulation of immune checkpoint programmed death protein-1 (PD-1) expressed on CD8+ activated T cells, and interaction of PD-1 with its ligand, PD-L1, strongly contributes to an immunosuppressive tumor microenvironment. Blockade of PD-L1 pathway with therapeutic antibodies have shown long-term survival in many cancer patients and several clinical trials are currently ongoing. However, <30% of patients respond to PD-L1 blockade, in part due to inaccurate identification of PD-L1 expression in tumors incurring high costs of immunotherapy and toxicities in patients. Therefore, an unmet clinical need exists for high resolution noninvasive detection techniques. Surface-enhanced Raman scattering (SERS) based imaging mediated by gold nanostructures has gained tremendous interest as a pre-clinical noninvasive diagnostic tool due to the high cellular-level spatial resolution delineating tumor margin from healthy tissue, multiplexed biomarker detection enabled by the narrow linewidths of vibrational signatures of molecules, portability, low cost, and exceptional temporal resolution.

In this work, we demonstrate the use of multibranched gold nanoantennas (MGNs) conjugated with Raman reporter molecules for multiplexed SERS imaging enabling the simultaneous diagnosis of PD-L1 and EGFR (epidermal growth factor receptor) in a breast cancer model in vivo. Nanoantennas conjugated with anti-PDL1 antibodies/ DTNB Raman molecule, and nanoantennas conjugated with anti-EGFR antibodies/pMBA Raman molecules were concurrently introduced in MDA-MB-231 breast cancer tumors, which are known to overexpress EGFR and have a high intrinsic expression of PD-L1. Longitudinal SERS analysis demonstrated maximum accumulation of nanoantennas occur 6 h post IV delivery. Ex-vivo SERS spatial maps correlated well with histological analysis and clearly show nanoantennas primarily accumulate in the tumor vasculature. Transmission electron microscopy (TEM) micrographs demonstrated that nanoantennas maintain their structural integrity in vivo. The gold content in tissues was quantified with inductively coupled plasma mass spectrometry (ICPMS) to evaluate their pharmacokinetics and uptake in tumor relative to other tissues. ICPMS analysis showed nanoantennas accumulation in tumors as well as the reticuloendothelial system and substantial clearance within 72 h. This work shows gold nanoantenna mediated SERS imaging provides a quantitative measure of PDL1 to allow predictive and personalized immunotherapies with minimal toxicities.

10352-12, Session 3

Nanophotonics-enhanced intraocular pressure sensor for glaucoma management *(Invited Paper)*

Hyuck Choo, Jeong Eon Lee, Haeri Park, Vinayak Narasimhan, Blaise Ndjamen, California Institute of Technology (United States); Juan Du, David W. Sretavan, Univ. of California, San Francisco (United States)

Glaucoma is a leading cause of irreversible blindness with 60 million cases worldwide. An elevated intraocular pressure (IOP) level has been identified as a major risk factor, and all the glaucoma therapies are aimed at lowering the IOP level. Moreover, in a recent large-scale NIH-sponsored study, researchers have found that IOP of an individual patient fluctuates largely over the course of the day, and continuous monitoring and aggressively lowering IOP in a timely manner is crucial for optimal disease management.

My research group has been developing a nanophotonics-enhanced implantable pressure sensor with remote optical readout. The sensor is compact for easy implantation, and its operation requires only a broadband light source, such as a tungsten light bulb. Bench testing has demonstrated that the sensor tracks pressures ranging from 0-40 mmHg within +/-1 mmHg, and we have been successfully performing short- and long-term in vivo IOP monitoring in live rabbits over two years now.

This presentation will describe our nanophotonics-enhanced IOP-sensor development and up-to-date progresses. I hope to leave you convinced that our approach will allow us to solve the long-standing challenge in glaucoma research and patient management.

10352-13, Session 4

Enabling rapid, quantitative detection of bacteria in blood with high resolution DNA melting, microfluidics, and machine learning *(Invited Paper)*

Stephanie Fraley, Daniel Ortiz Velez, Hannah Mack, Julietta Jupe, Sinead Hawker, Ninad Kulkarni, Behnam Hedayatnia, Yang Zhang, Shelley Lawrence, Univ. of California, San Diego (United States)

We report the development of an integrated platform enabling the identification and absolute quantification of bacterial DNA in blood samples in less than four hours. The system incorporates a 20,000 reaction digital PCR chip with sensitive imaging and controlled heating to produce for the first time high resolution melt (HRM) curves of pathogen DNA within picoliter scale reactions. Clinically relevant concentrations of bacteria are spiked into blood; then DNA is extracted and the molecules separated by digitization across 20,000 picoliter scale reactions. Pathogen DNA is amplified with universal primers targeting the bacterial 16S gene. Amplification is followed by HRM sequence fingerprinting in all reactions simultaneously using our custom device. The resulting bacteria-specific melt curves are identified by Support Vector Machine learning, and individual pathogen loads are quantified. The platform reduces reaction volumes by 99.995% and achieves a greater than 200-fold increase in dynamic range of detection compared to traditional PCR HRM approaches. Type I and II error rates are reduced by 99% and 100% respectively compared to intercalating dye-based digital PCR (dPCR) methods. This technology could impact a number of quantitative profiling applications, especially infectious disease diagnostics.

10352-14, Session 4

Nanostraw mediated non-perturbative cell access and transfection *(Invited Paper)*

Nicholas A. Melosh, Yuhong Cao, Martin Hjort, Stanford Univ. (United States)

The cell's lipid membrane is one of the most vital cell components as the gate-keeper in and out of the cytoplasm and a critical barrier to integrating technology with biological cells. Newly discovered forms cancer therapy and future biological technologies rely upon manipulating chemical or electronic flow across this membrane. Unfortunately, artificially controlling access through the lipid layer is surprisingly difficult; current techniques often involve harsh chemicals or creating holes that cause cell cytotoxicity. Here we investigate how scaling fluidic technology to the nanoscale can provide non-perturbative access through the cell wall and into biological cells, providing a long-term communication channel for chemical or biological signals. We achieved high-efficiency chemical delivery and control by mimicking natural gap junction proteins, creating arrays of 'nanostraws'. These nanoscale (100-500 nm) diameter straws are formed by templating high-aspect ratio pores, allowing precise control of height, diameter and thickness. The nanostraws deliver a wide variety of materials that could normally not pass through the cell wall, yet do not disturb natural cell function. Models of how these materials penetrate the lipid bilayer show that a simple impaling mechanism is insufficient, but instead rely upon cellular traction forces to drive membrane rupture.

Surprisingly, we discovered that these nanoscale conduits can not only deliver material into cells, but also can extract minute quantities of cellular proteins and small molecules out. Our data shows that intracellular contents from thousands of cells down to even a single cell can be non-destructively sampled and quantitatively analyzed multiple times over the course of one week, a feat which has not been previously possible. This advance enables new studies of how cells temporally evolve within fully interconnected cell monolayers in response to different therapies and lineage drivers. These, and other similar nanofluidic technologies, open a new area for engineered devices to play a leading role in future biological technologies and healthcare.

10352-15, Session 4

Double emulsion electrospun nanofibers as a growth factor delivery vehicle for salivary gland regeneration

Zahraa I. Foraida, SUNY Polytechnic Institute (United States); Alexander T. Khmaladze, Deirdre A. Nelson, Melinda Larsen, Univ. at Albany (United States); James Castracane, SUNY Polytechnic Institute (United States)

Sustained delivery of growth factors, proteins, drugs and other biologically active molecules is necessary for tissue engineering applications. Electrospun fibers are attractive tissue engineering scaffolds as they partially mimic the topography of the extracellular matrix (ECM). However, they do not provide continuous nourishment to the tissue. In search of a biomimetic scaffold for salivary gland tissue regeneration, we previously developed a blend nanofiber scaffold composed of the protein elastin and the synthetic polymer polylactic-co-glycolic acid (PLGA). The nanofiber scaffold promoted in vivo-like salivary epithelial cell tissue organization and apicobasal polarization. However, in order to enhance the salivary cell proliferation and biomimetic character of the scaffold, sustained growth factor delivery is needed. The composite elastin-PLGA nanofiber scaffold was optimized to act as a growth factor delivery system using epidermal growth factor (EGF) as a model protein. The nanofiber/EGF hybrid nanofibers were synthesized by double emulsion electrospinning where EGF is emulsified within a water/oil/water (w/o/w) double emulsion system. Ethyl cellulose was used as an emulsifying and release retardant agent. Successful incorporation of EGF was confirmed using fluorescence spectroscopy, Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy. EGF loading efficiency and release profile was characterized using fluorescently-labelled EGF/nanofibers and compared to standard blend electrospinning technique. Submandibular immortalized mouse salivary epithelial cells (SIMS) were cultured on the proposed EGF/nanofiber scaffolds where the cell proliferation was observed. We demonstrated the potential of the proposed double emulsion electrospun nanofiber scaffold for the delivery of growth factors and/or drugs for tissue engineering and pharmaceutical applications.

10352-16, Session 4

Magnetoresistive biosensors for quantitative proteomics *(Invited Paper)*

Xiahan Zhou, Chih-Cheng Huang, Drew Hall, Univ. of California, San Diego (United States)

Superparamagnetic magnetic nanoparticles (MNPs) exhibit a relaxation response due to a pulsed magnetic field, enabling a new time-domain magnetorelaxometry biosensing scheme. Giant magnetoresistive (GMR) sensors were used to detect this phenomenon due to their high transduction efficiency and small size. We report a novel biosensor system consisting of a GMR sensor array, a Helmholtz coil, an electromagnet driver, and an integrator-based analog front-end for magnetorelaxometry biosensing. The custom electromagnet driver reduces the switch-off time to < 10 ?s by applying a large negative voltage during switching enabling the system to monitor fast relaxation processes of 30 nm MNPs. Magnetic correlated double sampling is proposed to eliminate sensor-to-sensor variation, temperature drift, circuit offset, and non-linearity. An optimum integration time is calculated and experimentally verified to maximize the SNR. Lastly, experiments with dried MNPs show successful relaxation detection and immunoassay experiments demonstrate the binding kinetics.

10352-17, Session 4

Micro-array isolation of circulating tumor cells: the nanotube-CTC chip

Balaji Panchapakesan, Farhad Khosravi, Worcester Polytechnic Institute (United States); Eric Wickstrom, Thomas Jefferson Univ. (United States); Shesh N. Rai, Univ. of Louisville (United States); Alison Zibelli, Thomas Jefferson Univ. (United States); Goetz Kloecker, Univ. of Louisville (United States)

We demonstrate the rapid and label-free capture of breast cancer cells spiked in blood using nanotube-antibody micro-arrays. 76-element single wall carbon nanotube arrays were manufactured using photo-lithography, metal deposition, and etching techniques. Anti-epithelial cell adhesion molecule (anti-EpCAM), Anti-human epithelial growth factor receptor 2 (anti-Her2) and non-specific IgG antibodies were functionalized to the surface of the nanotube devices using 1-pyrene-butanoic acid succinimidyl ester. Following device functionalization, blood spiked with SKBR3, MCF7 and MCF10A cells (100/1000 cells per 5 ?l per device, 170 elements totaling 0.85 ml of whole blood) were adsorbed on to the nanotube device arrays. Electrical signatures were recorded from each device to screen the samples for differences in interaction (specific or non-specific) between samples and devices. A zone classification scheme enabled the classification of all 170 elements in a single map. A kernel-based statistical classifier for the 'liquid biopsy' was developed to create a predictive model based on dynamic time warping series to classify device electrical signals that corresponded to plain blood (control) or SKBR3 spiked blood (case) on anti-Her2 functionalized devices with ~90% sensitivity, and 90% specificity in capture of 1000 SKBR3 breast cancer cells in blood using anti-Her2 functionalized devices. Screened devices that gave positive electrical signatures were confirmed using optical/confocal microscopy to hold spiked cancer cells. Confocal microscopic analysis of devices that were classified to hold spiked blood based on their electrical signatures confirmed the presence of cancer cells through staining for DAPI (nuclei), cytokeratin (cancer cells) and CD45 (hematologic cells) with single cell sensitivity. We report 55%–100% cancer cell capture yield depending on the active device area for blood adsorption with mean of 62% (~12 500 captured off 20 000 spiked cells in 0.1 ml blood) in this first nanotube–CTC chip study.

10352-18, Session 5

Multi-area distributed network of implanted neural interrogators *(Invited Paper)*

David A. Borton, Marc Powell, Brown Univ. (United States)

Electrophysiological interrogation of the nervous system is today limited by our inability to simultaneously probe many areas of the brain with high spatial and temporal resolution to discriminate single neurons and their interactions. For example, countless microfabricated electrode arrays (MEAs) have been developed to densely record populations of single neurons and capture full spike waveforms, but have been limited to recording from a miniscule, mm3 volume of the cortex. Alternatively, electrocorticography (ECoG) and electroencephalography (EEG) can record from multiple cortical sites, but integrate the activity of many neurons together, obscuring the intricacies of the underlying circuit dynamics. There is a fundamental need to develop long lasting implantable devices that bridge the gaps between scale and scope. In this presentation, we will describe a platform technology for accessing a network of independently addressable neural interrogators, or nodes, each capable of recording from 100 individual channels with high temporal precision, distributed across the cortical surface. The system will enable clinicians and researchers to place nodes ad libitum on the cortex, agnostic to location and therefore customized to the specific needs of the treatment or research question, alleviating the surgical challenges currently faced while implanting traditionally tethered MEAs. The platform eliminates transdural cables, reducing surgical implantation site limitations and more importantly removing pathways for long-term infection directly to the meninges and damage due to micromotion between the interface

and the skull. Nodes are powered, and communicate, wirelessly enabled by the application of novel electromagnetically transparent ?hermetic ASIC packaging techniques for extended functionality.

10352-19, Session 5

Advances in flexible optrode hardware for use in cybernetic insects *(Invited Paper)*

Joe Register, Dennis Callahan, Carlos Segura, John LeBlanc, Charles Lissandrello, Parshant Kumar, Chris Salthouse, Jesse Wheeler, Aaron Stoddard, Draper Lab. (United States)

Optogenetic manipulation is widely used to selectively excite and silence neurons in laboratory experiments. Recent efforts to miniaturize the components of optogenetic systems have enabled experiments on freely moving animals, but a completely new approach is required to apply the same techniques to freely flying insects.

We present the design of lightweight optogentic hardware and supporting electronics for the untethered steering of dragonfly flight. The system is designed to enable autonomous flight and includes processing, guidance sensors, solar power, and light stimulators. The system will weigh less than 200mg and be worn by the dragonfly as a backpack. The flexible implant has been designed to provide stimuli around nerves through micron scale apertures of adjacent neural tissue without the use of heavy hardware. We address the challenges of lightweight optogenetics and the development of high contrast polymer waveguides for this purpose.

10352-20, Session 5

Electronic, optical, and chemical interrogation of neural circuits with multifunctional fibers *(Invited Paper)*

Andres Canales, Seongjun Park, Chi Lu, Yoel Fink, Polina O. Anikeeva, Massachusetts Institute of Technology (United States)

Despite recent advances in microfabrication and nanofabrication, integrating multiple modes of communication with the brain into a single biocompatible neural probe remains a challenge. These multifunctional neural probes may further our understanding of normal and disrupted functions of neural circuits manifested in neurological conditions, such as Parkinson's disease. Here, we present a novel family of probes fabricated using a thermal drawing process. In this process, a macroscopic template (preform) containing the desired features is drawn by applying heat and tension into a fiber that conserves the original geometry of the preform but at a much smaller scale. Being composed of soft materials, such as polymers, conductive composites, and low melting temperature metals, fiber based neural probes minimize the damage to the surrounding tissue when implanted. Furthermore, fiber drawing enables straightforward integration features allowing for simultaneous electrical, optical and chemical interrogation of the brain. We demonstrate the utility of these probes for one-step optogenetics, in which a viral vector carrying opsin genes is injected through the same device then used to optically stimulate neurons and record their response as electrical activity. With these probes, we also show, for the first time, recordings of electrical activity in the spinal cord of freely moving mice.

10352-21, Session 5

Neural signal transmission through brain tissue with high spatial and temporal resolution using near infrared light *(Invited Paper)*

Iman Hassani Nia, Skylar Wheaton, Michael Adoff, Daniel Dombeck, Hooman Mohseni, Northwestern Univ. (United States)

Interferometric optical methods have great potential to discern small changes in refractive index at each voxel of brain space with high speed. In this regard, various types of optical coherence tomography systems (OCTs) have been developed and improved such that shot-noise limited sensitivity is currently being pursued with scan rates close to a billion voxels per second. Therefore, there is tremendous potential for OCT to aid in the detection of neural activity in vivo. Here we introduce the idea of a novel optically linked implanted microprobe. When combined with a slightly modified OCT system, the approach could provide two-way communication with hundreds of thousands of neurons with high temporal and spatial resolution. We present our experimental methodology, including methods for implanting the microprobes and implementing our OCT apparatus. We then present the results of our in-vitro experiments, which are consistent with our optical simulations and in-vivo experiments. The in-vitro experiments demonstrate that action potential signals with 100mV amplitude could be retrieved through ~300 ?m of brain tissue, with high fidelity (SNR~18) and with less than 10 micro-Watt of optical power. Based on these results, we present our prediction for the performance limit of the proposed approach.

10352-22, Session 5

Inorganic semiconductor nanorods for neural voltage sensing

Yung Kuo, Joonhyuck Park, Univ. of California, Los Angeles (United States); Shvadchak Volodymyr, Institute of Organic Chemistry and Biochemistry (Czech Republic); Kyoungwon Park, Antonino Ingargiola, Jack Li, Shimon Weiss, Univ. of California, Los Angeles (United States)

Monitoring membrane potential in neurons requires sensors with minimal invasiveness, high spatial and temporal (sub-ms) resolution, and large sensitivity enabling detection of sub-threshold activities. While organic dyes and fluorescent proteins have been developed to possess voltage-sensing properties, photobleaching, cytotoxicity, low sensitivity and low spatial resolution have obstructed further studies. Semiconductor nanoparticles, as prospective voltage sensors, have shown large sensitivity based on Quantum confined Stark effect (QCSE), at room temperature and at single particle level. Both theory and experiment have shown their voltage sensitivity can be increased significantly via material, bandgap and structural engineering. We synthesized one of the optimal voltage sensors predicted by calculation: 10nm type-II ZnSe/CdS nanorods (NRs), with asymmetrically located seed. The voltage sensitivity and spectral shift were characterized in vitro using spectrally resolved microscopy and electrodes either lithographically patterned or grown by thin film deposition, which "sandwich" the nanoparticles. We characterized multiple batches of such NRs and iteratively modified the synthesis to achieve higher voltage sensitivity (?F/F>10%), larger spectral shift (5nm), higher quantum yield (~30%), better homogeneity, better colloidal stability and longer fluorescence lifetime. Furthermore, the NRs were functionalized with transmembrane alpha-helical peptides for membrane insertion. TEM images of the peptide-coated NRs (pcNRs) inserted in lipid vesicles and fluorescence image of cultured cells stained with pcNRs in the membrane ascertain their membrane insertion capacity. The voltage sensing feasibility of pcNRs was tested using spontaneously spiking HEK cells and voltage clamped HEK at single particle level.

10352-23, Session 5

Shedding light to sleep studies *(Invited Paper)*

Alper Bozkurt, James Dieffenderfer, North Carolina State Univ. (United States)

We present our efforts on development of a miniaturized wireless bandage with near-infrared spectroscopy (NIRS) capability to perform biophotonics based at-home or clinical sleep analysis. The smart bandage has dimensions of 25x15x5 mm3. It is capable of performing NIRS with 660nm, 850nm and 940nm wavelengths for up to 11 hours continuously. The system is placed on the forehead to measure from the prefrontal cortex and the raw data is continuously streamed over Bluetooth Low Energy to a nearby smartphone for post processing analysis. We performed traditional polysomnography simultaneously with the device to train a supervised machine-learning algorithm. Ultimately, this algorithm will generate a scored hypnogram based on optical data. The extracted features are heart rate, respiratory rate, tissue oxygenation, relative change in local oxy- and deoxy-hemoglobin concentrations, posture, and skin temperature. Preliminary results show significant feature variations for transitions from one sleep stage to another. We also added 2-channel wireless EEG functionality to the electronic bandage in parallel to the NIRS; in the event that the algorithm is unable predict sleep stages accurately with solely biophotonics data and motion. This small bandage serves as a potential alternative to traditional polysomnography and future work will determine the accuracy of the automated sleep scoring algorithm.

10352-24, Session 6

Dynamic materials inspired by cephalopods *(Invited Paper)*

Alon Gorodetsky, Univ. of California, Irvine (United States)

Cephalopods (squid, octopuses, and cuttlefish) have captivated the imagination of both the general public and scientists for more than a century due to their visually stunning camouflage displays, sophisticated nervous systems, and complex behavioral patterns. Given their unique capabilities and characteristics, it is not surprising that these marine invertebrates have recently emerged as exciting sources of inspiration for the development of unique materials. Within this context, our laboratory has explored the properties of structural proteins known as reflectins, which play crucial roles in the functionality of cephalopod skin. In this talk, I will discuss our work on new types of photonic and protonic devices fabricated from reflectin-derived and reflectin-inspired materials. Our findings hold implications for the development of adaptive camouflage systems, sensitive bioelectronic platforms, and renewable energy technologies

10352-25, Session 6

Microfluidic body-on-a-chip platforms for mimicking the human drug metabolism *(Invited Paper)*

Mandy Esch, Hidetaka Ueno, National Institute of Standards and Technology (United States); Yang Yang, Syracuse Univ. (United States)

Patients with incurable diseases often participate in clinical trials hoping to benefit from a drug that has cured the disease in animals. However, drugs that cure diseases in animals often do not work in human patients. Unless we develop better mimics of the human body, patients will continue to be disappointed.

We have developed body-on-a-chip systems that replicate key aspect amiss in animals: the devices can mimic part of the human metabolism. We demonstrate that by simulating the oral uptake and metabolism of acetaminophen using the developed devices. Our platforms also feature integrated sensors that can monitor tissue health throughout a drug exposure. Sensor elements are optical (for estimating the toxicity of a drug), and electrical (for estimating the transepithelial resistances of tissues). The platform allowed us to monitor tissues during a drug exposure.

10352-26, Session 6

On-demand drawing of high aspect-ratio, microsphere-tipped elastomeric micropillars

Qiang Li, Tara Mina, Jaeyoun Kim, Iowa State Univ. of Science and Technology (United States)

High aspect-ratio elastomeric micropillars are widely used in a plethora of applications, such as functional surfaces, smart windows, actuators, and sensors. Their fabrication at arbitrary positions on non-planar substrates, however, has rarely been reported. Here we demonstrate a new technique for facile fabrication of high aspect-ratio, microsphere-tipped elastomeric micropillars based jointly on controlled dispensing of elastomer droplets and direct drawing of micropillars induced by vacuum-assisted pipetted microspheres with in situ UV light curing. It enables on-demand realization of elastomeric micropillars on various structures with uncommon geometries, such as the curved outer surface of a cylinder or end facet of an optical fiber. The new technique also facilitates arrayed fabrication of micropillars with different heights on the glass substrate and micropillars with different heights and orientations on the curved outer surface of a cylinder, further strengthening the micropillars' potential for collective operation. The tapering index (ratio of the difference in diameters of base and tip to height) can also be controlled with the UV light on/off during pulling process. As a proof-of-concept exemplary application, a fiber optic contact sensor is realized by integrating a micropillar onto the end facet of an optical fiber. Overall, both the fabrication technique and the resulting outcomes of this work will add new tools to the toolbox of soft-MEMS and soft-robotics.

10352-27, Session PMon

Modeling electrical response of biofluids

Anays Acevedo Barrera, Univ. Nacional Autónoma de México (Mexico); Augusto García Valenzuela, Ctr. de Ciencias Aplicadas y Desarrollo Tecnológico (Mexico); Asur Guadarrama Santana, Univ. Nacional Autónoma de México (Mexico)

Physical and chemical properties of biofluids can be assessed by optical, electrical and acoustics measurerments. In particular, electrical and optical measurements can usually be implemented in a single device and their results are complementary, being the first at low frecuencies and the later at high frecuencies. In this work, we focus on electrical properties of biofluids in the range of tens of kilohertz to megahertz. A simplified model is proposed to study the electrical response of biofluids . This model facilitates interpreting the results in complex impedance measurements. The model consist of a biphasic system, a suspension of micrometric spheres embedded in an homogeneous fluid. Both mediums are considered electrolytes of different conductivities. An effective medium theory is used to analyze the composite as if it were an homogeneous medium. We find the equivalent circuit of the biofluid inside a parallel plate capacitor and obtain mathematical expressions for the equivalent capacitance and resistance. The behavior and sensitivity of electrical parameters to the density of free charges (ions and counterions) in both phases is studied. The application of our model to the characterization of osmotic fragility in human blood cells, as well as for sedimentation monitoring in a colloidal suspension of particles is presented. Measurements are realized using a low noise system based on differential capacitive sensor.

10352-28, Session PMon

Scale-selective polarimetry of the birefringence distribution of myocardium tissue

Olexander V. Dubolazov, Alexander Ushenko, Vladimir Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Among the numerous areas of optical diagnostics of biological tissues structure are widely used techniques that using laser polarized radiation. Particularly, laser polarimetry of microscopic images of polycrystalline protein networks was formed as a separate approach in the study of optically anisotropic component ?f different biological tissues biopsy.

Our research is aimed at designing the experimental method Fourier's polarimetry and spatial-frequency selection of parameter distributions of linear and circular birefringence of the biopsy of the myocardium in order to differentiate causes of death due to coronary heart disease (CHD) and acute coronary insufficiency (ACI).

The results of optical modeling of biological tissues polycrystalline multilayer networks have been presented. Algorithms of reconstruction of parameter distributions were determined that describe the linear and circular birefringence. For the separation of the manifestations of these mechanisms we propose a method of space-frequency filtering. Criteria for differentiation of causes of death due to coronary heart disease (CHD) and acute coronary insufficiency (ACI) were found.

A set of criteria for differentiation of CHD and ACI conditions of the myocardium has been revealed and substantiated:

- statistical moments of the 1st – 4th order which characterize a distribution of the phase shift between orthogonal components of the amplitude laser radiation, stipulated by linear birefringence of myosin fibers of the myocardium layer;

- statistical moments of the 1st – 4th orders which characterize a distribution of plane rotations of laser radiation polarization, stipulated by circular birefringence of the network of myosin fibrils of the myocardium layer.

10352-29, Session PMon

Wavelet analysis of myocardium polarization images in problems of diagnostic of necrotic changes

Olexander V. Dubolazov, Alexander Ushenko, Vladimir Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

This research presents the results of investigation of laser polarization fluorescence of biological layers (histological sections of the myocardium). The polarized structure of autofluorescence imaging layers of biological tissues was detected and investigated. Proposed the model of describing the formation of polarization inhomogeneous of autofluorescence imaging biological optically anisotropic layers. On this basis, analytically and experimentally tested to justify the method of laser polarimetry autofluorescent. Analyzed the effectiveness of of this method in the postmortem diagnosis of infarction. The objective criteria (statistical moments) of differentiation of autofluorescent images of histological sections myocardium were defined. The operational characteristics (sensitivity, specificity, accuracy) of these technique were determined.

On the basis of the model of generalized optical anisotropy myocardium analytically grounded and experimentally tested method of laser polarization autofluorescence.

Within the applied approach the interconnections between the statistical moments characterizing wavelet coefficients distributions polarization maps of laser autofluorescent images of histological sections of myocardium and the peculiarities of its pathological states were found.

Clinical efficiency of the technique of wavelet analysis of polarization of laser autofluorescence myocardium in the task of posthumous diagnosis is demonstrated.

10352-30, Session PMon

Electrical characteristics of Graphene Based Field Effect Transistor (GFET) biosensor for ADH detection

Azrul Azlan Hamzah, Reena S. Selvarajan, Burhanuddin Y. Majlis, Univ. Kebangsaan Malaysia (Malaysia)

FET biosensor could be utilized to detect antidiuretic hormone (ADH) in blood in order to regulate amount of urine production in artificial kidney. For this application, the most sensitive FET biosensor to date is graphene based field effect transistor (GFET) biosensor. The monoatomic structure of graphene biosensor offers unique properties such as high mechanical strength, distinctive electronic properties, high carrier mobility, high saturation velocity, and low charge scattering. Owing to these properties GFET has been used in sensitive detection of analytes. In this paper, GFET was designed using Lumerical software to obtain the I-V characteristics of GFET for ADH detection. P-doped Si was used as substrate, and active graphene layers are deposited on top of SiO_2 insulator layer. Aluminium electrodes were then deposited as source and drain, respectively. Highly conductive silver and silver nitride were used as gate and gate oxide respectively. Effect of gate characteristics on conductivity was observed by sweeping gate voltage from -1V to 1V at minimal electric field, V_{drain}= 0.1 V and 0.2 V respectively. It is observed that variation in drain current (Id) changes the conductivity of the graphene layer. At zero gate voltage, drain current of $9.90597e^{(-5)}$A was recorded. Drain current varies as ADH are attached to the aptamers on the graphene layers. The corresponding change in graphene resistivity is utilized to detect the presence of ADH molecules. The highly sensitive GFET makes it the most prominent biosensor in the detection of ADH, thus enables efficient control of fluid in artificial kidney.

10352-31, Session PMon

System of Mueller matrix polarization correlometry of biological polycrystalline layers

Olexander V. Dubolazov, Alexander Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

Biological tissues represent structurally heterogeneous optical anisotropic media with absorption. To describe interactions of polarized light with such complex systems more generalized approximations are required based on Mueller-matrix formalism. Nowadays many practical techniques based on the measurement and analyses of Mueller matrices of the investigated samples are applied in biological and medical research. A separate direction – laser polarimetry – was formed in matrix optics within 10-15 years. The work consists of investigation results of diagnostic efficiency of a new azimuthally stable 3D - Mueller-matrix method which using coherent reference wave. A new model of generalized optical anisotropy of biological tissues protein networks is proposed in order to define the processes of the formation of three-dimensional elements of the Mueller matrix. The influence of complex mechanisms of both phase anisotropy (linear birefringence and optical activity) and linear (circular) dichroism is taken into account. The interconnections between the series of layers of azimuthally stable Mueller-matrix imaging that characterizing different mechanisms of optical anisotropy are determined. The statistic analysis of coordinate distributions of such Mueller-matrix rotation invariants is proposed. Thereupon the quantitative criteria (statistic moments of the 1st to the 4th order) of differentiation of human prostate polycrystalline layers for the sake of diagnosing and differentiating benign (adenoma) and malignant (cancer) tumors are estimated.

10352-32, Session PMon

Two-point Stokes vector parameters of object field for diagnosis and differentiation of optically anisotropic biological tissues

Olexander V. Dubolazov, Alexander Ushenko, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

A new method of Stokes-corellometric evaluation of polarization-inhomogeneous image histological sections of optically-anisotropic biological tissues with different morphological structure is developed. Algorithms of analytical description and experimental determination of coordinate distributions of "two-point" Stokes vector parameters is defined. Within statistical (Statistical moments 1st - 4th order), correlation (half-width and sharpness of the peak of the autocorrelation function) and fractal (dispersion of distributions of logarithmic dependence of power spectra) analysis the objective criteria is defined, which describing the distribution of the module and the phase size of "two-point" Stokes vector parameters of polarization-inhomogeneous microscopic images of three groups of biological tissues samples with ordered and disordered birefringence-fibrillar networks. A comparative analysis of "single-point" distributions and "two-point" distributions of Stokes vector parameters of polarization-inhomogeneous images of histological sections is conducted. A higher sensitivity (2-5 times) of Stokes-correlometry method to variations in orientation-phase structure of biological tissues with different morphological structure is demonstrated.

10352-33, Session PMon

Photochemically synthesized heparin-based silver nanoparticles antimicrobial activity study

Pilar Rodriguez-Torres, Laura Susana Acosta Torres, Univ. Nacional Autónoma de México (Mexico); Luis Armando Díaz Torres, Centro de Investigaciones en Óptica, A.C. (Mexico); Paloma Netzayelli Serrano Díaz, Univ. Nacional Autónoma de México (Mexico)

The antimicrobial activity of silver nanoparticles has been extensively studied in the last years. Such nanoparticles constitute a potential and promising approach for the development of new antimicrobial systems especially due to the fact that several microorganisms are developing resistance to some already existing antimicrobial agents, therefore making antibacterial and antimicrobial studies on alternative materials necessary to overcome this issue. Silver nanoparticle concentration and size are determining factors on the antimicrobial activity of these nano systems.

Heparin is a polysaccharide that belongs to the glycosaminoglycans (GAGs) family, molecules formed by a base disaccharide whose components are joined by a glycosidic linkage that is a repeating unit along their structure. It is highly sulfated making it a negatively charged material that is also widely used as an anticoagulant in Medicine because its biocompatibility besides it is also produced within the human body, specifically in the mast cells. Heparin alone possesses antimicrobial activity although it has not been studied very much in detail, it only has been demonstrated that it inhibits E. coli, P. aeruginosa, S. aureus and S. epidermidis, so taking this into account, this study is dedicated to assess UV photochemically-synthesized (?=254 nm) heparin-based silver nanoparticles antimicrobial activity using the agar disk diffusion method complemented by the broth microdilution method to estimate de minimum inhibitory concentration (MIC), that is the lowest concentration at which an antimicrobial will inhibit visible growth of a microorganism. The strains used were the ones aforementioned to assess the antimicrobial activity degree these heparin-based nanoparticles exhibit.

10352-34, Session PMon

Jones matrix polarization-correlation mapping of biological crystals networks

Olexander V. Dubolazov, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

The theoretical background of azimuthally stable method of Jones-matrix mapping of histological sections of biopsy of myocardium tissue on the basis of spatial frequency selection of the mechanisms of linear and circular birefringence is presented. The diagnostic application of a new correlation parameter – complex degree of mutual anisotropy – is analytically substantiated. The method of measuring coordinate distributions of complex degree of mutual anisotropy with further spatial filtration of their high- and low-frequency components is developed. The interconnections of such distributions with parameters of linear and circular birefringence of myocardium tissue histological sections are found. The comparative results of measuring the coordinate distributions of complex degree of mutual anisotropy formed by fibrillar networks of myosin fibrils of myocardium tissue of different necrotic states – dead due to coronary heart disease and acute coronary insufficiency are shown. The values and ranges of change of the statistical (moments of the 1st – 4th order) parameters of complex degree of mutual anisotropy coordinate distributions are studied. The objective criteria of differentiation of cause of death are determined.

10352-35, Session PMon

Surface enhanced Raman spectroscopy in the prescense of hydroquinone assisted by gold nanorods

Rodrigo Cabrera Alonso, Francisco Javier González, Univ. Autónoma de San Luis Potosí (Mexico)

In particular, there are non-invasive analytical sciences to biomedical research in optical techniques. Which provide detailed information on the molecular composition, structure and interaction of the relationship between diseases and biochemical changes. One of the techniques most used today is Raman spectroscopy, which provides a "fingerprint" of the molecular structure of the sample that can be used to identify the material being analyzed.

However a disadvantage is that small amounts of clinically significant substances in biological samples beyond the detection limit of conventional Raman spectrometers, making them difficult or impossible to detect. Due to this low intensity in the Raman signal for biological samples, a variety of agents have been manufactured metal nanoparticles with unique optical properties for diagnostic and medical treatment. To perform Raman amplification of this signal, it is necessary to implement the technique known as surface enhanced Raman spectroscopy (SERS). A molecule of interest is an aromatic organic compound called hydroquinone. It is a substance found in skin lightening creams, which, when applied in high concentrations, it can be the cause of skin cancer. By means of Raman spectroscopy, a qualitative analysis for subsequent medical diagnosis is made.

Photonic-plasmonic hybrid single molecule nanosensor measures the effect of fluorescence labels to DNA-protein dynamics

Feng Liang, The Rowland Institute at Harvard (United States); Yuzheng Guo, Swansea Univ. (United Kingdom); Qimin Quan, Shaocong Hou, The Rowland Institute at Harvard (United States)

Photonic-plasmonic hybrid single molecule nanosensor

In single molecule research, the subject molecules are labeled with fluorescent reporters. The effect of the labels on molecular dynamics has not been quantified due to lack of alternative methods. Here we develop a hybrid photonic-plasmonic antenna-in-a-nanocavity system to achieve real-time kinetic measurement on single molecule interactions. We trap a single 50 nm gold particle in a photonic crystal nanobeam cavity. The nanoparticle acts as an optical antenna, which confines photons in a deep sub-wavelength mode volume while maintaining a high-quality factor of the photonic crystal nanobeam cavity. This hybrid structure improves the Q/V ratio by two orders of magnitude over previous systems, thus pushing the sensitivity to the single molecule level. Our system has several other advantages. First, it utilizes resonantly trapped photons to probe molecular interactions, thus is not limited by low photon counts or photobleaching. Second, current technique does not need any fluorescent labels, hence the measurement is genuinely reflecting the molecular dynamics. Third, our current implementation has time resolution at millisecond scale level, fast enough to study single molecule interactions.

As an example, we used our nanosensor to study DNA-protein (XPA) interactions. We measured the DNA-XPA binding kinetics using unlabeled DNA, FITC-labeled DNA and GFP-labeled DNA. We discovered that FITC and GFP can affect the DNA-XPA binding affinities up to 3 and 18 times, due to weakened electrostatic interactions.

Biocompatibility and toxicity of colloidal plasmonic titanium nitride nanoparticles in epithelial cells

Tejaswini Ronur Praful, Norfolk State Univ. (United States); Urcan Guler, Alexandra Boltasseva, Vladimir M. Shalaev, Purdue Univ. (United States); Nicholas A. Kotov, Univ. of Michigan (United States); Govindarajan T. Ramesh, Norfolk State Univ. (United States)

Titanium nitride (TiN) is an emergent plasmonic material with unique properties that promise solutions to existing challenges in a variety of applications including hyper-thermal medical treatment. In this work, we have studied biocompatibility of TiN nanoparticles. Studies from dynamic light scattering (DLS) indicated that the size of TiN nanoparticles was around 50 nm, and thus facilitates easier cellular uptake. This makes TiN promising material for bioelectrochemical sensing electrodes and a promising plasmonic photothermic and photocatalytic material. Gold nanoparticles were used as positive control. The biocompatibility was tested using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and live dead assay on epithelial cells. The TiN nanoparticles showed viability similar to that of control until 50x10^7 nanoparticles/ml concentration and dropped by several folds later.

Innovative strategies in hepatic tissue engineering

Laila M. Montaser M.D., Menoufia Univ. (Egypt); Sherin M. Fawzy, Society for Research on Nicotine and Tobacco (Egypt)

Failure of human body organs is believed to be one of the most important health problems all over the world. Tissue engineering aims at developing functional substitutes for damaged tissues and organs.

The application of stem cells in human regenerative medicine could be an alternative to organ transplantation, avoiding the problem of donor shortage and rejection. There is an increasing range of potential applications of stem cells in liver diseases. The great challenge for tissue engineers is to optimize suitable systems to separate, proliferate and differentiate the cells so that they can set out to create tissue. Stem cell-based therapy has received attention as a possible alternative to organ transplantation, owing to the ability of stem cells to repopulate and differentiate at the engrafted site.

Advancements in the fields of stem cell biology and biomaterials science and engineering have been combined to produce strategies by which stem cell attachment; proliferation and differentiation in vitro are supported and enhanced. Before transplantation, cells are generally seeded on biomaterial scaffolds that recapitulate the extracellular matrix and provide cells with information that is important for tissue development. Degradation of excess liver scar is thus a suitable target for cell therapy. In this manuscript, we offer our view on the applying nanotechnology and present current and emergent approach in the field of hepatic tissue engineering for specific application. The application of nanotechnology to stem cell biology would be able to address the challenges of the failure of injected cells to engraft to target tissues.

Conference 10353: Optical Sensing, Imaging, and Photon Counting: Nanostructured Devices and Applications 2017

SPIE. OPTICS+ PHOTONICS NANOSCIENCE+ ENGINEERING

Wednesday - Thursday 9 –10 August 2017

Part of Proceedings of SPIE Vol. 10353 Optical Sensing, Imaging, and Photon Counting: Nanostructured Devices and Applications 2017

10353-1, Session 1

UV and IR photodetection in single GaN/AlN nanowires *(Invited Paper)*

Jonas Lähnemann, Paul-Drude-Institut für Festkörperelektronik (Germany) and Univ. Grenoble-Alpes (France) and Institut NÉEL (France); Martien I. den Hertog, Univ. Grenoble-Alpes (France) and Institut NÉEL (France) and CEA-INAC-PHELIQS (France); Akhil Ajay, Maria Spies, Jakub Polaczy?ski, Univ. Grenoble-Alpes (France) and CEA-INAC-PHELIQS (France) and Institut NÉEL (France); Pascal Hille, Justus-Liebig-Univ. Giessen (Germany); María de la Mata, Institut Català de Nanociència i Nanotecnologia (ICN2) (Spain); Jörg Schörmann, Justus-Liebig-Univ. Giessen (Germany); Jordi Arbiol, Institut Català de Nanociència i Nanotecnologia (ICN2) (Spain); Martin Eickhoff, Justus-Liebig-Univ. Giessen (Germany); Bruno Gayral, Eva Monroy, Univ. Grenoble-Alpes (France) and CEA-INAC-PHELIQS (France) and Institut NÉEL (France)

Almost defect-free semiconductor nanowires (NWs) grown by molecular beam epitaxy have potential applications as miniaturized photodetectors. GaN is a promising choice to cover the ultraviolet (UV) spectral range. Recently, we have investigated the photoconductive properties of single, contacted GaN NWs incorporating GaN/AlN nanodisks [1]. A significant dispersion in the magnitude of the photo- and dark currents for different single NWs was attributed mainly to the coalescence of NWs with displaced nanodisk stacks, reducing the effective length of the heterostructure. A larger number of active nanodisks and AlN barriers in the current path results in lower dark current and higher photosensitivity, and improves the sensitivity of the NW to variations in the illumination intensity (reduced sublinearity). Based on these results, we have devised an improved design with higher reproducibility of the characteristics of individual NWs. A n/n+ doping profile of the stem and cap segments results in an improved photovoltaic response at low bias.

Finally, we have demonstrated the feasibility of IR photodetection around the telecommunication wavelength in single GaN/AlN-nanowires based on intraband transitions in doped nanodisks. The spectral characteristics are in agreement with three-dimensional simulations of the transition energies in the investigated nanostructures. In contrast to the UV photocurrent, the response with IR illumination intensity is perfectly linear over several orders of magnitude, which can be related to the decoupling of the IR photoresponse from surface related effects predominant in the UV response.

10353-2, Session 1

Colloidal quantum dots for mid-IR detection and emission *(Invited Paper)*

Philippe Guyot-Sionnest, The Univ. of Chicago (United States)

No Abstract Available.

10353-3, Session 1

Infrared imaging using low-cost II-VI colloidal quantum dots *(Invited Paper)*

Richard E. Pimpinella, Christopher Buurma, Anthony J. Ciani, Christoph H. Grein, Sivananthan Labs., Inc. (United States); Philippe Guyot-Sionnest, The Univ. of Chicago (United States)

II-VI colloidal quantum dots (CQDs) have made significant technological advances over the past several years, including the world's first demonstration of MWIR imaging using CQD-based focal plane arrays. The ultra-low costs associated with synthesis and device fabrication, as well as compatibility with wafer-level focal plane array fabrication, make CQDs a very promising infrared sensing technology. In addition to the benefit of cost, CQD infrared imagers are photon detectors, capable of high performance and fast response at elevated operating temperatures. By adjusting the colloidal synthesis, II-VI CQD photodetectors have demonstrated photoresponse from SWIR through LWIR. We will discuss our recent progress in the development of low cost infrared focal plane arrays fabricated using II-VI CQDs.

10353-4, Session 1

Interesting problems in superlattice detectors *(Invited Paper)*

Sanjay Krishna, The Ohio State Univ. (United States)

There has been significant progress on the development of Type II superlattice detectors in the past 15 years. As we have progressed in advanced heterostructure engineering of the devices, it has also provided insight into some of the challenges associated with the superlattices. In this talk, I will discuss some of our recent results on unipolar barrier detectors. I will also discuss some of the fundamental challenges that need to be addressed for the superlattice detectors such as vertical transport and surface passivation. I will also present some interesting problems including superlattice based avalanche photodiodes and the growth of metamorphic InAsSb absorbers.

10353-5, Session 1

ZnO: from material to unipolar devices *(Invited Paper)*

Maxime Hugues, Ctr. de Rechercher sur l'Hétéro-Epitaxie et ses Applications (France); Nolwenn Le Biavan, Denis Lefebvre, Ctr. de Recherche sur l'Hétéro-Epitaxie et ses Applications (France); Miguel Montes Bajo, Julen Tamayo-Arriola, Adrian Hierro, Univ. Politécnica de Madrid (Spain); Arnaud Jollivet, Maria Tchernycheva, François H. Julien, Univ. Paris-Sud 11 (France); Jean-Michel Chauveau, Ctr. de Recherche sur l'Hétéro-Epitaxie et ses Applications (France)

Although ZnO and its related heterostructures are really attractive for their potential application in optoelectronics, their developments have been limited by the p-type doping issue. Here, we will show why ZnO properties are also very attractive for unipolar structures, only dealing with electrons,

and how the material quality has been improved to reach these devices requirements.

First, the benefit of homoepitaxy through material quality improvement is presented. We will show that molecular beam epitaxy allows getting defect density, surface roughness, and residual doping, comparable to the state-of-the-art of GaAs. Moreover, (Zn,Mg)O alloy could be used to fabricate heterostructures with very good optical and transport properties.

In the second part, we will give a brief overview of the main transport results, especially bidimensional electron gas, reported in the literature. Few examples of possible applications will also be addressed. Then, we will focus on the potentialities of nonpolar ZnO heterostructures for unipolar devices based on intersubband transitions. Once the advantages of using ZnO for TeraHertz quantum cascade laser discussed, we will show that the structural properties of the ZnO/(Zn,Mg)O heterostructures fulfill the requirements of these devices operation. Moreover, we will finish with absorption measurements clearly showing intersubband transitions in agreement with the light polarization selection rule. The strong influence of physical parameters, like doping level, on the energy of these kind of transitions will also be discussed.

This work was funded by EU commission under the H2020 FET-OPEN program; project “ZOTERAC” FET-OPEN 6655107.

10353-6, Session 2

Single-photon detection and imaging by using superconducting nanowires *(Invited Paper)*

Karl K. Berggren, Qing-Yuan Zhao, Andrew E. Dane, Di Zhu, Massachusetts Institute of Technology (United States)

This talk will generally review the superconducting nanowire single-photon detector, explaining our current understanding of its performance capabilities and limitations. We will then discuss the applications of the technology to quantum information processing, in particular its integration with various optical waveguides for on-chip integrated photonic quantum-information processing. Beyond the review portion of the talk, this talk will also present our recent work in preparing a microwave-plasmonic transmission line that can be used to both time- and position-tag individual photons upon arrival at an imaging surface. The microwave plasmons are in practice simply the natural transmission character of thin superconducting films, and result in extraordinarily slow (~c/50 velocity) transmission of microwave signals along a co-planar on-chip microwave guide. Photon-incidence events send pulses propagating along the waveguide in both directions. The position and time of the photon arrival can be distinguished by considering the relative times of arrival of the pulses at the ends of the long transmission line.

10353-7, Session 2

Ultrafast single photon detectors *(Invited Paper)*

Wolfram Pernice, Simone Ferrari, Westfälische Wilhelms-Univ. Münster (Germany)

Nanophotonic integrated circuits are emerging as a promising platform for quantum photonics. A key building block are waveguide integrated detectors with superior performance. Detectors based on superconductor nanowires (SNSPDs) attached to optical waveguides have been shown to provide high efficiency and good timing performance, as well as broad bandwidth. To move towards applications in high bandwidth quantum communication and processing, ultrafast single-photon detectors with high efficiency are needed. The speed of meander type SNSPDs is limited because the required high absorption efficiency necessitates long nanowires deposited on top of the waveguide. This enhances the kinetic inductance and makes the detectors slow. We overcome this problem by aligning the nanowire perpendicular to the waveguide to realize devices with a length below 1?µm. By integrating the nanowire into a photonic crystal cavity, we recover high absorption efficiency, thus enhancing the detection efficiency by more than an order of magnitude. Our cavity enhanced superconducting nanowire detectors are fully embedded in silicon nanophotonic circuits and efficiently detect single photons at telecom wavelengths. The detectors possess sub-nanosecond decay (~?120?ps) and recovery times (~?510?ps), and thus show potential for GHz count rates at low timing jitter (~?32?ps).

10353-8, Session 2

Time jitter and time walk in SLiK APD: characterization, measurements and implications for single photon counting applications

Bernicy S. Fong, Excelitas Canada, Inc. (Canada); Murray Davies, Excelitas Canada Inc. (Canada); Pierre Deschamps, Excelitas Canada, Inc. (Canada)

Transit time (response time), timing jitter (or timing resolution) and time walk are three separate parameters associated with a detector’s response time. Studies have been done on mostly the time jitter of various single photon detectors. Being the designer and manufacturer of the ultra-low noise (?-factor) silicon avalanche photodiode the SLiK APD, which is used in many single photon counting applications, we often get inquiries and questions to better understand how this detector behaves under different operating conditions. Hence, here we will be focusing on the study of these three time related parameters specifically for the SLiK APD, as a way to provide the most direct information for users of this detector to help with its use more efficiently and effectively. We will be providing the study data on how these parameters can be affected by temperature (both intrinsic to the detector chip and environmental input based on operating conditions), operating voltage, wavelength of photons, as well as light spot size. How they can be optimized, the trade-offs from optimization of the desired performance and if adjusting one time aspect will affect the other will be presented. Subsequently we will outline the implications of each of these parameters on some of the key single photon counting applications such as Lidar and Lidar imaging, time correlated single photon counting, and quantum experiments.

10353-9, Session 2

Modeling single photon detection

Majeed M. Hayat, The Univ. of New Mexico (United States)

Single-photon avalanche diodes (SPADs) are important devices in photon counting systems employed by applications such as quantum cryptography, time resolved spectroscopy and photon counting optical communication, time-resolved reflectometry, quantum imaging and three-dimensional laser radar. SPADs convert each photo-generated electron hole pair to a measurable current via an avalanche of impact ionizations, thereby yielding a measurable photocurrent. In this talk we present a review of a generalized and rigorous analytical model for determining single-photon detection efficiency (SPDE) and dark-count rate (DCR) of SPADs. Both gated and free-running modes of operation are considered. The model assumes a general SPAD structure, with arbitrary absorber and avalanche regions, including nonplanar devices for which the avalanche region exhibits 3D electric fields for which the SPAD can be viewed as a continuum of SPADs in tandem. The model allows us to describe dependence of the SPDE versus DCR behavior on the structure and material of the avalanche region, temperature and over-bias. At the heart of the model is a generalized theory for breakdown probability in SPADs, which takes into account the random locations where dark and photo-generated carriers are produced. A simple analysis for the role of the SPDE and DCR on the information flow in a simple quantum communication system is also described using metrics such as the mutual information and channel capacity. Finally, the peculiar effects of negative feedback on the characteristics of the avalanche pulse and quenching time in a closed-loop avalanche system are also reviewed using a hybrid analytical and simulation-based approach.

10353-10, Session 3

Depth imaging using single photon detection *(Invited Paper)*

Gerald S. Buller, Aongus McCarthy, Ximing Ren, Aurora Maccarone, Rachael Tobin, Abderrahim Halimi, Yoann Altmann, Yvan R. Petillot, Stephen McLaughlin, Andrew M. Wallace, Heriot-Watt Univ. (United Kingdom)

Single-photon detection has emerged as a candidate for a number of depth imaging applications, including both free-space and underwater. This presentation will describe experiments and image processing analysis which highlight the virtues of the approach, including sensitivity, accuracy and resolution, long range and eye-safe capabilities. These applications include long-distance depth imaging (ie > 1km) where both superconducting and semiconductor-based single-photon detectors have been used to operate within the atmospheric windows around the 1550nm wavelength. We will also examine the possibilities of extending the operational wavelength to greater than 1550nm. In underwater applications, the operational wavelength is typically between 500nm to 700nm, within the high-efficiency band of high-performance, near-room temperature silicon-based single photon avalanche diodes. In underwater imaging, depth and intensity measurements were made at up to nine attenuation lengths between transceiver and target. Another area of emerging interest is the use of multiple wavelength single-photon LIDAR which may prove suitable for investigation of distributed targets. For example, an appropriate selection of wavelengths can reveal indications of the structural and physiological parameters of vegetation to provide a valuable insight into the carbon dioxide cycle for environmental research. Single photon lidar has also been used to both reconstruct and classify color detail of targets, even at low signal levels equivalent to less than 1 photon per pixel, on average.

10353-11, Session 3

Smart single-photon detectors in CMOS technology *(Invited Paper)*

Angel Rodríguez-Vázquez, Univ. de Sevilla (Spain)

The detection of single photons by CMOS-compatible structures opens new vistas for the implementation of low-light, photon counting image sensors, on the one hand, and Time-Flight sensors, on the other hand. Relevant applications include Flash-LIDAR cameras, PET scanners and ultra-fast laser spectroscopy, among others. CMOS-SPAD sensor arrays with combined 2D/3D imaging capabilities are also being explored for possible usage in automotive and are already being used for consumer applications. All these applications largely benefit from the compatibility with VLSI mixed-signal and logic circuits and the subsequent possibility to embed sensor intelligence along with the photo-sensors. This, imaging systems capable of single photon counting and time correlated single photon detection can be built with reduced SWaP (Size, Weight and Power) figures.

Sensor smartness starts at readout, includes sensor calibration and image error correction and progresses up to the extraction of information from the raw senor data. This talk presents architectures and circuits for embedding intelligence into SPAD-based arrays. Electrical interactions among photo-sensors and read-out circuits are addressed seeking for pixel optimization. Also, strategies for time-to-digital conversion are discussed. Results from TCAD tools and measurements from prototype chips for PET, Flash LIDAR and combined 2D/3D imaging are included for demonstration purposes.

10353-12, Session 3

Hot-spot relaxation time current dependence in niobium nitride waveguide-integrated superconducting nanowire single-photon detectors

Simone Ferrari, Wolfram Pernice, Westfälische Wilhelms-Univ. Münster (Germany)

We realize fast, efficient and small footprint niobium nitride superconducting nanowire single photon detectors atop of photonic waveguides. By reducing the bias current of the nanowire, in order to break the superconductivity and trigger a detection event, more than one photon needs to be absorbed in a localized section of the wire within a very short time delay (hot-spot relaxation time), making such devices promising also for multiphoton sensing applications. We adopt a near-infrared pump-probe technique in a cryogenic environment to investigate the bias current dependence of the hot-spot relaxation time. A minimum relaxation time of (22 ± 1) ps is obtained when applying a bias current of 50% of the switching current at a bath temperature of 1.7K. Our study reveals a strong increase of the picosecond relaxation time with increasing bias current. We further adopt the same technique for determining the multi-photon detection regimes of the detector, which are in agreement with standard quantum detector tomography. In this context, we introduce a practical model and reconstruction method for determining the detector sensitivity regimes. Our work provides a complete description of the detector working operation in both number photon threshold sensitivity and time-delay sensitivity. The results allow for implementing on-chip measurement architectures for the characterization of weak classical light emitters and fast single photon sources with only one detector, driven at different biasing currents, with a drastic reduction of the time uncertainty limitations of typical correlation measurement systems.

10353-13, Session 4

Electromechanically tunable photonic crystal sensors for integrated spectrometry and nanometrology *(Invited Paper)*

Zarko Zobenica, Rob W. van der Heijden, Maurangelo Petruzella, Francesco M. Pagliano, Technische Univ. Eindhoven (Netherlands); Rick Leijssen, FOM Institute for Atomic and Molecular Physics (Netherlands); Tian Xia, Leonardo Midolo, Michele Cotrufo, Yongjin Cho, Frank W. M. van Otten, Technische Univ. Eindhoven (Netherlands); Ewold Verhagen, FOM Institute for Atomic and Molecular Physics (Netherlands); Andrea Fiore, Technische Univ. Eindhoven (Netherlands)

An ultra-compact integrated optomechanical device is presented with a footprint of the order of 15x15 micronm^2, that operates as a spectrometer with sub-pm wavelength resolution. Alternatively, using a laser source with a known wavelength, it is converted to a displacement sensor with expected resolution of some tens of fm/Hz^1/2.

The device is based on a pin photodiode fabricated on two optically-coupled semiconductor membranes. Its absorption is controlled by quantum dots in the intrinsic layer. A photonic crystal cavity is defined in the double-membrane, acting as a narrowband filter (linewidth ~ 0.1 nm) to render the detector spectrally selective. The filter is tuned by changing the membrane separation by an electrostatic force from a voltage in a reversed biased diode configuration. Reversely, an unknown displacement of the top membrane can be measured from the peak photocurrent wavelength.

A cavity resonance modulation scheme, realized by applying an additional AC electrostatic tuning voltage, in combination with phase sensitive detection, greatly improves the resonant signal to nonresonant background ratio. It also enables a direct implementation of derivative spectroscopy, leading to a wavelength resolution orders of magnitude better than the cavity linewidth for wavemeter applications.

The operation as a spectrometer is proven by resolving the absorption line of a HF gas cell excited by a broadband source. The displacement sensing is demonstrated from the observation of the mechanical resonance excited by thermal Brownian motion.

The integrated manufacturing will lead to low-cost mass production or to massive parallelization with additional potential for hyperspectral imaging or increased-throughput.

10353-14, Session 4

Photodetector fabrication by dielectrophoretic assembly of GaAs nanowires grown by a two-steps method *(Invited Paper)*

Basilio J. García, Univ. Autónoma de Madrid (Spain); Carlos García Nuñez, Univ. Autónoma de Madrid (Spain) and Univ. of Glasgow (United Kingdom); Alejandro F. Braña, Univ. Autónoma de Madrid (Spain); Nair López, Univ. Politécnica de Madrid (Spain); José L. Pau, Univ. Autónoma de Madrid (Spain)

Mechanical manipulation of nanowires (NWs) for their integration in electronics is problematic because of their reduced dimensions. Contactless NW manipulation using electromagnetic fields is usually much softer than mechanical methods, often resulting less destructive.

We report on the growth of vertically aligned GaAs NWs by Ga-assisted chemical beam epitaxy on Si(111) substrates using triethylgallium and tertiarybuthylarsine as precursors. We have developed a novel two-steps growth method –by inserting an air oxidation process- to prevent the nucleation of parasitic structures during NW growth such as traces and nanocrystals, increasing the length of resulting NWs, and improving its aspect ratio for their easy integration in electronics.

We also describe a feasible and reproducible dielectrophoretic method to assemble a single GaAs NW on conductive electrodes with high assembly and alignment yields. The electrical characteristics of obtained contacts between the bare NW and the electrode have been measured, resulting in Schottky-like barrier contacts when Al-doped ZnO (AZO) or Al are used as electrode material. On the other hand, a low-resistance contact is formed between the Ga-droplet terminated NW tip and the AZO electrode. The current-voltage measurements of a single GaAs NW diode under different illumination conditions show a strong light responsivity of the forward bias characteristic mainly produced by a change on the NW series resistance.

10353-15, Session 4

Near-unity absorption in atomically thin optoelectronic devices with high quantum efficiency *(Invited Paper)*

Deep Jariwala, California Institute of Technology (United States)

The isolation of stable atomically thin two-dimensional (2D) materials on arbitrary substrates has led to a revolution in solid state physics and semiconductor device research over the past decade. While, graphene is the poster child of 2D materials family, a variety of other 2D materials (including semiconductors) with varying structures and opto-electronic properties have been isolated over the last few years raising the prospects for a new class of devices assembled by van der Waals forces. A fundamental challenge in using 2D materials for opto-electronic devices is enhancing their interaction with light, ultimately responsible for higher performance and efficiency in the devices.

In this seminar, I will show our recent work on photovoltaic devices from transition metal dichalcogenides of molybdenum and tungsten (MoS_2, WSe_2 etc.). We have recently demonstrated near-unity absorption in the visible part of the electromagnetic spectrum in < 15 nm films of these semiconductors by placing them on reflecting metal substrates such as gold and silver. We have further shown that these highly absorbing, ultrathin films can be further used for fabrication of simple Schottky junction photovoltaic devices with microfabricated metallic top contacts. While, this work helps solve the light-absorption problem, the external quantum efficiency (EQE) was < 10% for our Schottky junction devices Very recently, we have extended this early work to fabricate p-n heterojunctions (p-WSe_2/n-MoS_2) and use graphene as a transparent top contact to amplify our current collection efficiency and push the EQE up to 50%, approaching that of many emerging photovoltaic technologies with active layers in the 100s of nm range. This represents a significant development as both light-absorption and charge collection have been addressed in these devices. Finally, I will present scope for future work using just monolayers of materials to engineer near unity light absorption and collection.

10353-16, Session 4

Photonic waveguide based evanescent excitation and near-field collection for improved surface to bulk fluorescence separation

Md. Mahmud-Ul-Hasan, KU Leuven (Belgium) and IMEC (Belgium); Pieter Neutens, Rita Vos, IMEC (Belgium); Liesbet Lagae, Pol Van Dorpe, IMEC (Belgium) and KU Leuven (Belgium)

Fluorescence is a widely used transduction mechanism in bio-imaging, sensing or physical chemistry characterization applications. The ability to selectively excite desired molecules without generating considerable bulk background from nearby molecules is very important for all these applications. A near field excitation using an exponentially decaying evanescent field is often used to reduce the bulk background by selectively exciting molecules near to the surface. We propose an on-chip platform to improve the surface and bulk fluorescence separation by combining near-field excitation and near-field collection. We used the exponentially decaying evanescent tail of a Silicon Nitride rib waveguide to excite molecules and coupled the subsequent emission back via the same waveguide. We observe from the finite difference time domain simulation that both the excitation and coupling efficiency depend exponentially on the surface-molecule distance. Thus, combination of near field excitation and collection improves surface-bulk separation. A reduction by half in effective 1/e decay length was found experimentally for this combined near-field excitation and collection technique compare to the conventional only near-field excitation based technique.

An analytical model is derived to find the optimum device efficiency for bio-sensing applications and established a general condition for sensor length to maximize the device efficiency and validated by experimental data.

Finally, we used this platform for Fluorescence Correlation Spectroscopy and steady-state fluorescence anisotropy measurement.

In this talk, I will present the fabrication, characterization and experimental results obtained using this proposed waveguide based platform.

10353-32, Session PWed

Scalable nanoantennas

Dmitrii Poletaev, Bogdan V. Sokolenko, Anna Kovaleva, V.I. Vernadsky Crimean Federal Univ. (Russian Federation); Nikolay V. Petrov, Igor A. Shevkunov, ITMO Univ. (Russian Federation)

Nanoantenna are important elements of modern photonics, along with traditional oscillators and receivers of radiation. They are widely used for the detection and conversion of electromagnetic waves. But there is the problem of expanding the operating frequency band. The purpose of work is to construct a numerical model of nanoantenna and its optimization for the expansion of the operating frequency band. In the work developed numerical model, based on Vivaldi antenna. The analysis of the parameters of the antenna (radiation pattern, Purcell factor, gain) and their optimization are carried out in the work. The conclusions of it usability for wideband transducers and Raman spectroscopy were made.

10353-33, Session PWed

Etched multimode fiber Bragg gratings based refractometer

Umesh Kumar Tiwari, Central Scientific Instruments Organisation (India); Siddharth Kaushik, Central Scientific Instrumentation Organisation (India)

A Multimode Fiber Bragg Gratings for refractive index sensing has been demonstrated experimentally. The fabrication of Bragg gratings in the Standard step-index multimode fiber with a core diameter of 50 μm and a numerical aperture of 0.20 is carried out by phase mask method. The periodic modulation of refractive index in the core region of fiber is done by KrF excimer laser operating at 248 nm as ultraviolet (UV) light source with repetition rate of output pulses is 200 Hz and energy density per pulse of 3 mJ, respectively. The beam expander enlarges the UV beam, which is then projected by a mirror into the phase mask. Focussing of enlarged UV beam is achieved with a cylindrical lens onto the fiber. The period of the phase mask is 1064 nm. The etching of cladding portion of grating region (2 cm) is carried out by Hydrofluoric acid (48%) for 15 minutes. The etching process causes reduction of cladding diameter by 55 μm which further enhances the interaction of light propagating in core mode with higher cladding modes. Solutions of varied concentrations of glycerol were prepared having corresponding refractive index. Shift in wavelength in the reflection peak of high-order mode L1 is observed when glycerol solution is passed over the cladding surface of grating region. The proposed sensor with 1-pm resolution was successfully employed for sensing of different glycerol solutions and can be used as potential sensing platform for bio-chemical applications.

10353-34, Session PWed

HgTe quantum dot photovoltaic detector at 5 micron

Matthew Ackerman, Philippe Guyot-Sionnest, The Univ. of Chicago (United States)

Mid-infrared (MIR) imaging is a currently expensive technology largely restricted to military and surveillance. A lower cost technology with similar performance would open many new civilian applications in chemical identification, driverless vehicles, and biosensing. Recent advances with colloidal quantum dots (CQDs) indicate that they may lead to very significant cost reductions in the production of focal plane arrays, while also promising higher operation temperature. To investigate the basic potential of the CQD approach, we study single element photovoltaic (PV) devices for MIR detection in the 3-5 micron range. We use HgTe CQDs in an inverted photovoltaic architecture. Interfacial layers such as titanium, Ag2Te, and MoO3 are incorporated as electron and hole barrier materials, to optimize short-circuit current (Isc) and minimize thermal noise. PV devices are characterized by current-voltage-temperature measurements, spectral response, responsivity, and specific detectivity from 50K to 295K. Time-of-flight photoconductivity measurements on HgTe thin films in conjunction with the photovoltaic devices are used to elaborate on carrier transport and carrier lifetime, and their contribution to the device operation. Our present structures show improved quantum yield, up to 30%, specific detectivity up to 10^11 Jones at 80K, and background limited detection up to 120K, and much improved stability compared to the prior report of MWIR HgTe CQD PV devices.

10353-35, Session PWed

PbS quantum dots with long wavelength absorption for SWIR photodetectors

Chen Dong, Jaewoong Lee, Shuyi Liu, Franky So, North Carolina State Univ. (United States)

Lead Sulfide nanoparticles (PbS NPs) are widely used in short-wavelength infrared (SWIR) photodetectors and solar cells due to their excellent photosensitivity, bandgap tunability, and solution processability. By varying the size of quantum dots, PbS NPs photodetectors with light sensitivity from 900 nm to 2000 nm have been demonstrated. However, there has not been any report of PbS NPs SWIR photodetectors with light sensitivity beyond 2000 nm wavelength. Larger PbS NPs require a higher reaction temperature and longer reaction time, during which second nucleation and Ostwald Ripening readily occurs leading to highly dispersion of the NPs size. In this work, we report a successful synthesis of large mono-dispersed PbS NPs with an absorption peak over 2500 nm and diameter up to 15.8 nm with good mono-dispersity, resulting in a very small half-width-at-half-maximum (HWHM) of 12 meV. Our work paves the way for fabricating broadband photodetectors with photo-response covering almost the entire visible and SWIR region.

10353-17, Session 5

III-nitride terahertz photodetectors for the reststrahlen gap of intersubband optoelectronics *(Invited Paper)*

Roberto Paiella, Habibe Durmaz, Faisal F. Sudradjat, Denis Nothern, Gordie C. Brummer, Wei Zhang, Jeffrey Woodward, Theodore D. Moustakas, Boston Univ. (United States)

Terahertz light sources and photodetectors based on intersubband (ISB) transitions in GaAs/AlGaAs quantum wells (QWs) have been the subject of extensive research efforts in the past several years, and already offer excellent performance for many applications. The operation of these devices, however, is fundamentally limited to incomplete coverage of the THz spectrum, due to the prohibitively strong lattice absorption in the (Al)(Ga)As Reststrahlen band around 8-9 THz. Recently, it has been argued that this prominent gap in the spectral coverage of semiconductor optoelectronics can be overcome using GaN/AlGaN QWs, by virtue of their large optical phonon frequencies above 15 THz.

At the same time, however, the development of III-nitride ISB devices is complicated by the large internal electric fields that exist in GaN/AlGaN QWs grown along the polar crystallographic c-axis (the most common growth direction for these materials), due to spontaneous and piezoelectric polarizations. These internal electric fields tend to distort the QW lineups and blue-shift the ISB transition energies. Here we present two different approaches that we have recently employed to address this issue for the development of THz ISB photodetectors: the use of suitably designed double-step quantum wells, and epitaxial growth on semi-polar GaN substrates. In both cases, the deleterious effects of the intrinsic electric fields are strongly reduced and promising device characteristics are demonstrated, with responsivity spectra covering the entire Reststrahlen band of arsenide semiconductors.

Hybrid cavity for photo-conductive detectors with nanoantenna arrays and distributed Bragg reflectors *(Invited Paper)*

Oleg Mitrofanov, Univ. College London (United Kingdom)

Efficiency of photoconductive detectors is limited by the bulk optical properties of photoconductive materials. The absorption length is on the order of several hundred nanometers, which limits the device thickness. Optical absorption however in the photoconductive layer can be modified substantially by using the concept of hybrid cavity, which consists of nanoantennas and a Distributed Bragg Reflector. A hybrid cavity containing a GaAs photoconductive layer of just 50 nm can be used to absorb >75% of incident photons by trapping the light within the cavity. We will discuss an intuitive model, which describes the dependence of the optimum operation wavelength on the cavity thickness. We will also show that the nanoantenna size is a critical parameter, small variations of which lead to both wavelength shifting and reduced absorption in the cavity. This behavior suggests that impedance matching is key for achieving efficient absorption in the hybrid cavities.

10353-19, Session 5

Light polarization sensitive photodetectors with non-polar and semi-polar homoepitaxial ZnO/ZnMgO MQWs *(Invited Paper)*

Gema Tabares, Univ. Autónoma de Madrid (Spain); Adrian Hierro, Alejandro Kurtz, Elias Muñoz, Univ. Politécnica de Madrid (Spain); Borge Vinter, Jean-Michel Chauveau, Ctr. de Recherche sur l'Hétéro-Epitaxie et ses Applications (France)

In this work, light polarization-sensitive UV photodetectors (PSPDs) using non-polar and semipolar ZnMgO/ZnO multiple quantum wells grown both on sapphire and ZnO substrates have been demonstrated. For the PSPDs grown on sapphire with anisotropic biaxial in-plain strain, the responsivity absorption edge shifts by ?dE ~ 21 meV between light polarized perpendicular and parallel to the c-axis, and the maximum responsivity contrast is (RE\C/ RE c)max~ 6. For the PSPDs grown on ZnO, with strain-free quantum wells, ?dE ~ 30-40, and 21 meV for non-polar and semipolar heterostructures, and maximum (RE\C/ RE c)max ~ 10, for non-polar heterostructure was achieved. These light polarization sensitivities have been explained in terms of excitonic transitions between the conduction and the three valence bands.

10353-20, Session 5

High-sensitivity refractometric sensor in a cylindrical resonator

William Morrish, Peter West, Nathan West, Univ. of Alberta (Canada); Elizaveta Klantsataya, The Univ. of Adelaide (Australia); Kirsty Gardner, Stephen Lane, Raymond G. DeCorby, Univ. of Alberta (Canada); Alexandre François, Univ. of Adelaide (Australia); Al Meldrum, Univ. of Alberta (Canada)

Microcapillaries are well-known to support whispering gallery resonances that can be employed for refractometric sensing. Here we instead report on an optical sensor for liquids and gases based on cross-channel Fabry-Pérot resonances. The device is comprised of a capillary with a thin film coated on the channel walls. The films tested included a reflective metal (i.e., silver) or a high-index polymer (i.e., poly-pentabromophenyl acrylate) deposited on the channel. The optical boundaries perpendicular to the capillary axis resulted in multiple resonances that resemble Fabry-Pérot interferences between a set of nested cylindrical mirrors. The reflective films strongly enhanced the cross-channel modes in comparison to the case of a bare capillary. Due to the improved visibility of these channel modes, it is in principle possible to track changes in the refractive index of an analyte flowing through the capillary by monitoring the resonance wavelengths. Here we tested the sensitivity of the device to both liquid and gaseous analytes. For gases such as Ar and N2, we found a 3?? detection limit of (6.3 ± 1.1) x 10-6 as the minimum detectable change in the index of refraction. When used as a gas pressure sensor, the device was found to have a limit of detection of 3.3 ± 0.1 kPa based on the pressure dependence of the refractive index. For liquids with a refractive index close to that of water, the detection limit was (1.000 ± 0.002) x 10-5. These results were interpreted in terms of a simple model for a cylindrical Fabry-Pérot cavity.

10353-21, Session 6

Time-resolved cathodoluminescence for wide bandgap nanostructures *(Invited Paper)*

Gwénolé Jacopin, Mehran Shahmohammadi, Wei Liu, Jean-François Carlin, Nicolas Grandjean, Benoit Deveaud, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

As demonstrated by our laboratory [1], the use of the picosecond time resolved cathodoluminescence (p-TR-CL) is suitable to locally study the dynamics of excitons. Indeed, by combining the spatial resolution of a scanning electron microscope and the temporal resolution of a streak camera, it becomes possible to investigate processes, which happen at such scales. In particular, I will present recent studies of wide bandgap nanostructures such as bent ZnO microwires [2–4] or InGaN nanowires [5] realized by using the TR-CL. Finally, I will present the exciton dynamics on single dislocations in GaN [6], providing critical information about the nature of dislocation as non-radiative centers.

10353-22, Session 6

Biaxial strain tuning of the optical properties of single-layer transition metal dichalcogenides *(Invited Paper)*

Riccardo Frisenda, Andres Castellanos-Gomez, David Perez de Lara, IMDEA Nanociencia (Spain)

Strain engineering has been proposed as a promising route to modify the electronic and optical properties of two-dimensional (2D) materials. These materials can stand to large mechanical deformations, of the order of 10%, while conventional 3D semiconductors tend to break at moderate deformations of 0.5-1.5%. Another key feature of strain engineering of 2D materials stands in the way in which they can be strained. In fact, while 3D systems are typically stressed by epitaxial growing them onto substrates with a certain lattice parameter mismatch, strain in 2D systems can be applied by stretching or bending. Experiments on MoS2 single-layer and few-layers flakes have already demonstrated that the optical band gap can be changed of 50 meV/% for uniaxial strain and of 100 meV/% for biaxial strain. Most of these strain engineering experiments to date, however, study uniaxial tensile strain under static conditions and, apart from few exceptions, are limited to MoS2. In this talk I will present results on biaxial straining, both tensile and compressive, of single-layer transition metal dichalcogenides (TMDC). We studied the effect of strain on mechanically exfoliated flakes of monolayer MoS2 deposited on different polymeric substrates. We apply the strain exploiting the large mismatch between the thermal expansion coefficients of the polymeric substrates and the fabricated TMDCs flake deposited on top. We studied the substrate dependency of the strain transfer efficiency and we find that for substrates with Young's modulus larger than 1 GPa, biaxial strain can be applied reproducibly without slippage. We investigate the effects of strain on the optical properties of single-layers MoS2, MoSe2, WS2 and WSe2 and we observe a redshift of the optical band gap of these 2D TMDCs for increasing tensile strain. The observed bandgap shifts as a function of substrate extension/compression follow the order MoSe2 < MoS2 < WSe2 < WS2, i.e. with WS2 providing the largest bandgap tunability and MoSe2 the lowest. This method can be readily applied to other 2D materials and be used to vary the strain in real time.

10353-23, Session 6

Multi-purpose highly sensitive room temperature nano based detector *(Invited Paper)*

Yossi Paltiel, The Hebrew Univ. of Jerusalem (Israel)

The ability to integrate electronics with Nanocrystals (NCs) allows utilizing their unique properties for a future optoelectronic device. Combing top down approach using self-assembled hybrid organic-NCs systems, with bottom up components can revolutionize devices in future. In my talk I will present an ultra-high light sensing device based on InAs NCs acting as an optical gate to high electron mobility transistor (HEMT) device. Using a very narrow channel the device quantum efficiency is high as 106V/W, while the single to noise ratio (SNR) enables high sensitivity photon detection. In addition a side gate detector will be present showing enhancement in the sensitivity for light and gas detection. The same concept can be used to develop tunable, simple and flexible detector for the IR range printing semiconducting/conducting carbon nanotubes layer mixed with doped semiconductor nanocrystals.

10353-24, Session 6

Ratiometric 2D temperature mapping around plasmonic nanoparticles with one CCD using directional anisotropy in fluorescence

Chen Chen, Zhidong Du, Liang Pan, Purdue Univ. (United States)

Optically measuring two-dimensional (2D) temperature fields around plasmonic structures is of great importance for their thermal management considering the strong energy dissipations along with the extraordinary abilities of light coupling. Among all the available methods, ratiometric studies are particularly desirable since they suppress the influence of trivial factors, such as temporal fluctuations in excitation and spatial non-uniform distributions of fluorescent species, and thus gives reliable temperature dependence. Typical ratiometric mapping methods measure fluorescence signals on the emission side. They require additional modification to the detection beam path so that two images can be recorded simultaneously. Here we report a new ratiometric thermometry that modifies the excitation side and only needs one detector. This thermometry measures fluorescent anisotropy based on the directionality of emission. With just one CCD, ratiometric measurements of temperature are achieved by alternating two orthogonal polarizations on the excitation side. We show that this thermometry shares the same advantages claimed for anisotropy based methods, including robustness against intensity variations, compatibility with biological tissues, suitability for two-dimensional imaging and readout rate comparable to the detector's framerate. Besides, it can be easily integrated into commercial microscope systems since only rotation of excitation polarization is needed. We foresee it to trigger interests of a large community who desire simultaneous thermal characterization along with the optical imaging. Moreover, it brings out a general idea to simplify ratiometric setups if inequalities exist on the excitation side, which may reach for a larger number of researchers.

10353-25, Session 6

Microring resonators for real-time study of antibody interaction

Tatevik Chalyan, Univ. degli Studi di Trento (Italy); Geert A. J. Besselink, Eric Schreuder, Lennart Wevers, Floris H. Falke, René G. Heideman, LioniX BV (Netherlands); Lorenzo Pavesi, Univ. degli Studi di Trento (Italy)

Integrated optical (IO) biosensors based on Mach-Zehnder Interferometers or microring resonators are widely used for food and drug monitoring and protein studies thanks to their properties such as high intrinsic sensitivity, easy integration, miniaturization, low cost [1, 2]. In this study we present a system to perform faster antibody interaction analysis using a photonic chip made of an array of six microring resonators (MRRs) based on TriPleX platform. The input light is generated by a Vertical Cavity Surface Emitting Laser (VCSEL) pigtailed to a single mode fiber operating at 850nm wavelength. The output signal is detected by PIN photodetectors placed in optical signal read-out module (the so-called OSROM) and processed by an easy-to-use Fourier Transform algorithm which optimized to use most of the available data, reducing the noise. Measured bulk sensitivity (Sb =104 ± 0.04 nm/RIU) and Limit of Detection (LOD = 2 ? 10-6 RIU) are very similar for the six MRRs in the same chip [3], which is a good precondition for using proposed system for multianalyte detection.

Analyses of anti-biotin interaction with immobilized biotin by using different concentrations of anti-biotin antibody is performed. Dependence of resonance wavelength shift from antibody concentration, as well as association and dissociation rate constants were calculated. For the average dissociation constant (KD) of anti-biotin antibody toward immobilized biotin, a value of 2.3?10-7 M is achieved, that is in the same order of magnitude with published results in literature [4]. Furthermore, the specificity of the interaction was confirmed by using negative control antibodies. In addition, the functional surface of the sensors could be regenerated up to ten times by using 10 mM glycine/HCl pH 1.5.

InP-based platform for sensing using telecom building blocks

François Lelarge, Almae Technologies SAS (France)

In this contribution, we will introduce the Almae-Technologies InP platform proposing processed wafers for DFB and diffused APD wafers. This telecom based 3- and 4-in InP-based PIC platform is using Ebeam, GSMBE and MOCVD production tools for developing DFB lasers with extreme wavelength control. Al-based and Al-free MQWs epiwafers from 1,3μm up to 2μm are available, opening the way to cover most of sensing applications. The Almae-Technologies integration schemes for PIC will be illustrated and discussed.

10353-26, Session 7

Plasmonic bio-sensing based on highly doped semiconductors *(Invited Paper)*

Thierry Taliercio, María José Milla-Rodrigo, Fernando Gonzalez Posada Flores, Mario Bomers, Franziska B. Barho, Eric Tournié, Laurent Cerutti, Institut d'Électronique et des Systèmes (France)

Plasmonics is one of the best suited approaches for bio-sensing. Based on the concept of surface plasmon polaritons, electromagnetic waves strongly coupled to collective oscillation of free carriers, plasmonics offers the possibility to detect and identify the presence of biomolecules at a metal surface. Plasmonics is mainly based on gold but it was recently demonstrated that alternative materials, such as highly doped semiconductors (HDSC), can outperform the plasmonic properties of gold in the mid-infrared spectral range. In this work, we will present surface plasmon resonance (SPR) detection and surface enhanced infrared absorption (SEIRA) spectroscopy obtained on periodic arrays of nano-antennas developed on an InAsSb/GaSb platform. These nano-antennas of Si doped InAsSb alloy are able to sustain localised surface plasmon resonances (LSPR) used in SPR and SEIRA experiments exploiting the strong electric field enhancement appearing at the HDSC surface. Adjusting the carrier concentration in the HDSC by the doping level allows to control the value of the plasma frequency which is linked to the LSPR frequency. The smaller the plasma frequency, the smaller the LSPR frequency. The nano-antennas have been fabricated by optical lithography and wet etching. As expected, when changing the size and the shape of the nano-antennas it is possible to cover a large spectral range and to be sensitive to the polarization of the incident light. Additionally, monitoring the carrier concentration of the InAsSb, make possible to lead up the maximum field enhancement in the targeted spectral range of the biomolecular fingerprints.

10353-27, Session 7

Low-loss dielectric nanoantennas for surface-enhanced spectroscopies and nonlinear photonics *(Invited Paper)*

Gustavo Grinblat, Yi Li, Javier Cambiasso, Toshishiko Shibanuma, Michael P. Nielsen, Emiliano Cortés, Pablo Albella Echave, Aliaksandra Rakovich, Rupert F. Oulton, Stefan A. Maier, Imperial College London (United Kingdom)

The initial excitement about the use of plasmonic nanostructures for the development of nanophotonic devices operating in the optical regime was later partially eclipsed with the observation that losses could, in some cases, overtake actual radiative properties [1]. In this scenario, dielectric nanoantennas have recently emerged as promising alternative candidates to plasmonic systems in the visible range [2]. When excited above their bandgap energies, high-refractive-index dielectric nanostructures can highly concentrate electric and magnetic fields within subwavelength volumes, while presenting ultra-low absorption compared to metals [3]. In particular, by locally enhancing the incident light intensity, dielectric nanoantennas are expected not only to produce negligible heating, but also boost nonlinear phenomena and surface-enhanced spectroscopies, since their efficiencies increase with the excitation density.

In this presentation, Si, Ge, and GaP nanoantennas will be introduced as promising nanosystems for surface-enhanced fluorescence and Raman spectroscopies, as well as for generating efficient second and third harmonic light on the nanoscale at visible wavelengths [2,4-7]. It will be shown that their associated temperature increase at resonance can be over one order of magnitude lower than that corresponding to metals. At the same time, fluorescence enhancement factors of over 3000 and harmonic conversion efficiencies of nearly 0.01% will be demonstrated for suitably engineered dielectric nanostructures. Finally, hybrid dielectric/metallic nanoantennas will also be analyzed, and, in all cases, comparison will be made with reference plasmonic nanosystems.

10353-28, Session 7

Surface plasmon enhanced FRET

Jennifer M. Steele, Chae Ramnarace, William Farner, Trinity Univ. (United States)

We demonstrate enhanced fluorescence from Förster Resonance Energy Transfer (FRET) paired fluorescent molecules on a single metal enhanced fluorescence (MEF) substrate. MEF substrates support two mechanisms of enhancement via surface plasmons (SPs). In the first mechanism, if the absorption spectrum of the fluorophore overlaps a SP wavelengths, the excitation of the fluorophore is increased from the enhanced electromagnetic field from the SP. Second, when in the excited state, the fluorophore can relax back to the ground state by exciting a SP instead of emitting a photon. This increases the number of decay channels available to the fluorophore, decreasing the lifetime of the excited state, and therefore increasing the quantum yield. Previous work has shown that the second mechanism dominates the enhancement.

For grating structures, the periodicity allows for a broad range of SP wavelengths following a dispersion relationship. This is in contrast to nanoparticles, which have a narrow range of SP wavelengths available. Here, gold wire nanogratings with a period of 500 nm were fabricated as the MEF substrate, ensuring SP modes throughout the visible spectrum. We used Atto 532 and Atto 633 as the donor and acceptor FRET molecules respectively. A thin layer of PVA containing different concentrations of the donor and acceptor FRET molecules was spin coated onto the gratings. The donor molecules were excited with a 532nm laser, and the fluorescence emission from both the donor and acceptor molecules were recorded. We found that the enhancement was consistent over all concentration combinations of donor and acceptor molecules.

10353-29, Session 7

Hydrogel-integrated plasmonic nanostructures on optical fiber facet for remote and real-time pH sensing

Shijie LI, Wen-Di LI, The Univ. of Hong Kong (Hong Kong, China)

Plasmonic optical fiber probes have particular merits to be in vivo sensors. Besides its excellent biocompatibility, it also has small cross-section size and is capable of remote sensing. By integrating pH-responsive hydrogel on the probes, human body pH value can be monitored in real-time, which is helpful for diagnosis of diseases such as stomach disorder and Gastroesophageal reflux.

In this work, we use double-transfer ultraviolet nanoimprint lithography (UV-NIL) to transfer metallic nanostructures from a polymer mold to the facet of the optical fiber with 200 ?m core diameter. Once a polymer mold carrying nanopillar array is fabricated by thermal embossing, a thin layer of gold is deposited on it by thermal evaporation. Then the metallic nanostructure is transferred onto fiber facet by the cross-linked UV-cured resist. The transferred metallic nanostructures feature closely spaced double layers of disks and holes. The electric field is enhanced in between the metal disk and hole and generates resonantly enhanced local electrical field as revealed by peaks/dips in reflection spectra.

By dipping the plasmonic fiber probe into hydrogel precursor, a small amount of hydrogel is cross-linked on fiber facet with 365nm UV light exposure through the fiber. Hydrogel shrinks in acid and swells in basic solutions by containing different amount of water and thus has a different refractive index. Resonant reflection peaks/dips of plasmonic fiber probe were responsive to refractive index changes. Our hydrogel fiber probe shows obvious spectrum response to solutions with pH values ranging from 1 to 8. And when hydrogel fiber probe is under cycling test its spectrum response remains stable for three cycles when switching between acid and basic solutions. pH sensing was performed with fixed ionic strength, and hydrogel fiber probe's response to ionic strength was also investigated.

10353-30, Session 7

Nanostructured diodes for the infrared detection through two photons absorption

Baptiste Fix, Julien Jaeck, ONERA (France); Benjamin Vest, Lab. Charles Fabry (France); Jean-Luc Pelouard, Ctr. de Nanosciences et de Nanotechnologies (France); Riad Haïdar, ONERA (France)

Two-photon absorption (TPA) in semiconductors has drawn much interest in the past 20 years, as it allows photo-current generation by absorption of sub-band-gap photons pairs. In particular it can be an alternative scheme of infrared detection, where mid-wave IR signal photons and pump photons of smaller wavelength are simultaneously absorbed in a wide band gap semiconductor, reducing the need for cryogenic cooling.

Such applications are currently limited by the low efficiency of TPA processes in conventional photodiodes. To obtain measurable levels of photocurrent we propose to enhance the electrical field in the photodiode with functionalized electrode. In this paper we demonstrate the use of a 1D nanostructure in an InP diode to detect a signal at 3.39µm through non degenerate TPA.

The device consists in a thin Indium Phosphide P-i-N photo-diode with a thickness of 580nm and both p and n-layer thickness of 50nm. The bottom electrode is a plain gold mirror and the top electrode is a grid nanostructure defined by a period of 1780nm, strips width of 700nm, and a thickness of 100nm. It generates a resonance at 3.39µm that amplifies the intensity of the signal wave by 40 as compared to the incident intensity. Using a dedicated experimental bench, we detect a two-photon photo-current with a SNR of 13. The spectral and polarization dependence of the diode reflectivity and photo-current confirm the origin of this photo-current.

Wednesday - Thursday 9 –10 August 2017

Part of Proceedings of SPIE Vol. 10354 Nanoengineering: Fabrication, Properties, Optics, and Devices XIV

10354-500, Session Plen

3D laser nanolithography

Martin Wegener, Karlsruher Institut für Technologie (Germany)

Three-dimensional (3D) laser lithography has become a versatile, reliable, and widespread workhorse for fabricating 3D micro- and nanostructures. I will illustrate the current state-of-the-art by selected examples, including free-form micro-optics, 3D optical and other metamaterials, as well as functionalized 3D scaffolds for biological cell culture. I will speculate about near-term industrial applications and outline remaining technological challenges regarding spatial resolution, scalability, and multi-material 3D nano-printing.

10354-1, Session 1

Large-scale fabrication of LP-CVD Si3N4 photonic crystal structures as freestanding reflectors with 1 mm aperture for Fabry-Pérot interferometers

Christian Helke, Karla Hiller, Technische Univ. Chemnitz (Germany); Marco Meinig, Steffen Kurth, Fraunhofer-Institut für Elektronische Nanosysteme (Germany); Christoph Nowak, Herberth Kleinjans, AMO GmbH (Germany); Thomas Otto, Fraunhofer-Institut für Elektronische Nanosysteme (Germany)

Further development of miniaturized spectrometry systems require tunable Fabry-Pérot-interferometers (FPI). A main part of the FPI is the reflector, which is usually realized as a stack of alternating dielectric layers with high and low refractive index. To achieve high reflectivity adequate material property homogeneity for each layer is needed. For stacks with larger number of layers, the integration with MEMS processes is challenging. Particularly, stack structuring and the achievement of process compatibility to moveable MEMS structures are important.

Alternative to the alternating layer stack reflector, nanostructured photonic crystal (PC) reflectors indicate equivalent performance by using only one layer leading to a minimized reflector complexity.

This contribution presents a novel PC reflector consisting of a 400 nm thin moveable nanostructured LP-CVD Si3N4 PC realizing an aperture of 1 mm for reflectivity in the VIS range. Manufacturing of the reflectors is done on 6" wafers. The array of nanostructures is designed as 1 mm circular dies consisting of 436 nm wide holes with 545 nm pitch. The circular dies are arranged in an 8x8 matrix with 7.5 mm pitch.

The manufacturing and integration of the PC reflector into MEMS is realized by eBeam lithography and nanoimprint lithography nanostructure replication on 50 µm thin pre-etched silicon membranes combined with further dry and wet etching processes. The fabricated PC reflectors showed 424 nm wide holes and pitch of 549 nm.

The measured reflectivity is above 90 % in the spectral range from 560 to 583 nm with a maximum reflectivity of 97 %.

10354-2, Session 1

Actuated polymer based dielectric mirror for visual spectral range applications

Pedro Pablo Vergara Gonzalez, Leda Lunardi, North Carolina State Univ. (United States)

Miniature dielectric mirrors are useful components for lasers, thin film beam splitters and high quality mirrors in optics. These mirrors usually made from rigid inorganic materials can achieve a reflectance of almost one hundred percent. Being structural components, as soon as fabricated their reflectance and/or bandwidth remains constant. Here it is presented a novel fabrication process of a dielectric mirror based on free standing polymer layers. By applying an electrostatic force between the top and the bottom layers the reflectance can be changed. The large difference between the polymers refractive index and the air allows to achieve a reflectance of more than 85% using only six pairs of nanolayers. Preliminary simulations indicate an actuation speed of less than 1ms. Experimental optical characterization of fabricated structures agrees well with simulation results. Furthermore, structures can be designed to reflect a particular set of colors and/or isolated by using color filters, so a color pixel is fabricated, where the reflectance for each isolated color can be voltage controlled. Potential applications include an active component in a reflective screen display.

10354-3, Session 1

Highly sensitive tunable room temperature infrared hybrid organic-nanocrystals detector

Avner Neubauer, Shira Yochelis, Yossi Paltiel, The Hebrew Univ. of Jerusalem (Israel)

The integration of nanostructures in electronic devices utilize their unique advantages of quantum properties for future discrete measuring systems. Using self-assembled organic monolayers with nano-crystals (NCs), together with bottom up components was proven as appropriate approach for future electronic devices. In our work, we present a wavelength tunable near-infrared detector device based on NCs acting as an optical gate on top of a high-mobility shallow two-dimensional electron gas channel.(1) By using shallow and very narrow channel, the device's quantum efficiency can go as high as 10^6V/W at room temperature, with a signal-to-noise ratio (SNR) that enables sensitivity for very low photon power.(2) Further improvement of light detection is achieved by applying horizontal electrical field resulting narrower the conductive channel. This approach, enhance the detector response and the SNR at different operation conditions. In addition, a new concept of AC electrical field modulation will be presented and compared to DC measurements by analyzing response, SNR and noise behavior. We find that our experimental results are compatible with simulation. Lastly, expanding to a non-binary logical device is achievable due to the detector wavelength tunability.

10354-4, Session 1

Pixel-sized guided-mode resonance filters for multispectral infrared focal plane arrays

Antoine Bierret, ONERA (France) and Ctr. de Nanosciences et de Nanotechnologies (France); Grégory Vincent, ONERA (France); Fabrice Pardo, Lab. de

Photonique et de Nanostructures (France); Jean-Luc Pelouard, Ctr. de Nanosciences et de Nanotechnologies (France); Riad Haïdar, ONERA (France)

Multispectral imaging of an infrared scene allows better identification of objects and materials. Numerous strategies can be implemented, involving for example Fourier transform or multichannels optical architectures. Another strategy, which simplifies the conception of snapshot imagers, is the "colorization" of infrared pixels thanks to the integration of filters in the vicinity of the detectors. The most common filters at pixel-level in the infrared are interferential filters, such as multilayer Bragg filters and Fabry-Perot filters. Fabrication process becomes complicated when numerous spectral bands are required, because filters are made of numerous thick dielectric layers. Furthermore, edge-effects restrict the minimal accessible size and lead to photon loss.

In our contribution, we present the use of nanostructured spectral filters at pixel level for MWIR focal plane arrays, with 15µm x15µm sized pixel. In the case of an imaging optical system, we must investigate the response of the filters to various incidence angles at pixel level. We thus lead numerical simulations on nanostructured filters under focused beams. We report the optical and spectral properties of these filters, highlighting the crucial issue of the angular acceptance, and describe the fabrication process. Finally, we examine the features of a mosaic of such filters and address the issue of the crosstalk.

10354-5, Session 1

Slotted photonic crystal nanobeams for enhanced light-matter interaction and optical forces

Francis Afzal, Sharon M. Weiss, Vanderbilt Univ. (United States)

Enhancement of light-matter interaction is key for achieving higher efficiency and lower threshold power in optical signal processing, photovoltaics, optical sensing and optical trapping. An important metric for light-matter interaction is the ratio of the quality factor (Q) to the mode volume (V). Resonant photonic structures typically have Q/V metrics of order 10^5 - 10^6. By utilizing deterministic design to taper the cavity defect in a continuously slotted photonic crystal nanobeam, our calculations suggest that metrics of Q > 10^6 and V ~ 0.02 (?/n)^3 can be readily achieved in a one-dimensional photonic crystal structure. Furthermore, the enhanced light-matter interaction in this high Q/V platform can be used to amplify optical forces and efficiently couple the optical cavity to mechanical modes of the physical device. The optomechanical coupling coefficient, g = ∂?/∂x, is numerically calculated to be > 400 GHz/nm. The designed slotted photonic crystal nanobeams are fabricated by electron beam lithography and reactive ion etching, and then undercut using buffered oxide etch. Both in-line and side-coupled configurations of the slotted photonic crystal nanobeams are measured. Comparisons in the tradeoff between the loaded Q and device footprint will be discussed: in general, side-coupling enables the measurement of a higher Q but requires more real estate on chip. Loaded quality factors of order 10^4 have been measured. Due to the high Q/V and large optomechanical coupling coefficient of the slotted nanobeams, slight fabrication deviations can dramatically affect the cavity optical and mechanical properties, as will be discussed in detail.

10354-6, Session 1

Color-selective and versatile light steering structure designed for up-scalable fabrication

Giorgio Quaranta, Guillaume Basset, Benjamin Gallinet, Ctr. Suisse d'Electronique et de Microtechnique SA (Switzerland); Olivier J. F. Martin, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

In planar optics, beam steering techniques is a widely used technique to create specific phase and amplitude profiles by micro and nano-structuring surfaces. Nevertheless, the integration of beam steering structures in a user-friendly device for visible light is still challenging, due to the intrinsic optical response and the low throughput fabrication. Here we present a new thin-film single-layer device that allows selectively color-filtering and beam steering, compatible with up-scalable fabrication processes such as roll-to-roll replication and therefore relevant for high-volume production. The structure works in any part of the visible spectrum and can steer white light from low coherent source without need of any filter or polarizer. Furthermore, it versatilely works in both reflection and transmission.

In particular, the unit cell consist of two adjacent finite-length and cross-talking resonant waveguide gratings (RWGs). Their guided wave allows a stronger color-selectivity with respect to the localized energy of a standard resonator due to the leaky propagation and accumulation in the RWGs. It is possible to steer the light in any desired direction by engineering particular pairs of impedance-matched RWGs, where the former acts as in-coupler and the latter acts as out-coupler. Finally, the structure is made by only one nano-imprint lithography replication and one thin-film layer deposition. Functional proof-of-concepts will be presented with complex patterns to provide optical security features for smartphone authentication.

Widespread applications are foreseen in a variety of fields, such as multifocal or monochromatic lenses, solar cells, biosensors, security devices and see-through optical combiners for near-eye displays.

10354-7, Session 2

Novel Light Effect Transistors (LET) based on hybrid Coupled Organic-Inorganic Nanostructures (COINs)

Kai Braun, Alexander Andre, Marcus Scheele, Alfred J. Meixner, Eberhard Karls Univ. Tübingen (Germany)

Since the last decades, various different types of Field Effect Transistors (FET) have been developed. Later developments focused on 2D Materials as active layers. One promising candidate is based on coupled organic inorganic nanostructures (COINs) [1] which are formed by quantum dots linked by numerous different molecules e.g. Phthalocyanines. Consequently the COINs show also interesting optical properties and distinct absorption maxima in the visible range, which allow the construction of so called Light Effect Transistors (LET). Such a device works similar to a FET but instead of a gate voltage, light illumination is used to modulate the current flow. To characterize the LETs we use confocal microscopy and spectroscopy with different laser wavelengths (633, 488, 532 nm) and measured the currents across the source drain junction as a function to the illumination power. On gold, the luminescence of the COIN monolayer is quenched and the electrodes appear dark, while on glass a weak signal is detected. We assume that the very low quantum efficiency of the optically excited states on glass is due to efficient charge carrier separation inside the COIN monolayer. Furthermore we measured drain current vs. drain-to-source voltage under illumination, were the devices show a clear linear regime with ohmic behavior. Since the absorption resonances have diverse strengths' for different wavelength each color could be used as single gate and allow for a multi-gate device on a single chip.

10354-8, Session 2

Capacitive-based adiabatic logic

Yann Perrin, Gaël Pillonnet, CEA-LETI (France)

The Field-Effect Transistor (FET) might not be the adequate technology for improving the energy-efficiency of logic devices. Nowadays, the lowest dissipation per operation is 6 to 10 decades higher than the theoretical limit predicted by Landauer [1]. Although this fundamental limitation is still discussed, there is room for decreasing the energy dissipation inherent to any logic operation. For this purpose, adiabatic computing based on FET has been introduced [2]. It consists of using slow transitions between logic

states. The charge and discharge of the capacitance of the FET gate through the resistance of the FET channel then become slower. Therefore, the energy dissipation decreases proportionally to the driving ramp duration. However, leakage and threshold voltage inherent to FET limit the energy saving to only one decade, compared to conventional FET circuits.

In this contribution, we introduce a new paradigm to implement logic gates. Instead of FET transistors, we use MEMS capacitors with a capacitance strongly influenced by its own polarization voltage. Each MEMS capacitor forms a building-block of a logic gate. This new type of logic is able to discriminate logic states by modulating capacitances values. In order to save energy, we use adiabatic transitions. We show how MEMS building-blocks can be cascaded and assembled, in order to form a logic capacitive unit. We describe the logic operation at the gate-level. We then focus on the energy transfer inside and between capacitors, during adiabatic charging and discharging phases. We finally suggest different MEMS devices suitable for adiabatic logic applications.

Nanoimprinting optical fibers

Peipei Jia, The Univ. of Adelaide (Australia); Depeng Kong, Xi'an Institute of Optics and Precision Mechanics, CAS (China); Heike Ebendorff-Heidepriem, The Univ. of Adelaide (Australia)

Nanoimprinting has been applied on optical fiber tips to generate various nanostructures. In these techniques, additional layers are required to act as imprinting targets. However it is difficult to coat a thin layer on the micro-size fiber facets. Moreover these host layers might exfoliate in some harsh cases. Here, we develop a nanoimprint technique to directly pattern optical fiber facets without host layers. With this one-step method, nanohole arrays and nanoslit arrays can be imprinted into the plastic optical fiber end faces. These structures have high surface quality and uniformity due to the nature of replication. After metallization, these arrays are transformed to be functional devices such as plasmonic sensors and polarizers. Besides the depth of nanostructures can be adjusted by varying the imprinting pressure. Accordingly, their optical properties can be modulated through such topographic changes with one imprinting mold.

10354-10, Session 2

Development of highly sensitive holographic devices for metal ion detection

Sabad E. Gul, Suzanne Martin, John Cassidy, Izabela Naydenova, Dublin Institute of Technology (Ireland)

There is an urgent requirement for inexpensive mass producible clinical diagnostic devices that allow measurements on site. Biosensors are important tools in biomedical research. They are becoming an essential part of modern healthcare. The development of selective alkali metal ions sensors in particular is a subject of significant interest.

The research efforts in this area aim to increase sensitivity, reduce sample size, lower operating costs and make single-use disposable devices and improve portability. In this respect, the level of blood electrolytes, particularly H+, Na+, K+ and Cl- , is widely used to monitor aberrant physiologies associated with pulmonary emphysema, acute and chronic renal failure, heart failure, diabetes. Particularly K+ ions analysis attracts great attention due to interference from high concentrations of Na+ in blood.

The sensors reported in this paper are created by holographic recording of surface relief structures in a self-processing photopolymer material. The structures are functionalized by ionophores dibenzo-18-crown-6 and tetraethyl p-tert-butylcalix [4] in plasticised polyvinyl chloride. Interrogation of these structures by light allows indirect measurements of chemical analytes' concentration in real time. We present results on the optimisation and testing of the holographic sensor. Self-processing acrylamide-based photopolymer was used to fabricate the required photonic structures. The performance of the sensors for detection of K+ and Na+ was investigated. It was observed that the functionalisation with dibenzo-18-crown-6 provides a selective response of the devices to K+ over Na+. The sensor responds to K+ within the physiological ranges.

10354-11, Session 2

Pressure measurement using "photo-piezoelectric" effect: new MEMS design

Boris Oskolkov, Saint-Petersburg State Univ. of Aerospace Instrumentation (Russian Federation)

This work - a continuation of the previous one, which had shown perspective photovoltaic effects. In this paper we will explore one of the effects, namely "photopiezoelectric effect".

The effect begins to occur when compressed a doped semiconductor (silicon, for example) illuminated by light.

As a result of the new design of the sensor from the doped silicon is created and researched. Different designs and some of them will be most effective in measuring pressure are shown.

Own laboratory setup was collected. The laboratory setup consists of a sample, adjustable pressure screws, lamps illuminating the sample and the amplifier, from which readings are taken.

Such sensors will be in demand due to its low cost in the automotive industry, instrument making, in IoT systems in the field of portable electronics and so on.

10354-13, Session 3

Scalable maskless patterning of nanostructures using high-speed scanning electrical probe arrays

Chen Chen, Zhidong Du, Liang Pan, Purdue Univ. (United States)

Nanoscale patterning is the key process to manufacture important semiconductor products such as microprocessors and data storage devices. Many studies have shown that it has the potential to revolutionize the functions of a broad range of products for a wide variety of applications in energy, healthcare, civil, defense and security. However, tools for mass production of these devices usually cost tens of million dollars each and are only affordable to the established semiconductor industry. In this paper, we report a method, nominally known as "pattern-on-the-fly", that involves scanning an array of electrical probes at high speed to form nanostructures and offers a new low-cost approach for nanoscale additive patterning. Using this method, we show that silicon lines as thin as 25 nm using diphenylsilane as precursor molecules can be directly written on a silicon substrate coated with a self-assembled monolayer of phenethyltrichlorosilane (PETS). In addition, we propose a possible reaction pathway of the electro-chemical process and build up a multiphysics model in the commercial software COMSOL to study the corresponding reaction rates. The demonstrated results reveal the scalability potential of this maskless patterning method, which enables it to become a strong candidate for the next generation nano-manufacturing.

10354-14, Session 3

Self-catalyzed patterned growth of GaAs(Sb), GaAsSbN nanowires by molecular beam epitaxy

Manish Sharma, Joint School of Nanoscience and Nanoengineering (United States); Pavan K. Kasanaboina, North Carolina A&T State Univ. (United States); Md Rezaul Karim, Joint School of Nanoscience and Nanoengineering (United States); Shanthi Iyer, North Carolina A&T State Univ. (United States)

Nanowire (NW)-based optical devices have been enticing great interest due to its ability to enhance entrapment of light inside nanowire array and better strain accommodation due to its small footprint on the substrate. To achieve large scale homogeneous NW arrays with consistent device performance, it is important to have precise control in positioning, size and the alignment of the nanowires, in addition to high quality and compositional uniformity. The active sites on the silicon substrate for NWs growths are created by electron beam lithography. There have been numerous reports on patterned GaAs NWs [1, 2], with the primary focus on the growth parameters namely, Ga pre-deposition and V/III flux ratio to improve pattern coverage. In this work, the emphasis is on the effect of processing conditions along with growth parameters and their inter-dependency on the yield of self-assisted growth of vertical nanowires GaAs, using molecular beam epitaxy on patterned Si (111) substrate for different pitch size. The optimized processing condition for GaAs NW growths was then extended to the growth of patterned GaAsSb axial and GaAs/GaAsSb core-shell NWs. Further fine tuning of these parameters led to >90 % occupancy of patterned holes with nanowires. The observed pitch dependent optical absorption for NW array was correlated using, finite difference time domain (FDTD) simulation with wavelengths in the range of 400-1200 nm using Lumerical FDTD Solution software. The introduction of the dilute amount of N in the GaAsSb NWs on the patterning of the NW will also be presented.

Acknowledgment: This work is partially supported by the Army Research Office (Grant No. W911NF-15-1-0160), National Science Foundation (Grant No. 1649517) and the Office of Naval Research (Grant No. N00014?16?1?2720).

Innovative patterning method for modifying few-layer MoS2 device geometries

Fernando Jiménez Urbanos, Andrés Black, IMDEA Nanoscience (Spain); Ramón Bernardo Gavito, Lancaster Univ. (United Kingdom); Manuel R. Osorio, Santiago Casado, Daniel Granados, IMDEA Nanoscience (Spain)

Mono-Layer and few-layer Tansition Metal Dichalcogenides (TMDCs) have attracted great interest since the discovery of graphene due to their oustanding properties. Semiconducting 2D Molybdenum Disulfide (MoS2) is considered a good candidate for opto-electronic applications due to its remarkable electrical and optical properties. However when mechanically exfoliated, these properties strongly depend on the geometry and number of layers present in the flake. In general, these properties cannot be modified once a device is fabricated out of an exfoliated flake. In this work we present a novel nano-patterning method for 2D material based devices, Pulsed eBeam Gas Assited Patterning (PEBGAP), that allows us to fine tune their properties once the device fabrication steps have been completed. This post-processing technique allows us to modify the channel geometry or thickness of MoS2 FETs.

PEBGAP post-processing technique is based on using a scanning electron microscope equiped with a gas injection system, and employing XeF2 as an etching agent. The etchant gas enters the chamber through a small nozzle situated in close proximity to the desired device, adsorbing locally on the substrate. The focused electron beam is then scanned and pulsed over the device to etch away the desired geometry onto the MoS2 flake.

Field effect devices were fabricated from mechanically exfoliated few-layer MoS2 flakes via optical beam lithography followed by a metal evaporation and lift-off process to define the gate-contact structures. The devices were characterised employing μ-Raman mapping spectroscopy, transport measurements and AFM/SEM microscopy. Afterwards, PEBGAP was utilized to alter device geometries and performance.

10354-16, Session 4

Update on bio-refining and nanocellulose composite materials manufacturing *(Invited Paper)*

Michael T. Postek, Dianne L. Poster, National Institute of Standards and Technology (United States)

Nanocellulose is a high value material that has gained increasing attention because of its high strength, stiffness, unique photonic and piezoelectric properties, high stability and uniform structure. One of the factors limiting the potential of nanocellulose and the vast array of potential new products is the ability to produce production quantities of this nano-material. However, recent research has demonstrated that nanocellulose can be produced in large volumes from wood at relatively low cost via ionizing radiation processing. Ionizing radiation causes significant break down of the polysaccharide and leads to the production of potentially useful gaseous products such as H2 and CO. Ionizing radiation processing remains an open field, ripe for innovation and application. This presentation will review the strong joint collaboration between NIST and its academic partners pursuing the demonstration of applied ionizing radiation processing to plant materials for the manufacturing and characterization of novel nanomaterials.

All dielectric metasurface nano-fabrication based on TiO2 phase shifters

Jeong Yub Lee, Jae Kwan Kim, Kiyeon Yang, Byonggwon Song, Yongsung Kim, Chang Seung Lee, Samsung Advanced Institute of Technology (Korea, Republic of)

Recently, various optical elements at infrared ranges have been developed using silicon and plasmonic metasurfaces. However, optical loss of silicon dielectric or plasmonic nanostructures restricts realization of highly efficient metasurfaces in visible wavelengths (400nm-700nm).

In this study, all dielectric metasurface of low loss TiO2 in visible wavelength was devised forming subwavelength-scale nanostructures. Because crystalline anataze-TiO2 layer has a rough surface of 11nm Ra, amorphous phase of TiO2 is essential to fabricate nano-scale patterns by reducing surface roughness to 1.35nm Ra. Compared to DC reactive sputtering by Ti target materials resulting anataze-TiO2 for all the process ranges and RF sputtering of low deposition rate (5nm/min, 1kW power), DC magnetron sputtering of oxygen-reduced conductive TiOx (x=1.67) target with reactive oxygen gas has advantages of amorphous phase formation and high rate deposition (21nm/min, 1kW power), therefore makes dense amorphous TiO2 thin films. We investigated density variations of TiO2 according to oxygen gas contents for high refractive index, and stoichiometric composition control of TiO2 for loss reduction. A 380 nm-thick TiO2 thin film was obtained having low extinction coefficient (k) under 1x10-5 and transparency of 98.33% as well as high refractive index (n) of 2.55 at 485nm wavelength. Highly precise patterning was performed for TiO2 meta-atoms by mass productive ICP-RIE etching, forming nano posts, grating array patterns of 100nm-300 nm size. Phase shift properties at visible wavelength of TiO2

metasurface were matched well with designed value. Finally, we constructed dielectric metaphotonic platform for various optical devices such as band pass filters, flat lens and beam deflectors in visible ranges.

A nanostructure based on metasurfaces for optical interconnects

Shulang Lin, Huarong Gu, Tsinghua Univ. (China)

Optical-electronic Integrated Neural Co-processor takes vital part in optical neural network, which is mainly realized by optical interconnects. Because of the accuracy requirement and long-term goal of integration, optical interconnects should be effective and pint-size. In traditional solutions of optical interconnects, holography built on crystalloid or law of Fresnel diffraction exploited on zone plate was used. However, holographic method cannot meet the efficiency requirement and zone plate is too bulk to make the optical neural unit miniaturization. Thus, this paper aims to find a way to replace holographic method or zone plate with enough diffraction efficiency and smaller size. Metasurfaces are composed of subwavelength-spaced phase shifters at an interface of medium such as TiO_2. Metasurfaces allow for unprecedented control of light properties. They also have advanced optical technology of enabling versatile functionalities in a planar structure. In this paper, a nanostructure is presented for optical interconnects. The comparisons of light splitting ability and simulated crosstalk between nanostructure and zone plate are also made.

10354-19, Session 4

Nanostructures for commercial approaches

Jae Hong Park, National Nanofab Ctr. (Korea, Republic of)

One of the two main processes of engineering nanostructures is the top down method, which is a direct engineering method for Si-type materials using photolithography or e-beam lithography. The other method is the bottom-up method, using nano-imprinting. However, these methods are very dependent on the equipment used, and have a high process cost. They are also relatively inefficient methods in terms of processing time and energy. Therefore, some researchers have studied the replication of nano-scale patterns via the soft lithographic concept, which is more efficient and requires a lower processing cost. In this study, accurate nanostructures with various aspect ratios are created on several types of materials. A silicon (Si) nanomold is preserved using the method described, and target nanostructures are replicated reversibly and unlimitedly to or from various hard and soft materials. The optimum method of transferring nanostructures on polymeric materials to metallic materials using electroplating technology was also described. Optimal replication and demolding processes for nanostructures with high aspect ratios, which proved the most difficult, were suggested by controlling the surface energy between the functional materials. Relevant numerical studies and analysis were also performed. Our results showed that it was possible to realize accurate nanostructures with high depth aspect ratios of up to 1:20 on lines with widths from 50~500 nm.

In addition, we were able to expand the applicability of the nano structured mold by adopting various backing materials, including a rounded substrate. The application scope was extended further by transferring the nanostructures between different species of materials, including metallic materials as well as an identical species of material. In particular, the methodology suggested in this research provides the great possibility of creating nanostructures composed of various materials, such as soft polymer, hard polymer, and metal, as well as Si. Such nanostructures are required for a vast range of optical and display devices, photonic components, physical devices, energy devices including electrodes of secondary batteries, fuel cells, solar cells, and energy harvesters, biological devices including biochips, biomimetic or biosimilar structured devices, and mechanical devices including micro- or nano-scale sensors and actuators.

10354-20, Session 4

Handling and assembling of low-density foam structures fabricated by two-photon polymerization

Ori Stein, Schafer Corp. (United States); Ying Liu, Univ. of Nebraska-Lincoln (United States)

The handling and assembling of micro-parts are usually considered as a main limitation in the fabrication process of microsystems. To support the research of High-Energy-Density Physics (HEDP), low-density materials (LDM, foams) were designed as a component of complex targets which are comprised of a range of materials (e.g., metals, polymers, glasses, ceramics, cryo-liquids, and gases) in various shapes and morphologies (e.g., capsules, enclosures, films, foams, composites, tubes, supports, etc.). In this work, laser direct writing of 2 mm x 0.25 mm x 0.3 mm (X x Y x Z) foam structures were carried out via two-photon polymerization (TPP) with high precision and submicron resolution. Commercially available TPP system (Photonic Professional GT, Nanoscribe GmbH) and commercially available photoresists (IP series, Nanoscribe GmbH) that are optimized for TPP were used for three-dimensional laser direct writing (LDW). The targets fabricated were then released from glass substrates by etching of a sacrifice layer followed by a subsequent lift-off process. Supercritical extraction and drying with liquid CO_2 were used in the developing and drying processes to minimize the mechanical deformation of components by post process shrinkage, stitching mismatch, bending, buckling and/or shearing. Although the foam's pore size is micron sized, capillary pressure developed within nano-sized cracks in the structure's struts during the drying process may cause the internal collapse of the structures.

Several log-pile configured foam structures were printed and assembled on specially designed holder in order to serve as a target for laser induced shock propagation experiments. The procedure developed for removing, handling, and assembling the printed foams into the final configurations laser targets will be discussed.

10354-21, Session 4

Carbon films on silicon substrates made from polydopamine films at the air/water interface

Hiroya Abe, Tomokazu Matsue, Hiroshi Yabu, Tohoku Univ. (Japan)

Polydopamine (PDA), easily formed by the oxidative polymerization of dopamine, is expected to the material sciences due to its spontaneous adhesion properties to the universal surface. PDA is known to form hollow particles, nanofilms, and fibers with sacrificial templates, such as solid substrates, micelles, and oil droplets in an emulsion, at the solid / liquid (S / L) interface or the liquid / liquid (L / L) interface. It is known that a PDA thin film spontaneously forms at the A / L interface under a non-stirred condition. The films formed twice as quickly as the film formation at the S / L interface.?In this study, we report a method of scooping up the PDA films formed at the A / W interface. And we succeeded in a preparation of a conductive thin film by calcinating of the PDA film. The thin films are expected to applied to new carbon materials.

PDA films were formed at the A / W interface under alkaline and non-stirring conditions, and scooped up on SiO_2 / Si substrate by Langumuir – Blodgett method. From atomic force microscopy, an average thickness of the PDA films was 39.1 ± 1.9 nm. Carbon films can be fabricated by calcinating the PDA films under nitrogen atmosphere at 1000 °C. A conductivity of the calcinated PDA films is 1100 ? / sq. A patterning of calcinated PDA films were fabricated by using masked the SiO_2 / Si substrate with a sacrificial layer before scooping up the films.

Design and calibration of a nano dimensional standard

Junjie Wu, Guoqing Ding, Xin Chen, Tao Han, Shanghai Jiao Tong Univ. (China); Yuan Li, Shanghai Institute of Measurement and Testing Technology (China)

A nano dimensional standard named SIMT100 is designed and fabricated. The standard consists of a tracking area, a step height area, a 1D grating area and a 2D grating area. All the structures are fabricated with a height of 100 nm in a 3 ? 3 mm silicon substrate. To calibrate the standard, a white light interference microscope is constructed and integrated to the nano measuring machine (NMM). The height of a 10 µm width step measured by the white light interference (WLI) microscope is 100.2 nm with a standard deviation of 0.41 nm. Due to low lateral resolution of the optical microscope, a metrological atomic force microscope (AFM) is used as an auxiliary tool to measure the 1D and 2D gratings. The period length of the 1D grating evaluated by using the fast Fourier transform (FFT) method is 2999.7 nm with a standard deviation of 0.36 nm. The FFT method is also expended for evaluation of the 2D grating. The calibrated value of 2D grating along the x- and y-axes are 3001.2 and 3000.7 nm with standard deviations of 0.73 and 0.64 nm, respectively. All the measurement results are traceable because the data are recorded by three stabilized laser interferometers embedded in the NMM.

10354-38, Session PWed

Influence of electron interference effects on reflection of electron waves from potential barrier in 2D semiconductor nanostructures

Victor Petrov, Institute of Radio Engineering and Electronics (Russian Federation); Andrey V. Nikitin, Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation)

The influence of the interference of electron waves in the case of their reflection from potential barrier on the spatial distribution of the density of quantum-mechanical current ej?(x,z) (e – electron charge) in 2D semiconductor nanostructure which is represented by rectangular narrow (x < 0, QW1) and wide (x > 0, QW2) quantum wells (QWs) sequentially oriented along the direction of the propagation of electron wave (x-axis) has been studied theoretically. We investigated behavior of the ej? (x, z) at falling of the electron wave on rectangular semi-infinite potential barrier in height V0 . We have considered a situation when in such a nanostructure at the left, from QW1 the electron wave of unit amplitude with energy ?x < V0 on the barrier in QW2 falls. It has been analytically demonstrated that in case of an electron wave falling along the lower quantum-dimensional subband in QW1 and Ex being less than the energy positions of all the other subbands in QW1 (i.e., the undamped propagation of the wave reflected from the barrier with real quasi-momentum is possible only along this lower subband) ejx(1) (x,z) in QW1 and ejx(2) (x,z) in QW2 are equal to zero. However, if a particle has such the energy that the refection of the wave with real quasi-momenta is possible along more than one subband, then the situation completely changes due to the interference of the reflected waves. In this case the interference leads to an existence of a complicatedly oscillating spatially inhomogeneous distribution ?jx(1)(x,z). Under the barrier ?jx(2) ≠ 0 and its amplitude exponentially dumped at ? ? ∞.

10354-39, Session PWed

Extreme-ultraviolet and electron beam lithography processing using water-developable resist material

Satoshi Takei, Toyama Prefectural Univ. (Japan)

Extreme-ultraviolet (EUV) and electron beam (EB) lithography processing using a resist material has been carried out for the manufacture of advanced application such as semiconductor, MEMS, NEMS, and photomask. This study indicates fundamental progress of developing the high-sensitive and resolution negative type of water-developable resist material using pure water instead of spin coating solvent and alkaline developer. EB and EUV lithography techniques using a new type of inedible biomass-based resist material derived from woody biomass with beta-linked disaccharide unit for environmental affair, safety, easiness of handling, and health of the working people. 80 nm dense line patterning images with exposure dose of 20 ?C/cm2 and CF4 etching selectivity of 1.8 with hardmask layer were provided by specific process conditions.

Bi-based Pb-free ceramic multilayer actuators using composite inner electrodes

Jae-Shin Lee, Univ. of Ulsan (Korea, Republic of)

Multilayer ceramic actuators (MLAs) including Nb-doped Bi1/2(Na,K)1/2TiO3 (BNKT:Nb) ceramic layers with electrically conducting AgPd-ABO3 thick films were prepared using tape-casting and screen-printing. The co-firing induced defects in the MLAs were analyzed by examining co-firing induced deflections and microcracks as a function of sintering temperature as well as the composition of the inner electrode. It was found that co-firing induced deflections were significantly relieved by employing AgPd-ABO3 composite layers as inner electrodes instead of pure AgPd via reducing thermal mismatch between the electromechanical and electrode layers. We have successfully fabricated lead-free electrostrictive multilayer actuators with normalized strain Smax/Emax of 350 pm/V. The results are believed to be very promising for lead-free precision actuator applications.

10354-41, Session PWed

Physical and micro-mechanical properties of nanocomposites: iron-copper and iron with carbon nanotubes

Mykola Kyruata, Sergey Revo, Mykola M. Melnichenko, Catherine Ivanenko, Taras Shevchenko National Univ. of Kyiv (Ukraine)

The use of high-energy mechanical-chemical activation of metal powders and mixtures of powders in planetary ball mills opens wide prospects for creation of new nanocomposite materials.

The structure of composite nanomaterials is characterized by the presence of the second phase, the particle size of a few (1-100) nanometers. The properties of the final nanocomposite material depend on the nature of the interaction between the phases and structure of interphase volume fraction which is extremely high.

The nanocomposites possess superior physical and chemical properties due to its structure and can be used in a variety of areas, including electronics manufacturing and new materials, in medicine and in ecology, in the aerospace and automotive industries.

In this work the technique of obtaining and processing of nanocomposite materials in the iron-copper and iron with multi-walled carbon nanotubes is presented. The structure and morphology of the obtained samples of the nanocomposite materials was studied by transmission electron microscopy.

Microhardness was determined by two methods a static method of Vickers and the method of continuous indentation with plotting the load-depth of indentation.

The method allows to obtain uniform distribution of components in volume of the composition, efficient pulverization of agglomerates of multi-walled carbon nanotubes and to optimize the characteristics of the nanocomposite materials.

10354-42, Session PWed

Modularized and water-cooled photo-catalyst cleaning devices for aquaponics based on ultraviolet light-emitting diodes

Henglong Yang, Louis Lung, Yu-Chien Wei, Yi-Bo Huang, Zi-Yu Chen, National Taipei Univ. of Technology (Taiwan); Yu-Yang Chou, National Taipei Univ of Technology (Taiwan)

The feasibility of applying ultraviolet light-emitting diodes (UV-LEDs) as triggering sources of photo-catalyst based on titanium dioxide (TiO2) nano-coating specifically for water-cleaning process in an aquaponics system was designed and proposed. The aquaponics system is a promising eco-environmental system in the future. It integrates aquaculture and hydroponics into a single system to establish an environmental-friendly and lower-cost method for farming fish and vegetable all together in a modern building. The uniqueness of aquaponics system is that water circulated from the fish tank can also be nutritious for vegetable. Proper water treatments are still required in this system to avoid mutual contamination. One of the critical treatments is to remove organic contaminant. Traditionally it can be done by UV tubes with proper coating. However, this approach consumes higher energy with relatively lower treatment efficiency. We proposed an electro-optical device benefited from photo-catalyst effect triggered by UV-LEDs on TiO2 nano-coating. This modularized and water-cooled device consists of two hollowed cylindrical pipes to form a coaxial structure. The LED module equipped with UV-LED arrays on outer surface and water-cooling mechanism on inner surface. The nano-coating module is on the external transparent pipe coated by TiO2. As the device submerges in circulating water, the coaxial structure allows UV radially emitted from LED arrays on internal pipe can efficiently reach the TiO2 coating on outer surface to trigger photo-catalyst effect for water treatment. The quantitative analysis will be conducted by analyzing the quantity of organic dye decomposed by photo-catalyst effect as the function of time.

A study on high sensitivity planar waveguide Bragg grating sensor on Fabry-Perot cavity

Junhan Park, Sang-Mae Lee, Bo-Sung Shin, DanHee Yun, Gyeong Ju Je, Pusan National Univ. (Korea, Republic of)

Two types of evanescent field-based refractive index sensor having a Fabry-Perot(FP) cavity between dual bragg grating were fabricated and spectra of light reflected from bragg grating were measured.

One of sensor is embedded structure polymeric sensor and the other is rib structure SOI sensor.

To fabricate polymeric waveguide, we used ZPU 13-436(n=1.436 at 1550nm, Chemoptics, Korea) as clad and ZPU 12-480(n=1.480 at 1550nm, Chemoptics, Korea) as core.

Waveguide having 8um width was fabricated by photolithography and bragg grating on core layer was fabricated by two-beam interference lithography. Also, SOI sensor was fabricated by e-beam lithography. The period of the bragg grating was designed to be 528 nm and 226nm for polymeric and SOI sensor respectively, so that the Bragg wavelength of the Bragg grating should be obtained to be around 1550 nm.

When refractive index of the surrounding medium on the bio-sensitive area is changed, Bragg wavelength is changed by change of effective index of effective optical length.

To measure sensitivity of sensors, water, isopropyl alcohol was dropped on cavity between the two Bragg gratings and bragg wavelength shift measured. And, to confirm sensor can be used to biosensing, biotin was held on cavity and attenuated streptavidin was dropped on biotin to measure bragg wavelength shift by change of refractive index from biotin-streptavidin reaction.

Octopus-frog inspired programmable hierarchical architectures for skin patches and medical applications

Da Wan Kim, Sang Yul Baik, Changhyun Pang, Sungkyunkwan Univ. (Korea, Republic of)

Nanoscale observation of attachment systems of animals has revealed various exquisite multiscale architectures for essential functions such as gecko's locomotion, beetles' wing fixation, octopuses' sucking and crawling. In particular, the hierarchical 3-dimensional hexagonal architectures in the tree frog's adhesion is known to have the capability of the enhancement of adhesion forces on the wet or rough surfaces due to the conformal contacts against rough surfaces and water-drainable micro channels. Here, we report that octopus-frog inspired patches using octopus sucker-like 3-dimensional nanostructures on unique artificial 3-dimensional hierarchical hexagonal structures can be exploited to form reversibly enhanced adhesion and peeling off energy against various highly curved and rough surfaces in dry and wet condition. To investigate the adhesion effect of micro-channels, we changed the arrangement of microstructure and spacing gaps between micro-channels. In addition, we introduced the 3-dimensional hexagonal hierarchical architectures to artificial patches to enhance to conformal contacts on the various rough surfaces such as skin and organs. Using the robust adhesion properties, we demonstrated the self-drainable and comfortable skin-attachable devices. As a result, bio-inspired hierarchical architectures can be applied in versatile devices such as, medical patches, skin-attachable electronics etc., which would shed light on future smart, directional and reversible adhesion systems.

Meniscus-controllable hierarchical architectures for wet and dry adhesion

Sang Yul Baik, Jiwon Kim, Ui Dam Jung, Changhyun Pang, Sungkyunkwan Univ. (Korea, Republic of)

Adhesion strategies that rely on mechanical interlocking or molecular attractions between surfaces and interface can suffer when coming into contact with liquids. To improve wet and dry adhesion, some approaches have been investigated, including the employment of hierarchical structures, supramolecular structures, and catechol chemistries. In this work, we present reversible wet and dry adhesion system having meniscus-controllable hierarchical architectures inspired by dome-like protuberances found in the suckers of octopi. Based on a simple model, the doom-like structures in artificial suction-cup can be controllable by changing various parameters such as the applied pressure, curing-time, and surface properties of a patterned mould during the processes. As a result, our bio-inspired programmable architectures can be applied in versatile devices such as medical patches, skin-attachable electronics, micro-robots, which would shed light on future smart, directional and reversible adhesion systems in various wet and dry rough surfaces.

High resolution patterning of ultraviolet cross-linked resins using gas permeable mold derived from cellulose in nanoimprint lithography

Shinya Nakajima, Satoshi Takei, Makoto Hanabata, Toyama Prefectural Univ. (Japan); Naoto Sugino, Takao Kameda, Sanko Gosei Ltd. (Japan); Yoko Matsumoto, Atsushi Sekiguchi, Litho Tech Japan Co., Ltd. (Japan)

A cellulose-based gas permeable mold having thermal crosslinking group for nanoimprint lithography has been developed to prevent transcriptional defects by volatile solvents from nanoimprinting materials. 3 wt.% of thermal initiator was required for producing the cellulose-based gas permeable mold. The void on 10 μm line structure of imprinted UV cross-linked resin with acetone as volatile solvents in nanoimprint lithography process using non-gas permeable mold was significantly removed using the cellulose-based gas permeable mold due to its high oxygen gas permeability. The cellulose-based gas permeable mold allows the employment of solvent including imprinting materials such as compounds and alloy particle.

High resolution optical system for the magnetic characterization of thin films by longitudinal magneto-optic Kerr effect

Iulian Ionita, Mircea Bulinski, Univ. of Bucharest (Romania); Victor Kuncser, National Institute for Materials Physics (Romania)

We report about development of a high resolution scanning magnetometer based on longitudinal magneto-optic Kerr effect (MOKE). Due to the high sensitivity to the skin region magnetization MOKE is already well established technique to study magnetization properties of nano-layers. Longitudinal MOKE was found to be the most sensitive in order to measure a small rotation angle of polarization as happens in nano-layers. Due to the miniaturization race of devices the magnetic domains become smaller and smaller (micron range) and their characterization is a real challenge for optical system of the magnetometer that is near the diffraction limit.

We describe the performances required to the optical system and solutions we have found to overpass the contradictions. It is about lateral resolution, numerical aperture, working distance, spectral range, keeping a high degree of polarization, and the signal to noise ratio of entire measurement system (light source, optics, detector, amplifier). Another challenging feature of the system is the sample scanning capability in order to obtain a map of its magnetization.

Our main objective is to build a reliable and performant device with a submicron lateral resolution that will become a powerful tool for magnetic characterization of thin films and multilayers.

The challenge of screen printed Ag metallization on nano-scale poly-silicon passivated contacts for silicon solar cells

Lin Jiang, Heraeus Inc. (United States)

Passivated contacts can be used to reduce metal-induced recombination for higher energy conversion efficiency for silicon solar cells, and are obtained increasingly attention by PV industries in recent years. The reported thickness of passivated contact layers are mostly within tens of nanometer range, and the corresponding metallization method are realized by plating/evaporation technology majorly. This high cost of metallization can't compete with screen printing technology, and may affect its market potential compared to present dominant solar cell technology. Very few work has been reported on screen printing metallization on passivated contact solar cells. Hence, there is a rising demand to realize screen printing metallization technology on this topic. In this work, we investigate modifications of screen printing metallization paste on various thickness of poly-silicon passivated contacts. The critical challenge for us is to build low contact resistance competitive to standard technology and meanwhile restrict the paste penetration within the thin nano-scale passivated contact layers. The contact resistivity of 1.1mohm-cm2 and open circuit voltages > 660mV are achieved, and the most appropriate thickness range is found around 50-100nm.

Temperature dependency of mechanical properties for crystalline cellulose added to silicone elastomer

Takao Kameda, Naoto Sugino, Sanko Gosei Ltd. (Japan); Makoto Hanabata, Satoshi Takei, Toyama Prefectural Univ. (Japan)

In recent years, development has been actively conducted targeting electronic devices such as solar cells, antennas, and conductive films using cellulose nanofibers. In the parts for the car, the development of the electronic device is prosperous.??In case of the car, as a change of the atmosphere temperature is large, it is demanded that the stable properties of material with a widespread temperature change.

In this study, crystalline cellulose (hydroxypropyl cellulose; HPC) is mixed with silicone elastomer . We have obtained elastic material. In order to obtain high modulus of the composite material, the nanofibers is added in matrix material. The shear elasticity modulus of a provided sample was 2 (MPa) at room temperature. The shear elasticity modulus did not change from a room temperature to 140 (deg. C). The elasticity modulus of the sample fell to half when we increased to 200 (deg. C).

10354-51, Session PWed

Temperature dependence of viscoelasticity of crystalline cellulose with different molecular weights added to silicone elastomer

Naoto Sugino, Takao Kameda, Sanko Gosei Ltd. (Japan); Satoshi Takei, Makoto Hanabata, Toyama Prefectural Univ. (Japan)

There are many reports that cellulose is mixed with resin and used as a composite material.

It is expected that these composite materials will be used as parts for automobiles (exterior / interior parts to engine peripheral parts) as a substitute for metals.

Therefore, in this study, crystalline cellulose (hydroxypropyl cellulose; HPC) with different viscosity is mixed with silicone elastomer with good flowability, the temperature dependence of the elastic modulus was investigated.

As a result, the storage modulus of the crystalline cellulose having a high viscosity was lower than the storage modulus of the crystalline cellulose having a low viscosity.

Formation of thin metal silicide (Ni, Ti) film by nano-second Nd:YAG laser annealing with Gaussian and flat-top beam profiles

Sang Min Jung, Chul Jin Park, Jin Hwan Kim, Moo Whan Shin, Yonsei Univ. (Korea, Republic of)

The thin metal silicide has been widely investigated for contact materials in microelectronic devices. The formation of metal silicide thin film determines mainly the contact resistance between metal layer and p-type silicon substrate. As the device scaling becomes more important, the metal silicide must become thinner to achieve the more shallow contact junction depth for avoiding high contact leakage.

The laser thermal annealing (LTA) is considered as an effective method to form thin metal silicide and reduce annealing time. In this study, we have formed thin metal silicide (< 10nm) at p-type (100) silicon wafer using LTA process and investigated phase of various metal silicide by various analysis. The temperature distribution of laser annealed sample is calculated by COMSOL. The LTA system consisted of ND:YAG laser (532 nm, 355 nm) with 6 ns pulse width. The samples were annealed by laser energy density was 100 – 1000 mJ/cm2 at N2 ambient chamber. The sheet resistance was measured by a four point probe method. The specific contact resistance was measured the circular transmission line method (CTLM). The inner radius is 50? and gap spacing ranging from 2 to 48?. To analyze formation of metal silicide, X-ray photoelectron spectroscopy (XPS) and Raman spectroscopy were performed. Metal diffusion profiles were analyzed by secondary ion mass spectrometry (SIMS). In this work, thin metal silicide was formed by laser annealing with two different beam shapes. We achieved small metal diffusion into the silicon with thin metal silicide thickness.

One-dimensional metallodielectric photonic crystal (tantalum and aluminum oxide) as selective thermal emitter for thermophotovoltaic systems

Jin Hwan Kim, Sang Min Jung, Chul Jin Park, Moo Whan Shin, Yonsei Univ. (Korea, Republic of)

Because of its simplicity, one-dimensional metallodielectric photonic crystal (1D MDPhC) is a promising nanostructure for the selective thermal emitter of thermophotovoltaic systems. Because it is high-temperature application (typically exceeding 1200 K), thermal stability of the nanostructure must be ensured. Coefficient of thermal expansion (CTE) matching among the substrate and adjacent materials is essential, and thus we select Ta, Al2O3 sputtered layer and Al2O3 substrate that are similar in CTE and thermally stable at the high temperatures. We optimize the multilayer structure by using transfer matrix method (TMM). Further, we fabricate the optimized structure by alternately depositing the Ta and Al2O3 by using DC and RF sputter, respectively on sapphire substrates. The emissivity of the samples is calculated from measurement data of UV-Vis-NIR spectrophotometer. In order to minimize plasma damage on the films during the sputtering process, we insert a few nm-thick Al2O3 layer deposited by Atomic Layer Deposition (ALD) at each interface of the sputtered Ta and Al2O3. The fabricated structures with and without ALD layer are compared in terms of thermal stability at 1200 K, 1300 K, and 1400 K under high vacuum condition (low 10-5 torr). It is demonstrated from cross-sectional observation via transmission electron microscope (TEM) that the ALD layer minimize inter-diffusion of Ta and Al2O3 at the high temperatures as well.

Mechanical performance of SiC based MEMS capacitive microphone for ultrasonic detection in harsh environment

Azrul A. Hamzah, Siti A. Zawawi, Burhanuddin Y. Majlis, Univ. Kebangsaan Malaysia (Malaysia); Faisal Mohd-Yasin, Griffith Univ. (Australia)

In this work, we develop a SiC based MEMS capacitive microphone for detecting gas leak in extremely harsh environment such as coal mines and petroleum processing plants. The microphone detects gas leaks via ultrasonic detection. The MEMS capacitive microphone consists of two parallel plates; top plate (movable diaphragm) and bottom (fixed) plate, separated by an air gap. Vent holes were fabricated on the back plate to release trapped air and reduce damping. In order to withstand high temperature and pressure, a 1.0 μm thick SiC diaphragm was utilized as the top membrane. The SiC can withstand a temperature up to 1400°C. A 3 μm air gap is fabricated between the top membrane and the bottom plate via wafer bonding. COMSOL Multiphysics was used for design optimization. Various diaphragms with sizes of 600 μm2, 650 μm2, 700 μm2, 750 μm2 and 800 μm2 are loaded with external pressure. Performance of microphones with circular and square diaphragms are also compared. It is observed that SiC microphone with diaphragm width of 650 μm2 produces optimal surface vibrations, with first-mode resonance frequency of approximately 35 kHz. The maximum deflection value at resonance frequency is less than the air gap thickness of 3 μm, thus eliminating the possibility of shortage between plates during operation. It is also observed that circular membrane produces less stress as compared to its square counterpart. The designed SiC capacitive microphone is suitable to be used in ultrasonic gas leak detection at harsh environment.

MoS2 thin films prepared by sulfurization

Michaela Sojkova, Institute of Electrical Engineering SAS (Slovakia)

The discovery of graphene has stimulated an extensive research on other 2D materials. The 2D structure determines the electronic properties that may exhibit correlated electronic phenomena such as charge density waves and superconductivity. Especially transition metal dichalcogenides (TMDs) with the formula MX2, where M is a transition metal (Mo, W, and so on) and X is a chalcogen (S, Se or Te), have attracted much attention due to their layer structure and semiconducting properties.

Among metal dichalcogenides, molybdenum sulfide (MoS2) material has been extensively investigated for its interesting properties including enhanced optical absorption, thermoresponsive photogeneration, efficient hydrogen evolution reaction capability, valley polarization and high on/off ratio with low subthreshold swing, which can lead to ultrathin and highly efficient photovoltaics, photo-thermoelectrics, and catalysis for sustainability.

A large effort has been made to develop methods for growing high quality layers. Recently, methods of physical vapor deposition; especially pulsed laser deposition (PLD) and sulfurization have successfully been used for the fabrication of ultrathin films. Sulfurization is very simple and effective method for the preparation of a few layers films.

Here we present fabrication of MoS2 thin films using sulfurization of Mo and MoO3 films on c-plane sapphire and silicon substrates. As-prepared films were characterized by number of techniques including XRD, AFM, SEM, Raman, Auger and Rutherford backscattering spectroscopy, transport and optical measurements. From thorough analyses we can assess the advantages and disadvantages of the source films as well as the substrate on the properties and quality of the final films.

Damage-free laser annealing process via heat transfer layer

Chul Jin Park, Sang Min Jung, Jin Whan Kim, Moo Whan Shin, Yonsei Univ. (Korea, Republic of)

Laser thermal annealing (LTA) has received substantial attention as it has been regarded as the most suitable annealing method for next generation semiconductor manufacturing process. However, laser annealing process using intensive photon energies, induces thermal and optical stress on the silicon substrates. Furthermore, directly incident laser pulse on the surfaces of silicon produces a variety of melting patterns and laser-induced damages that are crucial problems on next fabrication steps. For this reason we investigated heat transfer layer which conducts generated heat to silicon surfaces deposited on the silicon substrates because of indirectly incident laser pulse avoiding optical and thermal stress. We present an experimental characterization of the laser-induced damages after LTA with and without heat transfer layer by using atomic force measurement (AFM), scanning electron microscopy (SEM) and transmission electron microscope (TEM). Also, numerical simulations are carried out by using COMSOL multiphysics based on heat transfer equations in order to predict surface and interface temperature profiles. According to optical and thermal properties of materials, several candidates as the heat transfer layer are selected and the thickness of heat transfer layers are optimized by the simulations. Concretely, heat transfer layer consisted of SiO2, Si3N4, and Al2O3 is deposited on silicon wafer and then, based on simulation results, LTA (532nm, 5ns) with flat-top beam profiles was executed. Finally, this heat transfer layers are removed with etchants. The observed results clearly show that through this in-direct laser annealing process with heat transfer layer, the surfaces of silicon can be efficiently annealed without remarkable damages, melting patterns and with LTA's merits. This approach could improve the feasibility of LTA in semiconductor manufacturing process such as ultra shallow junction (USJ) formation, laser crystallization, and low resistant metal contact formation.

Complementary methods of study for Zr1-xCexO2 compounds for applications in medical prosthesis

Alina Bruma, National Institute of Standards and Technology (United States); Adriana Savin, National Institute of Research & Development for Technical Physics (Romania); Mihai-Liviu Craus, Vitalii Turchenko, Joint Institute for Nuclear Research (Russian Federation); Pierre-Antoine Dubos, Sylvie Malo, ENSICAEN (France); Tatiana Konstantinova, Valerii Burkhovetsky, The National Academy of Sciences of Ukraine (Ukraine)

Zirconia (ZrO2)-based ceramics are preferred due to their advanced mechanical properties such as high-fracture toughness and bulk modulus, corrosion resistance, high dielectric constant, chemical inertness, low chemical conductivity and biocompatibility. The medical prosthesis components made from ZrO2 oxides present a very good biocompatibility as well as especially mechanical properties. In order to ensure implant safety of these prostheses, a wide range of examinations based on non destructive testing are imperative for these medical implants.

In this study, we aim to emphasize the improvement of Zr-based ceramics properties as a function of addition of Ce ions in the structure of the original ceramics. The substitution of the Zr with Ce in the Zr1-xCexO2 compounds, where x = 0.0–0.17, leads to a change of the phase composition, a gradual transition from the monoclinic to tetragonal structure, at room temperature. The structural investigations proposed in this paper are based on X-ray and neutron diffraction in order to establish a first indication of the variation of the phase composition and the structural parameters, as well as micro-hardness measurements and non-destructive evaluations in order to establish a correlation between the structural parameters and mechanical properties of the samples. These range of tests are imperative in order to ensure the safety and reliability of these composite materials which are widely used as hip-implants or dental implants/coatings. In combination of Resonant Ultrasound Spectroscopy, which makes use of the resonance frequencies corresponding to the normal vibrational modes of a solid in order to evaluate the elastic constants of the materials, we emphasize a unique approach on evaluating the physical properties of these ceramics, which could help in advancing the understanding of properties and applications in medical fields.

Highly transparent phthalocyanine derivative nanocrystal dispersions and their photopatterning

Yutaro Hirai, Tohoku Univ. (Japan); Toshihiko Takaki, Sawano Bunji, Yamamoto Chemicals, Inc. (Japan); Yasutaka Matsuo, Hokkaido Univ. (Japan); Hiroshi Yabu, Tohoku Univ. (Japan)

Metal phthalocyanines (PCs) and their derivatives (PCDs) have been considered for applications in color filters, photovoltaic cells and photodynamic therapy, owing to their unique optical properties, high chemical and thermal stabilities and good electron mobility. Nano-crystals (NCs) of metal PCDs have received much attention, because the optical and electronic properties of metal PCDs are considerably improved by reducing their sizes to the nanoscale. In the present study, we revealed that metal PCD NCs having various pi-conjugated substituents (tetra-2,3-pyridoporphyradine and naphthalocyanine) could be synthesized in nano-micells with UV irradiation to prevent micelle from breaking due to conventional heating process.

The resulting metal PCD NCs were found to form stable dispersions in an aqueous PEG solution and these dispersions exhibited significant visible light absorption from 500 to 800 nm as well as high transparency at

wavelengths in the non-absorption region.

These results indicate that these PCD NCs can be applied to such as the pigments for color filters.

We also demonstrated photo-patterning of PCDs. Precursors of PCDs were dispersed in polyvinylbutyral methanol solution, casted on glass and UV was irradiated through photo mask. PCD patterns were clearly evident in their precursor solutions. The patterning of PCDs may be applicable to the fabrication of photoelectric conversion layers in organic thin-film solar cells.

Designer metamaterials using graphene for integrated nano-photonic applications

Xinbo Wang, Berardi Sensale-Rodriguez, The Univ. of Utah (United States)

During recent years, graphene-based waveguide-integrated electro-optic modulators have been demonstrated to attain very good modulation depth as well as fast speed. By electrically tuning the Fermi level on a graphene sheet, it is possible to change its absorption at infrared wavelengths. Our work aims to explore the feasibility of employing the recently proposed "designer metamaterial" concept so to dramatically reduce the footprint of such devices. Designer metamaterials offer a new degree of design freedom that can enable unique and efficient integrated-photonic applications in very compact areas. The premise of this approach is that via nanofabrication, one can control the local refractive index of the device. By spatial engineering of the refractive index, it is possible to design devices with much higher performance than what is otherwise achievable. In order to show the applicability of this design approach, we applied nonlinear optimization so to design an optical modulator with very small footprint. A silicon ridge-waveguide couples light in and out of the device, which consists of a nano-pattern with graphene on top. The nano-pattern contains multiple "pixels", i.e. regions which may be comprised entirely of silicon or air. For given nano-pattern dimensions, we selected "seed" geometries from a pool of randomly generated patterns. After that, a search algorithm was ran. Because of the enhanced local fields in the optimized nano-pattern, the light-matter interaction in graphene is enhanced thus leading to a superior modulation performance and a reduced footprint.

Study of the change in electrical properties of mechanically vibrating FET device with graphene

Sungbae J. Lee, Gwangju Institute of Science and Technology (Korea, Republic of)

Graphene is a single layer of graphite, the honeycomb lattice structure of carbon allotrope. Most of the existing studies about graphene is performed with FET devices. The structure of typical FET devices is composed by graphene placed on the oxide layer substrate. Because of the interaction between the graphene and the substrate, studying the electric properties of genuine graphene itself is limited. The pure electric properties of graphene can be measured by suspending the graphene over the substrate. The suspended graphene is free to vibrate so the effect of mechanical vibration to the electric properties becomes important. In this study, the preliminary calculation is performed for the device to detect the effect of vibration before the measurement. The CVD growth graphene sheet is positioned over 50 nm thick metal electrode. The effect of quantum capacitance is negligible because it is about 100 times bigger than geometric capacitance. The typical doubly fixed beam model for natural frequency and spring constant does not match well for the 2 dimensional material so the thickness-modifying is necessary. The effect of mechanical vibration can be detected as difference between measured current and theoretic current calculated with calibrated and modified mechanical properties.

Zig-zag grating with quasi-random array for single order diffraction

Ziwei Liu, Tanchao Pu, Lina Shi, Changqing Xie, Hailiang Li, Institute of Microelectronics (China)

We present the design of a novel single order diffraction grating with quasi-random array of zigzag grating. The fundamental structure consists of a series of quasi-random spaced slits along a 150nm thick Cr grating on a glass substrate. Both numerical simulation results and the experiment prove the effectiveness of single order diffraction. The 2n, 3n and 5n (n=1, 2, 3...) order diffractions can be completely suppressed. Especially, the critical dimension is kept to 1/2 of the grating period, which is highly advantageous to the spectrum measurement from the infrared to the x-ray region. The 1st order diffraction can be achieved to 24.26% in theory. We noted that the critical dimension is kept to 1/2 of the grating period. The simpler shape structure is much easier to fabricate in applications, especially the measurement in short wavelength. As a crucial factor for applying this grating to practical applications, we discuss the angle factor in fabrication error can be allowed and study the tolerance budget for the critical parameters. In addition, we further investigate dependences of these parameters on the suppression and derive a useful relation based on the Fraunhofer diffraction theory. Based on the theory, the parameters can be properly optimized with the special relation with a_1=1/3P_x , a=1/2P_x , d=1/10P_x. Our study provide an efficiency grating realization with high line density employing today's nanofabrication technology, and be of great significance to extend a wide range of spectrum.

N-state random switching based on quantum tunnelling

Ramón Bernardo Gavito, Lancaster Univ. (United Kingdom); Fernando Jiménez Urbanos, IMDEA Nanociencia (Spain); Jonathan Roberts, Lancaster Univ. (United Kingdom); James Sexton, The Univ. of Manchester (United Kingdom); Benjamin Astbury, Hamzah Shokeir, Thomas McGrath, Yasir J. Noori, Christopher S. Woodhead, Lancaster Univ. (United Kingdom); Mohamed Missous, The Univ. of Manchester (United Kingdom); Utz Roedig, Robert J. Young, Lancaster Univ. (United Kingdom)

Random number generation is important for many computational processes, including cryptography. True random number generation (TRNG) is desirable but it is difficult to achieve in practice. Systems based on quantum physics are guaranteed to be random, as the fundamental laws governing their behaviour are fundamentally probabilistic. Random number generation based on quantum physics has been demonstrated previously, but commercial solutions are bulky, inefficient and unsuitable for integration.

In this work, we show that a compact semiconductor device, the resonant tunnelling diode (RTD), can be employed as a practical TRNG. The diodes in our demonstration contain a single quantum well, the most basic structure to exhibit quantum confinement. A pair of tunnelling transport mechanisms through the active region of the diode result in the voltage measured across it being a multivalued function of current. Thus, when driven with current pulse trains, the output voltage will be in one of two possible states, which is a randomly chosen value. The voltage measured across the RTD then depends on whether the electrons are resonantly tunnelling through the quantum well, or are subject to thermionic emission over the barriers – a naturally probabilistic outcome.

We show results from the physical characterisation of RTDs operating in a random number generating regime. A security analysis of the RTDs acting as a source of true randomness for on-chip cryptographic applications will also be presented.

Three-dimensional printing and deformation behaviour of low-density target structures by two-photon polymerization

Ying Liu, Univ. of Nebraska-Lincoln (United States); Ori Stein, Schafer Corp. (United States); Yongfeng Lu, Univ. of Nebraska-Lincoln (United States)

Two-photon polymerization (TPP) is of increasing interest due to its unique combination of truly Three-dimensional (3D) fabrication capability and ultrahigh spatial resolution. The technique enables the fabrication of customized polymeric low-density materials (“foams”) over a large volume (up to millimeter scale in lateral sizes) with sub-micrometer resolution which could find practical applications as laser target components. Foam structures of 2 mm ? 0.25 mm ? 0.3 mm (X ? Y ? Z) size, in a log-pile structure with covered with 15 µm high fully- densified layer were fabricated using a commercial TPP system (Photonic Professional GT, Nanoscribe GmbH) and commercially available photoresists (IP series, Nanoscribe GmbH) that are optimized for TPP.

Deformation control of low-density structures with large dimensions during the development and subsequent drying processes still remains to be a challenge. In this work, deformation behaviors, including side-shrinkage, arc-shape deformation, stitching mismatch, bending, buckling and/or shearing, have been identified. The mechanical strength of polymeric foam structures depends on the photoresist properties, the foam density, the structure designs as well as the developing and drying processes. Methods to control deformation by using photoresist with high mechanical strength, optimized structure design, and developing process with supercritical drying were studied. The results obtained show obviously reduced deformation in large foam structures. These findings, coupled with the superior resolution of TPP technique, makes the foam structures an excellent target component designed to study plasma physics and high-energy-density (HED) conditions important to astrophysics, planetary science, shock physics, and radiation transport.

Implement of multi-channel spectral sensor by hybrid-coating and a related algorithm

Yu-Jen Chen, Yu-Kuan Hsiao, VisEra Technologies, Inc. (Taiwan)

A four-channel spectral sensor is implemented by the optical filers based on integrated organic–inorganic layers. The multi-channel spectrum is provided by the unique M-I-M structure which is deposited on the whole photo-diodes on chip. Four photo-diodes are grouped as a four-channel spectral sensor, i.e. the spatial resolution is one fourth of the photo-diode density. Three specific photo-resists are applied on the set of four-diodes in different arrangements, so that each photo-diode catches one or more channel signal. A specific algorithm is also proposed to separate signals of the four channels. An Intuitive process of n-channel sensor consists of n photo-resists and procedures. Although this article demonstrates the process strategy and algorithm to build four-channel spectral sensor by three photo-resists, it presents a common rule to build n-channel spectral sensor by (n-1), or less, photo-resists and procedures.

Nanofiber optic force transducers for high-resolution mechanical studies

Donald J. Sirbuly, Univ of California San Diego (United States)

Ultrasensitive force transducers such as the atomic force microscope (AFM) and optical/magnetic tweezers have been instrumental in quantifying fine nanomechanical events in static and dynamic environments. However, as more detailed information is sought after deep inside of systems such as the body, it becomes apparent that new technologies are needed given the difficulty in scaling down the size of the feedback mechanisms associated with the aforementioned techniques. In this talk we describe a novel approach to intercept small forces and quantify them with a pure optical read-out. The platform leverages a nanofiber optic equipped with a compressible plasmonic cladding that modulates the guided light when forces as low as 200 femtonewtons interact with the fiber. The device operates through a non-interferometric transduction mechanism and relies on strong plasmon-dielectric coupling effects in the near-field to achieve angstrom-level distance sensitivity. The distance-sensitive optical signals are converted into force by placing a mechanically compliant polymeric coating between the plasmonic structures and fiber. The ability of the nanofiber system to probe the local nanomechanical environment is first demonstrated by detecting forces generated by bacteria motion without physically touching the organisms. With their high force resolution, the nanofibers can also listen to acoustic signature generated by nearby biomechanical sources and pick up sound waves with a sensitivity of -30 dB in solution. With the ability to tune the mechanical response and detect forces independently from multiple sites on a single fiber, these devices should become a valuable tool for cellular mechanics and stethoscopic applications.

Summary: A novel nanofiber optic force transducer is discussed that leverages near-field plasmon-dielectric interactions to detect local nanomechanical events with sub-piconewton force resolution. A pure, non-interferometric optical read-out of the mechanical environment is achieved by placing a compressible polymer cladding between the waveguide and plasmonic nanoparticles and tracking the distant-dependent scattering in the far-field. The performance of the nanofiber platform is demonstrated through various experiments including the monitoring of bacterial motion and hear-cell beating as well as detecting infrasound power in solution.

10354-69, Session PWed

High throughput fabrication of transparent anti-reflective polymer foils by roll-to-roll extrusion coating

Swathi Murthy, Inmold (Denmark); Henrik Pranov, Heliac a/s (Denmark); Peter Johansen, Danapak Felxibles A/S (Denmark); Guggi Kofod, Inmold a/s (Denmark)

We investigated fabrication and performance of broadband and omnidirectional anti-reflective (AR) polymer foils, in visible range, consisting of inverted moth eye structures formed as tapered nano-pits with sub-wavelength size originated by electron beam lithography and reactive ion-etching in Si. The AR foils were fabricated by a novel, high throughput roll-to-roll extrusion coating process that allowed subsequent structuring with the AR relief on both sides at a rate of 60 m/min, with a web width of 45 cm. The highest, average total transmittance obtained in visible range, was (98 ± 1) %, with minimal scattering and absorption losses. For comparison, the unstructured foil has an average transmittance of (92 ± 1) %. The broad-band reduction in reflection is documented by transmittance measurements, in visible range (400 nm - 800 nm). The AR foils showed good omni-directional performance, with no significant difference in transmittance between normal incidence and incidence up to at least 60?, higher angles could not be measured due to limitation of the set-up. The AR performance of the foil was also investigated for different depth (Dp) and shape of the nano-pits. The transmittance initially increased with Dp and reached a maximum at Dp ~ 120 nm. For process parameters yielding higher depths, we found that other shape factors along with the depth played a critical role for the AR properties.

10354-22, Session 5

Direct laser writing of carbon nanotubes

Kentaro Yamada, Makoto Nakazumi, Satoru Odate, Koichiro Iwahori, Nikon Corp. (Japan)

Carbon nanotubes (CNTs) have been expected for applications in many future electronic devices. To fabricate CNT structures on substrates, several techniques such as spray coating, spin coating and vacuum filtration have been proposed so far. In this work, we report a very simple and efficient method to deposit CNTs on a glass substrate by only scanning a focused light in CNT dispersion. This fabrication technique can provides a bottom up method for the deposition of CNTs in arbitrary shape on the substrate.

We placed the dispersion of single-walled carbon nanotubes (SWCNTs) on a glass substrate. From the back side of the substrate, a laser (?=975 nm; 100 mW) was focused on the interface between the substrate and the SWCNT dispersion by an oil immersion objective lens (Nikon 100X 1.25NA). Once the focal spot of the light is in focus on the substrate, it began to deposit SWCNTs around the spot (~1 um). Then, the linewidth of the deposition of SWCNTs was approximately 30um, and its electrical conductivity was 12.5 S/cm. We measured the Raman spectrums of the SWCNT dispersion and the deposited SWCNTs. Their G/D ratios were the same value, which indicated that any lattice defects were hardly occurred to SWCNTs in this process. Hence, this method can be useful application for fabrication processes of a variety of CNT devices. We have built the prototype of CNT field-effect transistors. In this presentation, we will show that a collimated light instead of the focused light can be applicable also.

10354-23, Session 5

Low contact resistance of the MWCNTs ohmic contact to p-GaN and its application for high power LED

Toshiya Yokogawa, Yamaguchi Univ (Japan); Syota Miyake, Yamaguchi Univ. (Japan)

Recently optoelectronic devices and electronic power devices using GaN-based materials have attracted much attention because they exhibit high optical and electrical power with high efficiency due to the wide band-gap. These power devices are generally used in high temperature operation by the heat dissipation. For high device reliability, it is important to design the mounting structure for heat sink to obtain efficient heat spreading. Carbon nanotube is expected to be excellent heat conductor for heat spreading because of extremely high thermal conductivity. Therefore, it is thought that carbon nanotube is very useful for electrode material with high thermal conductivity in the GaN device.

We confirmed the large workfunction of metallic multi-wall carbon nanotubes (MWCNTs). The work function of metallic MWCNTs was determined to be 4.84 eV as high as that of Au, Pd and Ni which are generally used for the p-GaN contact. We concluded that there is possibility to exhibit ohmic property to p-GaN. Finally, the specific contact resistance of the MWCNTs electrode was as low as 2.6?10-3 ?cm2. We obtained low contact resistance of the MWCNTs ohmic contact to p-GaN. And we demonstrate LEDs using the MWCNTs ohmic contact for p-GaN. Low operation voltage and high optical power was successfully obtained. Threshold voltage was as low as about 2.7 V, and high optical power more than 1 W was also realized. Stable operation and good reliability of the LED were also obtained.

10354-24, Session 5

High aspect ratio CNT structures produced by energetic ion bombardment

Gregory A. Konesky, National Nanotech, Inc. (United States)

Earlier research has sought to utilize the exceptional thermal conductivity of CNTs to produce a heat spreader by bulk cross-linking the CNTs into an interpenetrating network. An isotropic thermal conductivity of 2150 W/m-K was measured in a 5 ?m thick MWCNT film which had been subject to argon ion bombardment with an ion energy of 4 keV and a fluence on the order of 10^17 ions/cm2. While energetic ions will randomly bombard the entire CNT network, on occasion, one will strike a junction where two or more CNTs are touching, momentarily disrupting them. CNTs have the remarkable ability to self-heal, and in doing so, the disrupted junction self-heals into a new interpenetrating junction. However, practical heat spreader applications require films at least 100 times thicker than this initial demonstration. In an attempt to achieve this, substantially higher ion energies and fluence were applied. But rather than forming interpenetrating junctions deeper into the bulk of a CNT thick film, an interesting new form of high aspect ratio structure results, where groups of CNTs are now vertically aligned, even though the original CNT thick film was randomly oriented. There is also a sharp transition at the base of these structures from the new aligned form to the original randomly oriented form. We consider various aspects of ion-induced sputter dynamics coupled to the growth processes of CNTs to account for these new aligned high aspect ratio structures. The role of ion channeling within and between CNTs is also considered.

10354-25, Session 5

Time-domain finite-difference based analysis of induced crosstalk in multiwall carbon nanotube interconnects

Amit Kumar, Brajesh K. Kaushik, Vikas Nehra, Indian Institute of Technology Roorkee (India)

Graphene rolled-up cylindrical sheets i.e. carbon nanotubes (CNTs) is one of the finest and emerging research area. Carbon nanotubes can be classified as single walled known as single-walled carbon nanotubes (SWCNTs) or multi-walled known as multi-walled carbon nanotubes (MWCNTs). The diameter of an SWCNT can be in the range from 1nm to 5nm while for MWCNT the diameter can range from few nanometers to several tens of nanometers. MWCNTs have been given intensive importance as compared to SWCNTs due to their better conduction properties, and ease

of fabrication. CNTs can be conducting or semiconducting depending on their chirality. MWCNTs will have better conductance than SWCNTs due to more number of conduction channels in comparison to SWCNTs. The ITRS reports have projected that beyond 8nm technology node, conventional copper interconnect technology will not be able cop-up with the device performance requirements. Thus, researchers have started looking for alternative interconnect technologies, and CNT seems to be one of the most prominent interconnect technology to replace conventional on-chip interconnect technology.

This paper presents the investigation of induced crosstalk in coupled on-chip multiwall carbon nanotube interconnects using finite-difference analysis (FDA) method in time-domain. The exceptional properties of versatile MWCNTs profess their candidacy to replace conventional on-chip copper interconnects. Time delay and crosstalk noise have been evaluated for coupled on-chip MWCNT interconnects. With a decrease in CNT length, the obtained results for an MWCNT shows that transmission performance improves as the number of shells increases. It has been observed that the obtained results using the finite-difference time domain (FDTD) technique shows very close match with the HSPICE simulated results.

10354-26, Session 5

Optical models for atomically thin sheets

Jessica R. Piper, Exponent (United States)

Over the last decade, the proliferation of experimental and theoretical interest in atomically thin materials, such as graphene and monolayer transition metal dichalcogenides, has lead to a great interest in the optics of ultra-thin films.[1] Two formalisms are generally used in electromagnetics to account for the properties of thin layers: the permittivity/thickness model, and the conductive sheet model. For atomically thin layers, the sheet conductor model feels intuitively correct. However, for convenience many electromagnetic simulation codes represent such layers using a finite thickness (often chosen based on a simulation grid size), and an effective permittivity. We show that for non-magnetic media, the permittivity-thickness model directly reduces to the sheet conductance model for very thin layers. Likewise, we show that an atomically thin sheet conductor can be represented as a thicker layer with an effective permittivity, and quantify the realm of applicability of this approximation. Finally, we compare our results with the polarization sheet models of Felderhof and Marowsky,[2] and of Sipe.[3]

10354-27, Session 5

Surface plasmon resonance based electro optic measurement of SBN thin films

Surbhi Gupta, Ayushi Paliwal, Vinay Gupta, Monika Tomar, Univ. of Delhi (India)

Surface plasmon resonance (SPR) technique is a versatile tool for investigating the optical properties of different materials [1]. Among the known photo-refractive materials, strontium barium niobate (SBN) possesses a large value of diagonal electro-optic (EO) coefficient making it suitable for wide range of EO applications [2]. An effort has been made in the present work for the measurement of EO effect in SBN thin films using SPR technique. The $Sr_{0.6}Ba_{0.4}Nb_2O_6$ (SBN:60) thin films were positioned in Otto configuration for studying the variation in refractive index with the incident light using SPR. For application of electric field, LSCO has been grown using Pulsed Laser Deposition (PLD) technique providing epitaxial growth of SBN. The SPR resonance angle for prism/air-gap/gold/Si system was observed to be at 47.27° which increase to 52.05° for prism/air-gap/gold/SBN/LSCO/Si system. This may be due to change in dielectric media for the system which does not allow maximum light to couple with the SPR mode leading to increase in resonance angle. Further, the value of SPR reflectance was obtained by fixing the system in resonance angle and varying the applied electric field to monitor change in refractive index. Also, SPR reflectance curves were obtained by keeping the value of applied electric field to be constant.

10354-28, Session 6

Symmetry-breaking in light-trapping nanostructures on silicon for solar photovoltaics

Seok Jun Han, Swapnadip Ghosh, Omar Abudayyeh, Brittany Hoard, Ethan Culler, Jose Bonilla, Sang M. Han, Sang Eon Han, The Univ. of New Mexico (United States)

While various materials have been investigated for photovoltaics, solar cells based on crystalline silicon (c-Si) dominate the current photovoltaics market. To reduce the cost of c-Si cells, wafer manufacturing companies have produced competitively priced thin c-Si films, ranging from a few microns to tens of microns, using a kerfless process. In such thin-film c-Si cells, light absorption becomes poorer than in thick films and light trapping is crucial to increase the photovoltaic efficiency. Han et al. have demonstrated that, among various light-trapping schemes, symmetry breaking in photonic nanostructures can approach the Lambertian light-trapping limit very closely. However, fabricating symmetry-breaking nanostructures in a scalable, cost-effective, manufacturable manner remains elusive. Here, we introduce a new approach to systematically break the symmetry in photonic nanostructures on c-Si surface. Using our approach, we fabricate low-symmetry inverted nanopyramid structures. Our method makes use of low-cost, manufacturable wet etching steps on c-Si(100) wafers without relying on expensive off-cut wafers. Our experiment and computational modeling demonstrate that the symmetry breaking can increase the detailed balance efficiency from 27.0 to 27.9% for a 10-micron-thick c-Si film. Further, our computation reveals that this improvement would increase from 28.1 to 30.0% with over-etching for a 20-micron-thick c-Si film.

10354-29, Session 6

Chromatic mechanical response in 2D layered Transition Metal Dichalcogenide (TMDs) based nanocomposites

Balaji Panchapakesan, Vahid Rahneshin, Worcester Polytechnic Institute (United States)

The ability to convert photons of different wavelengths directly into mechanical motion is of significant interest in many energy conversion and reconfigurable technologies. Here, using few layer 2H-MoS2 nanosheets, layer by layer process of nanocomposite fabrication, and strain engineering, we demonstrate a reversible and chromatic mechanical response in MoS2-nanocomposites between 405?nm to 808?nm with large stress release. The chromatic mechanical response originates from the d orbitals and is related to the strength of the direct exciton resonance A and B of the few layer 2H-MoS2 affecting optical absorption and subsequent mechanical response of the nanocomposite. Applying uniaxial tensile strains to the semiconducting few-layer 2H-MoS2 crystals in the nanocomposite resulted in spatially varying energy levels inside the nanocomposite that enhanced the broadband optical absorption up to 2.3?eV and subsequent mechanical response. The unique photomechanical response in 2H-MoS2 based nanocomposites is a result of the rich d electron physics not available to

nanocomposites based on sp bonded graphene and carbon nanotubes, as well as nanocomposite based on metallic nanoparticles. The reversible strain dependent optical absorption suggest applications in broad range of energy conversion technologies that is not achievable using conventional thin film semiconductors.

10354-30, Session 6

Luminescence studies of laser MBE grown GaN on ZnO nanostructures

Sheetal Dewan, Monika Tomar, Univ. of Delhi (India); Ashok K. Kapoor, Solid State Physics Lab. (India); Ram Pal Tandon, Vinay Gupta, Univ. of Delhi (India)

Gallium Nitride (GaN) thin films and nanostructures feature highly promising material properties which have revolutionized the field of Photonics in last few decades. Growth of good quality defect free GaN films is of utmost importance for the development of high performance photonic devices, which inherently depends on the choice of substrates. GaN grown directly on sapphire (lattice mismatch-14%) usually suffers from cracks and high density of threading dislocations, which is circumvented by employing buffer layers like AlN, ZnO, etc. In the present work, GaN films have been fabricated on bare sapphire and ZnO nanostructures decorated Si substrates for luminescence studies.

ZnO nanostructures were grown using Excimer Laser (?=248 nm) assisted Pulsed Laser Deposition technique at optimized processing parameters. FESEM images of the ZnO nanostructures revealed a nano-columnar morphology with hexagonal facets. An Ultra High Vacuum-Laser MBE system equipped with RF Cell for Nitrogen dissociation was used for the growth of GaN films at 500?C.

The ?-2? mode X-Ray diffraction studies confirmed the formation of highly (002) plane oriented wurtzite GaN films on nitridated sapphire. However, the (002) peak intensity of GaN was significantly enhanced for GaN/ZnO/Si system owing to low lattice mismatch (1.8%) between GaN and ZnO. Subsequently, the near band edge emission in Photoluminescence studies of GaN film was found to be superior (high UV emission intensity and narrow FWHM) when grown on ZnO nanostructures. The hexagonal nucleation sites provided by the ZnO nanostructures strategically enhanced the emission characteristics of GaN film grown at relatively lower temperature. The obtained results are attractive for the realization of highly luminescent GaN films on Si for photonic devices.

10354-31, Session 6

Ultra low reflectivity black silicon surfaces and devices enable unique optical applications

Karl Y. Yee, Victor E. White, Kunjithapatham Balasubramanian, Daniel J. Ryan, Jet Propulsion Lab. (United States)

Optical devices with features exhibiting ultra low reflectivity on the order of 1e-7 specular reflectance and 0.1% hemispherical TIR in the visible spectrum enable unique applications in astronomical research and instruments such as coronagraphs and spectrometers. Nanofabrication technologies have been developed to produce such devices with various shapes and feature dimensions to meet these requirements. Infrared reflection is also suppressed significantly with chosen wafers and processes. Very low levels of specular and scattered light are achievable over a very broad spectral band. We present some of the approaches, challenges and achieved results in producing and characterizing such surfaces and devices currently employed in laboratory testbeds and instruments. The level of blackness achievable in relation to basic material properties such as conductivity and process variables are discussed in detail.

10354-32, Session 6

Quasi-triangle array of hexagonal aperturesboardband binary transmission gratings

Tanchao Pu, Ziwei Liu, Lina Shi, Changqing Xie, Hailiang Li, Institute of Microelectronics (China)

We propose a novel binary transmission grating based on a membrane with quasi-triangle array of hexagonal apertures based on the Fraunhofer diffraction theory. The shift of every unit's centers in the array positions follow a uniform distribution, keeping its absolute value <1/10, resulting in a sinusoidal average diffractive effect that suppresses high-frequency components. A grating on a quartz substrate for the visible light region was fabricated using laser beam direct writing technique. Through this quasi-triangle array grating, the normal incident light, with only 0th and +1st /-1st orders on the observation line, show good correlation with the theoretical predictions. The dependence of the high order diffraction property on the holes shape and size was investigated and the simpler shape and free-standing structure make it easy to fabricate. This compact method enables higher-order suppression be easily extended to other wavelength ranges of radiations, for example, microwave, infrared rays, Gamma rays, etc. We also discuss the tolerance of the parameters due to the fabrication errors in practical application. Furthermore, our design is optimized by selectingdifferent parameters of the gratings to get a more stable grating for the further application in soft X-ray. It offers a new opportunity for the grating monochromator with harmonics suppression. This idea can be scalable from X-rays to far infrared wavelengths and of great significance the grating application. Especially, our gratings can form free-standing structure which is highly desired for nanofabrication.

10354-33, Session 7

Subwavelength 2D segmented waveguide taper light coupling optimization by evolutionary algorithms

Anderson Dourado Sisnando, Vitaly F. Rodriguez-Esquerre, Univ. Federal da Bahia (Brazil); Cosme Eustaquio Rubio Mercedes, Univ. Estadual de mato Grosso do Sul (Brazil)

We propose a design for light coupling optimization between an optical fiber and a sub-micrometer waveguide using a subwavelength segmented waveguide taper with subwavelength periodicity. The power coupling and light coupling of the output waveguide are calculated, optimized and compared with other designs and values found in the literature. The optimized tapers has been successfully and efficient designed using evolutionary algorithms based on artificial immune system (AIS), the genetic algorithm (GA) and ant colony optimization (ACO). Power coupling above 75 % have been obtained with the evolutionary algorithms.

10354-35, Session 7

Narrow line-width reflection infrared filter using subwavelength metal-dielectric grating structure

Ziyi Wang, The Univ. of Alabama in Huntsville (United States); Rong-Jun Zhang, Fudan Univ. (China); Junpeng Guo, The Univ. of Alabama in Huntsville (United States)

It has been well-known that subwavelength metal slits grating structures function as extraordinary optical transmission filters due to excitation of surface plasmon-polaritons. In this work, we show that complex metal-dielectric subwavelength grating structures can also be designed to function as reflection-type optical filters with narrow spectral line-width in the infrared regime. Unlike extraordinary transmission filters, the new reflection optical filters with sharp spectral profiles can be designed within the entire infrared range by adjusting the height and period of the subwavelength grating structure. Detailed analysis has shown that the contrast of refractive indices of two dielectric materials embedded in the metal-dielectric structure is critical for giving sharp reflection spectral profiles.

10354-36, Session 7

Design of binary patterns for speckle reduction in holographic display with compressive sensing and direct-binary search algorithm

Thibault Leportier, Korea Institute of Science and Technology (Korea, Republic of) and Korea Univ. of Science and Technology (Korea, Republic of); Do Kyung Hwang, Korea Institute of Science and Technology (Korea, Republic of); Min-Chul Park, Korea Institute of Science and Technology (Korea, Republic of) and Korea Univ. of Science and Technology (Korea, Republic of)

One problem common to imaging techniques based on coherent light is speckle noise. This phenomenon is caused mostly by random interference of light scattered by rough surfaces. Speckle noise can be avoided by using holographic imaging techniques such as optical scanning holography. A more widely known method is to capture several holograms of the same object and to perform an averaging operation so that the signal to noise ratio can be improved. Several digital filters were also proposed to reduce noise in the numerical reconstruction plane of holograms, even though they usually require finding a compromise between noise reduction and edge preservation. In this study, we present the design of a digital filter based on compressive sensing algorithm. Our proposed method gives results equivalent to the average of multiple holograms, but only a single hologram is needed.

Filters for speckle reduction are applied on numerical reconstructions of hologram, and not on the hologram itself. Then, optical reconstruction cannot be performed. We propose a method based on direct-binary search (DBS) algorithm to generate binary holograms that can be reconstructed optically after application of a speckle reduction filter. Since the optimization procedure of the DBS algorithm is performed in the image plane, speckle reduction techniques can be applied on the complex hologram and used as a reference to obtain a binary patterns where the speckle noise generated during the recording of the hologram have been filtered.

10354-43, Session 7

Vanadium dioxide switchable components based on wiregrids for mid-infrared applications

Pengfei Guo, David Lombardo, Andrew M. Sarangan, Univ. of Dayton (United States)

Vanadium dioxide (VO2) is a polycrystalline material that exhibits reversible transition from a monoclinic semiconducting phase to a tetragonal metallic phase in the temperature range of 55 – 68 °C. The refractive index of VO2 (both real and imaginary parts) also undergoes a dramatic change during this phase change. Furthermore, the finite conductivity of the wiregrids in both phases allows for ohmic heating as the source of the temperature change, circumventing the need for an external heat source. This provides an attractive means for designing switchable optical components such as polarizers and beam steerers. In this work, we study the optical properties of vanadium dioxide wire grid structures in the mid-infrared region using the Rigorous coupled-wave analysis (RCWA). The polarizers' extinction and transmission performance was modeled as a function of temperature using measured data of the refractive index and sheet resistance as a function of temperature for various wire grid periods and heights. For the fabrication, the VO2 films were grown by ion-assisted deposition (IAD) using electron beam evaporation on sapphire substrates. The films were then patterned with interference lithography and etched using a fluorinated plasma to create the wiregrid structures.

Conference 10355: Nanobiosystems: Processing, Characterization, and Applications X

DNA scaffold nanostructures for efficient and directional propagation of light harvesting cascades *(Invited Paper)*

Carl W. Brown III, Anirban Samanta, Sebastián A. Diaz, Susan Buckhout-White, Scott A. Walper, Ellen R. Goldman, Igor L. Medintz, U.S. Naval Research Lab. (United States)

The development of light harvesting systems for directed, efficient control of energy transfer at the biomolecular level has generated considerable interest in the past decade. Molecular fluorophores provide a straightforward mechanism for determining nanoscale distance changes through Förster resonance energy transfer (FRET), and many systems seek to build off of this simple yet powerful principle to provide additional functionality. The use of DNA-based integrated biomolecular devices offer many unique advantages towards this end. DNA itself is an excellent engineering material – it is innately biocompatible, quickly and cheaply synthesized, and complex structures can be readily designed in silico. It also provides an excellent scaffold for the precise patterning of various biomolecules. Here, we discuss the systems that have been recently developed which have added to this toolbox, including nanostructural dye patterning, photonic wires, and the incorporation of alternative energy propagation modalities, such as semiconductor quantum dots and the bioluminescent protein luciferase. In particular, we explore the incorporation of luciferase into various nanostructural conformations, providing the capability to efficiently control energy flow directionality. We discuss the nature of this system, including unexpected spectral complexities, in the context of the field.

10355-3, Session 1

Enhanced NLO response of lanthanides in DNA matrix *(Invited Paper)*

François Kajzar, Cosmina Andreea Lazar, Ana-Maria Manea, Ileana Rau, Univ. Politehnica of Bucharest (Romania)

Novel deoxyribonucleic acid (DNA) based materials, functionalized with hexadecyltrimethylammonium chloride (CTMA) and two lanthanide compounds: europium – (1.10 – phenanthroline) triazotate complex [Eu(NO3)3phen] and, separately, with terbium – bis – (2.2' – bipyridine) triazotate complex [Tb(NO3)3(bpy)2], were synthesized and characterized for their linear and nonlinear optical properties. The obtained complexes were processed into good optical quality thin films by spin coating method. The measured absorption spectra and fluorescence bands of studied solutions indicated the incorporation of Eu(NO3)3phen into DNA-CTMA backbones. The third-order nonlinear optical (NLO) properties of thin films were determined by the optical third-harmonic generation technique at 1 064.2 nm fundamental wavelength. For both compounds a large third-order NLO susceptibilities are observed. These enhanced NLO response of the studied compounds are due to highly polarisable 4f electrons of lanthanides showing their interest for application in third-order nonlinear optics.

10355-4, Session 2

Thin film DNA-complex-based dye lasers fabricated by immersion process *(Invited Paper)*

Yutaka Kawabe, Yuki Suzuki, Chitose Institute of Science and Technology (Japan)

Strong fluorescence enhancement of dyes was induced by their coupling to DNA or DNA-surfactant complex in hemicyanine and other dye systems, prompting the development of efficient thin film laser devices. Because fluorescence characteristics of the dyes were very sensitive to the interaction mode, laser performance can be optimized by the modification of preparation method. In this study, dye-DNA-surfactant complex films were fabricated with multiple methods and their lasing and ASE (amplified spontaneous emission) performance were investigated.

High quality dye-doped films were obtained with 'immersion method' where DNA-surfactant complex films were stained by immersing them into an acetone solution including hemicyanine dye. Because of strong electrostatic coupling established previously in the films, the interaction between DNA and the dye was supposedly not very direct as inferred from absorption spectroscopy results. Thus, it indicated the importance of the interaction between the dye and surfactant.

Laser oscillation was demonstrated with optical pumping by two nanosecond green laser beams interfering on the sample surface forming population grating. ASE was also obtained by the pumping with one of the two beams. Lasing was observed in three types of hemicyanines, and the typical laser threshold value obtained for pHemi1 (4-[4-(dimethylamino) stylyl]-1- methylpyridinium iodide) films was 0.35 mJ/cm2. The oscillation continued several minutes, although ASE has did for an hour. Lasing from other hemicyanines and wavelength tuning were also demonstrated.

10355-6, Session 2

Vegetable extracts embedded in biological matrices for applications in photonics

Ana-Maria Manea, Sorin Axinte, François Kajzar, Ileana Rau, Aurelia Meghea, Univ. Politehnica of Bucharest (Romania)

Limited mineral materials resources associated with their pollution problems push at present the interest of scientists onto biological materials which originate from renewable resources and are biodegradable. Among them the biopolymers like deoxyribonucleic acid (DNA) and collagen show very interesting properties as possible matrices for active molecules, being able to replace synthetic polymers [1] and bring more. These biopolymers are extracted from the waste of food processing industry and their sources are practically unlimited. However, their degradation time, if unprotected, is much faster than that of synthetic polymers in similar conditions.

On the other hand, the scientists turn their attention to natural photosensitive materials, which can be extracted from flowers or fruits, like

anthocyanines [2] showing some photosensitive properties for biophotonic applications. In this presentation we will describe and discuss the results of our study on bio-active molecules present in sea buckthorn, cranberries and blueberries extracts. It is well known that they exhibit a significant antioxidant activity.

In this context, the deoxyribonucleic acid (DNA) was functionalized with vegetable extracts in aqueous solution. The obtained material is soluble in water and form good optical quality thin films by spin coating and solution casting. The optical properties were characterized by UV –VIS spectroscopy.

The nonlinear optical (NLO) properties of functionalized thin films and membranes were studied by the optical third harmonic generation (THG) technique at 1064.2 nm fundamental wavelength. The results of spectroscopic studies and THG measurements indicate that the studied complexes are promising material for biophotonics.

Nanocrystal pinning for green perovskite distributed feedback lasers *(Invited Paper)*

Jonathon R. Harwell, Guy L. Whitworth, Graham A. Turnbull, Ifor D. W. Samuel, Univ. of St. Andrews (United Kingdom)

There is great interest in organic and hybrid lasers because of the scope they offer for simple tuning of the materials properties, and their potential for simple fabrication. For example both conjugated polymers and perovskites can be deposited on nanoscale gratings to make distributed feedback lasers. By using methyl ammonium lead bromide, the emission of perovskites can be tuned into the green, making such lasers a candidate to fill the "green gap." We find that by using nanocrystal pinning perovskite lasers emitting at 550 nm with a threshold of 6 kW/cm2 can be made and can operate in both transverse electric and transverse magnetic modes.

10355-8, Session 3

Fluorescent noncovalent functionalization of graphene by surface-confined supramolecular self-assembly: towards nano-optics on graphene *(Invited Paper)*

Sylvain Le Liepvre, Commissariat à l'Énergie Atomique (France); Ping Du, Fabrice Mathevet, David Kreher, Univ. Pierre et Marie Curie (France); Fabrice Charra, Commissariat à l'Énergie Atomique (France); André-Jean Attias, Univ. Pierre et Marie Curie (France)

The realization of light-emitting devices based on emitters-graphene assemblies remains challenging, since graphene is known as a strong quencher of electronic excited states through excitation transfer between the adsorbed emitters and the graphene. Hence, a strategy is needed to avoid this transfer through introduction of an accurately controlled emitter–to-graphene electron barrier, for which planar flat-lying molecules are inefficient.

Here, the quenching of the fluorescence of the adsorbed dye by the adjacent graphene is hindered at the molecular scale based on a spacer approach, through a specifically designed dual-functionalized self-assembling building block. This 3D tecton presents two faces, one forming a noncovalent graphene-binding pedestal and the other carrying a dye group linked by a spacer to the pedestal. The spontaneous ordering of the adsorbed layer is investigated by scanning tunneling microscopy, whereas the resulting optical properties of the whole graphene–dye hybrid system are characterized by absorption and fluorescence spectroscopies.

10355-9, Session 3

Next polymer nanofibers: merging light emission and piezoelectric properties *(Invited Paper)*

Luana Persano, Andrea Camposeo, Istituto Nanoscienze (Italy); Dario Pisignano, Univ. del Salento (Italy)

Polymer nanofibers are one-dimensional nanostructures exhibiting smart physicochemical properties which enable their use as building blocks of more complex architectures with applications ranging from photonics and biotechnology to optoelectronics and energy harvesting. Such systems are characterized by high surface to volume ratio, large area coverage, and availability of low-cost production technologies. In particular, the electrospinning method, which is based on the uniaxial elongation of a polymer jet with sufficient molecular entanglements in the presence of an intense electric field, is a versatile and high-throughput technique which empowers materials capability by tailoring shape, size and functional properties of the resulting fibers. In this paper we review our recent results on electrospun nanofibers for photonics and energy harvesting applications. Material optimization aspects, processing parameters, and light-emission performances as well as piezoelectric behavior are studied and optimized in view of realizing a new generation of multi-functional nanofiber materials and components. Applications of the new species of nanofibers for achieving new sensing schemes are presented and discussions. The research leading to these results has received funding from the European Research Council under the European Union's 7th Framework Programme (FP/2007-2013)/ERC Grant Agreement n. 306357 (ERC Starting Grant NANO-JETS).

10355-10, Session 4

Colloidal photonic crystals: from lasing to microfluidics *(Invited Paper)*

Koen Clays, KU Leuven (Belgium) and Washington State Univ. (United States); Kuo Zhong, KU Leuven (Belgium); Kai Song, Chinese Academy of Sciences (China)

Colloidal photonic crystals are photonic crystals made by bottom-up physical chemistry ciomimetic strategies from monodisperse colloidal particles. The self-assembly process is automatically leading to inherently three-dimensional structures with their optical properties determined by the periodicity, induced by this ordering process, in the dielectric properties of the colloidal material. The best-known optical effect is the photonic band gap, the range of energies, or wavelengths, that is forbidden for photons to exist in the structure and is eminent from irridescence or opalescence in nature. The photonic band gap is similar to the electronic band gap of electronic semiconductor crystals.[1] We have previously shown how with the proper photonic band gap engineering, we can insert allowed pass band defect modes and use the suppressing band gap in combination with the transmitting pass band to induce spectral narrowing of emission and improved energy transfer.[2] We show now how with a high-quality narrow pass band in a broad stop band, it is possible to achieve photonic crystal lasing in self-assembled colloidal photonic crystals with a planar defect.[3] In addition, with proper surface treatment in combination with patterning, we prepare for addressable integrated photonics. Finally, by incorporating a water in- and outlet, we can create optomicrofluidic structures on a photonic crystal allowing the optical probing of microreactors or micro-stopped-flow in the lab-on-an-optical-chip.[4]

Electrical performances of straight and castellated dielectrophoresis electrodes for biological molecules separation

Azrul Azlan Hamzah, Farahdiana Wan Yunus, Muhamad R. Buyong, Jumril Yunas, Burhanuddin Y. Majlis, Univ. Kebangsaan Malaysia (Malaysia)

Dielectrophoresis (DEP) exerts force on a dielectric particle using non-uniform electric field. DEP is utilized in separation of biological molecules in MEMS artificial kidney. In this work, interdigitated DEP electrodes are interwoven on the nanopores of silicon filtration membrane to act as anti-clogging mechanism for the MEMS nanofiltration system. Negative DEP is utilized to repel the larger molecules, in order to prohibit them from clogging the nanofilters. The intensities and distribution of electric fields generated by various electrode designs were studied using COMSOL software. Straight and castellated electrode designs were compared. The MEMS DEP electrodes were fabricated using aluminium, with total device area of 3500 μm x 3500μm. Spacing between the interdigitated electrodes for the straight and castellated designs were 100μm and 300μm respectively. The input voltage between the electrodes was 2V AC. It was observed that the electric field varies from positive to negative across the alternating electrodes for both designs. The castellated electrodes exhibited higher electric field, with a maximum value of 27.14kV/m at compared to 9.54 kV/m for the straight electrodes. Similar results were observed along the length of the electrodes, where the castellated design produced 1.85 kV/m of highly clustered electric field, compared to scattered field with maximum value of less than 100 V/m for the straight electrodes. These results suggest that the castellated design would cluster and separate biological molecules better compared to straight electrodes, thus making it more suitable to be used in artificial kidney nanofiltration system.

Effect of different AFM micro cantilever in fluid on the rough surface topography quality close to the surface

Alireza Habibnejad Korayem, Moharam Habibnejad Korayem, Iran Univ. of Science and Technology (Iran, Islamic Republic of)

The use of higher vibration modes and different geometries of the AFM ?piezoelectric MC is affected by the surface topography quality in a liquid medium. ?Therefore, utilizing an appropriate geometry and vibration mode is of a great importance. ?This paper analyzes AFM MC types with rectangular, dagger and V-shaped geometries in ?the noncontact and tapping modes in a liquid medium for rough surfaces in Nanoscale. The ?modified couple stress theory (MCS) in a liquid medium according to Timoshenko beam ?theory is used in order to enhance the accuracy of equations. In addition, the differential ?quadrature (DQ) method has been used to solve the equations. Identification of ?environmental forces helps an exact investigation of the system vibration amplitude. ?Investigating the effect of geometric and force parameters on the MC vibration behavior ?leads to understanding the system and to design it properly in a liquid medium. Also, due to ?oscillating the MC near the sample surface, the effect of interaction forces between the ?sample surface and the MC, including van der Waals, contact and squeeze forces is ?analyzed in a liquid medium in addition to the hydrodynamic forces. Furthermore, due to ?the sever reduction of the MC amplitude caused by the squeeze force; the MC is angled in ?comparison with the horizontal surface. ?

10355-15, Session 5

Influence of the biomatrix on fluorescence efficiency of luminophores

François Kajzar, Ana-Maria Manea, Cosmina Andreea Lazar, Ileana Rau, Univ. Politehnica of Bucharest (Romania)

Our recent studies on fluorescence of different luminophores embedded in deoxyribonucleic acid (DNA) matrix show that their fluorescence quantum efficiency is usually larger than in the case of a synthetic polymer matrix [1-4] This is due to the particular environment created by DNA, which behaves like a ionic liquid creating an important electric field exerted on embedded chromophores, modyfying their electronic structure. Several observations with different luminophores will be presented and discussed.

10355-16, Session 5

Fabrication of biomimetic sensing devices using bacteriorhodopsin via an inkjet printing method *(Invited Paper)*

Hiroyuki Hasegawa, Katsuyuki Kasai, Toshiki Yamada, Shukichi Tanaka, Yukihiro Tominari, Takahiro Kaji, Akira Otomo, National Institute of Information and Communications Technology (Japan); Yoshiko Okada-Shudo, The Univ. of Electro-Communications (Japan)

Bacteriorhodopsin is known as a photoreceptive membrane protein obtained from a cell membrane of Halobacterium salinarum. In the device fabrication using this material, the process that needs post-processing to remove a part of the film unused has been utilized such as dip-coating or spin coating method. However, it is difficult to apply some processes for semiconductor industry such as lithography to the material due to its chemical stability. Therefore, an on-demand and pinpoint 'soft' patterning is required to realize highly integrated device fabrication using such biomaterials. Here, we present an attempt of the soft patterning using a material printer in the device fabrication.

The details of device fabrication via the ink-jet patterning, and characteristics of the devices will be presented.

10355-17, Session 6

Conjugated polymer thin films for dynamic generation of photothermal patterns *(Invited Paper)*

Eunkyoung Kim, Yonsei Univ. (Korea, Republic of)

Near infrared (NIR) photothermal pattern on conjugated polymer film enabled unique approaches to harvest thermal energy with various patterns. The NIR photothermal pattern was generated from a patterned optical lens (POLs), which created dynamic Near IR light pattern (NLP) and the corresponding photothermal pattern (PTP) on the conjugated polymer thin film. The POL was prepared from transparent polydimethylsiloxane (PDMS) designed to generate various light patterns. The PTPs allowed a wet transfer of films coated on top of the PTPs in aqueous media. Various PTPs were generated by the diffraction of NIR light through POLs having different micro-patterns, which afforded wet transfer with a desired pattern. This provided cell sheet patterns without changing the original cell morphology at cultured state. Further optical engineering of the wet transfer system allowed multiple transfer of active thin films and productions of multiple cell sheets with one dose of light.

DNA brush-assisted vertical alignment of gold nanorods and those chiral plasmonics *(Invited Paper)*

Hideyuki Mitomo, Satoshi Nakamura, Hokkaido Univ. (Japan); Andrew Pike, Newcastle Univ. (United Kingdom); Yasutaka Matsuo, Kuniharu Ijiro, Hokkaido Univ. (Japan)

Control over the assembly of metal nanorods are important for creating high-performance nanomaterials. Alignment of gold nanorods in one direction was observed by adsorbing gold nanorods on a double stranded DNA brush through electrostatic interactions. Those ordered structures were attributed by optimizing the density of positive charge on gold nanorods and the density of grafted DNA chains. In agreement with a theoretical simulation, the resultant structure exhibit plasmonic properties depending on the orientation of the gold nanorods relative to the direction of oscillating electric field. We observed those gold nanorods condugated with DNA provided CD bands due to chiral plasmonic effects. Our approach is new one utilizing a conformation of a polymer chain for control over the assembly of metal nanorods and could form ordered matal nanorods not only in a large area but also on a non-flat surface.

10356-1, Session 1

Ultrahigh field enhancements from nanostructured metal thin films *(Keynote Presentation)*

Ibrahim Abdulhalim, Ben-Gurion Univ. of the Negev (Israel) and Nanyang Technological Univ. (Singapore)

Enhancing the optical fields near metal nanostructures is of high importance for sensing, energy harvesting and improving the efficiency of optoelectronic devices. Surface enhanced spectroscopies such as Raman scattering (SERS), fluorescence (SEF) and infrared absorption (SEIRA) are enhanced significantly thus allowing lower detection limit and supresolved imaging. Solar energy harvesting can be improved by designing structures that enhance the local optical field over wide spectral and angular ranges covering the whole solar spectrum. Detectors for the short wave and mid-IR ranges with higher efficiencies started to appear following an optimum designs incorporating plasmonic nanostructures.

During the last few years we have been investigating several plasmonic nanostructured thin films for improved biosensors and lately for energy harvesting devices using variety of configurations: standard Kretchmann-Raether configuration, grating coupling, free space excitation of localized plasmons (LSPs) from nanosculptured thin films, and lately excitation of LSPs via extended surface plasmons (ESPs). The later configuration was shown both theoretically and experimentally (using SEF and SERS) to reveal extraordinary enhancement when the matching conditions between the ESP and the LSP are met. Several configurations for improved SPR biosensors and ultrahigh enhancement of local optical fields will be presented with the potential applications in sensing, solar energy harvesting and optoelectronic devices.

Acknowledgments:

This research was conducted partially by NTU-HUJ-BGU Nanomaterials for Energy and Water Management Programme under the Campus for Research Excellence and Technological Enterprise (CREATE), that is supported by the National Research Foundation, Prime Minister's Office, Singapore.

Optical liquid monitoring with sculptural multilayers Bragg microcavities incorporated to microfluidic chips *(Invited Paper)*

Francisco Yubero, Manuel Oliva, Jorge Gil-Rostra, Agustín R. Gonzalez-Elipe, Instituto de Ciencia de Materiales de Sevilla (Spain)

Porous Bragg microcavities (BMs) formed by the successive stacking of sculptural SiO_2 and TiO_2 layers with slanted and zig-zag configurations are prepared by glancing angle deposition (PVD-GLAD). These BMs act as wavelength dependent optical retarders. This optical behavior is attributed to a self-nanostructuration mechanism involving a fence-bundling association of nanocolumns as observed by Focused Ion Beam- Scanning Electron Microscopy (FIB-SEM). The retarder response of these optically active BMs can be modulated by dynamic infiltration of their open porosity with liquids or solutions with different refractive indices. The unprecedented polarization and tunable optofluidic properties of these nanostructured photonic systems have been successfully simulated with a simple model that assumes a certain birefringence for the individual stacked layers and accounts for the light interference phenomena developed in the BM. This type of self-associated nanostructures has been incorporated to microfluidic chips for free label liquid sensing. Several examples of the detection performance (experimental sensitivity to variations below 0.001 liquid refractive index units) of these chips, working either in reflection or transmission configuration, for the optical characterization of liquids of different refractive index and aqueous solutions of glucose flowing through the microfluidic chips are described.

10356-3, Session 2

High efficient light absorption and nanostructure-dependent birefringence of a metal-dielectric symmetrical layered structure

Yi-Jun Jen, Yi-Ciang Jhang, Wei-Chih Liu, National Taipei Univ. of Technology (Taiwan)

A multilayer that comprises ultra-thin metal and dielectric films has been investigated and applied as a layered metamaterial. By arranging metal and dielectric films alternatively and symmetrically, the equivalent admittance and refractive index can be tailored separately. The tailored admittance and refractive index enable us to design optical filters with more flexibility. The admittance matching is achieved via the admittance tracing in the normalized admittance diagram. In this work, an ultra-thin light absorber is designed as a multilayer composed of one or several cells. Each cell is a seven-layered film stack here. The design concept is to have the extinction as large as possible under the condition of admittance matching. For a seven-layered symmetrical film stack arranged as Ta_2O_5 (42 nm)/ a-Si (13 nm)/ Cr (20 nm)/ Al (30 nm)/ Cr (20 nm)/ a-Si (13 nm)/ Ta_2O_5 (42 nm), its mean equivalent admittance and extinction coefficient over the visible regime is 1.2+0.08i and 2.04, respectively. The unit cell on a transparent BK7 glass substrate absorbs 98.26% of normally incident light energy. On the other hand, a transmission-induced metal-dielectric film stack is investigated by considering the dielectric film as a bi-deposited thin film. The equivalent birefringence of the structure varied with wavelength and nanostructure are investigated here

10356-4, Session 2

Third order non-linear response as function of the laser power in SiO2:DR1 mesostructured and amorphous films

Jorge A. García-Macedo, Gerardo S. Gámez, Univ. Nacional Autónoma de México (Mexico)

Non-linear optical behavior can be obtained in materials exposed to laser radiation. There are no much results of these properties as function of the structure of the samples. In our case we prepared SiO2;DR1 amorphous samples by sol-gel method, and mesostructured ones by using cethylmethyamonium bromide (CTAB). The hexagonal structure was evidenced by X-ray diffraction. The transmittance of a focused Helium-Neon 394nm laser light was studied in these samples when moving around the focal point. With the results and using the Sheik-Bahae model the third order non-linear optical absorption coefficient ? and refractive index n2 were obtained. The dependence of ? as function of the laser power is shown in Figure 1 for both samples. They can be fit with an exponential curve that reaches saturation. It is clear the hexagonal structured helps to increase the sensitivity of the sample. In the case of the refractive index as function of the laser power the response is similar, but in this case the mesostructure does not give a strong difference, as shown in Figure 2.

Exotic nanophotonic behavior in systems of reduced dimensionality *(Invited Paper)*

Marin Soljacic, Massachusetts Institute of Technology (United States)

Systems of reduced dimensionality can enable a variety of novel nanophotonic phenomena. Some of our recent investigations in this field will be presented.

10356-6, Session 3

Engineered metasurface of gold funnels for microwave filtering

Shayan Moghaddas, Masih Ghasemi, Pankaj K. Choudhury, Burhanuddin Y. Majlis, Univ. Kebangsaan Malaysia (Malaysia)

Surface plasmon polariton (SPP) excitation of the coupled light at small contact area of chromium pillars as the interface of metastructured gold funnel layer and silicon medium can be enhanced locally in the gold meta-funnel-structured filter. The structure of this filter is comprised of three layers, namely gold meta-funnels, nanostructured chromium pillars and silicon as the substrate. The quantum energy of microwave field in the range of 0.01 eV to 0.04 eV, coupled with the excited plasmon at the first and second layers, form an excitation, known as deformed plasmon polariton. Asymmetric distribution of localized SPPs takes place owing to the inherent converging plasmonic feature of the gold funnel structure. The nano-sized thick chromium pillars act as interface medium for better adherent for the gold metasurface and silicon substrate. The formation of sharp reflection peaks with different magnitudes at different incident angles of the polarized wave in the spectral characteristics makes the structure prominent for filtering microwaves and infrared waves. Moreover, the gold meta-funnel-structured filter possesses the additional feature of distinguishing the type of polarized incident wave. It has been found that the transmission spectrum corresponding to the TM polarized waves over the same wavelength range are almost blocked at any incident angle. However, the transmission peaks corresponding to the TE waves greatly demonstrate another application of this device as a meta-polarizer filter.

10356-7, Session 3

Amorphous Fe-Dy-Tb-O (FDTO) thin films with transparent, magnetic, and semiconducting behaviors

Abhinav Malasi, Humaira Taz, The Univ. of Tennessee Knoxville (United States); Tamil Sakthivel, Univ. of Central Florida (United States); Rama Vasudevan, Oak Ridge National Lab. (United States); Connor Carr, The Univ. of Tennessee Knoxville (United States); Nano Yamoah, North Carolina A&T State Univ. (United States); Benjamin J. Lawrie, Raphael C. Pooser, Oak Ridge National Lab. (United States); Hernando Garcia, Southern Illinois Univ. Edwardsville (United States); Dhananjay Kumar, North Carolina A&T State Univ. (United States); Gerd Duscher, The Univ. of Tennessee Knoxville (United States); Art P. Baddorf, Oak Ridge National Lab. (United States); Sudipta Seal, Univ. of Central Florida (United States); Ramki Kalyanaraman, The Univ. of Tennessee Knoxville (United States)

Functional amorphous thin films are attractive because they can be made at low temperatures and have smooth films over large areas. In the past decade amorphous oxide semiconducting thin films combining transparency and conductivity, such as In-Ga-Zn-O have been used in display devices, solar energy harvesting, and flexible electronics. We discuss here a new class of amorphous thin film materials made from Fe-Dy-Tb-O that display extraordinary multifunctional properties. Thin films in the range of 9 to 70 nm were deposited by pulsed laser deposition (PLD) or by e-beam co-evaporation at room temperature onto a variety of substrates. Films deposited by PLD from terfenol-D target showed a combination of high optical transparency (>90% for 9 nm films @ 500 nm wavelength), very large n-type carrier mobility (>30 cm^2/V-s) and large conductivity. Films with different Fe to lanthanide (Tb+Dy) ratio were prepared by e-beam co-evaporation. Lower Fe/(Tb+Dy) ratio films showed semiconducting behavior, optical transparency, low sheet resistance (<200 Ohm-sq) and room temperature ferromagnetism. Higher Fe/(Tb+Dy) content films showed metallic behavior. Energy dispersive spectrometry, X-ray photoelectron spectroscopy, x-ray diffraction and electron microscopy investigations were used to determine the mcirostructure and chemical composition. Amorphous films with generally homogenous distribution of metal and oxygen was found. The properties of the films appears to be critically linked to the oxidation state of the cations and the metal to oxygen ratio. This material could be a promising new option as a transparent conductor or a ferromagnetic semiconductor for applications in energy harvesting and spintronics.

10356-8, Session 3

Topology controlled functional nanoclustered thin films with tendency to superconductivity

Sergey M. Arakelyan, Alexey O. Kucherik, Stella V. Kutrovskaya, Anton V. Osipov, Vladimir State Univ. (Russian Federation)

The physical properties of nanocluster/granular systems are very sensitive to the form, size and distance between their composing elements. The thin films can be easily modified both in necessary direction and by controlled way in femto- nanophotonics experiments under normal environmental conditions.

The variation of the enumerated above topology parameters can result in new type of quantum correlation states for charged particles. Moreover, the electronic energetic bands/gaps of the materials in such system can vary dramatically for the case resulting in new physical behavior of the system.

We used different laser ablation and deposition technique to induce the topology controlled nanoclustered thin films of semiconductor (PbTe), monometallic (Au, Ag, Cu, Ni) and bimetallic (Au+Ag, Au+Cu, Ag+Ni) materials deposited (thickness 5-100nm) on solid substrate.

In experiment, we have seen competition between increase conductivity while opening new channels in a spatially inhomogeneous charged structure and increase the resistance by increasing of the area between the conductive grains.

Such electrical transport properties (due to tunnel and quantum correlated states resulting in jumps electroconductivity in experiment) may be presented as a tendency to high temperature superconductivity due to special type of topological surface structures (both localized and delocalized coupled states for charge carriers).

Obtained results give us an opportunity to establish the basis of new physical principles to create the functional elements for the optoelectronics and photonics in hybrid set-up (optics + electrophysics) by the different topology control nanoclusters with dramatic increase of electroconductivity vs spatial structure of nanoclusters at room temperature.

10356-26, Session PWed

Development of batch producible hot embossing 3D nanostructured surface-enhanced Raman scattering chip technology

Chu-Yu Huang, Ming-Shiuan Tsai, National Chung Hsing Univ. (Taiwan)

To date, the major drawback of the existing Surface-Enhanced Raman Spectroscopy (SERS) active chip design is the need for complicated and expensive microfabrication process. The complexity of the production process lead to the SERS active substrate quality is hard to control. Therefore, the measurement results are different each time, repeatability is not good. In addition, the fabrication cost of these SERS active chips is too expensive to be widely used.

The main purpose of this project is to develop a batch producible hot embossing 3D nanostructured surface-enhanced Raman chip technology for highly sensitive label-free plasticizer detection. This project utilizing the AAO self-assembled uniform nano-hemispherical array barrier layer as a template to electroforming a durable nanostructured nickel mold. With the hot embossing technique and the durable nanostructured nickel mold, we were able to mass produce the 3D Nanostructured PC (Polycarbonate) substrates with consistent quality. Gold nanodots array were formed uniformly by the spontaneous separation and coalescence of gold ultrathin film when deposited onto the 3D Nanostructured PC substrate. It provides high spatial density of hot spots. The FDTD (Finite-difference time-domain method) simulation and experiments were conducted to study how the geometric parameters such as: pitch distance of gold nanodots and diameter of the nano-hemisphere affect the resulting SERS enhance factor. The optimized the 3D nano composite structured SERS active chips were able to detect the type and the concentration of the plasticizers from food and beverages samples.

The batch producible hot embossing 3D nanostructured SERS chip proposed in this study possess many advantages such as high sensitivity, low cost, and high consistency over currently available SERS chips. It is very promising to be widespread and extensively use in many rapid detection applications, such as food safety, environmental monitoring, and pathogen detection.

10356-27, Session PWed

The effect of ion-beam etching on the sol-gel coating in the preparation of tri-wavelength antireflection coating

Siyu Dong, Lingyun Xie, Tao He, Hongfei Jiao, Jinlong Zhang, Bin Ma, Zhanshan Wang, Xinbin Cheng, Tongji Univ. (China)

In high power laser system, it is highly desirable to develop antireflection (AR) coatings exhibiting high transmittance simultaneously at 355, 532, and 1064nm. Its realization usually needs multilayers and the film thickness and refractive index of each layer must be controlled precisely to ensure the transmittance in these specific wavelengths. Besides, in order to improve the laser damage resistance of AR coating, sol-gel process provides a preferable choice due to the great advantage on the damage characteristic. Unfortunately, it is challenging to prepare tri-wavelength AR coating by sol-gel method for its low controlling accuracy of film thickness. To modify the sol-gel film thickness, ion-beam etching process has been proposed by us to remove the redundant material at a low rate. However, owing to the characteristics as porous structure and relaxed texture, the nanostructure of sol-gel coating will be changed under the ion-beam, resulting in the change of refractive index. The key challenge lies in obtaining the relationship between the refractive index and etching depth. In this work, a systematic and comparative study was designed to reveal the evolution of nanostructure and refractive index of the SiO_2 sol-gel coating under the ion-beam etching. Based on the above findings, a hybrid approach that combined conventional sol-gel process with ion-beam etching was successfully applied to prepare the sol-gel coating with both the controllable thickness and refractive index. Finally, after modifying the thickness and refractive index of each layer, a tri-wavelength AR coating featured excellent AR properties was achieved, and its laser-induced damage threshold (LIDT) was increased significantly.

Transition from Dyakonov and Dyakonov-Tamm surface waves to surface-plasmon-polariton waves induced by temperature

Tom G. Mackay, The Univ. of Edinburgh (United Kingdom); Francesco Chiadini, Univ. degli Studi di Salerno (Italy); Vincenzo Fiumara, Univ. degli Studi della Basilicata (Italy); Antonio Scaglione, Univ. degli Studi di Salerno (Italy); Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

Temperature-induced changes in the propagation of electromagnetic surface waves, guided by the planar interface of a temperature-sensitive isotropic material (namely, InSb) and a temperature-insensitive anisotropic material were investigated theoretically in the terahertz frequency regime. Two types of anisotropic partnering material were considered: (i) a homogeneous material and (ii) a periodically-nonhomogeneous material. As the temperature increases, the isotropic partnering material is transformed from a weakly dissipative dielectric material to a metal. As a consequence, the surface waves change from Dyakonov surface waves to surface-plasmon-polariton waves for (i), and change from Dyakonov--Tamm surface waves to surface-plasmon-polariton waves for (ii). Numerical investigations demonstrated that dramatic changes in the numbers of propagating Dyakonov or Dyakonov--Tamm surface waves, their angular existence domains, their propagation constants, and their decay constants, could arise from modest changes in temperature.

Non-linear and linear optical techniques for identification of functional groups on plasma treated surfaces on the monolayer level

Munise Cobet, Matthias Kehrer, David Stifter, Johannes Kepler Univ. Linz (Austria)

We present a comprehensive study of the plasma modification of metals and polymers by combining non-linear and linear optical techniques as complementary sources of information. The used plasma is of a novel type of atmospheric pressure jet plasma, where also liquids can be ignited into the ionized state in a defined manner.

Among non-linear optics, IR-visible sum-frequency-generation (SFG) is used to obtain the vibrational spectral resonances of the treated surfaces which are not readily accessible by other optical methods. Since at surfaces the inversion symmetry is broken (centrosymmetric bulk) , spectroscopic features are highly sensitive to molecular adsorbates, such as small functional groups attached to the very surface and bond orientation. For a sufficiently intense illumination for this 2nd-order process, a pulsed IR-tunable laser source is used which overlaps with the second harmonic output from the 1064nm-laser. The orientation of molecules can be obtained by variation of polarization for the excitation and signal light beams.

While SFG is probing molecular adsorbates induced by the plasma, linear optics like confocal Raman and ellipsometry provide valuable information about the oxidation of metals, i.e. the formation of amorphous transparent layers on the surface and the degree of crystallinity in polymers.

The plasma processed species show a high level of functionalization with hydroxy-, carboxyl-, and carbonyl-groups as well as amino- and nitro-groups.

SFG, Raman and Ellipsometry optical responses are crosschecked with chemical composition obtained by X-ray photoelectron spectroscopy and HREELS in order to give a certain quantification of the found features.

Oblique angle deposition of Al films on nanopatterned substrates for wire grid polarizers

Wonyoung Kim, Sungmin Hwang , Tae Young Kim, Won Gyu Ham, Myung Hoe Koo, Minbaek Lee, Chang Kwon Hwangbo, INHA Univ. (Korea, Republic of)

Wire grid polarizers (WGPs) comprised of 1D metal nanograting structures are drawing attention to industrial applications in display and optics. A WGP transmits the transverse magnetic (TM) wave and reflect the transverse electric (TE) wave. It is well-known that the realization of WGPs with a large area requires high-cost facility such as E-beam lithography, serial etching, and deposition. In this study, we employed oblique angle deposition (OAD) and nanoimprint lithography (NIL) methods to fabricate the broadband Al WGPs in visible and infrared wavelength regime. Firstly, polymer nanostructures were patterned by NIL, which resulted in nanopatterns with a pitch of 120 nm, width of 50 nm, and height of 160 nm. And then, Al was selectively deposited on the ridge of polymer nanopatterns by OAD. The result shows that the average transmittance of TM wave is 67% and the polarization extinction ratio is 22 dB in the visible and near infrared wavelength regime. Finite differential time domain simulation and SEM images were employed to analyze the various Al structures shaped by the different OAD conditions on top of the nanopatterns. The analysis and experimental results in this study may afford a simple and effective way for fabrication of large-scale and high-performance WGPs and can be applied to non-conformal deposition of metamaterials in near future.

Non-exhibition of Bragg phenomenon by chevronic sculptured thin films: experiment and theory

Vikas Vepachedu, Patrick D. McAtee, Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

A sculptured thin film (STF) is an array of parallel nanocolumns separated by a void network. If the individual nanocolumns take on the form of a zig-zag as they grow, then the resulting STF is known as a chevronic STF. To grow a chevronic STF, a collimated vapor flux is directed towards a substrate in vacuum. The plane of the substrate is oriented so that the vapor flux is directed towards it at a specified angle chi_v. Once a deposition of thickness h is over, the substrate is rapidly rotated about its normal axis by 180 deg and a second deposition of the same thickness is made, thereby completing a chevron. Multiple chevrons are deposited to yield a thin film that is periodically nonhomogeneous in the thickness direction.

We experimentally investigated the exhibition of the Bragg phenomenon for light incident normally as well as obliquely on a 10-period thick chevronic STF of zinc selenide. The period of this thin film was 330 nm and it was fabricated with chi_v = 20 deg. Measurements of the four linear reflectances and four linear transmittances were made as functions of both the free-space wavelength and the angle of incidence. The absence of the Bragg phenomenon for a wide range of angles of incidence was observed and compared with previous theoretical work of Maksimenko and Slepyan for normal incidence. Additional calculations were carried out at non-normal incidence.

Electrophysical and gas-sensing properties of the nanoscale thin films of tin dioxide modified with silver and yttrium and with catalytic additives (Pt/Pd, Ag, Au or Pt/Pd/Au) on the surface

Aleksei V. Almaev, Stanislav Kim, National Research Tomsk State Univ. (Russian Federation)

The results of researches of the electrophysical and gas-sensing properties of the nanoscale thin polycrystalline tin dioxide films with a thickness of 120 nm are presented. It is shown that the introducing of the silver and yttrium in the bulk of tin dioxide control temporal drift of the characteristics of sensor based on these materials, but the resistivity and gas sensing properties of the films are determined by the dispersed layers of the catalysts (Pt/Pd, Ag, Au or Pt/Pd/Au) deposited on the surface of tin dioxide. The dispersed double layers of Pt/Pd on the surface of these films increase the resistivity, the response to hydrogen and decrease the operating temperature of the sensors. Replacement of catalytic layers of platinum and palladium on Ag or Au leads to a decrease of resistivity of the films, but also increase the operating temperature of the sensors. Deposition of the gold in the case of the triple catalyst Pt/Pd/Au also helps to reduce the resistivity of the films and increase the operating temperature of the sensors. Measurements of the conductivity in the thermo-cyclic operation mode show that the behavior of the films is caused by the dependence of the surface density of chemisorbed oxygen ions on the type of catalyst on the surface of tin dioxide films.

Enhanced water stability and thermoelectric properties of PEDOT:PSS films via a glycerol vapor treatment

Sung Hyun Kim, Wonkwang Univ. (Korea, Republic of)

Thermoelectric (TE) energy harvesting devices, which recovered energy from waste heat, has been attracted much interest as environmentally friendly devices. The performance of TE is evaluated by the figure of merit (ZT) which is expressed as ZT = S2?T/? where S, ?, and ? is the Seebeck coefficient, electrical conductivity, thermal conductivity. The power factor (PF) is given by S2?. In order to achieve high a high ZT, thermoelectric materials have to show high power factor and low thermal conductivity. PEDOT:PSS has been considered as one of the most promising thermoelectric materials owing to its high electrical conductivity, high Seebeck coefficient, and low thermal conductivity. Especially, the value of Seebeck coefficient is easily fluctuated by water. Only a few research focusing on water stability of TE devices were reported. Therefore, the effect of water on the TE devices and the relationship between water-related TE performances are required to develop in the field of organic TE devices.

In this work, we reported a simple method using vapor treatment of glycerol, simultaneously leading to enhanced PF which was increased from 0.03 to 5.93 ?V/mK2 at optimal treatment condition as well as water stability compared to control device. We systematically investigated the effect of glycerol on PF by using IR, AFM, and XRD analysis. Based on that results, we found that glycerol induced morphological change of PEDOT:PSS film originating from cross-linking reaction where sulfonic ester formed between glycerol and PSS. In addition, the modified PSS induced lowering hygroscopic property of PEDOT:PSS thus the resultant films shows better water stability in highly humidity condition.

Photonic nanostructure design for high efficiency light absorber

Yi-Fan Huang, National Taipei Univ. of Technology (Taiwan) and Institute of Atomic and Molecular Sciences - Academia Sinica (Taiwan); Yi-Jun Jen, National Taipei Univ. of Technology (Taiwan)

An ideal light-absorbing surface is able to collect light energy from wide ranges of wavelengths and angles of incidence. It has been reported that photonic and plasmonics structures can manipulate and couple light on the nanoscale surface. The properties of nanostructures which can enhance light absorption and improve solar energy conversion also have been expected. In this report, we design two types of photonic nanostructure for light absorption surfaces, metal nanohelices array on glass substrate and antireflecting structures on semiconductor substrates (moth eye's surface). The optical properties of these two types of structures were been analyzed using finite difference time domain (FDTD) calculations. FDTD simulation demonstrates that the aluminum-silver nanohelices array with thickness about ~500 nm have strong rod to rod localized surface plasmons which can absorb wavelength of light from UV to NIR region and angle of incidence up to 70 degree. Antireflecting structures utilize design parameters of spacing/wavelength and length/spacing, which could be expected exhibiting ?99% optical absorption over wavelength from UV-vis region and angle of incidence up to 60 degree in low-index and high-index semiconductor materials.

Influence of the crystal potential on the energetic spectrum of the vicinal superlattices in the quantum: confined films

Victor Petrov, Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation)

As is known, the existence of superlattice effects in quantum - confined films (QCFs) on vicinal planes initiated with the appearance in these systems of a new crystallographic translation period in the plane of the film A >>a0 (a0 - lattice constance). The emergence in these QCF of the periodic system of atomic steps on the high-index Miller boundaries allows explain in the effective mass approximation the appearance of minigaps (MGs) in the energetic spectrum of particles in such QCF by the scattering of electrons on such steps. At the same time it is evident that the contribution to the MGs formation should also be made by all crystallographic planes in the area of localization of the particle wave function. In this work shows theoretically that the consideration of only crystal potential and of the potential locating the particle in QCF on high-index Miller vicinal planes results in the appearance of MGs even without taking into account of the step structure of the film boundaries. A method has been developed that makes it possible to calculate the energetic spectrum of this QCFs for the arbitrary localizing potential by leaving the effective mass approximation in single-valley semiconductors of the GaAs - type. For the cases of the rectangular quantum well analytical expressions have been obtained for MGs magnitudes which depend on the parameters of the crystal potential and localizing potentials as well as on angles that define the orientation of the QCFs in the crystal.

Photo-excited carrier dynamics of CuPc/C60 organic thin film structure

Mitsuru Inada, Tomoki Miyake, Nozomi Isobe, Tadashi Saitoh, Kansai Univ. (Japan)

The structure of the sample was ITO/CuPc(30 nm)/C60(40 nm)/BCP(5 nm)/Al. These layers were deposited on SiO2 substrate by using vacuum evaporation. After the depositions, the sample was taken out into the atmosphere, and then, it was immediately sealed with epoxy resin.

Optical absorption spectra for each thin film layer were measured by ultraviolet to visible light absorption spectrometer (JASCO V-630). Current density-voltage characteristics of the sample were measured by using YOKOGAWA GS820 source measure unit with conventional two-terminal method. The spectral sensitivity characteristics were measured using a lock-in amplifier (Stanford Research SR830) and a xenon lamp as the irradiation source. The transient photocurrent properties were investigated irradiating third harmonic (532 nm) of pulsed Nd-YAG laser light (Quantel CFR200, pulse width: 7 ns) and the current decay characteristics were observed on a screen of digital oscilloscope. All measurements were carried out at room temperature and in air.

The obtained carrier lifetime is much longer than that of estimated lifetime from the mobility of thin-film layers. This means the carrier transport cannot be described by a general carrier drift model. In addition, the carrier lifetime become short under white halogen light illumination. The results suggest that the photo-excited carrier transport is affected by trapping levels in the organic layers.

Photoelectric properties of ITO-pSi structures

Tetiana Batsko, Sergiy Kondratenko, Taras Shevchenko National Univ. of Kyiv (Ukraine)

Study photoelectric effects in semiconductors occupies an important place in the analysis of the properties of semiconductors. Photocurrent spectroscopy and photo EMF is a powerful method for studing of nonequilibrium processes in semiconductors.

Purpose of the work was to study photovoltaic properties of structures ITO-Si and Ge-Si and mechanisms of spatial separation of nonequilibrium charge carriers in the space charge barrier.

Current-Voltage (I-V) characteristics, photovoltage spectra and kinetics of decline for two series of samples SiO2-pSi and iSi-pSi with different thicknesses deposition layer ITO was studied.

It was established that the formation of the ITO film on the surface of SiO2-pSi structures and iSi-pSi leads to the formation of a potential barrier, which causes the straightening of I-V curves and observation Photovoltage. It is shown that an increase in film thickness the value of the barrier increases.

Optical and structure properties of crystalline silver nano-layers with ultra-smooth surfaces

Husam Abu-Safe, German Jordanian Univ. (Jordan); Hameed Naseem, Univ. of Arkansas (United States)

Thin metal films with ultra-low scattering and ohmic losses are needed for plasmonic applications. Fabrication of noble metal nano-layers with ultra-smooth surfaces remains a challenge for this purpose. In this paper, silver layers of 3, 29, 60 and 122 nm thickness deposited directly on c-Si(111) substrates without any wetting layer are examined. The films were prepared at room temperature using electron beam evaporation with 0.5 Å/sec deposition rate. The optical and structural properties of the nano-layers depend on the experimental parameters of deposition process and the film thickness. The complex permittivity of the silver layers were parametrized using spectroscopic Ellipsometry measurements. The oscillatory patterns obtained from the x-ray reflectivity measurements indicated crystalline structure with ultra-smooth surfaces for all fabricated films.

10356-9, Session 4

Broadband perfect absorption of epsilon-near-zero thin films *(Invited Paper)*

Chang Kwon Hwangbo, INHA Univ. (Korea, Republic of)

Epsilon-near-zero (ENZ) metamaterials have been studied in various research areas such as wavefront engineering, supercoupling effect, strong coupling, nonlinear optics, and perfect absorption. An ideal ENZ material of ?=0 is highly omnireflective at any angle of incidence. For a real ENZ material of Re(?)≈0 the imaginary part Im(?) is not zero from the causality principle. At an ENZ wavelength at Re(?)≈0, the normal electric field (E_z) in an ENZ thin film with a very small Im(?) becomes very strong and the group velocity slows down; E_z is inversely proportional to the thickness of the film and the imaginary part of ?, resulting in a large light absorption in a low optical loss ENZ thin film. We investigate the tunable ENZ wavelength of indium tin oxide (ITO) thin films in the NIR wavelength regime which are controlled by the film growth conditions and demonstrate the broadband perfect absorption (PA) using the ITO multilayers of different ENZ wavelengths.

Coherent perfect absorption (CPA) is an optical phenomenon occurring in an absorbing thin film by the interaction of two counter-propagating coherent waves. We propose a new broadband CPA scheme based on ENZ multilayer films and investigate the multi-wavelength optical switching, indicating that the on- and off-states can be controlled by the phase shift and wavelength of the two incident waves.

In this lecture we provide design principles and fabrication guidelines for thin film ENZ devices for PA and CPA, which can find various applications in optical switches, modulators, filters, sensors, and energy harvesting devices.

10356-10, Session 4

Asymmetric metal-insulator-metal (MIM) structure formed by pulsed Nd:YAG laser deposition with titanium nitride (TiN) and aluminum nitride (AlN)

Yasushi Oshikane, Osaka Univ. (Japan)

A novel nanostructured end cap for a truncated conical apex of optical fiber has been studied experimentall and numerically. The peculiar cap is composed of asymmetric metal-insulator-metal (MIM) structure coupled with sabwavelength holes. The MIM structure may act as reflective band cut filter or generator of surface plasmon polariton (SPP). And nano holes in the thicker metal layer could extract the SPP from the MIM structure and lead it to outer surface of the metal layer. For the purpose, the author has started to create the asymmetric MIM structure with TiN and AlN by pulsed laser deposition (PLD). TiN is one of the candidates for alternative plasmonic materials in these days, and it seems that there are many difficulties to bring out its good plasmonic property as subwavelength thin film. In this research, hot pressed disc target, made of TiN powder, is irradiated by 355 nm laser pulses in high vacuum. A series of trial shots rerulted several passable films on glass slides which shows x-ray diffraction (XRD) and x-ray photoelectron spectroscopy (XPS) peaks related to TiN. But residual oxygen in high vacuum space got mixed in with the PLDed films. To avoid oxygen and lack of nitrogen, the PLD process is done in nitrogen based atmosphere at around several Pa. Desirable material of the insulator layer in MIM structure by PLD would be transparent nitrides in visible region because of the nitrogen atmosphere. Therefore AlN was selected as the material of insulator layer. Spectroscopic characteristic of the MIM will be reported.

10356-11, Session 4

An advanced plasmonic cermet solar absorbers for high temperature solar energy conversion applications

Maryna Bilokur, Angus R. Gentle, Matthew D. Arnold, Geoffrey B. Smith, Michael B. Cortie, Univ. of Technology, Sydney (Australia)

We examine the use of plasmonic cermet coatings based on nanoparticles of Au or Ag embedded in a dielectric medium including AlN and SiO2. The intended application is for enhancing solar absorption in solar-thermal conversion devices. For this application, coatings must have both the appropriate spectral selectivity and must be stable at high temperature. The nanoparticles in these materials provided a broad absorption peak due to localized surface plasmon resonances while the surrounding dielectric medium red-shifted the absorption range and provided mechanical support. Spectral tuning was also achieved by controlled variation of the thicknesses of individual layers in cermet-dielectric multilayer thin film stacks. These were produced by magnetron sputtering and possessed absorption efficiencies ranging between 91% and 97% with low thermal emittance. Thermal stability was assessed by annealing in vacuum at 800K while monitoring any changes in optical properties using high temperature ellipsometry. The results showed that this type of composite solar absorber exhibits very competitive solar absorptance and thermal stability. Thermal stability is also influenced by the stack profile. They are thus suitable for use in solar energy conversion applications at elevated temperatures.

10356-12, Session 4

Optical and electronic functionality of 2D crystal-metal hybrids: computation and microscopy

Donald K. Roper, Gregory T. Forcherio, Mourad Benamara, Univ. of Arkansas (United States); Luigi Bonacina, Univ. de Genève (Switzerland); Jeremy R. Dunklin, Univ. of Arkansas (United States); Drew DeJarnette, U.S. Dept. of Energy (United States); Claudia Backes, Yana Vaynzof, Ruprecht-Karls-Univ. Heidelberg (Germany)

Two-dimensional (2D) nanocrystals (NC) offer superior electron mobility, thermal conductivity, mechanical strength and broken inversion symmetry that could enable advanced sensors or quantum computing. But challenges in fabrication, assembly, and tunable coordination of optical and electronic activity have constrained their implementation in functional devices. This work examined optical modulation of carrier injection and second harmonic generation (SHG) in 2DNC, i.e., graphene and transition metal dichalcogenide (TMD) via localized plasmon modes. Monolayer 2DNC used were chemical vapor deposited (graphene) or liquid exfoliated from bulk (TMD). 2DNC were decorated by gold (Au) and silver (Ag) plasmonic structures through three methods (i) evaporation, (ii) drop-casting and (iii) direct reduction. Electron energy loss spectroscopy

(EELS) was used to predict and induce plasmon bright, dark, and hybrid modes. EELS enabled quantitative femtosecond-scale measurement of spectroscopic plasmon dephasing and nanometer-resolved mapping of electric fields on the 2DNC-metal hybrids. Coupled and discrete dipole simulations were used to characterize radiative and intraband dephasing in order to distinguish carrier injection. X-ray photoemission spectroscopy was used to contrast physicochemical metal-2DNC bonds vs. polyvinylpyrrolidone coatings representating alternate pathways for carrier injection. A tunable laser scanning confocal microscope (LSCM) was used to measure second harmonic generation of metal-2DNC hybrids. A computational scaffold supporting analysis spanning atom to nanometer scales was used to develop compact structure-function relations in order to rationalize measured values. Coordination of EELS, XPS, and LSCM offers a comprehensive approach to characterize plasmon-induction of carrier induction and SHG at high spatiotemporal resolution in metal-2DNC hybrids.

10356-13, Session 4

Angular-insensitive plasmonic filters based on ultrathin metal patch array

Chenying Yang, Weidong Shen, Yueguang Zhang, Xu Liu, Zhejiang Univ. (China); Jing Zhou, Chengang Ji, L. Jay Guo, Univ. of Michigan (United States)

We proposed a new scheme of omnidirectional plasmonic filters using ultrathin metal patch array structure. The two plasmonic filters comprised by single-layer of ultrathin metal patch array and three-layer of dielectric-metal-dielectric (DMD) patch array both can be used as reflective RGB filters as well as transmissive CMY filters simultaneously, which maintain the same perceived reflection/transmission color at unpolarized illumination for a broad range of incidence angles. The reflection/transmission curves are coincident at different angles and the color difference characterized by CIE DE2000 formula is inconceivably small, implying that no color variation can be observed for a large angle up to 60 degree. Various colors can be obtained by simply tuning the dimension of the patch structure and the thicknesses of the two dielectric layers for the DMD filter. The simulated reflectance/transmittance and electric field distribution profile of the plasmonic filter was performed by Finite-Difference Time-Domain (FDTD) method, while the color devices were fabricated by steps of sputtering deposition and focus ion beam (FIB) milling. The angle insensitive color filtering feature of this plasmonic filters is resulted from the localized surface plasmonic resonance excited in the single metallic patch. And as a result, great feature that patch array with as few as two periods were sufficient to demonstrate color filtering can be obtained.

10356-14, Session 5

Advanced light management for liquid phase crystallized silicon thin-film solar cells *(Invited Paper)*

Klaus Jäger, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany) and Konrad-Zuse-Zentrum für Informationstechnik Berlin (Germany); Grit Köppel, David Eisenhauer, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany); Duote Chen, Helmholtz-Zentrum Berlin (Germany); Martin Hammerschmidt, Sven Burger, Konrad-Zuse-Zentrum für Informationstechnik Berlin (Germany); Bernd Rech, Christiane Becker, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (Germany)

Liquid phase crystallized (LPC) silicon thin-film solar cells are a promising novel approach with a current efficiency record of 13.2%. The LPC process is performed on a nanocrystalline Si layer on an interlayer stack on glass. The high refractive index of crystalline silicon requires anti-reflective measures to maximize in-coupling of light from the glass superstrate into the c-Si absorber. Ideally, these nanotextures also scatter the incident light in order to trap more light in the absorber – especially at long wavelength. Light trapping is of special importance here because the absorber in LPC-Si solar cells is only 5 – 20 μm thick. Nanotextures for light management at the glass-Si interface can only be placed prior to the LPC process. Hence, they must be smooth in order to ensure LPC-Si with a high electronic quality.

In this contribution we discuss two types of nanostructures situated between glass and LPC-Si: (1) sinusoidal nanotextures and (2) smooth anti-reflective three-dimensional textures (SMART). Both textures are fabricated with nanoimprint lithography and enhance the optical performance of the solar cells. LPC-Si solar cells on these textures have excellent material qualities and hence electric properties, such that open circuit voltages exceeding 615 mV or even 640 mV are measured for sinusoidal or SMART structures, respectively. Numerical results obtained with the finite element method (FEM) match well with experimental data. This was achieved with a numerical correction, which is applied to FEM results a posteriori and allows to adequately take the thick glass superstrate into account at negligible numerical cost.

10356-15, Session 5

Wave front design using multi-scale metasurfaces

Didier Felbacq, Univ. Montpellier (France); Emmanuel Kling, Safran Electronics & Defense (France)

Metasurfaces are the bidimensional analog of metamaterials. There are made of resonant elements deposited on a thin film. They have been shown to allow for the control of polarization of light, in particular through topological effects and to make possible the transmission of a light beam under generalized refraction laws. In the present work, metasurfaces whose period is made of several resonant elements with both electric and magnetic dipoles are considered. A general theory of diffraction is developed and the possibility of optimization towards designing a predifined wavefront are investigated.

To do so, we use multiple scattering theory as well as a singular perturbation approach that allows us to obtain a simple setting of the scattering problem in terms of a generalized impedance operator. This formulation is then used within an optimization algorithm in order to investigate the range of parameters over which a fine control of the transmitted beam can be obtained.

10356-16, Session 5

Asymmetries in surface waves and reflection/transmission characteristics associated with topological insulators

Tom G. Mackay, The Univ. of Edinburgh (United Kingdom); Francesco Chiadini, Univ. degli Studi di Salerno (Italy); Vincenzo Fiumara, Univ. degli Studi della Basilicata (Italy); Antonio Scaglione, Univ. degli Studi di Salerno (Italy); Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

Three numerical studies were undertaken involving plane-wave interactions with topological insulators. In each study, the topologically insulating surface states of the topological insulator were represented by a nonzero surface admittance. Canonical boundary-value problems were solved for the following cases: (i) Dyakonov surface wave propagation supported by the interface of a columnar thin film and an isotropic dielectric topological insulator; (ii) Dyakonov-Tamm surface wave propagation supported by the interface of a structurally chiral material and an isotropic dielectric topological insulator; and (iii) reflection and transmission at the planar interface of a topologically-insulating columnar thin film and vacuum. For studies (i) and (ii) the nonzero surface admittance resulted in asymmetries in the wave speeds and decay constants of the surface waves, while in study (iii) the nonzero surface admittance resulted in asymmetries in the reflectances and transmittances.

10356-17, Session 5

On optical-absorption peaks in a nonhomogeneous dielectric material over a two-dimensional metallic surface-relief grating

Faiz Ahmad, The Pennsylvania State Univ. (United States); Thomas H. Anderson, Benjamin J. Civiletti, Peter B. Monk, Univ. of Delaware (United States); Akhlesh Lakhtakia, The Pennsylvania State Univ. (United States)

The rigorous coupled-wave approach was used to calculate the optical absorption in a dielectric material deposited over a two-dimensional metallic surface-relief grating. The dielectric material was taken to be nonhomogeneous in the direction normal to the mean plane of the grating. The grating corrugations were chosen to be hillocks on a hexagonal grid. The chosen structure should support two types of guided-wave modes: surface-plasmon-polariton (SPP) waves and waveguide modes (WGMs). The absorption varies with the direction, polarization state, and the free-space wavelength of the incident light.

The peaks of absorption were correlated with the excitations of SPP wave modes and WGMs predicted by the underlying canonical boundary-value problems for guided wave propagation. Two cases were considered: (i) a periodic photonic crystal made from layers of silicon oxynitrides of differing composition, and (ii) a solar cell comprising three amorphous-silicon p-i-n junctions.

10356-18, Session 6

New generation all-silica based optical elements for high power laser systems

(Invited Paper)

Tomas Tolenis, Lina Grineviciute, Ctr. for Physical Sciences and Technology (Lithuania); Andrius Melninkaitis, Vilnius Univ. (Lithuania); Algirdas Selskis, Rytis Buzelis, Ctr. for Physical Sciences and Technology (Lithuania); Lina Ma?ule, Vilnius Univ. (Lithuania); Ramutis Drazdys, Ctr. for Physical Sciences and Technology (Lithuania)

Laser resistance of optical elements is one of the major topics in photonics. Various routes have been taken to improve optical coatings, including, but not limited by, materials engineering and optimisation of electric field distribution in multilayers. During the decades of research, it was found, that high band-gap materials, such as silica, are highly resistant to laser light. Unfortunately, only the production of anti-reflection coatings of all-silica materials are presented to this day. A novel route will be presented in materials engineering, capable to manufacture high reflection optical elements using only SiO_2 material and GLancing Angle Deposition (GLAD) method. The technique involves the deposition of columnar structure and tailoring the refractive index of silica material throughout the coating thickness. A numerous analysis indicate the superior properties of GLAD coatings when compared with standard methods for Bragg mirrors production. Several groups of optical components will be presented including anti-reflection coatings, Bragg mirrors, spectral filters and etc. Structural and optical characterisation of the method have been performed and compared with standard methods. All researches indicate the possibility of new generation coatings for high power laser systems.

10356-19, Session 6

Pulsed laser deposition of multiferroic complex oxide superlattices

John G. Jones, Air Force Research Lab. (United States); Zhongqiang Hu, Universal Technology Corp. (United States); Krishnamurthy Mahalingam, UES, Inc. (United States); Lawrence Grazulis, Univ. of Dayton Research Institute (United States); Matthew P. Zielewski, Wright State Univ. (United States); Gerald R. Landis, Univ. of Dayton Research Institute (United States); Yalin Lu, U.S. Air Force Academy (United States); Gail J. Brown, Air Force Research Lab. (United States)

Oxide layered structures that exhibit both polarization and magnetization properties simultaneously at room temperature are of intense interest for applications in information processing, data storage, sensors, actuators and tunable filters. One approach to creating a naturally layered heterostructure of very thin FE and FM layers is to use an Aurivillius phase oxide. The bulk ceramic version of $Bi_5Fe_{0.5}Co_{0.5}Ti_3O_{15}$ has shown the co-existence of polarization and magnetization at temperatures well above room temperature. $Bi_5Fe_{0.5}Co_{0.5}Ti_3O_{15}$ (BFCTO) ceramics exhibits a naturally forming layered structure of perovskite-like layers separated by Bi_2O_2 layers. These bulk ceramic properties led to an interest in further exploring the material's potential for electronic and photonic applications when deposited as crystalline thin films. Using pulsed laser deposition (PLD) and a $Bi_5Fe_{0.5}Co_{0.5}Ti_3O_{15}$ target, desired thicknesses of 30 or 70 nm was achieved using a 248 nm KrF excimer laser, an energy of 450 mJ per pulse, and a background pressure of oxygen. Trends in material properties were identified by systematically varying growth conditions and using in-situ spectroscopic ellipsometry, ex-situ XRD and AFM measurements. A representative TEM with EDS measurement was measured for the sample with best corresponding XRD. The thin films replicated the oxide superlattice structure formed in the bulk ceramic targets.

Optical anisotropy due to perpendicular azimuth serial bi-deposition onto tilted substrates

Matthew Tai, Matthew D. Arnold, Angus R. Gentle, Geoffrey B. Smith, Univ. of Technology, Sydney (Australia)

Angled columnar structures produced by oblique angle deposition (OAD) possess optical polarization effects useful for filters, retarders and polarimeters. The anisotropy of these thin films is intriguing: it arises from the structures formed and is influenced by many factors including bulk refractive index, temperature, deposition rate and tilt angle. Serial bi-deposition (SBD) is an extension of the growth processes involved in OAD, by alternating deposition of thin layers with azimuthal substrate rotation. SBD typically increases the in-plane birefringence, but the relative importance of underlying processes requires further investigation. In this work, silicon nanostructures were constructed by modified SBD with perpendicular azimuths at a tilt angle range 50-80°. The silicon nanostructures were formed off-axis, meaning they did not develop along the deposition axes. The optical anisotropy and void fractions were compared with varying tilt angles to determine the greatest birefringence in these off-axis films. Growth processes and possible applications are discussed.

10356-21, Session 6

Graphene oxide reduction induced by femtosecond laser irradiation

Maren Kasischke, Stella Maragkaki, Evgeny L. Gurevich, Andreas Ostendorf, Ruhr-Univ. Bochum (Germany)

Abstracts should contain enough detail to clearly convey the approach and the results of the research. Accepted abstracts may be published and made available at the meeting. Please submit only 250-word abstracts for review.

Large-scale and low-cost fabrication of graphene is of great interest for employing it in diverse applications due to the outstanding electrical properties of the graphene layers. A promising fabrication method is

the reduction of graphene oxide (GO), which results in a graphene-like material. Beside thermal and chemical methods, reduction of GO can also be achieved photochemically by laser irradiation. In this study, we examine the efficiency of latter method with a fiber laser (1030 nm, 280 fs) in inert atmosphere varying following parameters: laser repetition rate, overlapping rate and fluence. The chemical properties of the irradiated areas were analyzed with Raman and X-ray photoelectron spectroscopy (XPS) while electrical properties were evaluated using contact resistance measurements. We found that, within a wide range of fluences at high overlapping rates, photochemical oxygen reduction can be achieved. However hybridization transition of sp3 to sp2 graphene-like structures only takes place at the upper fluence window of the mentioned range. This finding is in agreement with an existing hypothesis that heat deposition into the material is necessary for structural reorganization of GO.

10356-22, Session 7

Zero-contrast silicon-based metasurfaces: resonance physics and applications *(Invited Paper)*

Yeong Hwan Ko, Robert Magnusson, The Univ. of Texas at Arlington (United States)

Nanopatterned surfaces and films with subwavelength periodicity sustain striking resonance effects as input light couples to leaky Bloch-type waveguide modes. In 1990, we coined the term “guided-mode resonance (GMR)” to clearly communicate the fundamental physics at play. In recent years, traditional GMR resonance devices are often called metasurfaces or metamaterials. These devices can have 1D or 2D periodicity as the resonance is not dependent on the type of periodicity in any fundamental ways. By design, a plethora of differing spectral expressions is available with this device class. Wide parametric design spaces allow control of light amplitude, phase, polarization, near-field intensity, and light distribution on surfaces and within device volumes. Here, we review principles and applications of resonant nanophotonic devices, addressing the considerable divergence in the literature regarding their operational principles. In many cases, the fundamental Bloch-mode aspect of wave propagation in periodic media is dismissed or ignored. The coupling of evanescent diffraction orders that drive the resonant leaky modes is often misunderstood. Rather, local Fabry-Perot or Mie-type modes, naturally generated by the fundamental resonance effects, are taken to be the causal entities behind the observed spectral characteristics. Here, we discuss device design and optimization with rigorous mathematical methods while properly noting the physical processes in play. We present flat-top bandpass filters applying cascaded 1D or 2D GMR structures achieving spectra that are comparable to those found with hundreds of stacked layers. At the resonance wavelength, strong phase dispersion causes flatting of the transmission spectrum. Moreover, wideband unpolarized reflectors are enabled by sequentially arranged GMR devices; we provide both theoretical and experimental spectra pertinent to these. Finally, we present tunable narrow bandpass filters with double GMR structures. For polarization independence, the device is designed by identical orthogonal 1D GMRs. The compact nature and high-efficiency operation of this device class renders attendant technology particularly interesting for applications where minimal, robust, and lightweight devices are desired. The guided-mode resonance concept applies in all spectral regions, from the visible band to the microwave domain, with available low-loss materials.

10356-23, Session 7

Nitrogen doped silicon-carbon multilayer protective coatings on carbon obtained by TVA method

Victor Ciupina, Univ. Ovidius Constanta (Romania) and Academy of Romanian Scientists (Romania) and Univ. of Bucharest (Romania); Eugeniu Vasile, Univ. Politehnica of Bucharest (Romania); Corneliu Porosnicu, National Institute for Laser, Plasma and Radiation Physics (Romania); Gabriel C. Prodan, Univ. Ovidius Constanta (Romania); Cristian P. Lungu, National Institute for Laser, Plasma and Radiation Physics (Romania); Rodica Vladoiu, Univ. Ovidius Constanta (Romania); Ionut Jepu, National Institute for Laser, Plasma and Radiation Physics (Romania); Aurelia Mandes, Virginia Dinca, Aureliana Caraiane, Univ. Ovidius Constanta (Romania); Virginia Nicolescu, Ovidiu Cupsa, Ceronav (Romania); Paul Dinca, National Institute for Laser, Plasma and Radiation Physics (Romania); Agripina Zaharia, Univ. Ovidius Constanta (Romania)

Protective nitrogen doped Si-C multilayer coatings on carbon, used to improve the oxidation resistance of carbon, were obtained by Thermionic Vacuum Arc (TVA) method. The initial carbon layer having a thickness of 100nm has been deposed on a silicon substrate in the absence of nitrogen, and then a 3nm Si thin film to cover carbon layer was deposed. Further, seven Si and C layers were alternatively deposed in the presence of nitrogen ions, each having a thickness of 40nm. In order to form silicon carbide at the interface between silicon and carbon layers, all carbon, silicon and nitrogen ions energy has increased up to 150eV. The characterization of microstructure, electrical and tribological properties of as-prepared N-Si-C multilayer structures were done using Transmission Electron Microscopy (TEM, STEM) techniques, Energy Dispersive X-Ray Spectroscopy (EDXS), Thermal Desorption Spectroscopy (TDS), electrical and tribological measurements. N-Si-C multilayer samples were investigated up to 1000oC. Oxidation protection of carbon is based on the reaction between oxygen and silicon carbide, resulting in SiO2 and CO2, and also by reaction involving N, O and Si, resulting in silicon oxynitride (SiNXOY) with a continuously variable composition, and on the other hand, since nitrogen acts as a trapping barrier for oxygen. The tribological measurements reveal that the friction coefficient on the N-Si-C structures used is smaller than friction coefficient on uncoated carbon layer. To perform electrical measurements, 80% silver filled two-component epoxy-based glue ohmic contacts were attached on the N-Si-C samples. Electrical conductivity was measured in constant current mode. The experimental data show the increase of conductivity with the increase of the nitrogen content. To explain the temperature behavior of electrical conductivity we assumed a thermally activated electric transport mechanism.

10356-24, Session 7

Thin film grating reflector for high power lasers

Jinlong Zhang, Shuaikai Shi, Hongfei Jiao, Bin Ma, Xinbin Cheng, Zhanshan Wang, Tongji Univ. (China)

High reflection (HR) coatings are one of the key components in high power laser systems, and the stress and the thermal effect of HR coatings are always difficult to control and influence the quality of output laser pulse. In this paper we present approaches to realize the HR components based on the concept of thin film gratings. These gratings are composed with the nanostructured thin films of HfO2 and Ta2O5, which is proved to possess quite high laser damage threshold. We discuss the design of such HR gratings with broad bandwidth and optimized electric-field distribution. Several HR gratings will be fabricated and the spectral properties will be measured. Moreover, we will investigate the stress and laser damage characteristics. The possible damage mechanisms of NIR HR gratings are then discussed. Finally, we compare the advantages and challenges of these thin film gratings reflectors with HR coatings for applications in high power laser systems.

10356-25, Session 7

Advanced design of UV waveplates based on nano-structured silica thin films

Lina Grineviciute, Tomas Tolenis, Rytis Buzelis, Ctr. for Physical Sciences and Technology (Lithuania); Mindaugas Andrulevicius, Algirdas Lazauskas, Kaunas Univ. of Technology (Lithuania); Algirdas Selskis, Ramutis Drazdys, Ctr. for Physical Sciences and Technology (Lithuania)

Polymers, solid or liquid crystals and other materials with anisotropic refractive index can be used for production of waveplates. Unfortunately, most of aforementioned materials are fragile, unstable when environmental conditions changes, difficult to apply in microsystems and has low resistance to laser radiation. Retarders, fabricated by evaporation process, do not consist any of these drawbacks. A waveplate can be deposited on micro optics or other optical elements, essentially improving compact optical systems. The range of available materials is limited by absorption losses for waveplates in UV spectral region. Therefore, the full-scale investigation was accomplished with three eligible candidates – LaF_3, Al_2O_3 and SiO_2. Structural (XPS, XRD, SEM) and optical (spectrophotometry, elipsometry) analysis have shown superior properties of silica material for UV waveplate production. Previous researches indicate that the continuous deposition of nano-structured amorphous layer results in considerable optical losses. The expansion and coalescence of individual columns causes significant light scattering in UV spectral region. A novel approach was devised to overcome this drawback. Combination of homogenous and anisotropic all-silica thin films resulted in multilayer waveplate with low optical losses. The design enables to produce transparent (T~99%) UV waveplate with high laser induced damage threshold.

10357-1, Session 1A

Swapping spin currents and spin Hall magnetoresistance *(Invited Paper)*

Michel I. Dyakonov, Univ. Montpellier (France)

Two topics related to spin currents and the Spin Hall Effect [1] will be discussed.

Swapping spin currents [2] is a transformation of spin currents in which the direction of spin and the direction of flow are interchanged. Like the spin Hall effect and the anomalous Hall effect, this phenomenon is caused by spin-orbit interaction. It opens a way of re-directing spin currents.

Spin Hall magnetoresistance [3] is an effect of second order in spin-orbit interaction. It is a result of the combination of the direct and inverse spin Hall effects, and of the Hanle effect (depolarization by magnetic field).

Both effects have aroused considerable interest in recent years. The experimental results (mostly for metals) and the relevant theoretical ideas will be reviewed, open questions and related problems will be discussed

10357-2, Session 1A

Spintronic phenomena arising from bulk and interface spin-orbit interaction *(Invited Paper)*

Kazuya Ando, Keio Univ. (Japan)

Spin-orbit coupling (SOC) in solids plays a crucial role in modern spintronics. When a charge current passes through a heavy metal with strong SOC, electrons with opposite spins are deflected in opposite directions, resulting in the generation of a transverse spin current, which is known as the spin Hall effect. Another source of the charge-spin conversion is the Rashba-Edelstein effect, where a charge flow in a Rashba two-dimensional electron gas results in the creation of a non-zero spin accumulation. Here, we show that the Rashba-Edelstein effect drives a new type of magnetoresistance in a metallic heterostructure: the Rashba-Edelstein magnetoresistance [1]. We show that the simultaneous action of the direct and inverse Rashba-Edelstein effects in a Bi/Ag/CoFeB trilayer couples the current-induced spin accumulation to the electric resistance. We further show that, even when the magnetization is saturated, the resistance increases with increasing the magnetic-field strength, which is attributed to the Hanle magnetoresistance in this system. We also discuss recent experimental observation of enhanced spin-torque generation efficiency in a naturally-oxidized Cu, which is evidenced by measuring the spin-torque ferromagnetic resonance for Py/Cu bilayers [2].

10357-3, Session 1A

Theory of angular momentum transport *(Invited Paper)*

Shufeng Zhang, The Univ. of Arizona (United States)

The angular momentum currents have three distinct forms known as the electron spin current, the incoherent magnon current and the coherent macroscopic magnon current. We present a unified theory to correlate these different angular momentum currents in magnetic multilayered structures by using semi-classical approaches for electrons and magnons. Within each layer, which could be magnetic or non-magnetic and metallic or insulating, the non-equilibrium electron or magnon distributions satisfy the Boltzmann equations for fermions and bosons. The momentum and angular momentum transfer among electrons, incoherent magnons, and order parameters are explicitly taken into account via collision terms. By establishing boundary conditions for spin chemical potentials and the angular momentum current at the interfaces, we determine the distributions and subsequently find the spatial dependence of angular momentum currents. The formalism is applied to various multilayer systems and a few predictions are outlined.

10357-4, Session 1B

Ferromagnetism and spin-dependent transport in NdTiO3/SrTiO3 heterostructures *(Invited Paper)*

Vlad S. Pribiag, Univ. of Minnesota, Twin Cities (United States)

Complex oxide interfaces are a promising platform for studying a wide array of correlated electron phenomena in low-dimensions, including magnetism and superconductivity. The microscopic origin of these phenomena in oxide interfaces remains an open question. Evidence for magnetic order at oxide interfaces has been reported using various experimental techniques, including vibrating sample magnetometry, superconducting quantum intereference magnetometry, neutron scattering, and magneto-transport. Here we investigate electron transport in MBE-grown NdTiO3/SrTiO3 heterostructures as a function of magnetic field and time, at temperatures down to 150 mK. The magnetoresistance (MR) reveals steady-state signatures of ferromagnetic order below ~1.5 Kelvin. Moreover, the MR also shows transient hysteretic features with a characteristic timescale of ~100 seconds. We discuss the importance of time-dependent measurements for distinguishing signatures of magnetism from other effects that can produce hysteretic MR in experiments at low temperatures.

10357-5, Session 1B

Spin-dependant tunnelling in ultrathin Schottky junctions based on La0.66Sr0.33MnO3 / SrTiO3:Nb interfaces *(Invited Paper)*

Philippe Lecoeur, Univ. Paris-Sud 11 (France); Georg Kurij, Ctr. de Nanosciences et de Nanotechnologies (France); Aurélie Solignac, CEA-Ctr. de SACLAY (France); Thomas Maroutian, Institut d'Électronique Fondamentale, Univ. Paris-Sud II (France); Guillaume Agnus, Univ. Paris-Sud 11 (France); Ruben Guerrero, IMDEA Nanociencia (Spain); Laurie E. Calvet, Ctr. de Nanosciences et de Nanotechnologies (France); Myriam Pannetier-Lecoeur, CEA-Ctr. de SACLAY (France)

Since the first observation of tunnelling effect in La0.7Sr0.3MnO3 based magnetic structures, the search for high TMR values has been the main goal of research in this field, aiming at developing high sensitive magnetic sensors. Nevertheless, oxides TMR often have high level of noise when using SrTiO3 as insulating barrier drastically reducing the interest of such devices [1]. Recently we introduced the use of heavily doped n-type semiconductor SrTi0.8Nb0.2O3 as fully depleted layer to form the insulating barrier [2-3]. Magneto-transport properties of the MTJs were studied as a function of applied bias, temperature and barrier thickness. It is found that using semiconducting barrier at the place of the standard insulator, leads to a significantly improved reproducibility of results and in the spectral noise density reduced by three orders of magnitude at low temperature. We ascribe that fact to a strongly reduced amount of defects, such as oxygen vacancies, in doped SrTi0.8Nb0.2O3. This results brings novel opportunities to develop high sensitive magnetic devices working at low temperature.

10357-6, Session 2A

Theory of unidirectional magnetoresistance *(Invited Paper)*

Giovanni Vignale, Steven S. L. Zhang, Univ. of Missouri (United States)

Recent experiments have detected nonlinear unidirectional magnetoresistance (UMR) in metallic bilayers consisting of a heavy metal (HM) and a ferromagnetic metal (FM). That is to say, a small change in the longitudinal resistance of the bilayer has been observed when reversing the direction of either the applied in-plane current or the magnetization. We attribute such nonlinear transport behavior to the spin-polarization dependence of the electron mobility in the FM layer acting in concert with the spin accumulation induced in that layer by the spin Hall current originating in the bulk of the HM layer. An explicit expression for the nonlinear UMR is derived based on a simple drift-diffusion model, which shows that the nonlinear magnetoresistance appears at the first order of the spin Hall angle, and changes sign when the current is reversed, in agreement with the experimental observations. We point out that nonlinear UMR is quite generally expected to arise in non-magnetic spin-orbit coupled electronic materials from the concerted action of current-induced spin polarization and spin-polarization-dependent mobilities. Nonlinear UMR in spin-momentum-locked bands, such as surface states of three-dimensional topological insulators will also be discussed.

10357-7, Session 2A

Spin Hall magnetoresistance and spin orbit torques in metallic heterostructures *(Invited Paper)*

Masamitsu Hayashi, The Univ. of Tokyo (Japan)

Strong spin orbit effects in metallic heterostructures with broken structural inversion symmetry have opened new paradigms to control magnetic moments electrically. In particular, generation of spin current or spin accumulation via the spin Hall effect and/or the Rashba Edelstein effect has attracted great interests as its degree determine the efficiency of current induced control of magnetization via the spin orbit torques. We have studied the spin Hall magnetoresistance and the resulting spin orbit torque in metallic heterostructures to estimate the effective spin Hall angle and the spin mixing conductance of the interface. A large spin Hall magnetoresistance is found in structures that include W and Pt. We have also studied the spin Hall magnetoresistance caused by a temperature gradient applied across the films. We find signatures of the so-called spin Nernst effect in W. Spin current generated from other material systems including chiral antiferromagnets will be discussed.

10357-8, Session 2A

Nonlocal spin diffusion driven by giant spin Hall effect at oxide heterointerfaces *(Invited Paper)*

Jung-Woo Yoo, Mi-Jin Jin, Ulsan National Institute of Science and Technology (Korea, Republic of); Seon Young Moon, Korea Institute of Science and Technology (Korea, Republic of); Jungmin Park, Junhyeon Jo, Ulsan National Institute of Science and Technology (Korea, Republic of); Shin-Ik Kim, Hyun Cheol Koo, Byoung-Chul Min, Korea Institute of Science and Technology (Korea, Republic of); Hyun-Woo Lee, Pohang Univ. of Science and Technology (Korea, Republic of); Seung-Hyub Baek, Korea Institute of Science and Technology (Korea, Republic of)

The conductive interface at LaAlO3/SrTiO3 (LAO/STO) can be designed to exhibit high mobility with tunable carrier concentration and exhibits various unique electronic behaviors. This interface could be also interesting playground for "spin-orbitronics" as the structure itself strongly couple the spin and orbital degree of freedom through the Rashba spin-orbit interaction. One of core experiments toward this direction is the nonlocal spin transport measurement, which has remained elusive due to the low spin injection efficiency to this system. Here we bypass the problem by generating a spin current not through the spin injection from outside but instead through the inherent spin Hall effect and demonstrate the nonlocal spin transport. The Hall-bar (H-bar) like geometry was employed to generate a transverse spin polarized current, which in turn can be detected by the inverse spin Hall effect. Our results clearly demonstrated the non-local spin diffusion as well as effective spin charge conversion at this oxide heterointerface. The non-local spin resistance was confirmed through the signature of a Larmor spin precession and its length dependence. The analysis on the non-local spin voltage displays that both D'yakonov-Perel' and Elliott-Yafet mechanisms involve in the spin relaxation. Our results show that the oxide heterointerface is highly efficient in spin-charge conversion with exceptionally strong spin Hall coefficient ? ? 0.15 ± 0.05 and could be an outstanding platform for the study of coupled charge and spin transport phenomena and their electronic applications.

10357-9, Session 2A

Conditions for the existence of spin to charge current conversion in spin-Hall devices: the Hall bar versus the Corbino disk *(Invited Paper)*

Jean-Eric Wegrowe, Robert Benda, Ecole Polytechnique (France); Miguel Rubi, Univ. de Barcelona (Spain)

We investigate the compatibility of the concept of "charge to spin current conversion" with the second law of thermodynamics in the context of the spin-Hall effect (SHE).

This investigation is performed in the framework of the two spin channel model of the SHE.

It is first shown that the spin-accumulation due to spin-flip scattering at the interface is independent of the We investigate the compatibility of the electric charge to spin current conversion with the second law of the thermodynamics in the spin-Hall effect (SHE).

This investigation is performed in the framework of the two spin channel model of the SHE.

It is first shown that the spin-accumulation due to spin-flip scattering at the interface is independent of the spin-accumulation due to SHE, if the spin-flip scattering length is much larger than the electrostatic screening length [1].

A variational technique based on the least dissipation principle is then applied. We show that, for a bulk paramagnet with spin-orbit interaction, in the case of the Hall bar geometry the principle of minimum dissipated

power prevents the generation of transverse spin and charge currents while in the case of the Corbino disk geometry, transverse currents can be produced. More generally, we show that electric charge accumulation prevents the stationary spin to charge current conversion to occur inside the device [2].

10357-10, Session 2B

Control of ferromagnetism and transport by material growth and wavefunction engineering in ferromagnetic semiconductors and heterostructures

(Invited Paper)

Masaaki Tanaka, The Univ. of Tokyo (Japan)

Ferromagnetic semiconductors (FMSs) have been intensively studied for decades as they have novel functionalities that cannot be achieved with conventional metallic materials, such as the ability to control magnetism by electrical gating or light irradiation [1-3]. Prototype FMSs such as (Ga,Mn) As, however, are always p-type, making it difficult to be used in real spin devices. Here, we demonstrate that by introducing Fe into InAs, it is possible to fabricate a new n-type electron-induced FMS with the ability to control ferromagnetism by both Fe and independent carrier doping. The studied (In1-x,Fex)As layers were grown by low-temperature molecular beam epitaxy on semi-insulating GaAs substrates. Electron carriers in these layers are generated by independent chemical doping of donors. The ferromagnetism was investigated by magnetic circular dichroism (MCD), superconducting quantum interference device (SQUID), and anomalous Hall effect (AHE) measurements. With increasing the electron concentration (n = 1.8?1018 cm-3 to 2.7?1019 cm-3) and Fe concentration (x = 5 - 8%), the MCD intensity shows strong enhancement at optical critical-point energies E1 (2.61 eV), E1 + ?1 (2.88 eV), E0' (4.39 eV) and E2 (4.74 eV) of InAs, indicating that the band structure of (In,Fe)As is spin-split due to sp-d exchange interaction between the localized d states of Fe and the electron sea. SQUID and AHE measurements are also consistent with the MCD results. The Hall and Seebeck effects confirm the n-type conductivity of our (In,Fe)As samples. The electron effective mass is estimated to be as small as 0.03-0.175m0, depending on the electron concentration. These results reveal that the electrons are in the InAs conduction band rather than in the impurity band, allowing us to use the conventional mean-field Zener model of carrier-induced ferromagnetism [4]. This band picture is different from that of GaMnAs [5][6]. Our results open the way to implement novel spin-devices such as spin light-emitting diodes or spin field-effect transistors, as well as help understand the mechanism of carrier-mediated ferromagnetism in FMSs [7-14].

Furthermore, we demonstrate new phenomena in (In,Fe)As and its hetrerostructures: Novel crystalline anisotropic magnetoresistance with two fold and eight fold symmetry [7], and control of ferromagnetism by strain, quantum confinement, gate electric field and wavefunction engineering in quantum heterostructures with a (In,Fe)As quantum well [10-12]. Very recently, we have found a very intriguing phenomenon; sudden restoration of the band ordering associated with the ferromagnetic phase transition in the prototypical ferromagnetic semiconductor GaMnAs [15]. Also, we have successfully grown another narrow-gap p-type III-V-based FMS (Ga,Fe)Sb with high Curie temperature (TC>300K) [16]. Combining different n-type and p-type FMSs will lead to new spin-related functionalities and devices.

This work was carried out in collaboration with Drs. S. Ohya, P. N. Hai, I. Muneta, L. D. Anh, M. Kobayashi, S. Sakamoto, and A. Fujimori. This work was partly supported by Grants-in-Aid for Scientific Research, Project for Developing Innovation Systems of MEXT, and Spintronics Research Network of Japan (Spin-RNJ).

Spin signals in Si non-local transport devices with giant spin accumulation

(Invited Paper)

Ron Jansen, Aurelie M. Spiesser, H. Saito, National Institute of Advanced Industrial Science and Technology (Japan); Y. Fujita, S. Yamada, K. Hamaya, Osaka Univ. (Japan); Shinji Yuasa, National Institute of Advanced Industrial Science and Technology (Japan)

As silicon, the mainstream semiconductor, exhibits only weak spin relaxation, it is the logical material of choice for spin-based semiconductor devices. The electrical injection of a spin accumulation in Si is achieved by ferromagnetic tunnel contacts, whereas non-local (NL) spin transport devices provide a powerful tool to electrically detect spins and determine the important spin-transport parameters. Unfortunately, the observed NL spin signals are usually much smaller (~ 2 orders of magnitude) than predicted by theory. Thus, achieving large spin signals in Si non-local devices is still a major challenge. Moreover, an in-depth comparison of non-local spin signals with theory is still lacking and the connection between non-local spin signals and local 3-terminal (3T) Hanle spin signals has not been established.

Here we report on the electrical signals produced by spin accumulation in Si-based non-local devices having ferromagnetic contacts of various sizes. First, we present the observation of NL spin signals that correspond to a giant spin accumulation of more than 17 meV in the Si channel, and show that the non-local spin signals are in excellent agreement with numerical calculations of spin injection and diffusion, but not with widely used analytical expressions. Secondly, we provide a comprehensive characterization of 3T Hanle spin signals in the same non-local devices, and compare the results with non-local spin-transport data and numerical calculations.

10357-12, Session 2B

Magnetic and superconducting proximity effects on the transport properties of hybrid heterostructures *(Invited Paper)*

Alex Matos-Abiague, Igor Zutic, Univ. at Buffalo (United States)

Interfaces between different materials provide versatile opportunities to study emergent behavior. With the lack of inversion symmetry, the formation of interfacial spin-orbit fields (SOFs) is crucial for novel phenomena, absent or fragile in the bulk. We theoretically investigate the interplay between SOFs and proximity-induced magnetism in hybrid SM/F heterostructures (SM and F stand for semiconductor and ferromagnet, respectively) as well as its effect on spectral and transport properties. The anisotropic spin-dependent transport leads to the emergence of novel magnetoresistive phenomena in planar SM/F multi-terminal devices, where both the longitudinal and transverse Hall-like responses become anisotropic with respect to the orientation of the proximity-induced magnetization. Strategies for increasing the anisotropy of the charge and spin transport are discussed. In order to enhance the device functionalities, we explore, in addition to interfacial SOFs, the role of non-Abelian fields produced by magnetic textures. We also investigate the superconducting proximity effect in SM/S heterostructures (S stands for superconductor), where the interfacial SOFs can lead to the emergence of triplet pairing even for s-type S materials. The signatures of interfacial triple pairs on the supercurrent are analyzed.

Spintronics probed with soft x-rays *(Invited Paper)*

Elke Arenholz, Lawrence Berkeley National Lab. (United States)

The ever increasing importance of spintronics is based on our improved understanding spin based phenomena and our ability to engineer materials with specific materials properties. In this talk, we will highlight the contributions soft x-ray based characterization tools can make to the advancement of spintronics using two recent experiments.

Materials that exhibit simultaneous order in their electric and magnetic ground states hold promise for use in next-generation memory devices in which electric fields control magnetism. Such materials are exceedingly rare and engineering magnetoelectric multiferroic by interleaving two or more atomically thin layers is an intriguing new approach. A very recent example is establishing room temperature coexisting ferromagnetic and ferroelectric order in LuFeO3)m/(LuFe2O4)1 superlattices. [1]

Spin currents are mostly detected indirectly through measurement of spin-torque driven magnetization precession, spin-current induced second harmonic optical effects, inverse spin Hall effect (ISHE), etc. We have recently succeeded in monitoring a pure ac spin current through a Py/Cu/Co multilayer with by x-ray detected ferromagnetic resonance (XFMR) [2]

In both cases, the soft x ray based characterization techniques were crucial and will be discussed.

Operando XMCD experiments: a tool for the investigation of magnetoelectric coupling in multiferroics *(Invited Paper)*

Piero Torelli, Istituto Officina dei Materiali, Consiglio Nazionale delle Ricerche (Italy)

In this work we present an experimental set-up which permits the simultaneous investigation of the magnetic and electronic structure of materials and nanostructures by performing XMCD under applied bias voltage at the APE-HE beamline at Elettra the Italian synchrotron radiation facility [1]. With this technique we investigated the magnetic properties of the Fe/BaTiO3 interface, which is probably the most representative Ferroelectric(FE)/Ferromagnetic(FM) interface. In this work [2] thanks to the chemical sensitivity of the operando XMCD we have observed the formation of iron oxide at the interface that surprisingly shows a magnetic phase transition driven by the FE state of the BaTiO3.

In a second example we investigated the magnetic properties of the LSMO/BTO interface as a function of temperature and of the ferroelectric polarization. In this experiment we were able to separate the effect of strain and of the electric charge of the substrate ferroelectric polarization on the magnetic properties of the FM overlayer. In fact the BTO substrate as a function of temperature change the crystallographic structure inducing different strain on the overlayer, while we have at the same time switched the FE polarization of the substrate while recording XMCD and thus we were able to observe the changes induced by the strain or the charge separately.

Magnetoelectroelastic coupling at artificial multiferroic interfaces probed with soft x-ray techniques *(Invited Paper)*

Rajesh V. Chopdekar, Univ. of California, Davis (United States)

I will present our recent work in studying strain- and charge- mediated magnetoelectric coupling at the interface of ferromagnetic thin films and relaxor ferroelectrics. By using soft x-ray spectroscopy and spectro-microscopy, we have disentangled changes in electric field-driven remanent magnetization states in ferromagnets such as cobalt, nickel, and Sr-doped manganites. X-ray magnetic circular dichroism allows for interrogation of magnetization orientation in an elementally resolved manner, while X-ray magnetic linear dichroism provides insight into anisotropy effects such as anisotropic strain or magneto-crystalline anisotropy orientation. These dichroism effects can be probed as a function of applied electric field, magnetic field, or temperature in a spatially averaged spectroscopy or spatially resolved microscopy geometry (e.g. X-ray photoemission electron microscopy), giving direct evidence of reproducible and reversible room temperature magneto-electric interactions in these systems. Density functional theory calculations give insight into the relative contributions that charge and strain effects have on such artificial multiferroic interfaces. We illustrate that in both metallic and complex oxide ferromagnetic heterostructures that strain-mediated and charge mediated coupling have different interfacial length scales but their co-action results in a strong room temperature magneto-electric interactions.

10357-16, Session 3B

Monolayer transition metal dichalcogenide spin valves *(Invited Paper)*

Bo Hsu, Zheng Yang, Univ. of Illinois at Chicago (United States)

Spin valves with as-grown single-crystalline two-dimensional MX2 (M = Mo, W; X = S, Se) monolayers as spacer layer were fabricated. Ferromagnetic metals Co and permalloy (Py) were used as top and bottom layers in the spin valve devices. The spin valve effects at room- and variable low-temperatures are studied. The tunneling magnetoresistance up to ~0.6%, ~0.7%, ~0.2%, and ~0.2% were observed at room temperature for MoS2,

WS2, MoSe2, and WSe2 spin valve devices, respectively. The tunneling magnetoresistance up to ~0.9%, ~1.4%, ~0.4%, and ~0.4% were observed at 16 K for MoS2, WS2, MoSe2, and WSe2 spin valve devices, respectively. The temperature dependence tunneling magnetoresistance of the spin valves is studied and analyzed. The layer dependence of tunneling magnetoresistance of the spin valves is studied. The PtMn antiferromagnetic-layer coupling effect with Py in the spin valve is studied. The magnetic field angle dependent effect is preliminary studied. The aging effect is studied for spin valve devices measured up to >104 times and for devices measured multiple times with a time span of > 6 months.

10357-17, Session 3B

Magneto-optical spectroscopy of excitons in semiconducting transition metal dichalcogenides *(Invited Paper)*

Ashish Arora, Westfälische Wilhelms-Univ. Münster (Germany)

Semiconducting transition metal dichalcogenides (TMDs) have set a new paradigm for exploring atomic scale phenomena and future spin and valleytronic device applications. In this talk, I will present our recent investigations on TMDs, such as monolayers of WSe2, WS2, and MoTe2 using high-field magneto-optical spectroscopy. We use photoluminescence, photoluminescence excitation and reflectivity measurements to study the valley Zeeman splitting and valley polarization of neutral and charged excitons in these materials under magnetic fields up to 30 T at cryogenic temperatures [1-5]. While in MoTe2, the neutral A and B excitons as well as the charged A excitons show similar valley Zeeman splittings (g-factor ~ -4) [1], a more involved behavior is observed for singlet and triplet charged excitons in WS2 [3,4]. I will also present high-field Zeeman spectroscopy of single-photon emission in WSe2 [5]. Our results shine light on the salient aspects of the spin- and valley-resolved band structure of TMDs.

Spin-valley properties in transition metal dichacogenides monolayers and heterostructures *(Invited Paper)*

Cedric Robert, Gang Wang, Fabian Cadiz, Bernhard Urbaszek, Xavier Marie, Lab. de Physique et Chimie des Nano-objets (France)

The choice of two-dimensional (2D) materials to engineer devices with atomically flat active regions is currently extending beyond graphene to a wide range of semiconductors, insulators, metals and superconductors. Among the various families of 2D materials, semiconductor transition metal dichalcogenide (TMDC) materials MX2 (where M stands for Mo or W and X stands for S, Se or Te) exhibit especially exciting properties when thinned down to one monolayer (ML). In particular, they are ideal systems to study the physics related to the coupled spin-valley degrees of freedom[1]. Indeed, the absence of inversion symmetry and strong spin-orbit coupling along with a direct optical band gap in the visible range enable to selectively excite carriers in the K+ or K- valleys by using polarized excitation.

Here, we will present our experimental results on the creation of valley pseudospin states, coherent superposition and manipulation [2,3,4] in WSe2 and MoS2 monolayers. The population and polarization dynamics of excitons, trions and single carriers will be discussed in regards to our latest measurements in high quality charge tunable devices

Spintronic logic: from switching devices to computing systems *(Invited Paper)*

Joseph S. Friedman, The Univ. of Texas at Dallas (United States)

The most basic elements of a logical computing system are switching devices that can be cascaded to perform complex logic functions. This requires a circuit structure that provides a mechanism by which the output of each switching device can be used as the input to another switching device. This mechanism enables a logic family with the basic logic functions achieved by the switching devices. The unique switching mechanisms that characterize spintronic devices provide new opportunities and challenges for the development of computing systems. In particular, new mechanisms are required through which spintronic switching devices can modulate the switching behavior of other similar devices. The wide variety of physical phenomena underlying spintronic devices enable a range of potential strategies through which devices can be made to interact, including electrical and spin currents, magnetic fields, and voltages. However, it is often difficult to develop techniques that enable these interactions in a manner that permits cascaded logic gates, thus impeding the functionality of a computing system. Several techniques have been developed to cascade spintronic switching devices through a variety of different mechanisms. Many other spintronic switching devices have been proposed for which no cascading mechanism has been identified. The potential operation of several cascading mechanisms in a spintronic computing system is discussed here, particularly in relation to the following logic families: nanomagnet logic (NML), complementary magnetic tunnel junction logic (CMAT), spin-diode logic, emitter-coupled spin-transistor logic (ECSTL), magnetic domain-wall logic, domain-wall MTJ logic, and complementary spin-FET logic. For each logic family, the switching device and cascading mechanism is briefly described, followed by a discussion of the potential for integration into a computing system.

Spintronics: a potential pathway to enable an exponential scaling for beyond-CMOS era *(Invited Paper)*

Jian-Ping Wang, Univ. of Minnesota (United States)

Many key technologies of our society, including artificial intelligence (AI) and big data, have been enabled by the invention of transistor and its ever-decreasing size and ever-increasing integration at a large scale. There is a clear scaling limit to the conventional transistor technology, however. Many recently proposed advanced transistors are also having an uphill fight in lab because of necessary performance tradeoffs and limited scaling potential. In this talk, we argue for a new pathway that could enable exponential scaling for multiple generations. This pathway involves layering multiple technologies that are beyond the available functions of conventional and newly proposed transistors. We believe that this potential pathway is becoming clear through recent worldwide effort. In this talk, I will brief you my group's recent progress on two selected topics along this line, one on the STT-RAM and one on spin logic. Meanwhile I will also introduce a team effort of C-SPIN Center of STARnet program, where systems designers, devices builders, materials scientists and physicist all work under one roof to tackle the scaling issue and overcome key technology barriers. Several successful examples such as the logic in memory, cognitive computing, probabilistic computing and reconfigurable information processing will be discussed.

10357-21, Session 4A

Challenges and opportunities with spin-based logic *(Invited Paper)*

Michael Niemier, X. Sharon Hu, Robert Perricone, Li Tang, Univ. of Notre Dame (United States)

In this presentation, we will discuss work with various spin-based devices that can be used to process information. We will highlight the challenges and opportunities associated with individual devices, as well as computing with spin-based devices in general. A particular focus of this talk will be on how various devices and use cases for said devices might be used to realize non-volatile processors — which may have significant utility in power constrained environments, etc. At the device-level we will focus on structures that have evolved from various SRC, DARPA, and/or NIST initiatives — including nanomagnet logic (NML), all-spin logic (ASL), composite-input magnetoelectric-based logic technology (CoMET), as well as different types of magnetic memories.

10357-22, Session 4A

Energy efficient switching of fixed magnetic skyrmions with an electric field for nanomagnetic computing devices *(Invited Paper)*

Dhritiman Bhattacharya, Md Mamun Al-Rashid, Jayasimha Atulasimha, Virginia Commonwealth Univ. (United States)

Computing device proposals involving the movement of skyrmions with a current have been proposed [1]. Further, stable skyrmions have been demonstrated at room temperature [2].

We propose a novel nanomagnetic computing paradigm based on electric field mediated switching of a fixed magnetic skyrmion through voltage control of magnetic anisotropy (VCMA) without using a magnetic field and establish its feasibility and energy efficiency with rigorous simulations [3]. Such a device is unique as it is based on reversal of fixed skyrmions [3, 4]. Additionally, our modeling shows that, when VCMA is used in conjunction with spin current, the critical current required for reversal can be significantly reduced [5]. Besides being extremely energy efficient, the density of such fixed skyrmions based computing devices can be high as its states can be directly read out by vertically integrating an appropriate magnetic tunneling junction (MTJ). Furthermore, we will discuss:

1) Switching error in memory devices based on reversal of fixed skyrmions in the presence of thermal noise.

2) Possible implementations of neuromorphic computing elements such as spin neuron and synaptic memory using such fixed skyrmion devices.

Acknowledgement: This work is partly funded by NSF CAREER grant CCF-1253370.

Spin-orbit and exchange proximity effects in 2D materials *(Invited Paper)*

Jaroslav Fabian, Denis Kochan, Univ. Regensburg (Germany)

Graphene and novel 2d materials offer new perspectives for spintronics [1]. Graphene can reach spin lifetimes of 1-10 ns, limited currently by spin flips off magnetic moments [2]. However, graphene has no band gap, so its spintronic applications will be limited as a highly efficient spin transfer channel. Heterostructures of graphene and two-dimensional transition-metal dichalcogenides (TMDC) are emerging as systems in which both orbital and spin properties can be controlled by gating, thus offering a materials basis for spintronic applications, such as bipolar spin devices [3]. We have proposed that graphene on TMDCs can be used in optospintronics [4], since the direct gap of TMDCs allows optical spin orientation, with the successive transfer of spin into graphene. But these van der Waals stacks also yield interesting fundamental physics. We have recently shown that graphene on WSe2 exhibits an inverted band structure, which leads to helical edge states in graphene nanoribbons on WSe2 [5], with a bulk spin-orbit gap of about 1 meV, which is giant when compared to 24 micro eV in pristine graphene. In the talk I will also mention our most recent results the proximity effects in bilayer graphene as well as on engineering the proximity exchange in graphene and TMDCs in tunnel junctions with ferromagnetic metals [6]. I acknowledge support from EU Graphene Flagship and the DFG SFB 689.

First principles investigation of the Co(0001)/MoS2 and Ni(111)/WSe2 interfaces for spin injection in a transition metal dichalcogenide monolayer *(Invited Paper)*

Lionel Calmels, Ctr. d'Elaboration de Matériaux et d'Etudes Structurales (France); Thomas Garandel, Ctr. d'Elaboration de Matériaux et d'Etudes Structurales, Ctr. National de la Recherche Scientifique (France) and Lab* de Physique et Chimie des Nano-objets, Institut National des Sciences Appliquées de Toulouse (France); Rémi Arras, Ctr. d'Elaboration de Matériaux et d'Etudes Structurales (France); Xavier Marie, Lab. de Physique et Chimie des Nano-objets (France); Pierre Renucci, Institut National des Sciences Appliquées de Toulouse (France)

The valley index in two-dimensional semiconducting transition metal dichalcogenide (TMDC) monolayers (MoS2, WSe2 ...) [1] could constitute a novel degree of freedom to process information. Electrical generation and control of valley-polarized carriers, constitutes a key point for the use of this valley degree of freedom in nanoelectronics, and yet remains a formidable challenge [2]. Due the unique correlation between spin and valley indices of electric carriers in these materials [3], this crucial step is directly linked to the ability to electrically inject spin polarized carriers in the TMDC layer. Ferromagnetic metals constitute good potential candidates for such an injection. We used first principles methods based on the density functional theory to investigate the atomic and electronic structure at the Co(0001)/MoS2 and Ni(111)/WSe2 interfaces. Covalent bonding between the magnetic metal surfaces and S or Se atoms strongly modify the electronic structure of the TMDC layers, which behave like metals at the interface with Co or Ni. We give details on the magnetic moments, on the nature and spin-polarization of the electron states at the Fermi level and on the Schottky barrier height. These interfaces could be used to promote electrical spin-injection from a Co or Ni electrode to a single TMDC layer.

A comparative spectroscopic study of the charge density wave features in 2H-NbSe2 and 2H-TaS2 *(Invited Paper)*

Utpal Chatterjee, Junjing Zhao, Kapila Wijayaratne, Univ. of Virginia (United States)

Recent studies of incommensurate Charge Density Wave (CDW) order in TMDs, e.g., 2H-NbSe2 and 2H-TaSe2, have provided intriguing results. For example, spectroscopic measurements, using Angle Resolved Photoemission Spectroscopy (ARPES), have revealed that the CDW energy gap of 2H-NbSe2 opens up around selected regions of the Fermi surface (FS). FS nesting was shown not to drive the CDW instability in 2H-NbSe2. Moreover, particle-hole asymmetric CDW energy gap in 2H-NbSe2 persist even at temperatures (T's) greater than CDW transition temperature (Tcdw), reminiscent of the famous pseudogap behavior in underdoped cuprate high temperature superconductors (HTSCs).

In the light of the above described developments in our understanding of 2H-NbSe2 and 2H-TaSe2, and the close parallel between these systems and cuprate HTSCs, an important question emerges: which of the above described experimental observations are universal attributes of incommensurate CDW systems? In order to address this, we present here a comparative study of the CDW properties as a function of T and momentum (k) in 2H-TaS2 and 2H-NbSe2, which are two prototype incommensurate CDW systems.

Our conclusions are as follows: (i) like in 2H-NbSe2, the CDW gap in 2H-TaS2 is particle-hole asymmetric and it persists above Tcdw; (ii) in contrast to 2H- NbSe2, the gap in 2H-TaS2 is clearly visible along both K-centered FS barrels; (iii) the difference between the momentum anisotropy and FS specificity of energy gap in 2H-TaS2 and 2H-NbSe2 can be understood in terms of the difference in orbital selectivity of the electronic states responsible for their individual CDW orders.

10357-101, Session 4B

Nature of the electromagnetic force between classical magnetic dipoles *(Invited Paper)*

Masud Mansuripur, College of Optical Sciences, The Univ. of Arizona (United States)

The force exerted by one magnetic dipole on another is capable of performing mechanical work, which appears to be in violation of the Lorentz force law of classical electrodynamics. The discrepancy is resolved if one examines the model of a magnetic dipole as an Amperian current loop, which allows for the balancing of the translational kinetic energy gained (or lost) by the moving current loop against its rotational kinetic energy. This problem will be analyzed in some detail, where we show that the change in the loop's rotational kinetic energy is also related to its changing magnetic dipole moment in accordance with Larmor's diamagnetic susceptibility of the loop. We proceed to address the question of what would happen if a magnetic dipole failed to behave as an Amperian current loop. This brings up an alternative model of magnetism and magnetic dipoles, which will be treated in the context of the Einstein-Laub formulation of the classical theory. We examine the electromagnetic (EM) energy of an immobile magnetic dipole in the presence of an externally-applied static magnetic field. Two approaches to EM energy, the Lorentz approach (which considers magnetic dipoles as Amperian current loops), and the Einstein-Laub approach (which treats such dipoles as pairs of north-south magnetic monopoles) will be considered. We extend the discussion to the case of moving magnetic dipoles within a static magnetic field. The predictions of the Lorentz and Einstein-Laub formulations will turn out to be in complete agreement in all the cases considered.

10357-26, Session 5

Rashba effect on the photophysical properties of hybrid perovskites and topological insulators

(Invited Paper)

Andrew M. Rappe, Liang Z. Tan, Univ. of Pennsylvania (United States); Fan Zheng, Lawrence Berkeley National Lab. (United States); Shi Liu, Carnegie Institution for Science (United States); Youngkuk Kim, Univ. of Pennsylvania (United States); Maya Isarov, Efrat Lifshitz, Technion-Israel Institute of Technology (Israel)

In this talk, our focus is on the interplay of the Rashba effect with the photo-physics of semiconductors, including topological insulators. The influence of the Rashba effect on the electronic excited state is two-fold: firstly, the internal energy levels of the excited state (i.e. excitonic levels) may be modified by the spin-orbit interaction, and secondly, the lifetime of the excited state may change when a Rashba effect is present. Using first-principles electronic structure calculations and effective models, we show that both of these effects are present in the hybrid perovskites. Our magneto-optical measurements on CsPbBr3 reveal non-linear Zeeman splitting of the excitons as a result of the Rashba effect. We predict that carrier lifetimes are enhanced in the hybrid perovskites by opposing spin orientations of the conduction and valence Rashba bands.

We also consider the shift current bulk photovoltaic effect, which, like Rashba, only exists in non-centrosymmetric systems. We show that a crossing of Rashba bands results in a topological phase transition in a class of materials, including some halide perovskites, producing a ferroelectric topological insulator. At this band inversion transition, the magnitude of the shift current is sharply, and the direction of the shift current changes sign abruptly. We demonstrate that this effect is robust across different materials systems including layered BiTeI and perovskite CsPbI3.

10357-27, Session 5

Current-nonlinear magnetotransport and spin-orbit torque magnetization switching in a magnetic topological insulator *(Invited Paper)*

Kenji Yasuda, The Univ. of Tokyo (Japan); Atsushi Tsukazaki, Tohoku Univ. (Japan); Ryutaro Yoshimi, RIKEN (Japan); Kouta Kondou, RIKEN Ctr. for Emergent Matter Science (Japan); Kei S. Takahashi, RIKEN (Japan); YoshiChika Otani, Masashi Kawasaki, The Univ. of Tokyo (Japan); Yoshinori Tokura, RIKEN (Japan)

Efficient electrical reading and writing of the magnetization direction is one of the central research target in spintronic devices. Recently, topological insulator (TI) has attracted considerable attention because of the large spin Hall angle based on the spin-momentum locking at the surface state. Here, we report large current-nonlinear magnetotransport and efficient spin-orbit torque magnetization switching in magnetic/nonmagnetic TI heterostructures, $Cr_x(Bi_{1?y}Sb_y)_{2?x}Te_3/(Bi_{1?y}Sb_y)2Te_3$. Current-nonlinear, or current-direction dependent magnetoresistance is a recently discovered phenomenon called unidirectional magnetoresistance (UMR), which allows us to electrically read the magnetization direction with two-terminal geometry. The magnitude of the UMR is shown to be several orders of magnitude larger than those in other FM/NM heterostructures. From the angular, magnetic field and temperature dependence, the large

UMR is identified to originate from the asymmetric scattering of surface Dirac electrons by magnons, what we call asymmetric magnon scattering mechanism. Moreover, we find comparable magnitude of current-nonlinear Hall effect, or second harmonic Hall voltage. Although second harmonic Hall voltage has conventionally been attributed to the magnetization oscillation by spin-orbit torque (SOT), detailed study has revealed that the large voltage in TI heterostructure originates not from SOT but mainly from asymmetric magnon scattering mechanism without macroscopic magnetization oscillation. This means that the second harmonic Hall voltage method does not allow an accurate estimation of spin Hall angle. Instead, the SOT contribution in TI heterostructure is exemplified by current-pulse-induced non-volatile magnetization switching. The required current density is ~2.5 ? 10^{10} A/m^2, which is much smaller than other materials, showing its potential as spintronic materials.

10357-28, Session 5

Voltage-driven magnetization control in topological insulator/magnetic insulator heterostructures *(Invited Paper)*

Michael E. Flatté, The Univ. of Iowa (United States)

A major barrier to the development of spin-based electronics is the transition from current-driven spin torque, or magnetic-field-driven magnetization reversal, to a more scalable voltage-driven magnetization reversal. To achieve this, multiferroic materials appear attractive, however the effects in current materials occur at very large voltages or at low temperatures. Here the potential of a new class of hybrid multiferroic materi- als is described, consisting of a topological insulator adjacent to a magnetic insulator, for which an applied electric field reorients the magnetization. As these materials lack conducting states at the chemical potential in their bulk, no dissipative charge currents flow in the bulk. Surface states at the interface, if present, produce effects similar to surface recombination currents in bipolar devices, but can be passivated using magnetic doping. Even without conducting states at the chemical potential, for a topological insulator there is a finite spin Hall conductivity provided by filled bands below the chemical potential. Spin accumulation at the interface with the magnetic insulator pro- vides a torque on the magnetization. Properly timed voltage pulses can thus reorient the magnetic moment with only the flow of charge current required in the leads to establish the voltage. If the topological insulator is sufficiently thick the resulting low capacitance requires little charge current.

10357-29, Session 5

Superconductivity provides access to the chiral magnetic effect of an unpaired Weyl cone *(Invited Paper)*

Thomas O'Brien, Carlo W. J. Beenakker, Leiden Univ. (Netherlands); Inanc Adagideli, Sabanci Univ. (Turkey)

The massless fermions of a Weyl semimetal come in two species of opposite chirality, in two cones of the band structure. As a consequence, the current j induced in one Weyl cone by a magnetic field B (the chiral magnetic effect, CME) is cancelled in equilibrium by an opposite current in the other cone. Here we show that superconductivity offers a way to avoid this cancellation, by means of a flux bias that gaps out a Weyl cone jointly with its particle-hole conjugate. The remaining gapless Weyl cone and its particle-hole conjugate represent a single fermionic species, with renormalized charge $e^\ast$ and a single chirality $\pm$ set by the sign of the flux bias. As a consequence, the CME is no longer cancelled in equilibrium but appears as a supercurrent response $\partial j/\partial B=\pm(e^\ast e/h^2)\mu$ along the magnetic field at chemical potential μ.

10357-30, Session 5

Emergent nanoscale superparamagnetism and electronic phase separation at oxide interfaces *(Invited Paper)*

Eli Zeldov, Weizmann Institute of Science (Israel)

Atomically sharp oxide heterostructures exhibit a range of novel physical phenomena that do not occur in the parent bulk compounds including conducting, superconducting, and magnetic states. We present a new emergent phenomenon at the $LaMnO_3/SrTiO_3$ interface in which an antiferromagnetic insulator abruptly transforms into a superparamagnetic state. Above a critical thickness of $LaMnO_3$ of five unit cells, our scanning nanoSQUID-on-tip microscopy [1] shows spontaneous formation of isolated magnetic islands with in-plane moment of 10^4 to 10^5 ?_B with characteristic diameter of 10 to 50 nm [2]. The nanoscale islands display superparamagnetic dynamics of random moment reversals by thermal activation or in response to an in-plane magnetic field. We propose a charge reconstruction model of the polar $LaMnO_3/SrTiO_3$ heterostructure which describes a sharp emergence of thermodynamic phase separation leading to nucleation of metallic ferromagnetic islands in an insulating antiferromagnetic matrix. The model suggests that a gate tunable superparamagnetic-ferromagnetic transition can be induced, holding potential for applications in magnetic storage and spintronics.

Spin-orbit splitting in quantum wells and 2D topological insulators *(Invited Paper)*

Mikhail Nestoklon, Ioffe Institute (Russian Federation)

We discuss the results of recent theoretical studies of the spin structure of free carriers in semiconductor structures. In addition to spin-orbit splitting of the spectrum of bulk materials, in 2D systems, the spin degeneracy of the levels is lifted in presence of lateral wave vector. The linear spin splitting of the energy levels is important for spin relaxation in quantum well structures because the dominant mechanism of spin relaxation in 2D structures relies on the connection between spin and electron momentum. Also, it is important for description of states in semiconductor-based 2D topological insulators because the structure of the levels strongly depends on the spin-orbit interaction.

Combining the envelope function theory and atomistic tight-binding approach, we calculate spin-orbit splitting constants for realistic quantum wells, study the relative importance of the interface and the bulk contributions to the spin splitting; show that the strain due to lattice mismatch is important in both conventional GaAs/AlGaAs and InGaAs/GaAs structures; and describe the fine structure of Dirac states in the HgTe/CdTe quantum wells of critical and close-to-critical thicknesses.

10357-32, Session 6

Dynamical quantum anomalous Hall effect in the intense optical field regime *(Invited Paper)*

Wang-Kong Tse, The Univ. of Alabama (United States)

Topological insulators are characterized by the quantum anomalous Hall effect on the topological surface states under time-reversal symmetry breaking. While this effect has been recently observed in a magneto-optical setup upon illumination of weak linearly polarized light, the influence of intense optical field remains largely unexplored. Using the Keldysh-Floquet

Green's function formalism, we develop a theory for the dynamical Hall conductivity for arbitrary incident optical frequency in the intense optical field regime. We apply our general theory to the adiabatic, low-frequency regime, and study the breakdown of the one-half Hall quantization under intense optical field. Our results reveal a strong nonlinear dependence of the dynamical Hall conductivity on the incident optical field, which is triggered by the formation of Floquet subbands and the transitions between them.

10357-33, Session 6

Emergent orbitronics and dissipationless magnetization control in complex magnets *(Invited Paper)*

Jan-Philipp Hanke, Institut für Fortgeschrittene Simulation, Forschungszentrum Jülich GmbH (Germany); Dongwook Go, Pohang Univ. of Science and Technology (Korea, Republic of); Patrick Buhl, Frank Freimuth, Stefan Blügel, Yuriy Mokrousov, Institut für Fortgeschrittene Simulation, Forschungszentrum Jülich GmbH (Germany)

The topological properties of magnets, encoded in the reciprocal space distribution of the Berry phase, have caused a revolution in our understanding of their transport properties.

The discovery that the non-trivial geometry of states in a solid is ultimately related to the orbital properties of electrons allows us to predict from theoretical arguments a pronounced orbital magnetism in various situations ranging from Rashba systems to Chern insulators. Moreover, we demonstrate that a combination of complex geometry in real and reciprocal spaces leads to an emergence of topological orbital magnetism in non-collinear magnets, which overall opens new vistas in large current-induced orbital magnetization response and magnetization manipulation in antiferromagnets. Finally, we predict that in insulating systems with non-trivial topologies the strength of the magneto-electric response as manifested in the magnitude of the current-induced spin-orbit torques and Dzyaloshinskii-Moriya interaction can exceed significantly that of conventional metallic magnets, which opens new perspectives in dissipationless control of magnetization in magnetic materials.

In order to generate spin current in spintronic devices it is needed to find an efficient way to transform charge current into spin current and make the opposite conversion to detect spin current. Classical spintronics generally uses magnetic materials for such conversions but they can be obtained by exploiting the spin-orbit coupling in materials containing heavy atoms. An efficient current conversion can be obtained through Spin Hall Effect (and Inverse Spin Hall Effect) in heavy metals such as Pt or Ta. Yet a more efficient conversion can be obtained by exploiting the Rashba Edelstein Effect in two dimensional electron gas at surfaces and interfaces such as Rashba Interfaces and newly discovered materials topological insulators. Among these systems the Rashba interface STO/LAO and various topological insulators allows to obtain spin to charge current conversion one order of magnitude bigger than in Spin Hall Effect materials. These results suggest that surfaces and interfaces have a strong potential for spintronics, both for the generation or detection of spin currents through direct or inverse Edelstein effects.

An emerging direction in oxide research aims at discovering novel electronic phases at interfaces between two oxide materials. A well-known example is the STO/LAO system where a high-mobility two-dimensional electron system forms at their interface. Interestingly, LAO/STO possesses several remarkable extra functionalities, including a gate-tunable Rashba effect, which makes it particularly appealing for spintronics.

Another emerging field in spintronics is the conversion at the surface and interface states of Topological Insulator which are characterized by a locking between spin and momentum associated with a helical spin configuration of the Fermi contour. Recently discovered 3D topological insulators such as strained ?-Sn and HgTe could perform high spin to charge current conversion at room temperature.

Evidence for a common origin of spin-orbit torque and the Dzyaloshinskii-Moriya interaction at a Py/Pt interface *(Invited Paper)*

Andrew Berger, Eric R. J. Edwards, Hans T. Nembach, Justin M. Shaw, National Institute of Standards and Technology (United States); Alexy D. Karenowska, Univ. of Oxford (United Kingdom); Mathias Weiler, Walther-Meissner-Institute (Germany); Thomas J. Silva, National Institute of Standards and Technology (United States)

Spin-orbit coupling (SOC) can drive non-equilibrium spin-charge conversion through the reciprocal processes of current-driven spin torque and spin precession-driven current in ferromagnet/heavy metal (FM/HM) bilayers. Both damping-like and field-like spin-orbit torques (SOT) have been observed in the forward process of current-driven SOT, but details of the underlying physics are still debated. SOC also underlies the equilibrium antisymmetric exchange coupling, a.k.a. the interfacial Dzyaloshinskii-Moriya

interaction (DMI). It was recently proposed that a Rashba Hamiltonian at FM/HM interfaces serves as a common origin for both SOT and DMI, with a simple quantitative relation between the two. Here, we verify this relation by comparing inverse SOT (iSOT) measurements with previous characterization of DMI via spin wave spectroscopy. To perform the iSOT measurements, we have developed a technique for quantitative vector network analyzer ferromagnetic resonance to inductively detect the AC charge currents produced by spin-charge conversion processes in FM/HM bilayers. Our findings reveal that Py/Pt bilayers exhibit both damping-like and field-like iSOT, consistent with the presence of inverse spin Hall effect and Rashba-Edelstein effect, respectively.

10357-37, Session 7A

Theory of spin loss at metallic interfaces *(Invited Paper)*

Kirill D. Belashchenko, Giovanni G. Baez Flores, Alexey A. Kovalev, Univ. of Nebraska-Lincoln (United States); Mark van Schilfgaarde, King's College London (United Kingdom)

Interfacial spin-flip scattering plays an important role in magnetoelectronic devices. Spin loss at metallic interfaces has usually been quantified by matching the magnetoresistance data for multilayers to the Valet-Fert model, while treating each interface as a fictitious bulk layer whose thickness is $delta$ times the spin-diffusion length. However, the relation between the parameter $delta$ and the scattering properties of the interface has been missing. We establish this relation using the properly generalized magnetoelectronic circuit theory, for both normal and ferromagnetic interfaces. It is found that the parameter $delta$ extracted from the measurements on multilayers scales with the square root of the probability of spin-flip scattering. The spin-flip scattering probabilities are calculated for several specific interfaces using the Landauer-Büttiker method based on the first-principles electronic structure, and the results are compared with experimental data.

10357-38, Session 7A

Green's function formulation of spin pumping *(Invited Paper)*

Gen Tatara, RIKEN Ctr. for Emergent Matter Science (Japan)

Current pumping by an external potential is studied on the basis of the Keldysh Green's function method, and a pumping formula written in terms of retarded and advanced Green's functions is obtained. The formula is used to study the spin pumping effect in the case of strong s-d exchange interaction, and the driving field is identified to be the spin gauge field. At the lowest order in the precession frequency of magnetization, the spin gauge field works as a constant potential, and the system is shown to reduce to a static problem of spin current generation by a time-independent potential with off-diagonal spin components.

We theoretically explore the optical properties of a bulk Rashba conductor by calculating the transport coefficients at finite frequencies. It is demonstrated that the combination of direct and inverse Edelstein effects leads to a softening of the plasma frequency for the electric field perpendicular to the Rashba field, resulting in a hyperbolic electromagnetic metamaterial. In the presence of magnetization, a significant enhancement of anisotropic propagation (directional dichroism) is predicted because of the interband transition edge singularity. On the basis of an effective Hamiltonian analysis, the dichroism is demonstrated to be driven by toroidal and quadratic moments of the magnetic Rashba system.

10357-39, Session 7A

Auto-oscillation and spin-wave propagation in ultra-thin YIG microstructures *(Invited Paper)*

Martin Collet, Paolo Bortolotti, Vincent Cros, Abdelmadjid Anane, Unité Mixte de Physique CNRS/Thales (France) and Univ. Paris-Sud 11 (France) and Univ. Paris-Saclay (France); José Luis Prieto, Instituto de Microelectrónica de Madrid (Spain); Manuel Muñoz, Instituto de Sistemas Optoelectrónicos y Microtecnología (Spain); Jamal Ben Youssef, Lab. de Magnétisme de Bretagne, CNRS, Univ. de Bretagne Occidentale (France); Vladimir Naletov, Commissariat à l'Énergie Atomique (France) and Ctr. Miheev Institute of Metal Physics, Ural Branch of Russian Academy of Sciences (Russian Federation); Sergej O. Demokritov, Vladislav E. Demidov, Westfälische Wilhelms-Univ. Münster (Germany)

In recent years, Spin Orbit interaction as a source of spin current has been widely used through the physics of Spin Hall Effect (SHE). The peculiar symmetry of SHE allows creating a spin accumulation at the interface between a spin-orbit metal and a magnetic insulator that could lead to a net pure spin current flowing from the metal into the insulator. This spin current will induce a torque on the magnetization and eventually could drive it into steady motion. As a ferromagnetic insulator with a very low Gilbert damping, Yttrium Iron Garnet (YIG) is a very promising candidate to investigate pure spin current phenomena. Only very recently, with the developments in preparation of high-quality nanometer-thick YIG films, the implementation of insulator-based spin-torque devices became practically feasible.

Here, we report on the excitation of auto-oscillations in microstructures of YIG(20nm)Pt(8nm) driven by Spin Orbit torque (SOT). By injection of a dc current in the adjacent Pt layer, we have been able to prove that the SOT due to SHE is sufficiently strong and efficient to drive the YIG magnetization dynamics at frequencies that closely follow the ferromagnetic resonance mode. These auto-oscillations have been detected either inductively using a spectrum analyzer or directly observed using micro-focus Brillouin Light Scattering. Furthermore, we achieved an efficient control of spin waves attenuation length in a YIG waveguide using the SHE in the sub-critical regime i.e. below the auto-oscillations threshold. We believe that our finding pave the path to active magnonics devices made out of YIG films.

10357-40, Session 7B

Understanding magnetization relaxation dynamics in half ferromagnet La0.66Sr0.33MnO3 *(Invited Paper)*

Giancarlo Panaccione, Consiglio Nazionale delle Ricerche (Italy)

We present a pump-probe Hard X-ray Photoemission (HAXPES) study of the magnetic relaxation dynamics of LSMO thin films. We study the structure of the Mn 2p core level and, in particular, the bulk-only screening satellites proportional to the metallic and ferromagnetic state in LSMO [7-10]. We observe a large and 'slow' reduced lineshape change up to 200 picoseconds after the IR pumping. By comparison with all-optical techniques (Time-Resolved Magneto-Optical Kerr effect, TRMOKE) we are able to attribute

the observed quenching to a collapse of magnetic order. The sudden demagnetization reduces the mobility of electrons in the solid, inducing a localization similar to a metal-insulator transition. We are able to follow the relaxation dynamics as the energy is first dissipated in the lattice and then in a reduction of the magnetic order.

10357-41, Session 7B

Ultrafast electrical switching of ferrimagnetic metals *(Invited Paper)*

Richard Wilson, Univ. of California, Riverside (United States); Yang Yang, Jon Gorchon, Univ. of California, Berkeley (United States); Charles-Henri Lambert, Univ. of California, Riverside (United States); Sayeef Salahuddin, Jeffrey Bokor, Univ. of California, Berkeley (United States)

When electrons in a magnetic metal are driven far from equilibrium via ultrafast heating of the electrons, the magnetic order undergoes radical changes within tens of femtoseconds due to massive flows of energy and angular momentum between electrons, spins, and phonons. In ferrimagnetic metals such as GdFeCo, ultrafast optical heating can deterministically reverse the magnetization in less than a picosecond. In this talk, I describe our experimental work to gain a better understanding of how energy is exchanged between electrons, phonon, and spins in a magnetic metal following ultrafast heating. We use time-resolved measurements of the magneto-optic Kerr effect to record the response of ferro- and ferri-magnetic metals to heating via ultrafast optical or electrical pulses. Picosecond electrical pulses are generated with photoconductive Auston switches. By comparing the magnetic dynamics that result from electrical vs. optical heating, we identify differences in the rate of energy transfer to phonons from thermal vs. nonthermal electrons. We also find that both optical and electrical heating are effective for ultrafast switching of ferrimagnetic metals. We observe deterministic, repeatable ultrafast reversal of the magnetization of a GdFeCo thin film with a single sub-10 ps electrical pulse. The magnetization reverses in ~10 ps, which is more than one order of magnitude faster than other electrically controlled magnetic switching mechanisms.

Measuring ultrafast magnetisation dynamics in the sub 10 femtosecond regime *(Invited Paper)*

David Schmool, Univ de Versailles Saint-Quentin-en Yvelines (France); Helder M. Crespo, Ana S. Vieira Silva, David Navas, Francisco Silva, Univ. do Porto (Portugal); Miguel Miranda, Lund Univ. (Sweden); Aurelio Hierro Rodriguez, Univ. do Porto (Portugal); Cledson S. L. Gonçalves, Univ. Federal do Pará (Brazil)

Current time-resolution-limited dynamic measurements clearly show the necessity for improved techniques to access magnetic processes on the sub-10-femtosecond timescale. To access this regime, we have designed and constructed a state-of-the-art time-resolved magneto-optic Kerr effect apparatus, based on a new dual-color scheme, for the measurement of ultrafast demagnetisation and precessional dynamics in magnetic materials. This system can operate well below the current temporal ranges reported in the literature, which typically lie in the region of around 50 fs and above. We have used a dual-colour scheme, based on ultra broadband hollow-core fibre and chirped mirror pulse compression techniques, to obtain unprecedented sub-8-fs pump and probe pulse durations at the sample plane [1]. We will demonstrate the application of our system using ultrafast demagnetisation and precessional dynamics in thin magnetic films of GdCoFe and Ni. In particular we will show that a sub-10-fs laser pulse can be used to efficiently initiate magnetisation excitations.

10357-43, Session 7B

Non-equilibrium magnetic effects at interfaces for ultrafast dynamics *(Invited Paper)*

Ilya Razdolski, Alexandr Alekhin, Nikita Ilin, Fritz-Haber-Institut der Max-Planck-Gesellschaft (Germany); Jan P. Meyburg, Univ. Duisburg-Essen (Germany); Vladimir Roddatis, Institut für Materialphysik, Georg-August-Univ. Göttingen (Germany); Detlef Diesing, Uwe Bovensiepen, Univ. Duisburg-Essen (Germany); Alexey Melnikov, Fritz-Haber-Institut der Max-Planck-Gesellschaft (Germany)

Representing the future of spintronics, femtosecond spin current (SC) pulses constitute a versatile tool to transfer spin and control magnetization on the ultrafast timescale. It is therefore of paramount importance to understand the kinetics of these pulses and the fundamentals of their interaction with magnetized media. In our work, we demonstrate the key role of interfaces for the SC dynamics in Fe/Au/Fe multilayers. In particular, we argue that both (i) demagnetization caused by a pulse of hot electrons and (ii) spin transfer torque exerted by the orthogonal to the Fe magnetization projection of magnetic moment delivered by SC pulse are localized in the vicinity of the Fe/Au interface. We analyze both processes in details, showing that the SC-driven excitation of the sub-THz spin wave dynamics in Fe film is enabled by the spatial confinement of the exerted spin transfer torque. Moreover, a pulse of hot electrons leads to the efficient demagnetization of the Fe film. By disentangling the magneto-optical Kerr effect (MOKE) transients we demonstrate the strong spatial non-uniformity of this demagnetization. We argue that simultaneous recording of transient MOKE rotation and ellipticity is crucial for drawing such conclusions. Our findings have a twofold impact: firstly, they illustrate rich opportunities of utilizing SC pulses for manipulation of magnetization in ferromagnets and, secondly, they highlight the importance of spatial localization for understanding the ultrafast spin dynamics in multilayers.

10357-44, Session 8A

Studying pure spin currents in weakly spin-orbit coupled materials using the pulsed ferromagnetic resonance driven inverse spin-Hall effect *(Invited Paper)*

Christoph M. Boehme, Marzieh Kavand, Kipp J. van Schooten, Dali Sun, Hans Malissa, Chuang Zhang, Matthew Groesbeck, Z. Valy Vardeny, The Univ. of Utah (United States)

Spin-orbit coupling (SOC) and the spin diffusion length in condensed matter are crucial parameters for spintronics applications. In order to study these, we have succeeded in employing a pulsed spin-pumping method based on ferromagnetic resonance (FMR) to generate pure spin currents from ferromagnetic (FM) substrates into non-FM semiconductor layers [1] which can then be detected through the inverse spin-Hall effect (ISHE). When the FM is in FMR with a pulsed microwave (MW) excitation, a pure spin-current is generated in the non-FM layer which can circumvent potential impedance mismatches between the FM and the non-FM layer and, therefore generate a strong pulsed ISHE signal. Due to the low duty cycle of the pulsed excitation, MW excitation powers can be used that are strong enough to generate pronounced ISHE signals even in materials with weak SOC such as carbon-based materials. This sensitivity allows for the study of the quantitative nature of the ISHE and thus, to apply scrutiny to a number of questions about the ISHE effect in general, including how strongly FMR-driving field inhomogeneities affect a measured ISHE current, the relationship of ISHE voltages to the ISHE current in devices consisting of layers with different conductivities, as well the experimental conditions which have to be monitored during an ISHE experiment in order to ensure reproducibility.

This work was supported by the National Science Foundation (DMR-

1404634 – Sample preparation and Experiments) and the NSF-Material Science & Engineering Center (DMR-1121252- Polymer Synthesis and Facilities) at the University of Utah.

10357-45, Session 8A

Spin transfer torque mechanisms in three terminal spin-torque oscillators *(Invited Paper)*

Emilie Jué, National Institute of Standards and Technology (United States)

The manipulation of magnetization by an electric current can be obtained thanks to the spin-transfer torque (STT) phenomenon. The two main mechanisms that give rise to this phenomenon are the spin filtering torque (SFT) and the spin-orbit torque (SOT). The former is obtained in multilayer systems by passing a spin-polarized current through the multilayers, whereas the latter is achieved through a direct transfer of angular momentum from the crystal lattice through the spin–orbit interaction. In this work, we study the influence of these two mechanisms on the magnetization dynamics of a three-terminal spin-torque oscillator. The device is composed of either a spin-valve (SV) or a magnetic tunnel junction (MTJ) on top of a Pt wire. The system can be excited either by SFT or by SOT depending on whether the current is applied through the magnetic structure (SV or MTJ) or through the Pt wire. Finally, each device is compared to a reference sample where the Pt wire is replaced by a Cu wire. Therefore, no SOT is expected in this second set of devices. In this presentation, we compare the different types of devices in order to understand the transport in the three terminal devices and study the role of the different mechanisms (SFT and STT) on the magnetization dynamics. Finally, we propose a method to compare the spin transfer efficiency of the two mechanisms on a single device.

10357-46, Session 8A

Perpendicular magnetic anisotropy in Bismuth substituted nanometers thick YIG films *(Invited Paper)*

Lucile Soumah, Unité Mixte de Physique CNRS/Thales (France); Lilia Qassym, Thales Research & Technology (France); Cécile Carretero, Eric Jacquet, Unité Mixte de Physique CNRS/Thales (France); Jamal Ben-Youssef, Univ. de Bretagne Occidentale (France); Richard Lebourgeois, Thales Research & Technology (France); Nathan Beaulieu, Univ. de Bretagne Occidentale (France); Vincent Cros, Paolo Bortolotti, Abdelmadjid Anane, Unité Mixte de Physique CNRS/Thales (France)

Pulsed laser deposition (PLD) of high quality nanometers thick (YIG) films have recently allowed to open the field of spintronics and magnonics nanostructured magnetic insulators[1,2]. YIG is a versatile material in term of anisotropy or magnetization as doping and growth induced strain can significantly change those properties. We present here the effect of Bi substitution on Bi:YIG PLD grown films with thicknesses ranging from 10 nm to 40 nm. By using lattice matched substituted GGG substrates (sGGG) it is possible to stabilize for specific growth conditions an out-of plane easy magnetization axis. We present comprehensive structural charcterisation using X-ray diffraction and squid magnetometry that shows the transition from an easy in-plane magnetization direction to an out-of plane magnetization. The effect of Bi doping is to significantly increase the Faraday rotation of the films. Using magneto-optical Kerr microscopy, it is therefore possible to observ the shape and the sizes of the magnetic domains for films thicknesses down to 10 nm. Using the Kooy and Enz model it is possible to extract a domain wall energy of 0.49 erg/cm2.

Progress in the room temperature operation of GaAs-based lateral-type spin-LED and spin-PD in near-infrared wavelength region *(Invited Paper)*

Hiro Munekata, Ronel C. Roca, Kazuhiro Nishibayashi, Nozomi Nishizawa, Tokyo Institute of Technology (Japan)

Aiming at the incorporating spins in the future optical integrated circuit, we have been studying lateral-type spin photonic devices and memories. In this paper, we present recent progress in the room temperature operation of spin light-emitting diodes (LEDs) and photo-detectors (PDs). Our spin-LEDs consist of p-GaAs-based double heterostructures combined with Fe /crystalline AlOx contacts. Pure CP-EL occurs when a current of 100 A/cm2 or higher is sent to the device. This phenomenon arises due to the annihilation of minority-helicity EL component accompanied by slight narrowing in EL spectra, which lead us to the inference that the of minority helicity EL component is converted into that of the majority helicity in three steps: firstly, reversed spin polarization of the valence band resulting from injecting spin-polarized electrons into the conduction band; secondly, relatively strong re-absorption of minority helicity EL component; and thirdly, stimulated light emission of re-generated minority spin electrons in the relatively strong electromagnetic field of majority EL component. Spin-polarized rate equations will be discussed at the time of .presentation. Our spin-PDs consist of a Fe/crystalline AlOx/p-GaAs Schottky diode, and helicity-dependent photocurrent is yielded with the conversion efficiency F (the relative value of helicity-dependent photocurrent with respect to the total photocurrent) of 0.1 to 1 % for horizontal and oblique illuminations, respectively. The model calculation consisting of drift-diffusion and Julliere spin-dependent tunneling transports suggests that a possible cause of the reduced helicity-dependent photocurrent may be microscopic damages to the tunneling barrier at the cleaved edge.

10357-48, Session 8B

Efficient electrical spin injection into quantum dots at zero magnetic field *(Invited Paper)*

Fabian Cadiz, Delphine Lagarde, Lab. de Physique et Chimie des Nano-objets (France); Shiheng Liang, Institut Jean Lamour (France); Bingshan Tao, Institute of Physics, Chinese Academy of Sciences (China); Julien Frougier, Unité Mixte de Physique CNRS/Thales (France); Yuan Lu, Institut Jean Lamour (France); Bo Xu, Institute of Semiconductors, Chinese Academy of Sciences (China); Henri Jaffres, Unité Mixte de Physique CNRS/Thales (France); Zg Wang, Institute of Semiconductors, Chinese Academy of Sciences (China); X. Fhan, Institute of Physics, Chinese Academy of Sciences (China); Michel Hehn, Stephane Mangin, Institut Jean Lamour (France); Jean-Marie George, Unité Mixte de Physique CNRS/Thales (France); Thierry Amand, Xavier Marie, Bernhard Urbaszek, Lab. de Physique et Chimie des Nano-objets (France); Pierre Renucci, Institut National des Sciences Appliquées de Toulouse (France)

We have demonstrated for the first time at zero magnetic field a very efficient electrical spin injection into p-doped InAs/GaAs quantum dots (around one hole per dot in average) thanks to an ultrathin CoFeB (a few atomic planes)/MgO spin injector, presenting perpendicular magnetic

anisotropy. The circular polarization of the electroluminescence (EL) emitted by the Spin Light Emitting Diode (spinLED) follows the hysteresis cycle of the magnetic layer. At zero magnetic field, a Circular polarization as large as 22 percent is measured at low temperature, far above the values usually observed at zero magnetic field for spinLEDs. The dependence of the EL circular polarization rate on current intensity and on its duty cycle is investigated, in order to track the possible nuclear polarization of the nuclei in the dots. In addition, this structure is shown to operate also as a spin photodiode; spin polarized electrons are optically injected into the quantum dots, and then extracted towards theCoFeB layer.

The photocurrent is shown to be sensitive to the helicity of the incident light.

10357-49, Session 8B

Injection of sub-picosecond ultrashort spin current pulses in semiconductors *(Invited Paper)*

Marco Battiato, Technical Univ. Vienna (Austria)

The origin of the ultrafast demagnetisation has been a mystery for a long time. Recently we have proposed an approach based on spin dependent electron superdiffusion. [1-3] A number of experimental works have confirmed the importance and the amplitude of the superdiffusive spin transport for ultrafast magnetisation dynamics [4-7]. In particular the spin superdiffusion model predicted the transfer of magnetisation in the non-magnetic substrate and the possibility of increasing the magnetisation: both phenomena were experimentally confirmed. [4-5]

We predict the possibility of injecting ultrashort (sub-picosecond) spin current pulses from a ferromagnetic metallic layer undergoing ultrafast demagnetisation into a semiconducting substrate. [8] After laser excitation, energetic carriers can overcome the semiconductor bandgap. We address the complex interplay of spin diffusion, the formation of high electric fields at the metal/semiconductor interface, and the concomitant thermalisation of the laser excited carriers by ad hoc numerical techniques. We show that spin currents pulses hundreds of femtoseconds long are injected in the semiconductor and present a record spin polarisation.

Such spin current pulses have the possibility of becoming the carriers of information in future spintronics running at unprecedented frequencies above the THz regime.

Modeling the negative magnetoresistance of ferromagnet-graphene-ferromagnet junctions *(Invited Paper)*

Olaf M. J. van 't Erve, Enrique Cobas, Berend T. Jonker, U.S. Naval Research Lab. (United States)

Ferromagnet – multilayer graphene – ferromagnet junctions are predicted to yield low resistance devices with a high magnetoresistance (MR) due to a metallic minority spin transport channel [1]. We fabricated arrays of such junctions via chemical vapor deposition of graphene on lattice-matched single-crystal NiFe(111) films with a bcc-Fe top contact. The junctions exhibit negative MR and metallic transport behavior attributed to minority spin filtering, and low resistance. Existing models fail to predict the negative MR observed in our metallic junctions. Here we develop a model based on the Mott two spin current approximation where the two spin channels are treated independently. The model incorporates spin current conversion, the minority spin filtering predicted for the high quality lattice matched NiFe(111) /graphene interface, as well as a diffusive interface for the graphene / e-beam deposited bcc-Fe layer that is not expected to result in spin filtering. This model correctly predicts the observed negative MR and gives a lower bound for the minority spin polarization in graphene, exceeding 80% at low temperatures, for junctions that exhibit an MR of -12% at 10K. The model quantitatively predicts the dependence of the MR on the RA product at room temperature, and is consistent with the high minority spin polarization inside the graphene junction as predicted by Karpan.

This work was supported by internal programs at NRL.

Microwave magnetization dynamics in room temperature organic-based magnets: from fundamental studies to emerging applications *(Invited Paper)*

Ezekiel Johnston-Halperin, The Ohio State Univ. (United States)

Organic and organic-based materials are attractive candidates for applications in magnetoelectronics and spintronics due to their low cost, ease of fabrication, and low spin-orbit coupling (and consequently long spin lifetimes). More recently, advances in these fields have highlighted the potential for dynamic excitations to drive new phenomena such as ferromagnetic resonance generated spin-pumping. Here we present a series of recent breakthroughs in the synthesis, encapsulation, and measurement of organic-based magnets that lay the foundation for all organic magnetoelectronic and spintronic devices. We will discuss advances in encapsulation strategies that allow lifetimes of up to 1 month in air, the use of ligand substitution to generate a library of related magnetic materials, the growth of all-organic and hybrid organic/inorganic magnetic heterostructures, and measurements of ferromagnetic resonance (FMR) linewidths of ~ 1 Oe (comparable to polished spheres of yttrium iron garnet; YIG). Finally, we demonstrate the potential for real world applications in the construction of a V[TCNE]2 based spin-wave resonance device with spectral tuning from 1 – 5 GHz and a quality factor in excess of 3,200 that operates under ambient conditions. These results establish the validity of organic-based magnets for applications in next-generation magnetoelectronics and provide unique leverage on long-standing challenges in the field of organic spintronics.

Spin to charge conversion in graphene and carbon nanotube mats *(Invited Paper)*

Yuichiro Ando, Sergey Dushenko, Ei Shigematsu, Masashi Shiraishi, Kyoto Univ. (Japan)

The small spin-orbit interaction of carbon atoms in nanocarbon materials such as graphene and carbon nanotubes (CNT) promises a long spin lifetime and potential for the creation of a spin transport devices. Actually, spin transport in graphene and CNT has been demonstrated even at room temperature to date, which enable us to quest for novel physics of the spin transport phenomena. However, graphene and carbon nanotube were largely overlooked as possible spin-charge interconversion materials. In this study, we demonstrated spin to charge conversion in a single-layer graphene and a single-walled carbon nanotube mats (SWCNT mats). A pure spin current were generated in graphene or SWCNT mats from a yttrium iron garnet (YIG) layer by means of spin pumping method. The spin current, flowing in the normal direction, was converted into an in-plane charge current. Clear electromotive forces due to spin-charge conversion were detected for both materials at room temperature. From electric gate tuning of the electromotive force in the single-layer graphene, we showed the dominance of the conventional inverse spin Hall effect over the inverse Rashba-Edelstein effect despite of two dimensional nature. We also revealed that the SWCNT mat exhibits negative spin Hall angle, the first discovery of organic materials which shows a negative spin Hall angle.

10357-53, Session 9A

Magnetically controllable graphene plasmonics *(Invited Paper)*

Dmitry A. Kuzmin, Igor V. Bychkov, Chelyabinsk State Univ. (Russian Federation) and South Ural State Univ. (Russian Federation); Vladimir G. Shavrov, Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation); Vasily V. Temnov, Institut des Molécules et Matériaux du Mans, Univ. du Maine (France)

Graphene is a unique material to study fundamental limits of plasmonics. Apart from the fact that it possesses the ultimate single-layer thickness, its carrier concentration can be tuned by chemical doping or applying a bias voltage. Thus, the electrodynamic properties of graphene can be varied from highly conductive to dielectric. Graphene supports strongly confined, propagating surface plasmon-polaritons (SPPs) from terahertz to mid-infrared frequencies, in a broad spectral range where conventional noble metal-based plasmonics usually does not work. On the other hand, the magnetooptical response of nanostructures can be much larger as compared to the bulk magnetooptic materials. The magnetic field allows for controlling SPPs properties and there are different ways to design magnetoplasmonic structures base on magneto-optical metals or dielectrics. Graphene has a strong magnetooptic response and thus provides an alternative to conventional magneto-plasmonics. Despite of a large number of works devoted to plasmonic properties and applications of graphene, little is known about the graphene-based magnetoplasmonics, which represents the main subject of this work. Here we will discuss recent strategies to enhance magnetoplasmonic effects by going to low-dimensional structures, i.e. graphene planar waveguides, graphene nanotubes, cylindric nanocavities and toroidal nanostructures. We will review how combining the topological properties of graphene-based meta-surfaces with topologically different closed surface landscapes.

Spin orbit torque switching of compensated ferrimagnet *(Invited Paper)*

Luqiao Liu, Joseph Finley, Jiahao Han, Saima Siddiqui, Massachusetts Institute of Technology (United States)

There has been great interest recently in using antiferromagnetic materials (AFM) as opposed to ferromagnet (FM) to store information. Compared with FM, AFM exhibit fast dynamics as well as robust protection against external magnetic fields, which can enable spintronic devices with fast speed and high density. Rare earth (RE)–transition metal (TM) ferrimagnetic alloys have antiferromagnetically coupled sublattices. By varying the relative concentrations of the two species, one can reach the compensation points where the net magnetic moment or angular momentum is zero. Despite the appealing advantages close to the compensation point, few experimental works have explored this region, mostly due to the difficulty in controlling magnetic dynamics with external magnetic field. Here, we show that the spin orbit torque (SOT) provides the possibility of efficiently controlling the magnetic moment in CoTb ferrimagnet alloys. Current induced switching is demonstrated for both Co-rich and Tb-rich samples, including those near compensation point. We quantitatively measured the induced effective field in the domain wall motion regime and found that the largest effective field occurs near the magnetic compensation point. The strong SOT and the predicted fast magnetic dynamics in the ferrimagnet system could potentially lead to high speed spintronic applications.

10357-55, Session 9B

Spin-orbit fields at Fe/GaAs (001) interface *(Invited Paper)*

Lin Chen, Univ. Regensburg (Germany)

Interfacial spin-orbit torques (SOTs) enable manipulation of the magnetization through an in-plane charge current, which has drawn increasing attention for spintronic applications. In the search for material systems that can provide efficient SOTs, much work has been focused on polycrystalline ferromagnetic metal/non-magnetic metal bilayers [1-3]. Here the current flows in the non-magnetic layers and induces a torque at the interfaces via the spin Hall effect of the non-magnetic layer [1], the Rashba effect at the interface [2] or spin-momentum locking when a topological insulator is involved [3]. In this presentation, we report the observation of robust SOT occuring in a well characterized single crystalline Fe/insulating GaAs (001) interface at room temperature where the SOT is caused by the lack of space inversion symmetry at the interface. We find that the magnitude of the interfacial SOT per unit charge current density is comparable in strength with that in ferromagnetic metal/non-magnetic metal systems. This large magnitude also allows for the observation of spin-to-charge current conversion at the interface, which is known as spin-galvanic effect [4]. The results suggest that single crystalline Fe/GaAs interfaces may enable efficient magnetization manipulation through purely electric means [5].

Phonon-induced superconductivity in a self-consistent Hubbard model *(Invited Paper)*

Enrique Munoz, Pontificia Univ. Católica de Chile (Chile); Edson Vernek, Univ. Federal de Uberlândia (Brazil); Victor Apel, Univ. Católica del Norte (Chile)

We have studied an infinite Hubbard chain with a spin-orbit coupling term, submitted to a uniform magnetic field as well as local phonons. By means of a Lang-Firsov transformation, we show that an effective interacting fermion model emerges. Moreover, a self-consistent mean-field theory of this model, formulated in terms of thermal Green's functions, shows that a BCS term emerges, thus leading to a superconducting phase transition at zero temperature. We find analytical expressions for the phase boundary, that agree well with exact numerical diagonalization of the Hamiltonian.

10357-57, Session 9B

Characterizing spin orbit torque effective fields *(Invited Paper)*

Wen Siang Lew, Sarjoosing Goolaup, Feilong Luo, Nanyang Technological Univ. (Singapore)

The spin coupling between spins of conduction electron in heavy metal (HM) and localized electrons in ferromagnetic (FM) material influences the magnetization of the FM layer via the spin-orbit torque (SOT). The two main phenomena contributing to SOT are bulk spin Hall effect arising from spin scattering in the heavy metal layer and Rashba effect, which is an interfacial spin orbit coupling at the FM/HM interface. The intensity of the SOT is generally characterized by two effective fields: field-like term and damping-like term. Various techniques have been used to quantify the two effective fields, such as current-induced domain wall motion, ferromagnetic resonance techniques, and SOT-assisted magnetization switching. However, the reported amplitude of the fields is highly dependent on the experimental technique.

We present our recent results on the effective fields measurements in multilayered ferromagnetic films and introduce a self-validating method, which simultaneously quantify both the field-like and damping-like terms in structures with in-plane magnetic anisotropy. An analytical expression is derived and experimentally verified using the harmonic Hall resistance measurement. The second harmonic Hall resistance is fitted with our derived equation, to extract both the field-like and damping-like effective fields. We show that in structures with in-plane magnetic anisotropy, the field-like term comprises of a constant component and an azimuth-angular-dependent term. For structures with perpendicular magnetic anisotropy, our analytical expression and experimental results reveals an angular dependence of the damping-like term. Finally, a novel approach to achieving field free bipolar SOT induced magnetization is presented.

10357-58, Session 10A

The engagement of optical angular momentum in nanoscale chirality *(Invited Paper)*

David L. Andrews, Univ. of East Anglia (United Kingdom)

Wide-ranging developments in optical angular momentum have recently led to refocused attention on issues of material chirality. The connection between optical spin and circular polarization, linking to well-known and utilized probes of chirality such as circular dichroism, has prompted studies aiming to achieve enhanced means of differentiating enantiomers - molecules or particles of opposite handedness. Newly devised schemes for physically separating mirror-image components by optical methods have also been gaining traction, together with a developing appreciation of how the scale of physical dimensions ultimately determines any capacity to select for material chirality. The scope of such enquiries has further widened on recognition that suitably structured, topologically charged beams of light can additionally convey orbital angular momentum. Understanding the full scope and constraints upon chiroptical interactions in the nanoscale regime involves the resolution of CPT symmetry conditions governing the fundamental interactions between matter and photons. The emerging principles provide a theory test-bed for new methodologies.

10357-59, Session 10A

Spin-orbit interaction of light on the surface of atomically thin crystals *(Invited Paper)*

Hailu Luo, Hunan Univ. (China)

Two-dimensional (2D) atomic crystals have extraordinary electronic and photonic properties and hold great promise in the application of photonic and optoelectronics. A fundamental understanding of the light-matter interaction in the 2D atomically thin crystals is therefore essential to optoelectronics applications. As a fundamental physical effect in light-matter interaction, spin-orbit coupling of light is attributed to the transverse nature of the photonic polarization. The photonic spin Hall effect (SHE) can be regarded as a direct optical analogy of the SHE in electronic systems where the spin electrons and electric potential are replaced by spin photons and a refractive index gradient, respectively. The analogy has been extensively demonstrated effective for the photonic SHE in 3D bulk crystals. However, the effective refractive index fails to adequately explain the light-matter interaction in 2D atomic crystals. It would be interesting how to describe the spin-orbit interaction on the surface of 2D atomic crystals.

In this paper, we examine the spin-orbit coupling of light on the surface of atomically thin crystals. First, we develop a general model to describe the spin-orbit interaction of light on the surface of 2D atomic crystals. We find that it is not necessary to involve the effective refractive index to describe the spin-orbit interaction and photonic SHE in the atomically thin crystals. The strong spin-orbit interaction and giant spin-dependent splitting in photonic SHE is predicted, which can be explained as the large polarization rotation of plane-wave components in order to satisfy the transversality of photon.

10357-60, Session 10A

Controlling angular momentum at the micro scale *(Invited Paper)*

Daryl Preece, Univ. of California, San Diego (United States)

Beams with angular momentum are often used for experiments at the micrometer and nanometer length scales. These include optical trapping of microscopic particles, STED microscopy, as well as plasmonic applications amongst others. But how much control do we actually have over such beams?

Focal parameters of microscopy systems can lead to separation of optical vortices as well a to spin-orbit coupling. These effects may produce undesirable outcomes when highly focused light is used for experimental research. However, such effects can be obviated with sufficient control over the properties of the focused laser beam. We examine the how beams with orbital and spin angular momentum are affected by focusing and how the associated momentum of such beans can be controlled in the focal region. We also show how control over vortex topology allows unique momentum states to be generated in highly focused beams.

10357-61, Session 10A

Active mid IR plasmonics using giant magneto resistance *(Invited Paper)*

Gaspar Armelles Reig, Instituto de Microelectronica de Madrid, Consejo Superior de Investigaciones Cientificas (Spain); Alfonso Cebollada, Instituto de Microelectrónica de Madrid, Consejo Superior de Investigaciones Científicas (Spain); Fernando García, Instituto de Microelectrónica de Madrid (Spain)

Plasmonics has proven as a powerful tool to improve the performance of mid-IR devices, resulting in plasmon assited quantum cascade lasers, plasmon enhanced light detection, plasmonic beam steering, plasmonic

thermal emiters or plasmonic nanoantenas for vibrational spectroscopy. In this scenario, the possibility of modulating the emission, propagation and/or detection of mid-IR radiation constitutes a promising aspect to expand the limits of the currently used technologies. In this sense, fast and contactless actuation on plasmon resonances via the Magneto-Optical (MO) effect has been put forward by the inclusion of ferromagnetic components into noble metal layers and nanostructures, yet up to now restricted to the visible and near-infrared ranges.

Here we present our proposal and initial results on the magnetic field control of plasmon resonances in the mid IR region by the use of the Magneto-Refractive (MR) effect, i.e., a change in the optical properties of the system by magnetic field controlled electrical resistivity. For this we select a Giant Magneto Resistance model system (a Au/Permalloy multilayer), which exhibits changes in resisitivity of the order of 10% by the application of small (of the order of 20 Oe) magnetic fields. The experiments are carried out in a dedicated FTIR spectrometer with magnetic field capabilities.

Anomalous optical properties of Rashba conductor *(Invited Paper)*

Gen Tatara, RIKEN Ctr. for Emergent Matter Science (Japan)

We theoretically explore the optical properties of a bulk Rashba conductor by calculating the transport coefficients at finite frequencies. It is demonstrated that the combination of direct and inverse Edelstein effects leads to a softening of the plasma frequency for the electric field perpendicular to the Rashba field, resulting in a hyperbolic electromagnetic metamaterial. In the presence of magnetization, a significant enhancement of anisotropic propagation (directional dichroism) is predicted because of the interband transition edge singularity. On the basis of an effective Hamiltonian analysis, the dichroism is demonstrated to be driven by toroidal and quadratic moments of the magnetic Rashba system.

The effective theory of the cross-correlation effects has the same mathematical structure as that of insulating multiferroics.

10357-63, Session 10B

Acoustic driven magnonics *(Invited Paper)*

Ivan Lisenkov, Mikkel Hansen, Albrecht Jander, Pallavi Dhagat, Oregon State Univ. (United States)

Magnonics aims to utilize magnons (quanta of spin-waves) to process and transfer digital and analog information, promising high throughput, low power computing for the post-CMOS era. Any such future magnonic circuits will require spin wave signal sources and amplifiers. We propose that acoustic pumping of spin waves provides a mechanism to implement these functions in efficient and highly localized devices. In support of this, we have developed a general theoretical model of linear and parametric magneto-acoustic interactions, covering all possible polarizations of acoustic waves and spin wave modes. The model combines the predictive power of analytical techniques with numerical micromagnetic simulations and is thus well-suited for the design of complex physical devices. Based on this, we determine the configurations most amenable to spin wave generation and amplification. As an experimental prototype we demonstrate an acoustically-pumped amplifier for spin-waves. Our device consists of an yttrium-iron-garnet (YIG) film grown on a gallium gadolinium garnet (GGG) substrate, with a bulk acoustic waves (BAW) transducer fabricated on the top of the GGG substrate. We show experimentally that the amplitude of the propagating spin-waves increases with the application of the BAW. Moreover, this scheme can be used as a signal correlator, where the modulated spin-waves and acoustic waves serve as signal inputs and the resulting modulation of the amplified spin wave serves as the output.

10357-64, Session 10B

From non-linear magnetoacoustics and spin reorientation transition to magnetoelectric micro/nano-systems *(Invited Paper)*

Nicolas Tiercelin, Institut d'Electronique de Microélectronique et de Nanotechnologie (France); Vladimir Preobrazhensky, Institut d'Electronique de Microélectronique et de Nanotechnologie (France) and A. M. Prokhorov General Physics Institute of the Russian Academy of Sciences (Russian Federation); Olivier Bou Matar, Abdelkrim Talbi, Stefano Giordano, Yannick Dusch, Institut d'Electronique de Microélectronique et de Nanotechnologie (France); Alexey Klimov, Institute of Radio Electronics (Russian Federation) and Institut d'Electronique de Microélectronique et de Nanotechnologie (France) and Moscow Technological Univ. (Russian Federation); Théo Mathurin, Institut d'Electronique de Microélectronique et de Nanotechnologie (France); Omar Elmazria, Michel Hehn, Institut Jean Lamour (France); Philippe Pernod, Institut d'Electronique de Microélectronique et de Nanotechnologie (France)

The interaction of a strongly nonlinear spin system with a crystalline lattice through magnetoelastic coupling results in significant modifications of the acoustic properties of magnetic materials, especially in the vicinity of magnetic instabilities such as the spin-reorientation transition (SRT). The magnetoelastic coupling transfers the critical properties of the magnetic subsystem to the elastic one which leads to a strong decrease of the sound velocity in the vicinity of the SRT, and allows a large control over acoustic nonlinearities. The general principles of the non-linear magneto-acoustics (NMA) will be introduced and illustrated in 'bulk' applications such as acoustic wave phase conjugation, multi-phonon coupling, explosive instability of magneto-elastic vibrations, etc.

Then, the concept of the SRT coupled to magnetoelastic interaction has been later transferred into nanostructured magnetoelastic multilayers with uni-axial anisotropy. The high sensitivity and the non-linear properties have been demonstrated in cantilever type actuators, and phenomena such as magneto-mechanical RF demodulation have been observed. The combination of the magnetic layers with piezoelectric materials also led to stress-mediated magnetoelectric (ME) composites with high ME coefficients, thanks to the SRT.

The magnetoacoustic effects of the SRT have also been studied for surface acoustic waves propagating in the magnetoelastic layers and found to be promising for highly sensitive magnetic field sensors working at room temperature. The patterning of the magnetoelastic layer can more over allow the design of phononic crystals with tunable band gaps.

On the other hand, mechanical stress is a very efficient way to control the magnetic subsystem. The principle of a very energy efficient stress-mediated magnetoelectric writing and reading in a magnetic memory will be presented. Similar concepts are also applied to the magnetoelectric control of magnetic domain walls in microstructures. In conclusion, potential applications of 'magneto-electro-acoustic' devices in the field of plasmonics and photonics will be discussed.

10357-65, Session 10B

High field bipolar magnetic field sensors based on surface acoustic wave resonators *(Invited Paper)*

Vincent Polewczyk, Karine Dumesnil, Daniel Lacour, Mohammed Moutaouekkil, Hamid Mjadeh, Institut Jean Lamour (France); Nicolas Tiercelin, Institut d'Electronique de Microélectronique et de Nanotechnologie (France); Sébastien Petit Watelot, Institut Jean Lamour (France); Yannick Dusch, Institut d'Electronique de Microélectronique et de Nanotechnologie (France); Omar Elmazria, Institut Jean Lamour (France); Abdelkrim Talbi, Olivier Bou Matar, Institut d'Electronique de Microélectronique et de Nanotechnologie (France); Michel Hehn, Institut Jean Lamour (France)

Surface acoustic wave devices (SAW) have a major interest in sensor applications due to their ease of manufacturing, their sensitivity, small size, and wireless structures. Indeed, especially in SAW resonator geometry, the sensor can be wireless addressed and measured with any embedded power. Surface Acoustic Wave sensors have been used to measure a large variety of stimuli like temperature, pressure, constrain [ref]. It is also known that the velocity or resonant frequency of SAW devices including a magnetostrictive material can be changed by applying a magnetic field. By using magnetostrictive single materials or composites with enhanced magnetoelectric coefficients, various magnetic SAW sensors have been proposed during these last ten years. However, their use to sense magnetic fields is restricted to low magnetic fields and the capability to wireless measure bipolar fields and/or high fields is lacking. Furthermore, the occurrence of hysteresis in the SAW response has not been addressed. In this paper, we report magnetic Surface Acoustic Wave (SAW) sensors that consist of interdigital transducers made of a magnetostrictive material (Ni and $TbFe_2$) or based on exchange-biased multilayers (Co/IrMn and CoFe/IrMn). In the SAW resonator geometry, the wireless measure could be performed in a field range depending on the system studied. The intensity and sign of the applied field could be extracted. Finally, the control of the electrode magnetic properties insured reversible behavior in the SAW response.

10357-66, Session 10B

Traveling surface spin-wave resonance spectroscopy using surface acoustic waves *(Invited Paper)*

Praveen Gowtham, Univ. of California, Berkeley (United States)

Coherent gigahertz-frequency surface acoustic waves (SAWs) traveling on the surface of a piezoelectric crystal can, via the magnetoelastic interaction, resonantly excite traveling surface spin waves in an adjacent thin-film ferromagnet. These excited surface spin waves, traveling with a definite in-plane wave-vector, enforced by the SAW, can be detected by measuring changes in the electro-acoustical transmission of a SAW delay line. In this talk, we discuss how such measurements can be used as a precise and quantitative technique for spin-wave spectroscopy – providing a means to determine both isotropic and anisotropic contributions to the spin-wave dispersion and damping.

We also develop an analytical theory of the magnetomechanics of spin-wave resonance at the interface between the magnetic film and the piezoelectric. We use acoustical perturbation theory to find closed-form expressions for the back-action surface stress and strain fields and the resultant SAW velocity shifts and attenuation induced by elastically driven spin-wave resonance. The formalism can, with slight modification, be extended to magnetic thin films on top of various classes of acoustic resonators.

10357-67, Session 10B

Generation of ultrashort shear acoustic pulses by femtosecond laser demagnetization of highly magnetostrictive Terfenol *(Invited Paper)*

Thomas T. P. Pezeril, Univ. du Maine (France)

We experimentally and theoretically demonstrate that, upon femtosecond demagnetization of highly magnetostrictive Terfenol, the ultrafast release of the built-in strains generates ultrashort longitudinal and shear acoustic pulses. These ultrashort acoustic pulses gather new crucial information on the spin-lattice coupling at ultrafast timescale.

10357-68, Session 11A

Ultrafast terahertz spintronics *(Invited Paper)*

Dmitry Turchinovich, Max-Planck-Institut für Polymerforschung (Germany)

In this presentation we will review the spintronic terahertz (THz) phenomena such as ultrafast transient demagnetization [1], generation of spin waves via THz Zeeman torque [2,3], Mott scattering [4], and ultrafast inverse spin-Hall effect [5].

High performance THz emitters based on ferromagnetic/nonmagnetic heterostructures *(Invited Paper)*

Yang Wu, Mehrdad Elyasi, Mengji Chen, Hyunsoo Yang, National Univ. of Singapore (Singapore)

Terahertz spectroscopy is a powerful non-destructive and non-invasive characterization method, which can be applied for biological, medical, and chemical analysis applications. A low cost and versatile THz emitter is an important building block for a high performance THz system, which is lacking now. In this work, we report a THz emitter with excellent performances based on nonmagnetic (NM) and ferromagnetic (FM) heterostructures. The broadband THz waves emitted from our film stacks have a peak intensity exceeding 500 ?m thick ZnTe crystals (standard THz emitters). Our device is insensitive to the polarization of an incident laser beam which indicates the noise resistive feature. In contrast, the polarization

of THz waves is fully controllable by an external magnetic field. We have also fabricated the devices on flexible substrates with a great performance, and demonstrated that the devices can be driven by low power lasers. Together with the low cost and mass productive sputtering growth method for the film stacks, the proposed THz emitters can be readily applied to a wide range of THz equipment. Our study also points towards an alternative approach to characterize spintronic devices with NM/FM bilayers.

10357-70, Session 11A

Tunable THz emitters based on the magnetic heterostructure *(Invited Paper)*

Jingbo Qi, Univ. of Electronic Science and Technology of China (China) and The Peac Institute of Multiscale Sciences (China)

Terahertz (THz) wave, which lies in the frequency gap between infrared and microwave, has an electromagnetic spectrum conventionally defined in the range from 0.1 to 30 THz, which has a great potential in fundamental scientific research and other applications. Very recently, it was reported that the THz wave can be generated in heterostructure composed of ferromagnetic (FM) and non-FM metal films upon excitation of ultrafast laser pulses, which could open a new direction of ultrafast spintronics.

In this contribution, we report our study on the THz emission in Fe/Pt and Co/Pt magnetic heterostructures. We carried out a comprehensive investigation of THz emission from these magnetic heterostructures, employing time-domain THz spectroscopy. We revealed that by properly tuning the thickness of ferromagnetic or non-magnetic layer, THz emission can be greatly improved in this type of heterostructure. We further demonstrate that the THz field strength emitted from a newly designed multilayer [Pt/Fe/MgO]n can be strongly increased. Polarization of the emitted THz wave has been shown to follow the rotation of the applied magnetic field. In addition, the intensity and spectrum of THz wave is demonstrated to be tunable by the magnetic field applied on the patterned magnetic heterostructures. These findings thus promise novel approaches to fabricate powerful and tunable THz emitters based on magnetic heterostructure.

10357-71, Session 11A

Directly probing ultrafast spin dynamics in antiferromagnets using terahertz pulses *(Invited Paper)*

Pamela Bowlan, Stuart A. Trugman, Los Alamos National Lab. (United States); Xueyun Wang, Sang-Wook Cheong, Rutgers, The State Univ. of New Jersey (United States); Dmitry A. Yarotski, Antionette J. Taylor, Rohit P. Prasankumar, Los Alamos National Lab. (United States)

The ability to switch magnetization in a ferromagnet on an ultrafast timescale using femtosecond lasers is of longstanding fundamental interest, due to its potential applications in magnetic data storage. However, ultrafast control of antiferromagnetic (AFM) materials is arguably more promising, since a zero net magnetization makes it easier for the system to change while conserving spin, so that their spin dynamics should be much faster than in ferromagnets. Multiferroic materials, which are usually AFM, have coexisting and coupled magnetic and ferroelectric order, as well as the additional feature that ultrafast laser-induced changes to the ferroelectricity can change the magnetic order and vice versa. This leads to potential applications like ultrafast magnetoelectric switching. Although AFM materials could be quite useful, their magnetization, especially its temporal evolution, is more difficult to detect and therefore less well understood, since such experiments typically require x-ray pulses from large-scale free electron lasers.

We will discuss a new, relatively simple, table-top approach for probing the ultrafast dynamics of spin order in AFM manganites, using THz pulses resonant to magnons. Applying this method to two different AFM systems, hexagonal HoMnO3 and orthorhombic TbMbO3, clearly reveals picosecond spin dynamics in both cases, suggesting that this method is a rather general probe of spin dynamics in AFMs. Furthermore, our study of TbMnO3 shows that THz pulses are sensitive to both short and long range spin dynamics. Analysis of the measured dynamics, which show spin heating by phonon scattering, suggests a unique, direct exchange-mediated spin-phonon coupling mechanism in AFMs.

The skyrmion switch: turning magnetic skyrmions on and off with an electric field *(Invited Paper)*

Anne Bernand-Mantel, Marine Schott, Laurent Ranno, Stéfania Pizzini, Jan Vogel, Institut NÉEL, Ctr. National de la Recherche Scientifique (France) and Univ. Grenoble Alpes (France); Helène Béa, Commissariat à l'Énergie Atomique (France) and Ctr. National de la Recherche Scientifique (France) and Univ. Grenoble Alpes (France); Claire Baraduc, Commissariat à l'Énergie Atomique (France) and Univ. Grenoble Alpes (France); Gilles Gaudin, SPINTEC, Ctr. Grenoble Alpes (France); Stéphane Auffret, Commissariat à l'Énergie Atomique (France) and Ctr. National de la Recherche Scientifique (France) and Univ. Grenoble Alpes (France); Dominique Givord, Institut NÉEL, Ctr. National de la Recherche Scientifique (France) and Univ. Grenoble Alpes (France)

Magnetic skyrmions are nanoscale swirling spin structures with a non trivial topology. Recently several groups have reported the observation of magnetic skyrmions at room temperature (RT) in conventional transition-metal-based magnetic multilayers. This discovery has triggered a growing interest for the use of magnetic skyrmions as building blocks for memories which is reminiscent of the extensive research on magnetic bubble memories in the 1970s. The recent observation of current induced displacement of skyrmion bubbles using relatively low current densities reported at RT is very promising. The creation and annihilation of skyrmions have been addressed theoretically and experimentally by different techniques , however, those techniques are either energy consuming or difficult to integrate in functional devices. In this talk, we report on the room temperature switching of skyrmions bubbles with electrical gating, an energy efficient and easily integrable solution. The experiment is carried out on a Pt/Co/oxide trilayer which is imaged using magneto-optical Kerr microscopy under a transparent Indium Tin Oxide electrode. The spontaneous nucleation of skyrmion bubbles by thermal activation is observed. A classical magnetic bubble model, where the DMI interaction is directly imbedded in the domain wall energy, describes quantitatively the thermal nucleation and stability of the observed skyrmion bubbles. The observed efficient and reproducible electric field writing and deleting of skyrmion bubbles is well explaiend by our analytical isolated skyrmion bubble model. These results constitute an important milestone towards the use of skyrmions for memory or logic applications.

10357-73, Session 11B

Room-temperature skyrmion shift device for memory application *(Invited Paper)*

Guoqiang Yu, Pramey Upadhyaya, Qiming Shao, Univ. of California, Los Angeles (United States); Hao Wu, Institute of Physics, Chinese Academy of Sciences (China); Gen Yin, Xiang Li, Congli He, Univ. of California, Los Angeles

(United States); Wanjun Jiang, State Key Lab. of Low-Dimensional Quantum Physics, Tsinghua Univ. (China) and Collaborative Innovation Ctr. of Quantum Matter (China); Xiufeng Han, Institute of Physics, Chinese Academy of Sciences (China); Pedram Khalili Amiri, Kang L. Wang, Univ. of California, Los Angeles (United States)

Magnetic skyrmions are intensively explored for potential applications in ultralow-energy data storage and computing. To create practical skyrmionic memory devices, it is necessary to electrically create and manipulate these topologically-protected information carriers in thin films, thus realizing both writing and addressing functions. Although room-temperature skyrmions have been previously observed, fully electrically controllable skyrmionic memory devices, integrating both of these functions, have not been developed to date. In this talk, I will talk about our recent demonstration of a room-temperature skyrmion shift memory device, where individual skyrmions are controllably generated and shifted using current-induced spin-orbit torques. Particularly, it is shown that one can select the device operation mode in between: (i) writing new single skyrmions, or (ii) shifting existing skyrmions, by controlling the magnitude and duration of current pulses. Thus, we electrically realize both writing and addressing of a stream of skyrmions in the device. This prototype demonstration brings skyrmions closer to real-world computing applications.

Electric field induced switching of magnetic skyrmions and strain relief effects *(Invited Paper)*

Aurore Finco, Pin-Jui Hsu, Niklas Romming, André Kubetzka, Kirsten von Bergmann, Roland Wiesendanger, Univ. Hamburg (Germany)

In ultrathin magnetic films deposited on heavy elements substrates, the interface-induced Dzyaloshinkii-Moriya interaction allows to stabilize non-collinear spin structures like magnetic skyrmions. These topologically protected objects are interesting for future data storage technologies like racetrack memories.

We present spin-polarized scanning tunneling microscopy investigations on a three-atomic-layer thick Fe film deposited on Ir(111). In this system, the large epitaxial strain is relieved by the formation of a dense dislocation lines network. This particular structure of the film induces a symmetry breaking with dramatic consequences on the magnetic state. In zero field, spin spirals propagate along the dislocations lines and their period depends on the spacing between these lines, i.e. on the strain relief, which is locally varying [1]. We attribute this effect on the spirals to modifications of the exchange coupling.

Single skyrmions appear in external magnetic field. We demonstrate that they can reliably be written and deleted by an STM tip [2]. The strong-bias polarity dependence and the linear behavior of the threshold voltage for switching with the tip-sample distance shows that electric field plays the dominant role in the switching mechanism. This switching between the topologically distinct magnetic states by electric fields may be beneficial in future spintronic devices employing skyrmions as information carriers.

Skyrmion motion in inhomogeneous magnetic multilayers *(Invited Paper)*

William Legrand, Unité Mixte de Physique CNRS/Thales (France); Davide Maccariello, Unite Mixte de Physique CNRS/Thales (France); Nicolas Reyren, Karin Garcia, Karim Bouzehouane, Unité Mixte de Physique CNRS/Thales (France); Horia Popescu, Jean-Yves Chauleau, Nicolas Jaouen, Synchrotron SOLEIL (France); Christoforos Moutafis, The Univ. of Manchester (United Kingdom); Simone Finizio, Carlos A. F. Vaz, Jörg Raabe, Swiss Light Source, Paul Scherrer Institute (Switzerland); Stephen McVitie, Univ. of Glasgow (United Kingdom); Vincent Cros, Albert Fert, Unité Mixte de Physique CNRS/Thales (France)

Magnetic skyrmions are magnetic textures, topologically different from the uniform ferromagnetic state, holding a lot of promise for applications as well as of fundamental interest. They have been observed for the first time in magnetic multilayers at room temperature only a couple of years ago. Since their stability has been demonstrated at relatively low magnetic field (1), the new challenge is to control their motion. Already in 2016, velocities up to about 100 m/s were reported, but many questions are still open. In particular, the so-called skyrmion Hall angle was not systematically observed, the threshold current density J0 for their motion can be much larger than expected, and finally effects of the edge repulsion were still not reported experimentally.

In this presentation, we report about observations of current-induced skyrmion motion close to J0, evidencing a motion apparently disordered (2). This motion is observed by different techniques: atomic force microscopy (MFM), scanning transmission x-ray microscopy (STXM) and holography. The advantages of the two last techniques are the sub-100nm spatial resolution together with sub-ns time resolution for reproducible periodic variation of the magnetic configuration in absence of perturbation by external probing fields (such as the magnetic tip in MFM). These observations are explained qualitatively and to some extent quantitatively by the presence of crystalline grains of about 20nm lateral size with a distribution of magnetic properties (Dzyaloshinskii-Moriya interaction and anisotropy).

Nanodevices for bio-inspired computing *(Invited Paper)*

Julie Grollier, Unité Mixte de Physique CNRS/Thales (France)

In the last five years, Artificial Intelligence has made striking progress, and now defeating humans at subtle strategy games, such as Go, and even Poker. However, these algorithms are running on traditional processors which have a radically different architecture than the biological neural networks they are inspired from. This considerably slows them down and requires massive amounts of electrical power, more than ten thousand times what the brain typically need to function. This energy dissipation is not only becoming an environmental issue, but it also sets a limit to the size of neural networks that can be simulated. We are at a point where we need to rethink the way we compute, and build hardware chips directly inspired from the architecture of the brain. This is a challenge. Indeed, contrarily to current electronic systems, the brain is a huge parallel network closely entangling memory and processing.

In this talk, I will show that, for building the neuromorphic chips of the future, we will need to emulate functionalities of synapses and neurons at the nanoscale. I will review the recent developments of memristive nano-synapses and oscillating nano-neurons, the physical mechanisms at stake, and the challenges in terms of materials. Finally, I will present the first achievements of neuromorphic computing with novel nanodevices and the fascinating perspectives of this emerging field.

10357-77, Session 12A

Analogue spin-orbit torque device for artificial-neural-network-based associative memory operation *(Invited Paper)*

Shunsuke Fukami, William A. Borders, Aleksandr Kurenkov, Hisanao Akima, Satoshi Moriya, Shouta Kurihara, Yoshihiko Horio, Shigeo Sato, Hideo Ohno, Tohoku Univ. (Japan)

One of the great challenges of today's computer technology is a representation of the human brain in computers to execute complex tasks that the conventional von Neumann computers cannot efficiently complete. This has motivated many researchers to realize artificial neural networks, forming the field of artificial intelligence, or neuromorphic computing. So far, this trend has been mainly led by the software or CMOS based technologies, although it is difficult with such approaches to realize compactness and ultralow-power features as in the brain. Meanwhile, utilizing solid-state devices that function as artificial synapses is known to offer promising routes toward implementation of compact and ultralow-power neuromorphic computing. Here, we present an analog spin-orbit torque device based artificial neural network. The spintronics devices are nonvolatile and capable of virtually infinite read/write operation, which should be useful for edge computing with online learning capability. We will start from a brief description of the operation principle of the analog spin-orbit torque device with an antiferromagnet-ferromagnet structure [1]. Then, we will show a proof-of-concept demonstration of an associative memory operation using the analog spin-orbit torque device based artificial neural network [2].

This work is partly supported by ImPACT Program of CSTI and R&D Project for ICT Key Technology of MEXT.

Modulation and detection of single neuron activity using spin transfer nano-oscillators *(Invited Paper)*

Jose Miguel Algarin, Bharath Ramaswamy, Lucy Venuti, Matthew Swierzbinski, Pablo Villar, Univ. of Maryland, College Park (United States); Yu-Jin Chen, Univ. of California, Irvine (United States); Irving N. Weinberg M.D., Weinberg Medical Physics (United States); Jens Herberholz, Ricardo Araneda, Benjamin Shapiro, Edo Waks, Univ. of Maryland, College Park (United States)

The brain is a complex network of interconnected circuits that exchange electrical signals with each other. These electrical signals provide insight on how neural circuits code information, and give rise to sensations, thoughts, emotions and actions. Currents methods to detect and modulate these electrical signals use implanted electrodes or optical fields with light sensitive dyes in the brain. These techniques require complex surgeries or suffer low resolution. In this talk we explore a new method to both image and stimulate single neurons using spintronics. We propose using a Spin Transfer Nano-Oscillators (STNOs) as a nanoscale sensor that converts neuronal action potentials to microwave field oscillations that can be detected wirelessly by magnetic induction. We will describe our recent proof-of-concept demonstration of both detection and wireless modulation of neuronal activity using STNOs. For detection we use electrodes to connect a STNO to a lateral giant crayfish neuron. When we stimulate the neuron, the STNO responds to the neuronal activity with a corresponding microwave signal. For modulation, we stimulate the STNOs wirelessly using an inductively coupled solenoid. The STNO rectifies the induced microwave signal to produce a direct voltage. This direct voltage from the STNO, when applied in the vicinity of a mammalian neuron, changes the frequency of electrical signals produced by the neuron.

Topological Hall effect in a system with magnetic skyrmions *(Invited Paper)*

Igor Rozhansky, Konstantin Denisov, Ioffe Institute (Russian Federation) and Lappeenranta Univ. of Technology (Finland); Nikita S. Averkiev, Ioffe Institute (Russian Federation); Erkki Lahderanta, Lappeenranta Univ. of Technology (Finland)

Topological Hall effect (THE) is a recently discovered transport phenomenon occurring in various magnetic systems due to free carriers interaction with chiral magnetization textures, such as magnetic skyrmions. THE mechanism is based on exchange interaction, thus it is fundamentally different from normal Hall effect and anomalous Hall effect. THE is considered as a very perspective tool to probe topologically nontrivial spin structures as well as for potential device applications based on topology-related properties of nanostructures, one of the most popular concepts in this field is racetrack memory based on magnetic skyrmions.

Despite its great importance for fundamental and applied research, the topological Hall effect has still lacked a proper theoretical description. The existing theories of THE consider two limiting cases of either infinitely strong exchange interaction when an adiabatic Berry phase approach is applicable or the case of a weak exchange interaction allowing for perturbation theory analysis. These two theoretical approaches are known to give qualitatively different results regarding THE.

The adiabatic Berry phase approximation has revealed that THE is accompanied with a pronounced transverse spin current, so the appearance of transverse charge Hall current requires spin polarization of the carriers in the sample, similarly to the anomalous Hall effect [1]. In the opposite case of a weak exchange the transverse charge current can occur in the absence of a spin current, in this regime THE is expected even for non-polarized carriers [2]. We have developed a theory of THE based on exact solution of a problem of electron scattering on a chiral spin field. The suggested theory fills the gap between the two limiting regimes of THE. We discovered a nontrivial crossover between the two regimes, the transverse pure charge current in the weak coupling case transforms into a pronounced transverse spin current in the adiabatic regime. Thus, the apparent contradiction between the results of adiabatic and perturbative theoretical approaches to THE have been eliminated for the first time [3].

Magnetic skyrmions are nanoscale magnetic quasi-particles whose spin structure can be mapped continuously on a sphere. They are promising candidates for future spintronic devices such as the skyrmion racetrack memory.1 In interfacial systems, skyrmions are usually stabilized by the Dzyaloshinskii-Moriya interaction that favors a chiral spin canting.2,3 Additionally, these films can exhibit a significant spin Hall effect that leads to efficient spin dynamics, making thin film systems extremely promising for applications. Indeed, recently the possibility to move skyrmions efficiently in such geometries was reported by static imaging before and after pulse injection.4

In this work, we report the time-resolved pump-probe observation of magnetic skyrmion dynamics at room temperature in thin film devices by scanning transmission X-ray microscopy.5 Our findings reveal fully reproducible motion due to spin-orbit torques (SOT) and skyrmion velocities close to ideal micromagnetic predictions. We find that all skyrmions in the flow regime exhibit motion at an angle with respect to the current flow, demonstrating the presence of a drive dependent skyrmion Hall effect. One approach to explain this behavior is going beyond the rigid 1D-model and assumes a stronger influence of the field-like SOT than previously predicted, resulting in the insight that skyrmion dynamics might be more complex than expected.

Topological orbital magnetic moments *(Invited Paper)*

Manuel dos Santos Dias, Juba Bouaziz, Mohammed Bouhassoune, Stefan Blügel, Samir Lounis, Forschungszentrum Jülich GmbH (Germany)

The magnetic moment carried by electrons has two components: spin and orbital. The spin magnetic moment arises from the first of Hund's rule in most cases, also partially satisfied in magnetic solids. There are two well-known sources of the orbital magnetic moment: the second of Hund's rules, which applies only to localized electron orbitals, and spin-orbit coupling, which unquenches the orbital moment in a magnetic solid.

Here we discuss a third mechanism of orbital magnetic moment formation: magnetic structures with a special topology, where the spin magnetic moments do not all lie in the same plane. We illustrate the basic aspects considering magnetic trimers as model systems, e.g. Fe_3 on the Cu(111) surface. The symmetry of the effect is established, showing how to distinguish the topological and the spin-orbit contributions. We then focus on the implications of the topological orbital moments for single magnetic skyrmions formed in Pd/Fe/Ir(111) [1,2], using first-principles electronic structure calculations and a simplified tight-binding model. We propose that the topological orbital moments could enable detecting and distinguishing skyrmions from anti-skyrmions by soft x-ray spectroscopy [3], complementing transport measurements of the topological Hall effect [4], magnetic force microscopy [5] or scanning tunneling microscopy [2].

Memcomputing: a brain-inspired topological computing paradigm *(Keynote Presentation)*

Massimiliano Di Ventra, Univ. of California, San Diego (United States)

Which features make the brain such a powerful and energy-efficient computing machine? Can we reproduce them in the solid state, and if so, what type of computing paradigm would we obtain? I will show that a machine that uses memory to both process and store information, like our brain, and is endowed with intrinsic parallelism and information overhead - namely takes advantage, via its collective state, of the network topology related to the problem - has a computational power far beyond our standard digital computers [1]. We have named this novel computing paradigm "memcomputing" [2, 3]. As an example, I will show the polynomial-time solution of prime factorization and the NP-hard version of the subset-sum problem using polynomial resources and self-organizing logic gates, namely gates that self-organize to satisfy their logical proposition [4]. I will also demonstrate that these machines are described by a topological field theory and they compute via an instantonic phase where a transient long-range order develops due to the effective breakdown of topological supersymmetry [5]. The digital memcomputing machines that we propose are scalable and can be easily realized with available nanotechnology components, and may help reveal aspects of computation of the brain.

Neuromorphic computing with stochastic spintronic devices *(Invited Paper)*

Damien Querlioz, Adrien F. Vincent, Alice Mizrahi, Damir Vodenicarevic, Nicolas Locatelli, Univ. Paris-Sud 11 (France); Joseph S. Friedman, The Univ. of Texas at Dallas (United States); Jacques-Olivier Klein, Univ. Paris-Sud 11 (France); Julie Grollier, Univ. Paris-Sud (France)

Spin torque magnetic memory (ST-MRAM) is currently under intense academic and industrial development, as it features non-volatility, high write and read speed and high endurance. However, one of its great challenge is the probabilistic nature of programming magnetic tunnel junctions, which imposes significant circuit or energy overhead for conventional ST-MRAM applications. In this work, we show that in unconventional computing applications, this drawback can actually be turned into an advantage. First, we show that conventional magnetic tunnel junctions can be reinterpreted as stochastic "synapses" that can be the basic element of low-energy learning systems. System-level simulations on a task of vehicle counting highlight the potential of the technology for learning systems. We investigate in detail the impact of magnetic tunnel junctions' imperfections. Second, we introduce how intentionally superparamagnetic tunnel junctions can be the basis for low-energy fundamentally stochastic computing schemes, which harness part of their energy in thermal noise. We give two examples built around the concepts of synchronization and Bayesian inference. These results suggest that the stochastic effects of spintronic devices, traditionally interpreted by electrical engineers as a drawback, can be reinvented as an opportunity for low energy circuit design.

10357-89, Session 13A

Degree of match determination using coupled spin-torque oscillators *(Invited Paper)*

Matthew Pufall, National Institute of Standards and Technology (United States)

Determining a ranked list or degree of match is frequent computational task, and is one that does not require high numerical precision. A variety of methods for performing such calculations are being explored, such as hardware methods based on lower precision Boolean logic and threshold logic, among others. We have been exploring nonBoolean hardware methods of performing these calculations using phase locking of spin torque oscillator arrays. In this scheme, phase locking of the oscillators in the array maps on to a distance metric based on an L2 norm. We will discuss the progress and challenges of implementing larger (>4) arrays of independently controllable spin torque oscillators into microwave systems that exhibit phase locking, and require stable, high speed, phase sensitive detection. Finally, we will discuss how these results may impact the prospects for applying such oscillator arrays to computational schemes that are more bio-inspired or neuromorphic in nature.

10357-127, Session 13A

Implementation of energy efficient learning in neural networks based on synaptic devices *(Invited Paper)*

Yuhan Shi, Leon Nguyen, Duygu Kuzum, Univ. of California, San Diego (United States)

The biological brain has capability of learning, recognizing, and processing imprecisely defined data and execute extremely complex computational tasks with incredible computational efficiency. Inspired from biological counterparts, synaptic devices have been developed to enable new computational paradigms inspired from the unique features of the biological brain. The question of how to design and build compact synaptic devices for energy-efficient and robust neuromorphic architecture has been a challenge for industry and academia. Here we will describe desired device characteristics for the synaptic devices and potential programing techniques for system-level robustness and efficiency. Then we will discuss device-level and array-level approaches to implementation of multi-level resistance states and improvements in energy efficiency. We will also discuss future directions towards building computational systems with brain-like parallelism, computational efficiency and learning capability.

10357-85, Session 13B

High-frequency polarization dynamics in spin-lasers: pushing the limits *(Invited Paper)*

Nils C. Gerhardt, Markus Lindemann, Ruhr-Univ. Bochum (Germany); Tobias Pusch, Rainer Michalzik, Univ. Ulm (Germany); Martin R. Hofmann, Ruhr-Univ. Bochum (Germany)

While the high-frequency performance of conventional lasers is limited by the coupled carrier-photon dynamics, spin-polarized lasers have a high potential to overcome this limitation and to push the direct modulation bandwidth beyond 100 GHz. The key is to utilize the ultrafast polarization dynamics in spin-polarized vertical-cavity surface-emitting lasers (spin-VCSELs) which is decoupled from the intensity dynamics and its fundamental limitations. The polarization dynamics in such devices, characterized by the polarization oscillation resonance frequency, is mainly determined by the amount of birefringence in the cavity. Using an approach for manipulating the birefringence via mechanical strain we were able to push the polarization dynamics to resonance frequencies of more than 40 GHz. Up to now these values are only limited by the setup to induce birefringence and do not reflect any fundamental limitations. Taking our record results for the birefringence-induced mode splitting of more than 250 GHz into account, the concept has the potential to provide polarization modulation in spin-VCSELs with modulation frequencies far beyond 100 GHz. This makes them ideal devices for next generation fast optical interconnects.

Here we present our recent results for ultrafast polarization dynamics in spin-lasers and discuss different concepts to increase and control the amount of birefringence and thus the polarization dynamics of the laser. By comparing experimental and theoretical results we investigate the limitations for future polarization modulation concepts in spin-lasers and analyze the fundamentally important parameters.

10357-86, Session 13B

Quantum dot spin-V(E)CSELs: polarization switching and periodic oscillations *(Invited Paper)*

Nianqiang Li, Univ. of Essex (United Kingdom); Dimitris Alexandropoulos, Univ. of Patras (Greece); Hadi Susanto, Ian D. Henning, Michael J. Adams, Univ. of Essex (United Kingdom)

Spin-polarized vertical (external) cavity surface-emitting lasers, spin-V(E) CSELs are of interest since their output polarization can be manipulated by spin-selective pumping. Recently we reported [1] the first room temperature optically-pumped quantum dot (QD)-based spin-VECSEL operating at the telecom wavelength of 1300 nm. Under certain conditions it was found that the sign of the output polarization ellipticity could switch from following that of the pump to an ellipticity of the opposite sign. This was seen in experimental studies and theoretical simulations based on time?dependent solution of the rate equations for a spin-flip model (SFM) modified to apply to QD material [2]. The simulations also revealed regions of periodic oscillations at a frequency related to the birefringence rate.

A deeper level of understanding of these phenomena is gained by applying a stability analysis to the SFM equations used for simulations. The choice of in-phase and out-of-phase solutions that appear in a time-dependent simulation is found to be determined by the condition that the corresponding steady-state solutions are stable against small perturbations [3]. Whilst it is not yet possible to conclude that the observed behaviour in our 1300 nm device is caused by the same underlying physics as that of the model, it is nevertheless clear that stability analysis is a valuable theoretical tool for future studies of spin-V(E)SELs.

Theory of wurtzite-based spin lasers *(Invited Paper)*

Paulo E. Faria Junior, Univ. Regensburg (Germany); Gaofeng Xu, Univ. at Buffalo (United States); Yang-Fang Chen, National Taiwan Univ. (Taiwan); Guilherme M. Sipahi, Univ. de São Paulo (Brazil); Igor Zutic, Univ. at Buffalo (United States)

The injection of spin polarized carriers in semiconductor lasers greatly modifies the device operation. Although the vast majority of spin lasers are based on semiconductors with zinc-blende structure[1], there is a recent exception using nitride-based compounds with wurtzite structure[2], which still lacks a reliable theoretical description. In order to address such

deficiency, we investigated (In,Ga)N-based wurtzite quantum wells following typical device geometries[3]. The small spin-orbit coupling in such nitride materials allows the simultaneous spin polarization of electrons and holes, providing an unexplored path to control spin lasers. For instance, based on microscopic gain calculations[3,4] we found a robust gain asymmetry, one of the key signatures of spin laser operation. In addition, we combine these microscopic gain calculations with phenomenological rate equations[5] to investigate threshold reduction features. We show that the lasing threshold has a nonmonotonic dependence on electron spin polarization, even for a nonvanishing hole spin polarization. The complementary information of these theoretical frameworks provides a powerful predictive materials-specific tool to understand and guide the operation of semiconductor spin lasers. Eigenmodes of semiconductor spin-lasers with local linear birefringence and gain dichroism *(Invited Paper)*

Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France); Tibor Fordos, VŠB-Technical Univ. of Ostrava (Czech Republic) and Ecole Polytechnique (France); Kamil Postava, Jaromir Pištora, VŠB-Technical Univ. of Ostrava (Czech Republic); Arnaud Garnache, Univ. Montpellier (France); Henri-Jean Drouhin, Ecole Polytechnique (France)

We present a general method for modeling spin-lasers such as spin-polarized vertical cavity surface emitting laser (spin-VCSELs) with multiple quantum wells including anisotropic effects such as i) the emission of elliptically-polarized photons and originating from unbalanced spin-up and spin-down pumps, ii) the linear gain dichroism originating from the reduction from Td to C2v symmetry group at the III-V ternary interfaces and iii) the locally linear birefringence due to the anisotropic strain field at surface of ? VECSELs an optical birefringence of quantum wells from the Henry's factor. New recurrence calculations, together with analytically gain tensor derived from Maxwell-Bloch equations, enable to model emission from multiple quantum well active zones to find the laser resonance conditions and properties of eigenmodes.

The method is demonstrated on real semiconductor laser structures. It is used for the extraction of optical permittivity tensors of surface strain and of quantum wells (QWs). The laser structures are also experimentally studied via ellipsometry methods by measurement of the rotation spectra of complete Mueller matrix in the reflection geometry. The anisotropic optical permittivity constants in the spectral range from 0.73 to 6.4 eV are modeled in order to disantangle surface and QWs contributions to the linear optical birefringence of the structures.

Mutually synchronized spin Hall nano-oscillators for neuromorphic computing *(Invited Paper)*

Mykola Dvornik, Ahmad A. Awad, Philipp Dürrenfeld, Afshin Houshang, Ezio Iacocca, Randy K. Dumas, Johan Åkerman, Göteborgs Univ. (Sweden)

Deep Machine Learning is the emerging brain-inspired computing approach that employs artificial neural networks to solve such important problems as image and voice recognition, market behavior prediction, etc. It however still relies on digital CMOS technologies that approach their fundamental limits. As a consequence, there is now significant research activity aimed at finding hardware platforms that would allow for the native implementation of the artificial neural networks. There are already models available that describe human brain operation via synchronization phenomena in complex networks of nonlinear oscillators. This research topic remains mostly theoretical, or numerical, since large-scale oscillator networks are needed, but not easily implemented. However, it was recently demonstrated that so-called spin torque and spin Hall nano-oscillators can act as artificial neurons [1], and their propensity for mutual synchronization on the nano-scale can open up for very large non-linear oscillator networks with different degrees of mutual interactions.

To this end, we here present the first experimental demonstration of mutual synchronization of nano-constriction spin Hall nano-oscillators (SHNOs) [2]. The mutual synchronization is observed both as a strong increase in the power and coherence of the electrically measured microwave signal. The mutual synchronization is also optically probed using scanning micro-focused Brillouin light scattering microscopy (μ-BLS), providing the first direct imaging of synchronized nano-magnetic oscillators. By tailoring the connection region between the nano-constrictions, we have been able to synchronize SHNOs separated by up to 4 micrometers. In addition, we have demonstrated mutual synchronization of as many as nine SHNOs. Our results opens up a direct route for the design of very large SHNO based oscillator networks and pave the way for the development of a spintronic brain-inspired computing technology.

Stochastic p-bits for invertible logic *(Invited Paper)*

Kerem Yunus Camsari, Purdue Univ. (United States)

Conventional logic/memory devices are built out of deterministic units such as MOS transistors, or nanomagnets with energy barriers in excess of ~40 kT. We show that unstable, stochastic units which we call "p-bits" can be interconnected to create correlations that implement Boolean functions with impressive accuracy, comparable to digital circuits. At the same time they are invertible, a unique property that is absent in digital circuits. When operated in the direct mode, the input is clamped, and the network provides the correct output. In the inverted mode, the output is clamped, and the network fluctuates among all possible inputs that are consistent with that output. We present an implementation of such an invertible gate to emphasize the key role of a "transistor-like" building block to construct p-bit networks. The results for this hardware implementation agree with those from a universal model for p-bits, showing that p-bits need not be magnet-based: any "transistor-like" tunable random bit generator should be suitable. We present an algorithm for designing a bi-directional p-bit network that implements a given truth table. We then show such bi-directional units, such as Full Adders, can be interconnected in a directed manner to implement 32-bit addition, that correlate hundreds of stochastic p-bits to pick a single state out of (~8 billion) possibilities. We also show that despite the directed interconnections, invertibility is largely preserved. This combination of digital accuracy and logical invertibility is enabled by the hybrid design using bi-directional BM units to construct circuits with directed inter-unit connections.

10357-92, Session 14A

Shock-waves and commutation speed of memristors *(Invited Paper)*

Marcelo Rozenberg, Ctr. National de la Recherche Scientifique (France) and Univ. of California, San Diego (United States)

Progress of silicon based technology is nearing its physical limit, as minimum feature size of components is reaching a mere 10 nm. The resistive switching behavior of transition metal oxides and the associated memristor device is emerging as a competitive technology for next generation

electronics. Significant progress has already been made in the past decade and devices are beginning to hit the market; however, it has been mainly the result of empirical trial and error. Hence, gaining theoretical insight is of essence. In the present work we report the striking result of a connection between the resistive switching and shock wave formation, a classic topic of non-linear dynamics. We argue that the profile of oxygen vacancies that migrate during the commutation forms a shock wave that propagates through a highly resistive region of the device. We validate the scenario by means of model simulations and experiments in a manganese-oxide based memristor device and we extend our theory to the case of binary oxides. The shock wave scenario brings unprecedented physical insight and enables to rationalize the process of oxygen-vacancy-driven resistive change with direct implications for a key technological aspect – the commutation speed.

10357-93, Session 14A

Reservoir computing with spin-torque nano-oscillators

Flavio Abreu Araujo, Mathieu Riou, Jacob Torrejon, Unité Mixte de Physique CNRS/Thales (France); Guru Khalsa, Mark D. Stiles, National Institute of Standards and Technology (United States); Sumito Tsunegi, Akio Fukushima, Hitoshi Kubota, Shinji Yuasa, National Institute of Advanced Industrial Science and Technology (Japan); Damien Querlioz, Univ. Paris-Sud 11 (France); Vincent Cros, Julie Grollier, Unité Mixte de Physique CNRS/Thales (France)

In this work, we prove that nanoscale magnetic oscillators called spin-torque nano-oscillators[1-3] can be used to emulate the oscillatory behavior of collections of neurons. We first highlight their two main assets for neuromorphic computing: their exceptional ability to synchronize and their well-controlled magnetization dynamics. We then demonstrate experimentally that a single spin-torque oscillator can realize neuromorphic tasks such as spoken digit recognition reaching state of the art performances.

For many tasks such as facial recognition, speech recognition or prediction, the brain processes information much faster and with much less power than any computer. Some models interpret the way brain process information treating the neurons as interconnected non-linear oscillators. In particular, reservoir computing is a recently introduced braininspired computing paradigm [4]. Its efficiency at dealing with complex cognitive tasks such as speech recognition or chaotic series prediction has already been demonstrated [5].

Reservoir computing can be implemented with a recurrent network (the reservoir) composed of an assembly of interconnected oscillators with fixed connections. A fast input signal, encoding the data to process, is applied to the network. The input signal modifies the frequency and amplitude of each oscillator. Different input waveforms will create different transient dynamics in the network, allowing for separation and classification. The responses of all the oscillators are recorded and recombined. This recombination corresponds to the output of the computation. When the input signal is applied to the reservoir of coupled oscillators, the initial problem (classifying the inputs) is projected non-linearly in a higher dimensional state where separation is easier. If the number of non-linear oscillators is sufficient, the projection of the initial problem in the reservoir state is linearly solvable. It is then sufficient to recombine linearly the response of the different oscillators of the reservoir in order to generate different outputs for different inputs. The optimum coefficients are determined using a training procedure, which consists in a simple linear regression. In other words the working principle of reservoir computing is to leverage non-linearity to transform the problem in another one that is easier to solve. Reservoir computing is one of the few neural network approaches demonstrated in hardware. However, existing implementations are restricted to FPGAs or optical systems, where the power consumption is high and oscillators are not nanometric [4,5].

In this context, spin-torque nano-oscillators are particularly promising building blocks for reservoir computing. They have a nanometric size and low energy consumption, they are compatible with CMOS and can be built in large quantities. In addition, these oscillators are highly non-linear and can synchronize to each other. They are therefore ideal candidates to mimic neurons [6]. Here we give the first experimental demonstration of neuromorphic computing with spin-torque nano-oscillators. We show that a single oscillator can emulate the behavior of a whole neural network. By time multiplexing the input waveform we create a temporal complexity which is the analog of the spatial complexity of a network. By exciting the oscillator with this preprocessed signal, we generate complex transient dynamics that we record and recombine. In order to have good performances in term of noise, we use vortex based spin-torque nano-oscillators with FeB free layer. The dynamics of our oscillator is controlled through the applied dc current and magnetic field. By changing these two parameters we have tuned the oscillator operating point to optimize the neural network-like behavior. By leveraging the transient dynamics of our spin-torque vortex oscillator, we have performed several cognitive tasks. First we have tested our system with a simple pattern recognition task, which consists in discriminating sequences of sine and squares randomly disposed in the input waveform. This task is not trivial since the recognition is piecewise, which means that at each moment the system should recognize if the input value belongs to a square or a sine. We achieved a perfect recognition of sines and squares. Then we moved to speech recognition task, which is more complex (Fig1). Our input signals are recorded digits said by 5 different speakers. After recombining the transients of the oscillator response, we were able to recognize which digit was said and which speaker said it with a success rate of 99,8%. Our results are comparable to the best results observed in hardware reservoir computing [4,5] and open the path to building large spintronics neural networks that exploit magnetization dynamics for computing.

Dispersive elastic properties governing Dzyaloshinskii domain wall creep *(Invited Paper)*

Vincent Sokalski, James P. Pellegren, Derek Lau, Carnegie Mellon Univ. (United States)

Measuring asymmetric growth of chiral magnetic bubble domains has emerged as a popular technique for evaluating the interfacial Dzyaloshinskii-Moriya Interaction (DMI) in thin films, but the development of a complete theoretical model to explain the range of counterintuitive results has remained elusive. Here, we show that these anomalous trends are rooted in the highly anisotropic energy of Dzyaloshinskii domain walls (DWs), which has an immense impact on the governing elastic properties.[1, 2] Our model further suggests that there is a multitude of additional information built into the full asymmetric velocity measurements seen experimentally.

In the creep regime, velocity depends exponentially on the elastic energy, ?, often assumed to be equivalent to the wall energy, ?, which is strictly true only in the isotropic case. For the anisotropic case that emerges when the wall is subject to an external in-plane field, ? is given instead by the wall stiffness, ?(?)+?''(?), which adopts trends that are very different from ? itself including the striking result that higher energy walls are often more flexible than their low energy counterparts. We present analytic and numerical calculations of a dispersive stiffness that quantitatively predict many of the features seen experimentally including a reversal in the preferred expansion direction in magnetic bubbles. By fitting the full asymmetric velocity profile, it is now possible to, not only, measure DMI, but also estimate the lengthscale of the disorder; something notoriously difficult to study experimentally.

Stabilization and control of Majorana bound states with skyrmions *(Invited Paper)*

Alexey A. Kovalev, Univ. of Nebraska-Lincoln (United States)

Majorana bound states (MBSs) are a promising candidate for a realization of topological quantum computer and memory, which uses non-Abelian anyons to encode and manipulate quantum information. Since Kitaev's toy model for creating MBSs using the unpaired sites at the ends of a spinless p-wave superconducting wire, it has been shown that a conventional s-wave superconductor with spin-orbit coupling (SOC) subject to Zeeman or proximity-induced exchange field has effective p-wave pairing and thus can also support these nonlocal quasiparticles. In systems lacking an extrinsic SOC, an effective SOC can be provided through a nonuniform magnetic texture or field. Here, we explore stabilization of MBSs through a proximity effect with a noncollinear ferromagnet supporting skyrmions. Skyrmions can be easily manipulated via currents or temperature gradients thus providing means for braiding and manipulation of MBSs. In particular, we demonstrate how a nonabelian statistics of MBSs can be revealed by moving proximity coupled skyrmions in a vicinity of a tri-junction with different superconducting phases.

Charge-spin conversion in topological insulators and graphene *(Invited Paper)*

Ching-Tzu Chen, IBM Thomas J. Watson Research Ctr. (United States)

Topological insulators and graphene, the two representative 2D Dirac electron systems, have both been widely studied for spintronics applications. On the one hand, strong spin-orbit coupling in topological insulators makes them obvious spin source candidates. On the other hand, minute spin-orbit coupling in graphene makes it a promising spin transport channel. In this talk, I will first present our work on the charge-spin conversion in topological insulators. Our data demonstrate orders of magnitude improvement over conventional spin-Hall metals [1][2]. Furthermore, they indicate that the high spin generation efficiency originates from the spin-momentum locking of the topological surface states. In the second part of the talk, I will discuss the charge-spin conversion in graphene, when proximity coupled to a model magnetic insulator EuS. The interfacial exchange coupling produces a substantial Zeeman field (>= 14 T) in graphene, which yields orders-of-magnitude enhancement in spin generation by the Zeeman spin-Hall effect. Furthermore, the strong exchange field lifts the spin degeneracy in the graphene quantum Hall regime, which leads to novel spin-polarized edge transport features, potentially interesting for classical and quantum information processing [3].

AuCl3 doping-induced conductive unstability for CVD-grown graphene on glass substrate

Jiaqing Wang, Xianming Liu, Yun Luo, Peng Zhang, Xiaohua Lei, Weimin Chen, Chongqing Univ. (China)

Graphene is a candidate material for next-generation high performance transparent conducting film (TCF) to replace ITO materials. However, the sheet resistance of large area graphene obtained by the CVD method is higher than other kinds of TCFs. The main strategies for improving the electrical conductivity of graphene films have been based on various doping treatments. AuCl3 is one of the most effective dopants.

In the paper, we investigated the influence of AuCl3 doping on the conductive stability of CVD-grown graphene. Large area graphene film synthesized by CVD was transferred to glass substrates using poly(methyl methacrylate). AuCl3 in nitromethane was used to dope the graphene films to improve the electrical conductivity. A group of sample without doping were prepared for comparison. The resistances of graphene under periodic visible light irradiation with and without AuCl3 doping were measured. Results show that the resistances for all samples increased exponentially under lighting, while decreased slowly in an exponential form as well after the light was switched off. The change rate and degree for doped graphene were greater than that of undoped graphene. The relative resistance changes were up to 7% and 23% for undoped and doped samples under blue light irradiation with 80mW/cm2 in atmosphere. The corresponding value were 3.5% and 12.5% when the samples were in vacuum. It was evident from the experimental data that AuCl3 doping may induce conductive unstability for CVD-grown graphene on glass substrate.

Excitons and magnetic properties of InP nanowires in wurtzite phase

Paulo E. Faria Junior, Univ. Regensburg (Germany); Davide Tedeschi, Sapienza Univ. di Roma (Italy); Marta De Luca, Sapienza Univ. di Roma (Italy) and Univ. Basel (Switzerland); Benedikt Scharf, Univ. Regensburg (Germany) and Julius-Maximilians-Univ. Würzburg (Germany); Antonio Polimeni, Sapienza Univ. di Roma (Italy); Jaroslav Fabian, Univ. Regensburg (Germany)

Spin-dependent phenomena in III-V wurtzite semiconductor nanowires have recently attracted great attention. Unlike their zinc-blende counterparts, some basic properties of these novel non-nitride wurtzite materials are still unknown. Starting with a robust 8x8 k.p Hamiltonian which includes the k-dependent spin-orbit coupling terms[1], we investigate the excitonic and magnetic properties of InP in wurtzite phase. At low magnetic fields, the Zeeman splitting is linear and our calculated values of effective g-factors are in good agreement with experimental data[2]. Furthermore, our calculations allow us to distinguish the independent contributions of electron and hole g-factors, typically entangled due to excitonic effects. We also investigated the interplay between Landau levels (orbital effects) and the Zeeman splitting by including the spatial dependence of the vector potential. For large magnetic fields, we showed that the nonlinear features of the Zeeman splitting found in experiments[2] arise from the interaction between the different valence bands, mainly heavy and light holes from different Landau level indices. Spinorbitronics and spin Hall effects in metallic multilayers for THz emission and THz applications

Thi-Huong Dang, Unité Mixte de Physique CNRS/Thales (France); Jérôme Tignon, Lab. Pierre Aigrain (France); Jean-Marie George, Sophie Collin, Unité Mixte de Physique CNRS/Thales (France); Henri-Jean Drouhin, Ecole Polytechnique (France); Gaetan Bracciale, Laurent Divay, Thales Research & Technology (France); Paolo Bortolotti, Unité Mixte de Physique CNRS/Thales (France); Sukhdeep Dhillon, Lab. Pierre Aigrain (France); Henri Jaffrès, Unité Mixte de Physique CNRS/Thales (France)

In this work, we will present our last results of THz emission provided by optimized growth spin-orbitronics metallic bilayers (Co/Pt, NiFe/Au:W) via dynamical spin-to charge conversion from interfacial spin-orbit coupling (SOC) or inverted spin-Hall effect (ISHE) through time-dependent spectroscopy (TDS) [1-3]. The bilayer systems represent state-to-the art model systems in experiments combining RF-spin pumping and spin-to-charge conversion by ISHE principles [4-5]. Here, experiments consist in exciting correlated (in-plane) magnetization and spin-currents within the ferromagnet (FM) in the bilayer, in the picosecond regime via femtosecond laser excitation and measuring, in the picosecond timescale, the relaxation of the correlated spin and charge currents responsible for THz dipolar emission. We will compare performances of the different bilayer SHE systems in terms of the superdiffusive current point-of-view [6] to compare with spin-pumping like models. In particular, we will emphasize from a theoretical (analytical) and computational approach to the extension of the theory of parameterized spin-pumping [7-8] adapted to shorter timescale in the case of a FM/SOC bilayers.

Disentangling interface and bulk contributions to the anisotropic magnetoresistance in Pt/Co/Pt sandwiches *(Invited Paper)*

André Philippi-Kobs, Deutsches Elektronen-Synchrotron (Germany) and Univ. Hamburg (Germany); Hans Peter Oepen, Univ. Hamburg (Germany)

We report on interfacial contributions to the anisotropic magnetoresistance (AMR) in Co layers sandwiched between Pt. For that purpose we present the pure Co thickness dependence of the AMR in Pt(5nm)/Co/Pt(3nm) sandwiches at room temperature (Co thickness varied between 0.8 nm and 50 nm) obtained by a detailed analysis of the experimental data that were used to prove the existence of the anisotropic interface magnetoresistance (AIMR) effect [1]. The detailed analysis was triggered by a controversy that came up in a discussion about the properties of AIMR [2,3]. Utilizing the Fuchs-Sondheimer formalism interface contributions can be separated from bulk-like AMR. We demonstrate that for all-metal systems interfacial AMR is also present when varying the magnetization within the film plane [4]. This interfacial in-plane AMR is two times smaller than the contribution that arises when the magnetization is varied in the plane perpendicular to the current direction. This finding is in contrast to the spin Hall MR found for ferromagnetic insulator/Pt bilayers [5] revealing the existence of different MR effects at the interfaces of Pt with conducting and insulating ferromagnets.

Financial support by DFG via project OE 251/7-1 and SFB 668 is gratefully acknowledged. We thank S. Heße, A. Frauen, and A. Farhadi for technical support.

Engineering spin accumulation and giant magnetoresistance in metallic nanostructures *(Invited Paper)*

Gilles Zahnd, Laurent Vila, Van Tuong Pham, Paul Noël, CEA Grenoble (France); Alain Marty, Jean-Philippe Attané, Commissariat à l'Énergie Atomique (France)

Manipulation of spin accumulation has shown to be a versatile tool for both fundamental research and functional application since it enables to study spin injection and transport in non-magnetic materials, as well as spincaloritronics, spin-orbitronics effects and spin transfer torque [1].

In this presentation, we shows how spin accumulation can be engineered, and what functional behaviors can be obtain through spin accumulation control:

By manipulating spin accumulation in a lateral device through precession or absorption [2, 3], it is possible to extract independently transport parameters of a ferromagnetic material or of a heavy metal with strong spin orbit interaction. Anisotropic absorption in a ferromagnetic element notably enables to obtain both its spin diffusion length and its spin precession length.

Lateral devices are an adapted tool to manipulate spin accumulation for functional application thanks to the high flexibility of their geometry. Nevertheless, lateral devices had always been confined to fundamental research due to the smallness of the signal they emit. We briefly show that lateral devices can emit signal comparable to what is obtain from CPP geometry, as giant magnetoresistance exceeding 10% in an downscaled CoFe-based lateral spin valve [4,5]. We then highlight that the use of lateral devices enables many applicable functions as enhancing spin signal amplitudes, or engineering simultaneously several spin accumulation degrees of freedom. Finally, using a confined spin accumulation located between two tunnel barriers, we show that it is possible to observe a novel magnetoresistive effect that only requires one ferromagnetic element.

Temperature dependence of spin transport properties in Pt *(Invited Paper)*

Ryan Freeman, Andrei Zholud, Sergei Urazhdin, Emory Univ. (United States)

Despite extensive applications of Pt for spin-charge conversion in spintronics, its spin-dependent transport properties are still debated. We study spin transport in Pt by utilizing current perpendicular-to-plane (CPP) giant magnetoresistance (GMR) in nanoscale Permalloy (Py)-based spin valves with Pt inserted in the nonmagnetic spacer.

We will discuss our results for the temperature-dependent spin diffusion length (SDL) of Pt, extracted from the dependence of GMR on the Pt thickness and calculations based on the Valet-Fert model. By comparing samples with Pt sandwiched between Cu spacers and samples where Pt is in direct contact with Py, we determine that the spin relaxation rate at the Pt/Py interface is significantly smaller than at the Pt/Cu interface.

We interpret our results in terms of two relevant spin scattering mechanisms: spin flipping due to the orbital scattering (Elliot-Yafet mechanism, EY), and spin precession around the effective spin-orbit field (Dyakonov-Perel mechanism, DP). We argue that DP relaxation is suppressed at Pt/Py interfaces due to the dominance of the proximity-induced effective exchange field. By comparing the SDL as a function of temperature to the mean free path, we show that EY contribution to scattering in the bulk is dominant at temperatures above 150K. We also analyze samples with ultrathin Pt spacer, where scattering at interfaces should be dominant. Temperature dependence of GMR of these samples is consistent with the dominance of DP relaxation. Our results provide a pathway for the optimization of spin scattering and spin/charge current conversion in Pt-based spintronic devices.

Imaging electrical rotation of antiferromagnetic domains *(Invited Paper)*

Sarnjeet Dhesi, Diamond Light Source Ltd. (United Kingdom)

Antiferromagnetic spintronics aims to exploit zero net magnetic moment materials as efficient generators, detectors and transmitters of spin current. Recently, it was predicted that the Néel vector of an antiferromagnet could be rotated using staggered current-induced effective fields when the local inversion symmetry is broken [1]. This prediction has now been experimentally confirmed, for the collinear antiferromagnet CuMnAs, using current pulses applied along two different crystallographic directions [2].The current-induced rotation of the Néel vector was monitored using anisotropic magnetoresistance (AMR) measurements which provided spatially averaged information over the probed area of the microdevice.

Here we use PhotoEmission Electron Microscopy (PEEM), with magnetic contrast arising from X-Ray Magnetic Linear Dichroism, to directly image changes in the antiferromagnetic domain structure after electrical rotation. The combined PEEM-AMR study allows a clear observation of the CuMnAs submicron domain pattern before and after rotation of the antiferromagnetic domains. We find that the domain structure is systematically modified, by current pulses applied along two orthogonal directions, with a clear correlation between the AFM domain structure and the AMR results. Reversible switching of several domain features was also observed. However, there are regions exhibiting no change in XMLD-PEEM contrast implying inhomogeneous switching and highlighting the complex nature of the switching process in multi-domain antiferromagnetic films.

Non-stationary spin-polarized tunneling currents tuning by means of applied bias changing *(Invited Paper)*

Vladimir N. Mantsevich, Natalia Maslova, M.V. Lomonosov Moscow SU (Russian Federation); Petr Arseyev, P.N. Lebedev Physical Institute (Russian Federation)

We analyzed time evolution of the opposite spin electron occupation for the single-localized state with the Coulomb interaction coupled to two reservoirs in the presence of applied bias voltage. We revealed that in the presence of the second reservoir with non-zero applied bias, "magnetic" state can be distinguished from the "paramagnetic" one by analyzing time evolution of the electron occupation numbers. Typical time scales strongly depend on the value of applied bias and initial conditions.

We revealed that non-stationary spin-polarized currents can flow in the both leads and their direction and polarization depend on the value of applied bias. We revealed, that spin polarization and the direction of the non-stationary currents in each lead can be simultaneously inverted by the sudden changing of the applied bias voltage. But in the stationary state occupation numbers for the electrons with the opposite spins have the same values. Spin polarized tunneling currents in each lead also become equal.

We also investigated the changes of the time evolution regimes when the second lead is switched on at the particular time moment. We found out that switching on of the second lead with the non-zero applied bias destroys long-living "magnetic" moment.

10357-103, Session 15B

Spin-dependent electrical transport at finite temperatures from the first principles *(Invited Paper)*

David Wagenknecht, Charles Univ. in Prague (Czech Republic) and Institute of Physics of Materials of the ASCR, v.v.i., The Czech Academy of Sciences (Czech Republic); Karel Carva, Charles Univ. in Prague (Czech Republic); Ilja Turek, Charles Univ. in Prague (Czech Republic) and Institute of Physics of Materials of the ASCR, v.v.i., The Czech Academy of Sciences (Czech Republic)

Finite-temperature electronic transport properties of materials suitable for spintronic applications like halfmetalic semi-Heusler NiMnSb are examined from the first principles. The influence of various structural defects on different sublatices will be discussed.

Inclusion of lattice vibrations to ab initio calculations is substantial, because real spintronic devices operate at finite temperatures. However, it represents a difficult analytical and numerical problem.

Numerical codes based on the tight-binding linear muffin-tin orbital method in atomic sphere approximation (TB-LMTO ASA) in combination with the relativistic Dirac equation and the coherent potential approximation (CPA) [1,2] are used. Thermal displacements of nuclei from their equilibrium positions are included by a frozen phonon approach and the multicomponent CPA can describe both chemical (different atoms) and thermal (random displacements) disorder. Used approximation of phonons is general and may be employed to study any material. The method is in a good agreement with experimental or other theoretical studies for good metals and random alloys; consequently, it opens a way to study more complex materials.

The results of our thermal dependent calculations of NiMnSb exhibit a good match with experimental data and the fully relativistic approach makes possible to examine phenomena like the anomalous Hall effect. Moreover, the calculated temperature dependence of quantities may be used as an additional information to, e.g., identify chemical defects in real samples.

First-principles calculation of spin transport and relaxation in magnetic heterostructures *(Invited Paper)*

Zhe Yuan, Beijing Normal Univ. (China)

Manipulation of a spin current at nanoscale is desired in many proposed spintronics devices. Magnetic multilayers consisting of ferromagnetic, ferrimagnetic and nonmagetic materials show rich phenomena when a spin current propagates through the multilayers. An interface of ferromagnetic and nonmagnetic metals has been demonstrated to play an important role in the generation and dissipation of a spin current. Using first-principles scattering calculation, we study the transport and relaxation of spin currents in typical transition metals and alloys and their interfaces. In particular, we focus on identifying the correlation of spin transport and relaxation with the specific order parameters of magnetic materials. By examining the spin-Hall conductivity and spin-flip diffusion length as a function of conductivity (resistivity), we are able to distinguish different dominant physical mechanisms of the generation and dissipation of spin currents.

Spin superfluid triggered domain-wall motion and spin-transistor action *(Invited Paper)*

Pramey Upadhyaya, Se Kwon Kim, Yaroslav Tserkovnyak, Univ. of California, Los Angeles (United States)

Spin superfluidity, that is a coherent flow of spin in the presence of rotational (U1) symmetry, enables possibility of uncovering a new class of spin-based dissipationless phenomenon and devices by mimicking well-established superfluid-like phenomenon, for example those observed in superconductors (charge-based superfluids). Motivated by this, recently, theoretical possibilities of room temperature excitation of spin superfluid-like transport, via exploiting interfacial spin-orbit torque, have been proposed in a number of easy-plane magnetic systems. In this work [1], we present how the angular momentum carried by these spin superfluids be utilized to construct low-dissipation spintronic devices. Specifically, we theoretically investigate the transfer of angular momentum between a spin superfluid and a domain wall in an exchange coupled easy-axis and easy-plane magnetic insulator. A domain wall in the easy-axis magnet absorbs spin angular momentum via disrupting the flow of a superfluid spin current in the easy-plane magnet. We derive analytical expressions for the resultant domain-wall motion in the geometry where spin superfluidity is actuated by spin-orbit torques. Furthermore, by controlling the pinning of the domain wall, the so-called zero voltage to finite voltage transition of superconducting Josephson Junctions can be mimicked, which we utilize to propose a reconfigurable spin transistor.

Thermal generation of spin currents in oxides *(Invited Paper)*

Rafael Ramos, Takashi Kikkawa, Daichi Hirobe, Tohoku Univ. (Japan); Alberto Anadon, Irene Lucas, Univ. de Zaragoza (Spain); Ken-ichi Uchida, National Institute for Materials Science (Japan); Hiroto Adachi, Japan Atomic Energy Agency (Japan); Pedro Algarabel, Luis Morellon, Myriam Aguirre, Univ. de Zaragoza (Spain); Sadamichi Maekawa, Japan Atomic Energy Agency (Japan); Ricardo Ibarra, Instituto de Nanociencia de Aragon (Spain); Eiji Saitoh, Tohoku Univ. (Japan)

The spin-Seebeck effect (SSE) enables generation of a spin current in a magnetic material (F) by a temperature gradient. This spin current is injected in a contacting non-magnetic material (N) where it is electrically detected by means of the inverse spin-Hall effect (ISHE). The SSE offers a new paradigm for heat to electricity conversion, however, the main disadvantage of the SSE is the low value of the extracted voltage, with values significantly lower than conventional thermoelectrics.

Recently, we reported a substantial increase of the SSE thermoelectric voltage in magnetic multilayers formed by repeated growth of a basic Fe_3O_4/Pt bilayer structure [1]. As a consequence of the simultaneous increase in voltage and reduction of device resistance the multilayer system exhibits a two order of magnitude increase of the extractable thermoelectric power [2].

The observed enhancement of the SSE voltage, relative to its value in the single bilayer, monotonically increases as the temperature of the system is reduced [3]. This result can be possibly understood by an increase of the characteristic length for spin current propagation within the system, in qualitative agreement with the recently observed increase of the magnon diffusion length in Fe_3O_4 at lower temperatures [4]. Our results suggest that the thermoelectric performance of the SSE in multilayer system can be further improved by careful choice of materials with suitable spin transport properties.

During my talk, I will also introduce the results on spin current carried by spinons in a spin-liquid system [5] and the observation of magnon-phonon coupling by SSE [6]

The contribution of the thermal Hall effect in the anomalous Nernst and spin Seebeck effects *(Invited Paper)*

Ssu-Yen Huang, Yi-Jia Chen, National Taiwan Univ. (Taiwan)

The Anomalous Nernst effect (ANE) and the spin Seebeck effect (SSE) in spin caloritronics are two of the most important mechanisms to manipulate the spin-polarized and pure spin current, respectively, through thermal excitation. The ANE in ferromagnetic metals and the SSE in magnetic insulators have been extensively studied, while a recent theoretical work suggests that the thermal Hall effect (THE), has been overlooked, and it may significantly contribute to the ANE and the SSE. [1] Most strikingly, the THE, which results in the anisotropic transverse temperature gradient, has the exact same magnetic-field angular dependence as the ANE and the SSE. This anisotropic transverse temperature gradient can be converted into an electric signal by the thermocouple effect. Therefore, it is vital to investigate the contribution of the THE in the ANE and the SSE.

In this work, we experimentally demonstrate that the thermocouple effect in the ANE and SSE measured geometry is indeed inevitable. [2] By designing several special measured geometries, we are able to systematically study the THE by the thermocouple effect in the ferromagnetic metal, permalloy (Py), and the magnetic insulator, yttrium iron garnet (YIG). Our results show that the contribution of the THE by thermocouple effect in the Py and YIG is negligibly small, if one includes the thickness dependence of the Seebeck coefficient. The spin-polarized current in the ANE and the pure spin current in the SSE remain important elements for exploring spin caloritronics phenomena.

Spin-caloritronic nano-oscillator *(Invited Paper)*

Igor Barsukov, Univ. of California, Riverside (United States)

Energy-efficient generation of spin currents is an important step towards next-generation spintronics applications. In a nanowire, patterned from magnetic insulator/platinum (YIG/Pt) bilayer, electrical current generates a spin current due to the spin Hall effect (SHE). Furthermore, Ohmic heating in the Pt layer creates a large temperature gradient perpendicular to the YIG/Pt interface. The temperature gradient drives a spin current due to the spin Seebeck effect (SSE). Both spin currents exert spin torques, employed to reduce the magnetic damping of YIG. Different symmetries of the SHE and SSE can be used for their disentanglement. The SSE plays the dominant role in modification of the magnetization dynamics. With increasing temperature gradients, the damping can be compensated, leading to magnetic auto-oscillations and microwave emission from the nanowire. This result demonstrates that coherent magnonic condensates can be created by temperature gradients. It also points out that energy losses due to the Ohmic heating can be harvested by utilizing thermal spin currents in spintronics applications.

Optimisation of Co2MnSi:Pt multilayers for giant spin Seebeck devices *(Invited Paper)*

Christopher Cox, Kelly Morrison, Michael D. Cropper, Loughborough Univ. (United Kingdom); Andrew Caruana, Loughborough Univ. (United Kingdom) and Science and Technology Facilities Council (United Kingdom); Christy Kinane, Science and Technology Facilities Council (United Kingdom); Timothy Charlton, Oak Ridge National Lab. (United States)

The spin Seebeck effect[1] is defined as the generation of a pure spin current (Js) when a magnetised material (such as Co2MnSi[2]) is subjected to a temperature gradient (?T). To detect it, a thin non-magnetic layer [NM] such as Pt, is deposited on top of the material of interest. This converts Js into an observable thermoelectric voltage (VSSE) by way of the Inverse Spin Hall Effect (ISHE). We are interested in how this phenomenon might be applied to harvesting waste heat (thermoelectric generators) or spintronics applications (spin current source).

Our work initially encompasses the thin film deposition of Co2MnSi on amorphous glass substrates using Pulsed Laser Deposition (PLD) and optimisation of the deposition parameters in order to produce L21 ordered films, which exhibit larger VSSE than B2 disordered films[3].

Additionally, we will present results on exploring the potential Giant Spin Seebeck Effect (GSSE)[4] in [Co2MnSi /Pt]_n/SiO2 multilayers, where the GSSE is an enhancement of VSSE due to the increase in the volume of the spin injector (Co2MnSi).

All-optical magnetization switching of FePt magnetic recording medium *(Invited Paper)*

Markus Münzenberg, Ernst Moritz Arndt Univ. Greifswald (Germany)

Magnetization manipulation is an indispensable tool for both basic and applied research [1]. The dynamics of the response depends on the energy transfer from the laser excited electrons to the spins within the first femtoseconds. This determines the speed of the ultrafast magnetization. A special material of interest for magnetic storage development is FePt [2]. In a seminal experiment all optical writing had been demonstrated for FePt nanoparticle of a magnetic hard disc media, completely surprisingly, by Lambert et al. in Science 2014 [3]. But, the mechanism remained unclear and it opened many questions about the extension of possibilities of all optical writing as a general mechanism. Meanwhile writing experiments by single laser spots point to an asymmetric writing per each shot. This is consistently observed by different groups [4,5,6]. These effects can be described within different rate models. I will review the current understanding of the interaction of ultrafast excitation and heating, influence of magnetic dichroism and the presence of the inverse Faraday effect and attempts of understanding of these processes so far. From the experimental side in especial single shot writing experiments, that show a kind of accumulation effects of the writing, allow to pinpoint the underlying mechanism of writing in these media. Together, ab-initio calculations of the optical effects (inverse Faraday effect and magnetic dichroism induced heating) and the thermal modeling, allow to calculate the switching rates of the individual FePt nanoparticles. The latter then provides a rate of switching of the ensemble. A careful experimental determination of the absorbed fluence in the spherical geometry of the nanoparticles gives us a complete picture of the competing effects, of heating and writing asymmetries, and we can trace the different processes from the beginning of the laser pulse impact. In addition, this theoretical description allows us to optimize the number of shots needed to write the magnetization of the FePt nanoparticles and to pinpoint how to optimize the all optical writing. In my talk, I will review these recent developments that may lead to address an individual nanosized magnetic element in the far future all optically, for writing magnetic memory and memory storage.

Transient THz spin dynamics by spin pumping *(Invited Paper)*

Lars Bocklage, Deutsches Elektronen-Synchrotron (Germany)

Experiments on THz magnetization dynamics provide insights into a yet unexplored time scale of transient magnetics and spintronics [1-3]. Coherent responses of the magnetization to THz pulses have been demonstrated [1,2]. Further, THz spin currents can be generated by non-equilibrium hot electrons [3]. These THz transients provide new ways to ultrafast spin control and its technical applications. Here, an analytical model is presented that describes transient magnetization dynamics up to the THz regime [4]. The model is used to determine the magnetization response to ultrafast multi and single-cycle THz pulses for a variety of parameters like carrier frequency, width, phase, frequency chirp, and polarization. The THz pulse shape and polarization provide a vectorial control of the magnetization on the sub-picosecond time scale. It is shown that an optimum timing for coherent magnetization control can be achieved.

Dynamics of the magnetization induce a spin current in an adjacent non-magnetic material. This effect s known as spin pumping [5]. Here, calculations of THz transient spin current generation by spin pumping are presented. An effective spin current generation is found far above the ferromagnetic resonance up to THz frequencies although dynamic magnetization amplitudes are very small at THz frequencies. At THz frequencies, the coherent reaction of the magnetization also causes a coherent spin current. In contrast to the dc spin current which scales with the susceptibility of the magnetization, the ac spin current does not vanish above the ferromagnetic resonance. Instead the THz ac spin current reaches a value that is comparable to the dc spin current at resonance. The behavior far above resonance can be used to efficiently generate ultrafast spin currents without the need for magnetic systems with very high resonance frequencies. Spin currents on picosecond time scales can be achieved by THz magnetization dynamics.

Optically induced magnetization reversal dynamics in (Pt/Co)N multilayers *(Invited Paper)*

Roman Adam, Umut Parlak, Moritz Plötzing, Daniel E. Bürgler, Claus M. Schneider, Forschungszentrum Jülich GmbH (Germany)

The observation of optically-induced magnetization reversal in ferromagnetic alloys and ferromagnetic thin films raised many questions concerning the nature of the effect and triggered the search for fitting theoretical models describing the physical mechanism of the reversal. At the same time, the research is on the way to employ the effect for magnetic data-storage technology. Recent studies suggest that the interplay between light-induced heating of the electronic system and the polarization state of the laser beam plays a crucial role in achieving an efficient switching. We investigate the effect of laser pulse duration, laser fluence, multiple-pulse switching, and light polarization on the magnetization reversal in [Pt/Co]N multilayers, where N varies from 3 to 7. The multilayers were fabricated using magnetron sputtering at Ar gas pressure of 1?10-3 mbar. The response of the multilayers to the laser light was detected using a magneto-optical Kerr effect microscope combined with a Ti:Sapphire-based femtosecond laser amplifier generating a train of <70fs pulses with central wavelength of 800nm at 1kHz. Our results indicate that the optical pulses can trigger either demagnetization or magnetization reversal, and that the reversal process depends on extremely precise tuning of all the above-mentioned laser parameters. The dynamics of the reversal and demagnetization processes have been found to scale with laser fluence, external magnetic field, and multilayer repetition number N.

10357-112, Session 17A

Prolonging the coherence of spins in semiconductor quantum dots *(Invited Paper)*

Edwin Barnes, Virginia Polytechnic Institute and State Univ. (United States)

Future technologies based on electronic spins in semiconductor quantum dots require an unprecedented level of control over the spins. Achieving this level of control is made challenging by environmental decoherence and inhomogeneous dephasing. In this talk, I will present recent progress in understanding quantitatively the primary sources of noise for spins in semiconductor nanostructures, namely the hyperfine interaction with nuclear spins and charge fluctuations. I will present new theoretical techniques that capture the effects of multiple noise sources on the evolution of the spin coherence and show how they can be used to develop new ways to characterize and mitigate noise. I will then describe a new general theory for combatting decoherence and inhomogeneous dephasing by driving the system in a way that such adverse effects destructively interfere and cancel out, enabling precise and robust control of a broad range of coherent quantum systems. This theory generalizes and extends existing dynamical decoupling methods, making them much more precise and versatile for ultrafast spin manipulation.

10357-113, Session 17A

Optically probing spin qubit coherence without coherent control *(Invited Paper)*

Kai Müller, Alexander Bechtold, Walter Schottky Institut, Technische Univ. München (Germany); Fuxiang Li, Los Alamos National Lab. (United States); Tobias Simmet, Walter Schottky Institut, Technische Univ. München (Germany); Nikolai A. Sinitsyn, Los Alamos National Lab. (United States); Jonathan J. Finley, Walter Schottky Institut, Technische Univ. München (Germany)

We demonstrate an entirely new method to probe quantum measurement phenomena in semiconductor quantum dot (QD) spin qubits [1]. In addition to providing direct evidence for the quantum nature of solid state qubits, we show that our method has practical importance since it provides a completely alternative route for measuring ensemble and quantum dephasing times, T2* and T2, using only repeated projective measurements and without the need for coherent spin control.

Our approach is based on measuring time-correlators of a spin qubit in an optically active QD beyond the second order. We utilize a quantum dot spin-storage structure to initialize a single electron spin in a quantum dot subject to a magnetic field applied in Voigt geometry and perform repeated projective measurements of the spin at times t1 and t2. This measurement is repeated, corresponding to ensemble averaging, and the resulting third-order time correlations reveals rich physics: For times t1 or t2 < T2* Larmor precession is observed which reveals the ensemble dephasing time T2*. Importantly, even though the time-correlators were obtained through averaging many measurements for times t1 and t2 > T2* oscillations are observed that decay with the dephasing time T2 and allow its determination even without the need for coherent spin control. Finally, combining the third-order time correlator with the second-order time correlator allows to demonstrate a violation of Leggett-Garg type inequalities for certain times providing clear evidence for the quantum nature of the quantum dot spin.

10357-114, Session 17A

Defects in SiC: electronic structure and spin-photon interfaces *(Invited Paper)*

Sophia Economou, Virginia Polytechnic Institute and State Univ. (United States)

The interest in quantum information processing and related technologies has largely driven spin and photonic research in recent years. Deep defect centers such as the NV center in diamond have shown great promise for quantum technologies, but diamond-based devices are not practical. Silicon carbide has emerged as a technologically viable material for such technologies, as it hosts defects that can be exploited both for spintronics and for photonics applications. I will present our recent work on the silicon vacancy defect in SiC. Through a combination of group theory and density functional theory, we have calculated the electronic structure of the multi-electron spin states in this defect. Based on our results, we have designed spin-photon interfaces for the generation of entangled photons in this and in other SiC defects. Using these interfaces, highly entangled 'graph' states of photons can be generated for applications in quantum computation and communication by pumping and manipulating appropriately the spin states of these defects.

10357-115, Session 17A

Coherent phenomena in ferromagnetic GaMnAs films *(Invited Paper)*

Brenden A. Magill, Giti A. Khodaparast, Virginia Polytechnic Institute and State Univ. (United States); Stephen A. McGill, National High Magnetic Field Lab. (United States); Hiro Munekata, Tokyo Institute of Technology (Japan); Gary D. Sanders, Chris J. Stanton, Univ. of Florida (United States)

The manipulation of spins in semiconductors without the application of external magnetic fields opens the door to next-generation spintronic devices, where the electronic computation and magnetic memory can be performed on the same chip. Ferromagnetic semiconductors such GaMnAs are excellent prototype materials for these classes of devices, as the strong coupling of their magnetic and elastic properties allows the magnetic anisotropy to be manipulated by applying external strain, electric/magnetic fields, or light pulses. In this work, we investigate ultrafast optical processes in ferromagnetic (III,Mn)V semiconductors induced by femtosecond laser pulses. We report on two-color, time-resolved magneto-optical spectroscopy on MBE grown GaMnAs with the Tc, as high as 110 K. Our measurements allow us to observe dynamical phenomena such as coherent phonon dynamics, where acoustic phonon wavepackets, between 40.9 – 42.9 GHz, can be generated in the ferromagnetic layer with strong tunability from external magnetic fields. In addition, time-resolved optically induced birefringence measurements display oscillations with a lower frequency (?10 GHz). We explain our experimental observation using theoretical models that include ferromagnetic couplings of the magnetic Mn ions with the conduction and valence bands in GaMnAs.

This work was supported by the AFOSR through grant FA9550-14-1-0376.

10357-116, Session 17A

Molecular engineering with artificial atoms: designing a material platform for scalable quantum spintronics and photonics *(Invited Paper)*

Matthew Doty, Xiangyu Ma, Joshua M. Zide, Univ. of Delaware (United States); Garnett W. Bryant, National Institute of Standards and Technology (United States)

Self-assembled InAs Quantum Dots (QDs) are often called “artificial atoms” and have long been of interest as components of quantum photonic and spintronic devices. Although there has been substantial progress in demonstrating optical control of both single spins confined to a single QD and entanglement between two separated QDs, the path toward scalable quantum photonic devices based on spins remains challenging. Quantum Dot Molecules, which consist of two closely-spaced InAs QDs, have unique molecular properties that can be engineered with the solid state analog of molecular engineering in which the composition, size, and location of both the QDs and the intervening barrier are controlled during growth. Moreover, applied electric, magnetic, and optical fields can be used to modulate, in situ, both the spin and optical properties of the molecular states. We will first describe the origin of a unique molecular spin property known as hole spin mixing, which provides opportunities for all-optical coherent control of a single hole spin without transverse magnetic fields that would prevent nondestructive readout. We will then describe computational and experimental progress toward the design of new molecules and devices that could maximize and leverage this effect by manipulating spin interactions at the atomic scale. In the second part of the talk, we will describe how the unique photonic properties of engineered Quantum Dot Molecules can be leveraged to overcome long-standing challenges to the creation of scalable quantum devices that manipulate single spins via photonics.

10357-117, Session 17B

Observation of current-induced, long-lived persistent spin polarization in a topological insulator: a rechargeable spin battery *(Invited Paper)*

Yong P. Chen, Purdue Univ. (United States)

Topological insulators (TIs), with their helically spin-momentum-locked topological surface states (TSS), are considered promising for spintronics applications. Several recent experiments in TIs have demonstrated a current induced electronic spin polarization that may be used for all-electrical spin generation and injection. Here, we report spin potentiometric measurements in TIs that have revealed a long-lived persistent electron spin polarization even at zero current. Unaffected by a small bias current and persisting for several days at low temperature, the spin polarization can be induced and reversed by a large “writing” current applied for an extended time. While the exact mechanism responsible for the observed long-lived persistent spin polarization remains to be better understood, we speculate on possible roles played by nuclear spins hyperfine coupled to TSS electrons and dynamically polarized by the spin-helical “writing current”. Such an electrically controlled persistent spin polarization with unprecedented long lifetime could enable a rechargeable spin battery and rewritable spin memory for potential applications in spintronics and quantum information.

10357-118, Session 17B

Helicity-dependent photocurrent generation in Bi2Se3 probed by THz emission spectroscopy *(Invited Paper)*

Jong Seok Lee, Sun Young Hamh, Soon Hee Park, Gwangju Institute of Science and Technology (Korea, Republic of); Sahng-Kyoon Jerng, Seung-Hyun Chun, Sejong Univ. (Korea, Republic of)

We investigate photocarrier dynamics in a Bi2Se3 thin film via terahertz (THz) emission spectroscopy. We observed strong modulations in amplitude and phase of the emitted THz wave under the variations in a polarization of an input laser beam and sample azimuth. In particular, photon-helicity-dependent responses are manifested in both time and frequency domains, and azimuth dependence of such circular anisotropy exhibits a clear threefold periodicity. We analyze these results based on the symmetry of the bulk and the surface of Bi2Se3 and demonstrate that the observed helicity-dependent photocurrent originates from the circular photon drag effect, namely, linear and angular momentum transfers from photons to photocarriers.

10357-119, Session 17B

Chiral magnetic monopoles in artificial spin systems *(Invited Paper)*

Complex architectures of nanostructures are currently routinely elaborated using bottom-up or nanofabrication processes. This technological capability allows scientists to engineer materials with properties that do not exist in nature, but also to manufacture model systems to explore fundamental issues in condensed matter physics. Two-dimensional frustrated arrays of magnetic nanostructures are one class of systems for which theoretical predictions can now be tested experimentally.

In particular, magnetic imaging techniques offer the appealing opportunity to observe a wide range of phenomena within the concept of lab-on-a-chip. For example, several exotic magnetic phases have been discovered in artificial frustrated spin systems. Besides, these systems allow the study of classical analogues of magnetic monopoles. These recent results have stimulated new research activities motivated by the quest for magnetic monopoles in condensed matter physics.

In this contribution, we'll show that the micromagnetic properties of the elements constituting artificial frustrated arrays of nanomagnets introduce the concept of chiral monopoles. Injecting and manipulating experimentally the chirality of a magnetic monopole provide a new degree of freedom in the system. This offers the opportunity to control their motion under an external magnetic field, thus allowing to envision applications in magnetronics.

10357-120, Session 17B

Massively degenerated ground state manifold in artificial square ice *(Invited Paper)*

Yann Perrin, CEA-LETI (France); Nicolas Rougemaille, Benjamin Canals, Institut NÉEL, Ctr. National de la Recherche Scientifique (France)

In physics, frustration appears in a system when it is impossible to minimise all pairwise interactions simultaneously. Frustration exists in some particular rare-earth based compounds, such as spin ices [1]. Their internal frustration gives rise to unusual properties, like a residual entropy at low temperature or the presence of monopole-like excitations [2]. However, experimental techniques are unable to probe each spin individually in these compounds.

In 2006, Wang and coworkers opened a new way for studying magnetically frustrated spin systems [3]. Using e-beam lithography, one can make arrays of nanomagnets with the desired design. The state of each nanomagnet can then be probed individually in real space at room temperature using magnetic imaging (eg. Magnetic Force Microscopy). In this context, the square geometry received a considerable interest, since it is closely related to condensed matter spin ice compounds. But for geometrical reasons, this system orders instead of showing a disordered low energy manifold

In this contribution, we explain how to bring back the massive ground state degeneracy in the square array of nanomagnets. We present the first experimental evidence of a Coulomb phase in this system [4]. We also report the presence of magnetic monopoles defects within the Coulomb phase. This study makes a new step toward a direct study of the dynamic of monopoles excitations (e.g. creation, annihilation or diffusion processes).

Weyl node assisted conductivity switch in the interfacial phase change memory *(Invited Paper)*

Nicholas Kioussis, Jinwoong Kim, California State Univ., Northridge (United States); Ruqian Wu, Univ. of California, Irvine (United States); Young-Sun Song, Seung-Hoon Jhi, Pohang Univ. of Science and Technology (Korea, Republic of)

The interfacial phase-change memory (iPCM) GeTe/Sb2Te3 continues to attract a great deal of interest not only because they are promising candidates for the next generation non-volatile random-access memories but also for their fascinating topological properties. Depending on the atomic-layer-stacking sequence of the GeTe block the iPCM can be either in the “SET” (Ge-Te-Ge-Te) or “RESET” (Te-Ge-Ge-Te) states where the former exhibits a ferroelectric polarization and an electric conductivity which is two orders of magnitude higher than that of the RESET state. The presence of ferroelectric polarization which breaks the inversion symmetry and the fact that the system is close to the topological phase boundary raises the intriguing question of the emergence of a Weyl semimetal phase in the “SET” state between the topological and trivial insulator phases as proposed by Murakami. Ab initio electronic structure calculations reveal the emergence of a Weyl semimetal phase for the “SET” phase associated with a large electric conductivity due to the gapless Weyl nodes.

10358-1, Session 1

Super-resolution from single photon emission: toward biological application *(Invited Paper)*

Marco Genovese, Istituto Nazionale di Ricerca Metrologica (Italy)

Properties of quantum light represent a tool for overcoming limits of classical optics.

Several experiments have demonstrated this advantage ranging from quantum enhanced imaging to quantum illumination [1].

In this talk, after a general introduction discussing last developments in the field (as sub shot noise quantum microscopy) , I will present a work [2] where we experimentally demonstrate quantum enhanced resolution in confocal fluorescence microscopy. This is achieved by exploiting the non-classical photon statistics of fluorescence emission of single nitrogen-vacancy color centers in diamond. By developing a general model of super-resolution based on the direct sampling of the kth-order autocorrelation function of the photoluminescence signal, we show the possibility to resolve, in principle, arbitrarily close emitting centers.

Finally, possible applications in biology and future developments will be presented.

10358-2, Session 1

Preparation of single photon states with rising exponential shape *(Invited Paper)*

Christian Kurtsiefer, National Univ. of Singapore (Singapore); Bharat Srivathsan, National Univ. of Singapore (Singapore) and Max-Planck-Institut für die Physik des Lichts (Germany); Gurpreet Kaur Gulati, National Univ. of Singapore (Singapore) and Univ. of Sussex (United Kingdom); Mathias A. Seidler, Alessandro Cere, National Univ. of Singapore (Singapore)

e prepare single photons with a temporal envelope that resembles the time reversal of photons from the spontaneous decay process, based on a parametric conversion process in a cold atomic vapor. Photon pairs generated from from four-wave mixing inherit a particular time ordering from the atomic cascade decay in the atomic vapor. The detection of the first photon of the cascade is used as a herald after being time-reversed by reflection off an asymmetric Fabry-Perot cavity, reversing the temporal shape of the heralded photon to a rising exponential envelope. The photons have characteristic rise time of 12ns. Such a temporal single photon profile is ideal for absorption by a two level system. We demonstrate this in an experiment showcasing the absorption by a single atom.

10358-3, Session 1

From SHG to mid-infrared SPDC generation in strained silicon waveguides

Claudio Castellan, Alessandro Trenti, Univ. degli Studi di Trento (Italy); Mattia Mancinelli, Alessandro Marchesini, Univ. degli Studi di Trento (Italy) and Univ. degli Studi di Trento (Italy); Mher Ghulinyan, Georg Pucker, Fondazione Bruno Kessler (Italy); Lorenzo Pavesi, Univ. degli Studi di Trento (Italy) and Univ. degli Studi di Trento (Italy)

The centrosymmetric crystalline structure inhibits the existence of second order nonlinear optical processes in silicon. However, it has been recently reported on the possibility of breaking this symmetry with a stressing silicon nitride over-layer, inducing second order effects in silicon.

Here we report on Second Harmonic Generation (SHG) measurements on Silicon-On-Insulator (SOI) strained silicon waveguides designed to achieve multi-modal phase-matching between the pump and the SHG signal. Two-photon absorption effect was avoided using a laser source in the spectral region around 2.5 ?m, while walk-off effects were faced shaping the pulse temporal width from ?100 fs to ?13 ps. The pump laser externally triggered an InGaAs SPAD detector, determining a lowest detectable signal of ?0.01 fW. We realized a model for simulating the pulse propagation in waveguides, through which we estimated an effective strain-induced second order nonlinear coefficient of ?(2)=(0.304±0.025) pm/V. Due to experimental issues, this value is actually an underestimation. However, it agrees with high-frequency measurements of Pockels effect in strained silicon.

SHG observation provides a milestone for the Spontaneous Parametric Down Conversion (SPDC), where a single pump photon generates two entangled photons at a doubled wavelength. Here we report also on our preliminary results for measuring SPDC mid-infrared entangled photons generated in a strained silicon waveguide pumping at telecom wavelengths. The photon correlation properties are evidenced with a mid-infrared correlation set-up. This study is motivated by the great interest recently devoted to move quantum optics to the mid-infrared spectral region, where photons can be easily manipulated.

10358-4, Session 1

Quantum internet: the certifiable road ahead *(Invited Paper)*

Stephanie Wehner, QuTech (Netherlands)

No Abstract Available

10358-31, Session 1

Quantum optics with nanowires *(Invited Paper)*

Valery Zwiller, Technische Univ. Delft (Netherlands); Klaus D. Jöns, Ali W. Elshaari, M. Versteegh, Lucas Schweickert, KTH Royal Institute of Technology (Sweden)

Nanowires offer new opportunities for nanoscale quantum optics; the quantum dot geometry in semiconducting nanowires as well as the material composition and environment can be engineered with unprecedented freedom to improve the light extraction efficiency.

Quantum dots in nanowires are shown to be efficient single photon sources, in addition because of the very small fine structure splitting, we demonstrate the generation of entangled pairs of photons from a nanowire.

Another type of nanowire under study in our group is superconducting nanowires for single photon detection, reaching efficiencies, time resolution and dark counts beyond currently available detectors. We will discuss our first attempts at combining semiconducting nanowire based single photon emitters and superconducting nanowire single photon detectors on a chip to realize integrated quantum circuits.

10358-5, Session 2

Large-scale series-nanowire detectors packaged in a compact rack-mount cryostat *(Invited Paper)*

Vikas Anant, Photon Spot, Inc. (United States)

No Abstract Available

10358-6, Session 2

Quantum communication using amorphous SNSPDs *(Invited Paper)*

Félix Bussières, University of Geneva (Switzerland)

Progress in quantum communication has long been tied to the progress in single-photon detection technology. I will present some of the recent progress on superconducting nanowire single-photon detectors (SNSPDs) based on amorphous thin films such as WSi and MoSi, and the role this progress played in pushing limits in quantum communication. More precisely, I will discuss how such amorphous SNSPDs played an enabling role in the field of quantum repeaters with solid-state quantum memories. I will conclude with some remarks on the study of the detection mechanism in amorphous SNSPDs.

10358-7, Session 2

Towards integrated superconducting detectors on lithium niobate waveguides *(Invited Paper)*

Jan Philipp Höpker, Moritz Bartnick, Evan Meyer-Scott, Frederik Thiele, Stephan Krapick, Nicola M. Montaut, Matteo Santandrea, Harold Herrmann, Sebastian Lengeling, Raimund Ricken, Viktor Quiring, Torsten Meier, Univ. Paderborn (Germany); Adriana E. Lita, Varun B. Verma, Thomas Gerrits, Sae Woo Nam, National Institute of Standards and Technology (United States); Christine Silberhorn, Tim Bartley, Univ. Paderborn (Germany)

Superconducting detectors are now well-established tools for quantum optics, boasting high-efficiency, fast response and low noise. Similarly, lithium niobate is an important platform for second-order nonlinear optical process, such as high-speed electro-optic modulation and polarisation conversion, as well as frequency conversion and sources of quantum light. Combining these technologies completes the requirements for a single platform capable of generating, manipulating and measuring quantum light in many degrees of freedom, in a compact and potentially scalable manner.

We will report on progress combining tungsten transition edge sensors (TES) and amorphous tungsten silicide superconducting nanowire single photon detectors (SNSPDs) on titanium in-diffused lithium niobate waveguides. Crucial for quantum optics applications, our waveguides offer extremely low losses of <0.01dBcm-1, and support both polarisation modes. The ultimate goal is to couple the evanescent field from the waveguides into the superconducting absorber. We will report on simulations and measurements of the absorption, which we can characterise at room temperature prior to cooling down the devices. Independently, we show how the detectors respond to flood illumination, normally incident on the devices, demonstrating their functionality, and, in the case of the SNSPD structure, saturation of the internal detection efficiency. This result is assisted by the amorphous nature of the tungsten silicide, which is tolerant to the surface roughness of the lithium niobate waveguides, allowing us to demonstrate functional detectors deposited directly on top of the in-diffused structures. Finally, we report on efficient pigtailing at 77K from fibre to waveguide with 1dB interface loss.

10358-8, Session 3

Chip scale interactions of light and vapors *(Invited Paper)*

Uriel Levy, Liron Stern, Meir Grajower, Eliran Talker, Jonathan Bar David, The Hebrew Univ. of Jerusalem (Israel)

In this talk we will present our recent results related to chip scale integration of light with vapor cells. This include the interaction of vapors with waveguides, chip scale resonators and metasurfaces. We will also present the role of cell miniaturization. Linear and nonlinear effects will be demonstrated. The role of coherence will be explored. Finally, we will discuss applications such as all optical switching and frequency referencing.

10358-9, Session 3

Quantum nonreciprocal devices based on chiral light-matter coupling *(Invited Paper)*

Juergen Volz, Arno Rauschenbeutel, Vienna Ctr. for Quantum Science and Technology (Austria)

Nanophotonic components allow the control of the flow of light in integrated optical environments. Thereby, the light's strong confinement leads to an inherent link between its local polarization and propagation direction which fundamentally alters the physics of light-matter interaction and gives rise to phenomena such as directional emission and direction-dependent coupling strengths [1].

I will present the underlying principles of this chiral light-matter interaction and its consequences for integrated applications [1]. In particular, I will show how we employ this effect to control the direction of spontaneous emission [2] and to realize low-loss nonreciprocal transmission at the single-photon level through a silica nanofiber [3]. We use two different approaches where either an ensemble of spin-polarized atoms is weakly coupled to a nanofiber or a single atom is strongly coupled to the nanofiber via a whispering-gallery-mode resonator. The resulting optical isolators show a strong imbalance between the transmissions in forward and reverse direction and, at the same time, a forward transmissions exceeding 70%. We extended this system to a 4-port device, where a single atom routes photons nonreciprocally from one fiber port to the next. This realizes a quantum optical circulator [4] which can even be prepared in a superposition of its operational modes.

The demonstrated systems exemplify a new class of (quantum) nanophotonic devices that are ideally suited for photonic quantum information processing and quantum simulation.

10358-11, Session 3

Photostable molecules on chip: integrated single photon sources for quantum technologies *(Invited Paper)*

Costanza Toninelli, Istituto Nazionale di Ottica (Italy) and LENS - Lab. Europeo di Spettroscopie Non-Lineari (Italy); Pietro E. Lombardi, Consiglio Nazionale delle Ricerche (Italy) and LENS - Lab. Europeo di Spettroscopie Non-Lineari (Italy); Anna P. Ovvyan, Westfälische Wilhelms-Univ. Münster (Germany); Sofia Pazzagli, Giacomo Mazzamuto, LENS - Lab. Europeo di Spettroscopie Non-Lineari (Italy); Günter Kewes, Oliver Neitzke, Humboldt-Univ. zu Berlin (Germany); Nico Gruhler, Westfälische Wilhelms-Univ. Münster (Germany); Oliver Benson, Humboldt-Univ. zu Berlin (Germany); Wolfram H. P. Pernice, Westfälische Wilhelms-Univ. Münster (Germany); Francesco S. Cataliotti, LENS - Lab. Europeo di Spettroscopie Non-Lineari (Italy)

Efficient quantum light sources and non-linear optical elements at the few photon level are the basic ingredients for most applications in nano and quantum technologies. On the other hand, a scalable platform for quantum ICT typically requires reliable light matter interfaces and on-chip integration. In this work we demonstrate the potential of a novel hybrid technology which combines single organic molecules as quantum emitters and dielectric chips [1].

Dibenzoterrylene molecules in anthracene crystals (DBT:Ac) are particularly suitable quantum systems for this task, since they exhibit long-term photostability in thin samples [2], easy fabrication methods and life-time limited emission at cryogenic temperatures [3].

We demonstrate at room temperature the emission of single photons from DBT molecules into ridge waveguides with a branching ratio up to 40%. The overall single-photon source efficiency, including emission into the guided mode, propagation losses, and emission into a quasi-gaussian mode in free space, is estimated around 16%. These results are competitive with state-of-the-art single photon emission into propagating guided modes from solid state systems [4], while offering a novel platform with unprecedented versatility.

10358-12, Session 3

Superconducting atom chips *(Invited Paper)*

Rainer Dumke, Nanyang Technological Univ. (Singapore)

In recent years, microtraps for neutral atoms based on superconductors, i.e. 'superconducting atom chips' have become a subject of intensive research.

Motivated by the prediction of extremely low magnetic and thermal noise compared to normal conductors, superconducting atom chips have first been implemented in the expectation of improving the coherence of atomic quantum states close to surfaces by several orders of magnitude.

This boost in coherence time holds promising expectations for quantum information processing applications.

In particular, superconducting atom chips are ideal candidates for the realization of hybrid quantum systems between atomic and superconducting solid state qubits, merging the fast gate operation times for superconducting qubits with the long coherence times of atomic qubits.

In this talk I will discuss our work towards realizaing this hybrid quantun system via coupling ultracold atoms and superconducting circuits.

10358-13, Session 3

Integration of optically active neodymium (Nd) ions in niobium thin films by ion implantation: room temperature photoluminescence characteristics and photoconductivity

Patrick C. Sims, SPAWAR Systems Ctr. Pacific (United States); Brad Liu, SPAWAR Systems Ctr. Atlantic (United States); Saurabh Sharma, Carlos M. Torres, Lance Lerum, Mohammed Fahem, Sanja Zlatanovic, Vincent Dinh, Nenad Djapic, David Chao, Osama M. Nayfeh, Dave Rees, SPAWAR Systems Ctr. Pacific (United States)

We report on the integration of optically active rare earth Neodymium ions by implantation into 90 nm sputtered films of Niobium metal deposited on silicon-oxide wafers. The implantation conditions span doses of 1013 to 1014 ions/cm2 and energies of 10-60 keV. The resulting ion distribution and damage profiles were determined by ion implantation simulations. Energy-dispersive X-ray spectroscopy (EDX) measurements in a scanning electron microscope detects the signature of both the Neodymium and Niobium, and confirms a 1-3 % Nd concentration, where higher dose produces increased concentration. With laser confocal excitation at 785 nm, we observe photoluminescence (PL) emission in un-annealed samples at room temperature near ~850 nm and a robust peak at ~1064 nm. The PL wavelengths are consistent with the known 4F3/2 transitions of Nd3+ as well as an increased broad-wavelength co-contribution likely due to induced defects consistent with the implantation simulations. In comparison, Niobium control samples (i.e un-implanted) are devoid of pronounced peaks in the PL. We examine the effect of optical illumination on the electronic transport resistive properties of the films and find dependence between wavelength of excitation and modulating of the current conduction. We observe a selectivity in the resistance modulation when comparing excitation with an LED centered at 810 nm as compared to a broad-band Halogen lamp. We discuss use of these films as active elements in quantum memory.

10358-14, Session 4

Quantum light-matter interfaces based on rare-earth-doped crystals and nano-photonics *(Invited Paper)*

Andrei Faraon, Tian Zhong, Jonathan M. Kindem, Evan Miyazono, Ioana Craiciu, Jake H. Rochman, John G. Bartholomew, California Institute of Technology (United States)

Quantum light-matter interfaces that reversibly map the quantum state of photons onto the quantum states of atoms, are essential components in the quantum engineering toolbox with applications in quantum communication, computing, and quantum-enabled sensing. In this talk I present our progress towards developing on-chip quantum light-matter interfaces based on nanophotonic resonators fabricated in rare-earth-doped crystals known to exhibit some of the longest optical and spin coherence times in the solid state. We recently demonstrated coherent control of neodymium (Nd3+) ions coupled to yttrium orthosilicate Y2SiO5 (YSO) photonic crystal nano-beam resonator. The coupling of the Nd3+ 883 nm 4I9/2-4F3/2 transition to the nano-resonator results in a 40 fold enhancement of the transition rate (Purcell effect), and increased optical absorption (~80%) - adequate for realizing efficient optical quantum memories via cavity impedance matching. Optical coherence times T2 up to 100 ?s with low spectral diffusion were measured for ions embedded in photonic crystals, which are comparable to those observed in unprocessed bulk samples. This indicates that the remarkable coherence properties of REIs are preserved during nanofabrication process. Multi-temporal mode photon storage using stimulated photon echo and atomic frequency comb (AFC) protocols were implemented in these nano-resonators. Our current technology can be

readily transferred to Erbium (Er) doped YSO devices, therefore opening the possibility of efficient on-chip optical quantum memory at 1.5 ?m telecom wavelength. Integration with superconducting qubits can lead to devices for reversible quantum conversion of optical photons to microwave photons.

10358-15, Session 4

Engineering quantum emitters in wide bandgap semiconductors *(Invited Paper)*

Igor Aharonovich, Univ. of Technology, Sydney (Australia)

Solid State Single Photon Sources are vital components of integrated nanophotonic circuits. While research so far has been focused on quantum dots and color centers in diamond, other solid state platforms such as the nitrides and the oxides are of a great interest. In this talk I will show new results on engineering quantum emitters in wide range of materials including silicon carbide, gallium nitride and various oxides.

In the first part of my talk i will show new results on room temperature emitters in gallium nitride and silicon carbide. These emitters can be found in a variety of wafers and therefore offer a potential for scalable quantum photonic technologies. I will then show new ways to engineer emitters in oxides - including tungsten oxide and zinc oxide. I will summarize by highlighting the main challenges in the field of solid state single emitters and provide an outlook for further integration of these emitters with cavities and resonators.

10358-16, Session 4

Deterministic enhancement of coherent photon generation from a nitrogen-vacancy center in ultrapure diamond *(Invited Paper)*

Daniel Riedel, Immo Söllner, Brendan Shields, Sebastian Starosielec, Patrick Appel, Elke Neu, Patrick Maletinsky, Richard J. Warburton, Univ. Basel (Switzerland)

A key requirement for many applications in solid-state quantum sciences is a high fluence of indistinguishable photons. The spontaneous emission of these photons is governed by the coupling of an excited quantum system to electromagnetic vacuum fluctuations.

In our experiment, we enhance this coupling by engineering a tunable Fabry-Perot microcavity. The quantum system we study is the nitrogen-vacancy (NV) center in diamond, a workhorse for quantum science and engineering, due to its optical transitions and the coherent electron spin system it hosts. Our device consists of a high-quality, nano-fabricated, single-crystalline diamond membrane bonded to a planar mirror; the cavity is completed by a second, concave mirror. Using piezo positioners, we achieve full spectral and spatial tunability and freedom in selecting NVs with favorable emission properties in our low-temperature (4 Kelvin) experiments.

Upon tuning of the cavity into resonance, we find significant enhancement of the 637 nm zero phonon line for several individual NVs which is accompanied by a strong reduction of the overall photoluminescence (PL) lifetime. We infer a 30-fold enhancement of the zero-phonon transition rate at best. The fraction of the PL emission associated to this resonant transition is thereby increased from 3% to 46%.

Our results constitute a significant leap on the route towards the implementation of fast long-distance quantum networks, which are currently limited by the photon emission rate in their nodes. Furthermore, our versatile design is readily applicable to other solid-state quantum emitters like color centers in silicon carbide.

10358-17, Session 4

Formation of silicon carbide defect qubits with optically transparent electrodes and atomic layer deposited silicon oxide surface passivation

Brad Liu, Patrick C. Sims, Carlos M. Torres, Bradley M. Davidson, Lance Lerum, Hector Romero, Mohammed Fahem, Mark E. Lasher, Anna M. Leese de Escobar, Osama M. Nayfeh, Ken Simonsen, Ayax D. Ramirez, SPAWAR Systems Ctr. Pacific (United States); Hunter Banks, Sam G. Carter, D. Kurt Gaskill, Thomas L. Reinecke, U.S. Naval Research Lab. (United States)

Defect qubits in silicon carbide are an emerging system for quantum information science and technology. It is important to passivate and protect the surface to preserve the particular defect configurations as well as to provide means to tune the opto-electronic properties via electronic or opto-electronic gating. In this work, we construct defect qubit device structures that integrate Indium-Tin-Oxide (ITO) electrodes and a thin atomic layer deposited (ALD) silicon-oxide surface passivation. The devices are formed via 12C ion implantation and high temperature annealing of 4H and 6H silicon carbide. The process involves the integration of optically transparent indium tin oxide electrodes and a surface passivation film of silicon-oxide by atomic layer deposition. We find good contact is formed between ITO and SiC, and after complete processing, the measured broad-band photoluminescence (PL) with excitation at 785 nm in a scanning PL system is consistent with the formation of silicon vacancies. We find minimal change in the room temperature emission in regions beneath the ITO electrodes and the SiOx-SiC passivated surface. We evaluate the ability of electric field to tune the optically detected magnetic resonance (ODMR) response of the qubit system by simulations of the spectrum with a modified spin Hamiltonian that considers the Stark Effect. We quantify the simulated strength of the electric-field tuning of the energy levels and ODMR response for the various identified spin 3/2 transitions of the silicon vacancy

10358-19, Session 5

The COST action "Nanoscale Quantum Optics": implications for quantum photonics devices

Mario Agio, Univ. Siegen (Germany) and COST Action MP1403 (Germany); Costanza Toninelli, Istituto Nazionale di Ottica (Italy)

Several research efforts funded by national and EU projects in the last decades resulted into enormous progress in quantum physics and quantum optics, on the one hand, and in nano-optics and nanophotonics, on the other hand. The COST Action MP1403 "Nanoscale Quantum Optics" is the instrument to proactively increase the interaction among the communities of nanophotonics, quantum optics and materials science and to support them towards common objectives. The grand vision is the development of new ideas, materials, and techniques to control the interaction between light and matter at will, even down to the level of individual quanta. The potential breakthroughs will have profound implications in fields as diverse as classical and quantum information processing & communication, sensing & metrology, light sources, and energy harvesting. We have thus identified four research priorities that deal with problems and limitations in the operation of existing quantum technologies, and that may contribute to the discovery and understanding of novel quantum phenomena for future applications: Generation, detection & storage of quantum states of light at the nanoscale; Nonlinearities and ultrafast processes in nanostructured media; Nanoscale quantum coherence; Cooperative effects, correlations and many-body physics tailored by strongly confined optical fields. The first two priorities will also target technological aspects, such as performances and integrability of quantum photonics devices, whereas the other two include rather exploratory activities.

10358-20, Session 6

A universal quantum module for quantum communication, computation, and metrology *(Invited Paper)*

William J. Munro, NTT Basic Research Labs. (Japan) and National Institute of Informatics (Japan); Michael Hanks, Nicolò Lo Piparo, National Institute of Informatics (Japan); Michael Trupke, Jörg Schmiedmayer, Vienna Ctr. for Quantum Science and Technology (Austria); Kae Nemoto, National Institute of Informatics (Japan)

The development of devices that process information according to the principles of quantum mechanics is leading to a new technological revolution. There are many potential applications, ranging from sensing and metrology through to large scale quantum communication and computation, with various physical systems to realize them. Most physical are typically suited to a limited range of applications. In this presentation, we describe a simple module that could be ubiquitous for quantum information based applications, that is it can be used for metrology, communication and computation applications. Our basic modules, each comprising a single NV? center embedded in diamond embedded in an optical cavity, has the cavities mediate interactions between the photons and the electron spins (enabling entanglement distribution and efficient readout), while the nuclear spins constitute long-lived quantum memories capable of storing and processing quantum information. We will illustrate the design of such a module based on dipole induced transparency and its function using a single NV? center embedded in an optical cavity. Further we will show a network based architecture that while suitable for large scale fault tolerant computation can be easily used for communication and distributed metrology tasks. We will discuss these applications in detail. Finally, we will investigate the possible use of alternative newer diamond centers (for instance SiV/GeV) within our module and their applicability for our module based quantum information processing.

10358-21, Session 6

Towards fault-tolerant quantum computing with spins in diamond *(Invited Paper)*

Jiangfeng Du, Ya Wang, Univ. of Science and Technology of China (China)

The remarkable properties of spins in diamond make it promising candidate for quantum information processing. I will present our recent progress towards fault-tolerant quantum computing with the nitrogen-vacancy center in diamond. By using a hybrid electron-nuclear spin system we first demonstrate the three-qubit phase error correction protocol. We then provide advanced control techniques to realize fault-tolerant universal quantum gates. These results pave the way for fault-tolerant quantum computing.

10358-22, Session 6

Integrated single photon circuits with electrical light source *(Invited Paper)*

Wolfram Pernice, Westfälische Wilhelms-Univ. Münster (Germany)

Quantum photonic circuits based on nanophotonic components hold promise for overcoming scalability limitations in optical quantum systems. Functional systems will require the co-integration of single photon sources, detectors and tunable photonic components. Waveguide integrated single photon detectors based on superconducting nanowires (SNSPDs) have been shown to fulfill the demanding requirements for on-chip quantum photonics. Because they provide very wide optical detection bandwidth, their use with optically pumped single photon sources poses severe challenges for on-chip filtering. We overcome these challenges by co-integrating electrically driven single photon sources with superconducting detectors. Single photon sources with nanoscale footprint are realized by depositing electrically contacted carbon nanotubes (CNTs) across nanophotonic waveguides. CNTs under electrical current bias are shown to emit non-classical light which is coupled efficiently into the underlying photonic framework. The CNTs are shown to provide high count rates in the MHz range. The statistical characterization of the CNT light source crucially relies on the high timing resolution of the SNSPDs which allows for measuring photon statistics for emitters with sub-100ps lifetime. The combination of top-down nanofabrication with deposition by electrophoresis provides a waferscale approach for realizing non-classical circuits on chip. Such hybrid quantum photonic devices therefore hold promise for realizing complex integrated devices without additional optical input ports.

10358-23, Session 6

On-chip quantum photonics using quantum dots *(Invited Paper)*

Peter Lodahl, Niels Bohr Institute (Denmark)

Semiconductor quantum dots have excellent optical performance dramatically in recent years, and today a clear pathway is laid out for constructing a deterministic and coherent photon-emitter interface by embedding quantum dots in photonic nanostructures [1]. Such an interface can be employed as an on-demand single-photon source, but more generally enables deterministic quantum gates. We review the recent experimental progress on quantum dots coupled to nanophotonic waveguides including the internal single-photon coupling efficiency [2], coherence [3], and transfer efficiency to an optical fiber [4]. Currently, the first commercial products based on this technology are being brought to the market [5]. Finally the fundamental decoherence processes of a quantum dot single-photon source are discussed [6].

A heterogeneous III-V / Si3N4 quantum photonic integration platform *(Invited Paper)*

Marcelo I. Davanco, National Institute of Standards and Technology (United States); Jin Liu, Sun Yat-Sen Univ. (China); Luca Sapienza, Univ. of Southampton (United Kingdom); Chen-Zhao Zhang, South China Normal Univ. (China); Jose V. De Miranda Cardoso, Univ. Federal de Campina Grande (Brazil); Varun B. Verma, Richard P. Mirin, Sae-Woo Nam, National Institute of Standards and Technology (United States); Liu Liu, South China Normal Univ. (China); Kartik Srinivasan, National Institute of Standards and Technology (United States)

Photonic integration is an enabling technology for photonic quantum science, offering greater scalability, stability, and functionality than traditional bulk optics. Here, we describe a scalable, heterogeneous III-V/silicon integration platform to produce Si3N4 photonic circuits incorporating GaAs-based nanophotonic devices containing self-assembled InAs/GaAs quantum dots. We demonstrate pure single-photon emission from individual quantum dots in GaAs waveguides and cavities - where strong control of spontaneous emission rate is observed - directly launched into

Si3N4 waveguides with > 90 % efficiency through evanescent coupling. To date, InAs/GaAs quantum dots constitute the most promising solid state triggered single-photon sources, offering bright, pure and indistinguishable emission that can be electrically and optically controlled.

Si3N4 waveguides offer low-loss propagation, tailorable dispersion and high Kerr nonlinearities, desirable for linear and nonlinear optical signal processing down to the quantum level. We combine these two in an integration platform that will enable a new class of scalable, efficient and versatile integrated quantum photonic devices.

Electromechanical semiconductor quantum structures *(Invited Paper)*

Hiroshi Yamaguchi, NTT Basic Research Labs. (Japan)

The use of compound semiconductor heterostructures allows us to fabricate micro/nanomechanical systems with novel functionalities. In this invited talk, we present examples of experimental results that we have recently demonstrated in our investigations of electromechanical resonators made of semiconductor-based low-dimensional quantum structures.

The mechanical motion can be coupled to the photo-excited carriers in compound semiconductors by piezoelectricity. Through the carrier-mediated optomechanical effects, the thermal motion can be optically controlled in similar way as that in cavity optomechanics. The amplification and the damping of thermo-mechanical vibration have been demonstrated by simply applying a laser light with a near-bandgap wavelength. We proposed to utilize the carrier-mediated optomechanical interaction for characterizing the properties of semiconductors. Optical absorption properties and carrier dynamics are studied through the mechanical resonance characteristic.

We also investigate the coupling between carriers and mechanical degrees of freedom in low-dimensional electron systems. The back-action on the mechanical motion mediated by electron systems is studied. In high mobility two-dimensional electron systems, electron localization induced by quantum Hall effects strongly suppresses the damping of mechanical motion, showing the electron-induced mechanical damping. The carrier-medicated back-action is also confirmed in quantum dots systems, where both damping and amplification were observed depending on the relative position of Fermi level to the quantized electron energy in QD.

Single photons from electrically driven reconfigurable photonic crystal cavities *(Invited Paper)*

Maurangelo Petruzzella, Simone Birindelli, Francesco M. Pagliano, Daniele Pellegrino, Zarko Zobenica, Michele Cotrufo, Frank W. M. van Otten, Rob W. van der Heijden, Technische Univ. Eindhoven (Netherlands); Lianhe H. Li, Edmund Linfield, Univ. of Leeds (United Kingdom); Andrea Fiore, Technische Univ. Eindhoven (Netherlands)

Due to their deterministic nature and efficiency, devices based on quantum dots (QD) are currently replacing traditional single-photon sources in the most complex quantum optics experiments, such as boson sampling protocols. Embedding these emitters into photonic crystal (PhCs) cavities enables the creation of an array of Purcell-enhanced single photons required to build quantum photonic integrated circuits. So far scaling of the number of these cavity-emitters nodes on a single chip has been hampered by practical problems such as the lack of post-fabrication methods to control their relative detuning and the complexity involved with their optical excitation. Here, we present a tuneable single-photon source combining electrical injection and nano-opto-electromechanical cavity tuning. The device consists of a double-membrane electromechanically tuneable PhC structure. A vertical p-i-n junction, hosted in the top membrane, is exploited to inject current in the QD layer and demonstrate a tunable nano LED whose cavity wavelength can be reversibly varied over 15 nanometers by electromechanically varying the distance between membranes. Besides, electroluminescence from single QD lines coupled to PhC cavities is reported for the first time. The measurement of the second-order autocorrelation function from a cavity-enhanced line proves the anti-bunched character of the emitted light. Since electrical injection does not produce stray pump photons, it makes the integration with superconducting single-photon detectors much more feasible. The large-scale integration of such tuneable single-photon sources, passive optics and waveguide detectors may enable the implementation of fully-integrated boson sampling circuits able to manipulate tens of photons.

10358-27, Session 7

On-chip hybrid quantum circuits *(Invited Paper)*

Klaus D. Jöns, Ali W. Elshaari, KTH Royal Institute of Technology (Sweden); Iman Esmaeil Zadeh, Andreas Fognini, Kavli Institute of Nanoscience Delft (Netherlands); Michael E. Reimer, Univ. of Waterloo (Canada); Dan Dalacu, Philip J. Poole, National Research Council Canada (Canada); Val Zwiller, KTH Royal Institute of Technology (Sweden)

Quantum communication applications require a scalable approach to integrate bright sources of entangled photon-pairs in complex on-chip quantum circuits. Currently, the most promising sources are based on III/V semiconductor quantum dots. However, complex photonic circuitry is mainly achieved in silicon photonics due to the tremendous technological challenges in circuit fabrication. We take the best of both worlds by developing a new hybrid on-chip nanofabrication approach. We demonstrate for the first time on-chip generation, spectral filtering, and routing of single-photons from selected single and multiple III/V semiconductor nanowire quantum emitters all deterministically integrated in a CMOS compatible silicon nitride photonic circuit. Wavelength and polarization filtering is performed using an electrically-controlled integrated ring resonator filter. We achieve more than 95dB on-chip excitation laser suppression, allowing for the detection of light down to the single-photon level without the need of additional filtering. Taking advantage of our new on-chip single-photon filtering and routing we are able to perform the first quantum wavelength division multiplexing and de-multiplexing. We realize a multi-frequency quantum channel comprising two independently selected and deterministically integrated quantum emitters. By tuning the ring resonator voltage, we can sift single-photons from one or the other nanowire into the drop-port. Our new approach eliminates the need for off-chip components, opening up new possibilities for large-scale quantum photonic systems with on-chip single- and entangled-photon sources.

(Singapore) and Optoelectronics Research Ctr., Univ. of Southampton (United Kingdom) and Ctr. for Photonic Metamaterials, Univ. of Southampton (United Kingdom)

We demonstrate the integration of a metamaterial coherent perfect absorption (CPA) switch with mainstream telecommunication optical fibres, an ideal scalable platform for quantum photonic devices. Using the recently demonstrated concept of CPA in a thin plasmonic metamaterial [1,2] we realized fibre-based dissipative non-local quantum gates for polarization- or phase- entangled photon pairs. Similar to the scheme we previously developed in free-space, here entangled photon pairs are generated by type-II spontaneous parametric down-conversion in a beta-barium borate (BBO) crystal and the signal photon is sent to a Sagnac-like interferometer, that contains the metamaterial absorber. The idler photon is used to control the mutual polarization/phase of the entangled photons via a polarizer or a geometric phase shifter, enabling non-local control of the dissipation of the signal photon. We obtained contrasts between perfect absorption and perfect transmission, measured by correlated photon counting, as high as 82%. This first demonstration of polarization and phase controlled CPA in fibre integrated quantum gates provides a practical solution to transfer and manipulate information between qubits.

Engineering of spectral correlations of telecom-wavelength photons

Maciej Gałka, Univ. of Warsaw (Poland); Michał Mikołajczyk, Michał Karpiłski, Faculty of Physics, University of Warsaw (Poland)

Time-frequency domain is a promising platform for optical quantum technologies due to large Hilbert space available for quantum information encoding. Moreover, photons appear as perfect candidates for interface between different quantum systems as they can be transmitted over large distances in a low-loss manner. Obviously mostly desired would be such link at telecommunication wavelengths, because it can be integrated with classical communication schemes.

We report on a tunable telecom-wavelength photon pair source based on bulk periodically poled potassium titanyl phosphate (PPKTP) pumped by femtosecond laser pulses. The pairs are produced via type-II spontaneous parametric down conversion (SPDC). The spectra of photons, which lies in telecommunication range, in our source can be affected via both changing the spectrum of pumping laser and changing the phase matching by using crystals of different lengths. By appropriate choice of these parameters either the pair of photons occupy single-mode in frequency and is in a separable state or is multimode and entangled [1].

Here we report on experimental active modification the photon pairs’ spectral properties. We employ fast electro-optic temporal phase modulation to induce a deterministic change of photons’ joint spectral intensity (JSI). Central wavelength of one photon is shifted by up to 0.2 nm. The measurement of the spectrum of single photons is based upon frequency to time mapping, implemented by large group delay dispersion (GDD) in chirped fiber Bragg grating (CFBG) [2]. An unprecedented sub-10 pm resolution of correlated single-photon spectral measurements has been achieved.

Further work will be done to modify not only the position, but also the shape of JSI by using techniques based on the time-lens principle [3].

Quantum dynamics of confined modes of a metasurface

Didier Felbacq, Univ. Montpellier (France)

Meta—surfaces are the bidimensional analogues of metamaterials. They are made on resonant elements periodically disposed on a surface. In this work, we investigate the near-field properties of a metasurface whose basic elements possess an electric and a magnetic dipole resonance. We investigate the quantum dynamics of the coupling of a quantum emitter with Bloch surface modes localized on the meta—surface exist due the resonance of the dipoles. The strong coupling regime with a emitter can be reached when the Bohr frequency of the emitter is in resonance with the Bloch modes of the meta-surface. The approach is based on an impedance model for the metasurface allowing to obtain the dispersion relation for the electromagnetic modes below the light-cone, i.e. confined on the metasurface. The electromagnetic field can then be quantized canonically. The quantum oscillator is described as a two-level system situated in the vicinity of the metasurface and coupled with the electromagnetic field via a dipolar term. We are then able to describe the quantum electrodynamics of the coupled system and study the regime of weak and strong coupling.

Optimal quantum teleportation of coherent states of light

Gerardo Adesso, Pietro Liuzzo-Scorpo, The Univ. of Nottingham (United Kingdom)

We consider quantum teleportation of ensembles of coherent states of light with a Gaussian distributed displacement in phase space. We address the following general question: given a certain amount of entanglement available as a resource, what is the maximal fidelity that can be achieved on average in the teleportation of such an ensemble of states? We answer the question analytically by means of an optimisation within the space of Gaussian quantum channels, which allows for an intuitive visualisation of the problem. We first show that not all channels are accessible with a finite degree of entanglement, and then prove that practical schemes relying on non-symmetric entangled states (i.e., unbalanced twin beams) enable one to reach the maximal fidelity at the border with the inaccessible region. We further extend our study to secure quantum teleportation by considering the role of Gaussian steering as a resource. Our results provide a rigorous quantitative assessment of entanglement as a resource for quantum communication. The schemes we propose can be readily implemented experimentally by a conventional continuous variable teleportation protocol involving homodyne detections and corrective displacements with an optimally tuned gain. These protocols can be integrated as elementary building blocks in quantum networks, for robust storage and transmission of quantum optical states.

Tunable light superfluids using 4-level quantum atomic optical systems

Nuno Azevedo Silva, INESC Porto (Portugal) and Univ. do Porto (Portugal); Ariel Guerreiro, INESC TEC (Portugal)

In the paraxial approximation, the propagation of light in a bulk defocusing cubic nonlinear media is well described by a Nonlinear Schrödinger equation, which through the use of the Madelung transformation can be interpreted into a hydrodynamic description of light. In this description, the laser intensity maps into the light fluid density and the fluid velocity is related with the spatial phase gradient. Sharing similarities with the mean-field theory of Bose Einstein Condensates, the hydrodynamic description of light is capturing a lot of interest recently and opening new perspectives in different branches of physics by offering tabletop experiments of analogue many-body quantum systems with unprecedented control of the interactions which, in its turn, can model a wide range of phenomena in physics, ranging from superfluidity to Black Holes. Then, being able to tune the optical properties of the media is an important requirement of such analogue optical systems, in order to establish correct analogues of physical phenomena.

In this context, we will show theoretically how we can use a 4-level quantum atomic optical system to develop highly tunable optical media, with spatial control of both linear and nonlinear susceptibility. Also, we explore the superfluid behaviour of light in these atomic media and purpose a strategy to create connected geometries, discussing and investigating through GPU-enhanced numerical simulations the existence of quantized persistent currents, a phenomenon already observed in other superfluid systems such as liquid He or Bose Einstein Condensates.

Highly-multimode photonic quantum memory in cold atoms

Mateusz Mazelanik, Micha? D?browski, Micha? Parniak, Wojciech Wasilewski, University of Warsaw (Poland)

Quantum memories are essential for the development of quantum information processing devices. Among others, they have been proposed as on-demand photon sources and key elements of quantum repeaters - devices allowing entanglement distribution on truly long distances.

We demonstrate a highly-multimode quantum memory which can generate, store and retrieve photons. The operation scheme relies on Raman scattering in cold rubidium-87 atomic cloud prepared in magneto-optical trap. In write-in process the Stokes photons are created in random direction together with atomic collective excitations - spin waves. During the readout the excitations are converted to anti-Stokes photons. The wave-vector of anti-Stokes photon is correlated with the Stokes one due to phase matching condition. We shot-by-shot register those photons on separate regions of a fast single-photon-sensitive camera. From single-photon counts statistics we calculated that we can store over than 1000 independent spin-wave modes. Such feature combined witch fast single photon switch could speed up single photon generation dramatically. To verify quantum nature of the stored states we measurred the normalyzed g_(S,aS)^((2)) cross-correlation of the Stokes and anti-Stokes fields. We obtained values of g_(S,aS)^((2)) reaching 100 which is indicative of a true quantum memory, since this parameter is classically bounded by 2.

Controlling light at the atomic scale

F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

Atomically thin materials such as graphene and molecular aromatic hydrocarbon exhibit unique optical properties that allow us to control the flow of light down to the atomic scale. These materials can sustain collective electron resonances -plasmons- involving a relatively small number of electrons, therefore enabling unprecedented electrical, magnetic, optical, and thermal control of those properties. In this talk, I will review recent progress in this field and present illustrative examples of nonlinear, quantum, and ultrafast phenomena in these materials, along with applications to optical sensing, optoelectronics, and quantum optics.

Chiral quantum optics *(Invited Paper)*

Peter Lodahl, Niels Bohr Institute (Denmark)

Modern photonic nanostructures enable the full control of the interaction between a single quantum emitter and a single photon [1]. We will review the recent experimental progress on quantum dots coupled to nanophotonic waveguides offering a fully deterministic photon-emitter or photon-spin interface. We discuss how chiral light-matter coupling can be engineered enabling the construction of novel non-reciprocal photonic devices [2] and directional radiative coupling [3]. The light-matter coupling is inherently nonlinear and operational down to the level of single photons [4]. We finally discuss how chiral interaction may be advantageous for applications in quantum-information processing [5] and for scalable quantum network architectures [6]

Unidirectional electron tunneling via asymmetric plasmonic resonances *(Invited Paper)*

Matthew T. Sheldon, Texas A&M Univ. (United States)

Optically excited plasmonic nanostructures display remarkable electron dynamics in the form of coherent electron displacement motion, as well as efficient generation of non-thermal 'hot electrons' with large kinetic energy. Here, we provide a theoretical and experimental overview of our studies of photo-induced charge transport across plasmonic tunneling junctions composed of nanoscale metallic gaps, as a strategy for taking advantage of such electron motion for optoelectronic energy conversion.

In symmetric plasmonic tunneling gaps the energetic distribution of electrons due to photo-induced thermalization and hot electron generation is insufficient for significant electrical currents, either through excitation over the interface potential barrier, or via tunneling that exhibits a net preference for the direction of charge transfer. However, asymmetric resonant structures can provide optical absorption, photo-excitation and time-dependent electric fields that induce significant temperature gradients and local variations in the hot electron population. Such asymmetry can be used to promote unidirectional tunneling transport currents with significant enhancement compared with conventional photoelectron and thermionic emission (~ 10^15 enhancement), and thus comprises an intriguing mechanism for providing electrical work. This presentation will introduce the theoretical framework of tunneling phenomena associated with photon-induced hot electrons in plasmonic structures, including principles of electron distribution under photon excitation, strategies for amplifying hot electron generation (e.g. manipulating hot spots in nano-antennas) and provide a mechanistic quantum model of power conversion devices based on unidirectional electron tunneling across nanoscale plasmonic junctions. We also report on initial transport measurements of plasmonic tunnel junctions that exhibit optical power conversion by this method.

Giant vacuum friction: PT symmetric spectral singularity and negative frequency resonance *(Invited Paper)*

Sarang Pendharker, Yu Guo, Farhad Khosravi, Univ. of Alberta (Canada); Zubin Jacob, Purdue Univ. (United States)

Vacuum consists of a bath of balanced and symmetric positive and negative frequency fluctuations. Media in relative motion or accelerated observers can break this symmetry and preferentially amplify negative frequency modes as in Quantum Cherenkov radiation and Unruh radiation. Here, we show the existence of a universal negative frequency-momentum mirror symmetry in the relativistic Lorentzian transformation for electromagnetic waves. We show the connection of our discovered symmetry to parity-time (PT) symmetry in moving media and the resulting spectral singularity in vacuum fluctuation related effects. We prove that this spectral singularity can occur in the case of two metallic plates in relative motion interacting through positive and negative frequency plasmonic fluctuations (negative frequency resonance). Our work paves the way for understanding the role of PT-symmetric spectral singularities in amplifying fluctuations and motivates the search for PT-symmetry in novel photonic systems.

10359-4, Session 2

Rb atomic vapor interaction with nanophotonic and plasmonic devices *(Invited Paper)*

Hadiseh Alaeian, Northwestern Univ. (United States)

Over the past decades, alkali atoms have been the subject of intensive and diverse research, ranging from fundamental studies on ultra-cold atoms and Bose-Einstein condensates to technological applications. Since they possess only a single valance s-electron, the alkali atoms manifest a simple low-lying electronic structure compared to other atoms. Moreover, unlike conventional solid state systems their dispersion-free features make them an ideal candidate for sensing applications and referencing tasks. These two features have introduced alkali atoms as promising quantum emitters for the new paradigm of hybrid quantum optics and quantum electrodynamics. This new concept benefits from the existing integrated photonics technology for squeezing and confining the light in sub-wavelength scales to substantially enhance the light-atom interaction. The hybrid chip is envisioned to have light sources, waveguides, devices, and detectors to realize a complex quantum network down to a single photon level.

In this talk I will discuss about our recent theoretical and experimental works on atomic vapor spectroscopy in the vicinity of the plasmonic and nanophotonic devices. I start from a density matrix-based formalism describing the evolution of Rb vapor atomic levels, excited with an incoherent pump and coupled to a plasmonic lattice. When designed properly, the lattice plasmon mode efficiently captures the spontaneously emitted photons from the excited Rb atoms and a coherent coupling between the lattice mode and the atomic levels would occur. I will elaborate on the effect of pumping rate and decoherence on the steady state of the hybrid system and the feasibility of achieving a lasing state. In the second part of the talk I will present the results of our experiments on Rb vapor coupled to such a plasmonic lattice. Starting from the pumping mechanism, I describe the collisional scheme we employed to transfer the excited Rb atoms from (_^5)P_(3/2) to(_^5)P_(1/2) , hence achieving a population inversion between P and S levels and an optical gain at 795 nm, eventually. I present the experimental results of this atomic vapor interaction with a plasmonic lattice resonating at 795 nm. The spectroscopy of Rb cloud modified with tightly squeezed and enhanced field of the lattice plasmons shows the clear signature of Fano resonances in the passive gas, followed by amplified spontaneous emission in the active gas and the lasing at higher pumping powers. The results of this study would pave the way toward hybrid atom-quantum photonic chips.

10359-5, Session 2

Quantum state reconstruction and photon statistics for coherent states interacting with few quantum dot states *(Invited Paper)*

Fabian Boehm, Nicolai B. Grosse, Mirco Kolarczik, Nina Owschimikow, Ulrike Woggon, Technische Univ. Berlin (Germany)

Quantum-dot devices have been of special interest for the quantum optics community, since they allow for the creation of quantum optical states used e.g. for single-photon emitters. To characterize the quantum optical properties of emitters, quantum state tomography is a technique to reconstruct the full state from the quantum statistical measurement of the field fluctuations. We demonstrate the interaction of a coherent state with few quantum dot-systems by investigating how a femtosecond laser pulse propagates through a quantum dot optical amplifier. Using a balanced detection scheme in a self-heterodyning setup, we achieve precise measurements of the quadrature components and their fluctuations at the quantum noise limit [1]. We time-resolve the photon number distribution and the thermal-to-coherent evolution as a laser pulse is travelling through a semiconductor optical amplifier. We reconstruct the Wigner function and the photon statistics of the coherent input state before and after propagation through the amplifier with very high temporal resolution. The detection sensitivity is at a level where the fluctuations of the vacuum field can be clearly measured. An efficiency is achieved that photon numbers of as little as 2-4 photons can be observed. We also combine the techniques with a pump-probe setup, which allows us to directly manipulate the state inside the amplifier at a picosecond timescale. Using both electrical and optical carrier injection we measure the photon statistics as a function of carrier injection and demonstrate gain modulation of few-photon states.

10359-6, Session 2

Quantum localization issues in nonlinear frequency conversion and harmonic generation

David L. Andrews, Kayn A. Forbes, Jack S. Ford, Univ. of East Anglia (United Kingdom)

Issues of a fundamentally quantum origin are involved in determining the mode structures and quality of output in optically parametric processes such as harmonic generation. Any theory with an implicit assumption that each frequency conversion event occurs in an infinitesimal volume necessarily leads to an uncertainty in the output wave-vector. However, it is possible to construct a rigorous, photon-based theory that explicitly provides for a finite conversion volume, and which also identifies the intricate electrodynamic mechanisms at play within the corresponding region of space and time, on an optical wavelength and cycle time scale. This paper reports recent work on the development of this theory, based on quantum electrodynamical analysis. It identifies the form of specific material parameters that are engaged in determining the extent and measure of delocalised frequency conversion, and it leads to equations whose implementation, provided with data on the input beam structure, can deliver detailed information on the optical mode structures in the output.

10359-7, Session 2

Engineering quantum light on photonic chips *(Invited Paper)*

Qiang Lin, Univ of Rochester (United States)

In this talk, we will discuss our recent progress in engineering micro/nanophotonic device structures for producing and manipulating photonic quantum states on chip.

Recent advances in quantum photonics have resulted in broad applications ranging from secure communication, metrology, sensing, to advanced computing. Chip-scale implementation would not only enhance the complexity and capacity of information processing, but also enable novel functionalities which are otherwise inaccessible in room-wide/table-top experiments.

Lying in the heart of these applications is the capability of generating versatile high-purity entangled photonic quantum states. In this talk, we will discuss our recent effort in engineering micro/nanophotonic device structures for producing and manipulating photonic quantum states on various chip-scale device platforms, by taking advantage of enhanced four-wave mixing and parametric down conversion processes, via the second-order and third-order optical nonlinearities.

10359-25, Session PMon

Quantum photoemission of confined nonlinear optical materials *(Invited Paper)*

Subhamoy Singha Roy, JIS College of Engineering (India)

The photo emission also exhibits oscillatory variation with changing electron concentration and field thickness, respectively, for all types of quantum confinement. The photo emitted current density is the greatest for QDs and the least for QWs. In addition, the well-known results for bulk specimens of wide-gap materials have also been obtained as special cases from our generalized expression under certain limiting conditions.

10359-8, Session 3

Nanophotonic enhanced quantum emitters *(Invited Paper)*

Xin Li, Univ. of St. Andrews (United Kingdom); Zhang-Kai Zhou, Ying Yu, Sun Yat-Sen Univ. (China); Malte C. Gather, Andrea Di Falco, Univ. of St. Andrews (United Kingdom)

Quantum dots are excellent solid-state quantum sources, because of their stability, their narrow spectral linewidth, and radiative lifetime in the range of 1ns. Most importantly, they can be integrated into more complex nanophotonics devices, to realize high quality quantum emitters of single photons or entangled photon sources. Recent progress in nanotechnology materials and devices has opened a number of opportunities to increase, optimize and ultimately control the emission property of single quantum dots. In this work we present an approach that combines the properties of quantum dots with the flexibility of light control offered by nanoplasmonics and metamaterials structuring.

Specifically, we show the nanophotonic enhancement of two types of quantum dots devices, based on a single layer of low density (In)GaAs QDs grown via molecular beam epitaxy. The quantum dots are decorated on the facets of core-shell GaAs/AlGaAs nanowires, fabricated with a bottom-up approach, or inserted into optical-positioned micro-pillar cavities.

In both cases, the metallic nanofeatures, which are designed to control the emission and the polarization state of the emitted light, are realized via direct electron beam ion deposition. This approach permits to create three-dimensional features with nanometric resolution and positional accuracy, and does not require wet lithographic steps and previous knowledge of the exact spatial arrangement of the quantum devices.

10359-9, Session 3

Ultrafast spontaneous emission from single quantum dots coupled to plasmonic nanocavities *(Invited Paper)*

Maiken H. Mikkelsen, Duke Univ. (United States)

In this talk, we will describe the observation of ultrafast spontaneous emission from a single quantum dot coupled to a plasmonic structure that acts both as a small mode volume nanocavity and a nanopatch optical antenna. The nanocavity is composed of a colloidally-synthesized silver nanocube separated from a gold film by a single colloidal quantum dot and polymer layers. A 3 nm polymer layer above and below the quantum dot create a ~12 nm gap between the metal film and the nanocube which supports a highly confined plasmonic cavity mode. From white light scattering measurements, the resonance wavelength for a nanocube with a side length of ~75 nm is found to be 630 nm and colloidal quantum dots are chosen with an emission at the same wavelength to provide maximum spectral overlap with the plasmonic mode. In this way, the plasmonic nanocavity coupled to a single quantum dot acts as a single photon source operating in the regime of ultrafast spontaneous emission. The detector limited emission lifetime of 13 ps corresponds to a 540-fold enhancement in the spontaneous emission rate of the quantum dot, and points towards a single photon source operating at an ~80 GHz rate. The ~1,900-fold enhancement in the emission intensity shows that the fast emission lifetime is due to enhancement of the radiative rate rather than quenching. Furthermore, antenna action of the cavity results in a directional radiation pattern and allows for high collection efficiency by free space optics or into a single mode fiber.

10359-10, Session 3

Two-photon bundles from a single two-level system

Lukas Hanschke, Walter Schottky Institut, Technische Univ. München (Germany); Kevin A. Fischer, Ginzton Lab., Stanford Univ. (United States); Jakob Wierzbowski, Tobias Simmet, Walter Schottky Institut, Technische Univ. München (Germany); Constantin Dory, Ginzton Lab., Stanford Univ. (United States); Jonathan J. Finley, Walter Schottky Institut, Technische Univ. München (Germany); Jelena Vuckovic, Ginzton Lab., Stanford Univ. (United States); Kai Müller, Walter Schottky Institut, Technische Univ. München (Germany)

We demonstrate the generation of two-photon bundles from a single quantum two-level transition in a semiconductor quantum dots [1]. Quantum two-level systems in the solid state are poised to serve the pivotal role of an on-demand single-photon source by converting laser pulses with Poissonian counting statistics to single photons. More recently, multi-photon quantum state generators have engendered strong interest as replacements for the single-photon source in many quantum applications. Here we investigate theoretically and verify experimentally that the same two-level system that has long been studied for single-photon generation can surprisingly operate in a two-photon bundling regime.

For on demand single-photon generation, the two-level system is typically excited with a resonant pulse of area pi. This prepares the two-level system in its excited state from where it spontaneously emits a single photon. In contrast, when exciting the system with a pulse of area 2pi, the system is expected to be returned to the ground state. However, if the ratio of pulse length to excited state lifetime is finite, photon emission during the presence of the laser pulse is possible. This is most likely to happen when the system is in its excited state - after an area of pi has been absorbed. If such an emission occurs, the Rabi oscillation is restarted with a pulse area of pi remaining in the pulse which re-excites the system and leads to the emission of a second photon within the excited state lifetime.

10359-11, Session 3

Quantum emitters in flatland *(Invited Paper)*

Igor Aharonovich, Univ. of Technology, Sydney (Australia)

Engineering solid state quantum systems is amongst grand challenges in engineering quantum information processing systems. While several 3D systems (such as diamond, silicon carbide, zinc oxide) have been thoroughly studied, solid state emitters in two dimensional (2D) materials have not been observed. 2D materials are becoming major players in modern nanophotonics technologies and engineering quantum emitters in these systems is a vital goal.

In this talk I will discuss the recently discovered single photon emitters in 2D hexagonal boron nitride (hBN). I will present several avenues to engineer these emitters in large exfoliated sheets using ion and electron beam techniques. Density functional theory calculations suggest that that the studied defects are the antisite nitrogen vacancy in hBN. The formed emitters in 2D hBN flakes have extremely promising properties – including high brightness (~ millions counts/s), stability up to high temperatuers and linear polarization at excitation and absorption. Those properties make these emitters extremely attractive for their integration with optical resonators and waveguides. Finally, I will discuss several challenges and promising directions in the field of quantum emitters and nanophotonics with 2D materials and other wide band gap materials.

10359-12, Session 3

External quantum efficiency research of GaN-based laser diodes

Pengyan Wen, Suzhou Institute of Nano-Tech and Nano-Bionics (SINANO) CAS (China)

The GaN-based laser diodes (LDs) have attracted much attention due to their wide applications in laser display and laser lighting. As an important parameter of the LDs, the external quantum efficiency not only influences the output power but also plays an important role in the reliability. In this study, we observed the external quantum efficiency of our blue LD decreases after aging, which is contrary to the conventionally reported results. Further characterization on the microstructure of the LDs was carried out by transmission electron microscope (TEM) technique. Dislocation like defects in the waveguide region of the LD structure was observed. Furthermore, the defects extended during the aging. We attributed the reduction of the external quantum efficiency to the dislocation like defects in the waveguide layer of the LDs.

10359-13, Session 4

Flat and conformal optics with dielectric metasurfaces *(Invited Paper)*

Andrei Faraon, California Institute of Technology (United States)

Flat optical devices based on lithographically patterned sub-wavelength dielectric nano-structures provide precise control over optical wavefronts, and thus promise to revolutionize the field of free-space optics. I discuss our work on metasurfaces composed of high-index nano-posts supported

by transparent substrates. Complete control of both phase and polarization is achieved at the level of single nano-post. Using this nano-post platform, we demonstrate lenses, waveplates, polarizers, arbitrary beam splitters and holograms. Devices providing multiple functionalities, like simultaneous polarization beam splitting and focusing are implemented. By embedding the metasurfaces in flexible substrates, conformal optical devices that decouple the geometrical shape and optical function are shown. Multiple flat optical elements are integrated in optical systems such as planar retro-reflectors and Fourier lens systems with applications in ultra-compact imaging systems.

10359-14, Session 4

High performance metasurfaces based on inverse design *(Invited Paper)*

Jonathan A. Fan, Stanford Univ. (United States)

Metasurfaces have traditionally employed building blocks with physically intuitive optical responses. Many of these concepts utilize dielectric posts, which serve as waveguides and are stitched together with sufficient spacing to minimize coupling between adjacent elements. These design principles can produce single wavelength devices with good performance, but are difficult to generalize to multi-wavelength devices with exceptional performance. We show that concepts in inverse design can be used to produce dielectric metasurfaces with capabilities that exceed the current state-of-the-art. With swarm and topology optimization, we incorporate optical coupling between waveguide elements in the device designs, which yield physically non-intuitive mode profiles and coupling dynamics. To demonstrate the power and versatility of our design approach, we fabricate silicon devices that can efficiently deflect light to 75 degree angles and multi-functional devices that can steer beams to different diffraction orders based on wavelength. We also show that single crystal silicon can be used to realize efficient metasurface devices across the entire visible spectrum, ranging from 480 to 700 nanometers. Alternative forms of silicon, such as polycrystalline and amorphous silicon, suffer from higher absorption losses and do not yield efficient metasurfaces across this wavelength range. We envision that metasurfaces based on inverse design will serve as a hardware platform for the efficient routing, sorting, and manipulation of single or few photons for quantum optics applications.

10359-15, Session 4

Surface-wave phenomena and anisotropic Photoluminescence in nano-film structures

Jan Heckmann, Karsten Pufahl, Philipp Franz, Nicolai B. Grosse, Ulrike Woggon, Technische Univ. Berlin (Germany)

Intrinsically absorbing materials can sustain low-loss surface-waves with long propagation length if prepared as thin films embedded in symmetric, low-absorbing cladding materials. Semiconductors, transition metals, metal oxides, dichalcogenides and even disordered materials can thus support long-range surface polaritons (LRSP). However, the most compelling aspect of absorbing materials—their intrinsic nonlinear susceptibility—have not yet been studied in the context of LRSP. We show experimental results and theoretical calculations of the dispersion relation of LRSPs in the VIS and NIR regime. We combine the Otto configuration with nonlinear k-space spectroscopy to investigate the field-enhancement properties of long-range surface polariton modes. The excitation of these modes in the near-infrared has allowed us to gauge the strength of the near-field on resonance where a boost in second-harmonic yield was found. In addition, we support the nonlinear data with angle-resolved white-light spectra of the attenuated total internal reflection. Even excitation of a long-range surface wave on a rough and disordered surface, e.g. a functional gold filled PNIPAM films, could be demonstrated. Our results show that the excited modes have superior propagation lengths compared to bulk metal surface plasmon polaritons. Our findings open up new possibilities by releasing the restriction of high surface qualities for subwavelength guiding and focussing of light.

10359-16, Session 5

Measurement and control of nanomechanical motion with photons confined at the nanoscale *(Invited Paper)*

Ewold Verhagen, Rick Leijssen, Giada R. La Gala, Lars Freisem, John Mathew, Juha T. Muhonen, FOM Institute for Atomic and Molecular Physics (Netherlands)

The creation of non-classical states of mechanical motion is a long-standing goal in experimental physics. One promising approach to achieve this is measurement-based state preparation, where sufficiently strong interaction with a measurement device is used to project the mechanics into an eigenstate of the measured observable. In order to prepare non-classical states, one needs to move away from linear continuous displacement measurements towards non-linear (e.g. quadratic) and/or non-continuous measurements that evade backaction. We employ nanophotonic optomechanical systems, in which nanomechanical resonators are coupled to optical fields with extreme strength. The combination of strong photon-phonon interactions and narrow optical linewidths results in record single-photon cooperativities of ~1000. This means optomechanical measurements become nonlinear even for minute thermal displacements at cryogenic temperatures. We exploit this intrinsic optomechanical nonlinearity to perform a quadratic measurement of position with unprecedented sensitivity, and discuss the potential of using such methods to prepare non-classical states in the quantum regime. Moreover, we demonstrate the use of fast, pulsed measurements of position to perform backaction-evading displacement measurement. Finally, we explore the use of this platform to couple and simultaneously control multiple mechanical resonators through light fields, with the potential to realize nonreciprocal and topological photon-mediated transport of acoustic signals.

10359-17, Session 5

Molecular optomechanics in plasmonic cavities *(Invited Paper)*

Mikolaj Schmidt, Ctr. de Fisica de Materiales (Spain); Alejandro Gonzalez-Tudela, Max-Planck-Institut fur Quantenoptik (Germany); Geza Giedke, Donostia International Physics Ctr. (Spain) and Ikerbasque, Basque Foundation for Science (Spain); Tomas Neuman, Ctr. de Fisica de Materiales (Spain) and Donostia International Physics Ctr. (Spain); Yao Zhang, Ctr. de Fisica de Materiales (Spain) and Donostia International Physics Ctr. (Spain); Rubén Esteban, Ctr. de Fisica de Materiales (Spain); Javier Aizpurua, Ctr. de Fisica de Materiales (Spain) and Donostia International Physics Ctr. (Spain)

Surface-Enhanced Raman Scattering (SERS) is a fundamental spectroscopic technique that allows to access the rich vibrational structure of molecules. A typical SERS configuration with a molecule located in a plasmonic cavity acting as an optical nanoantenna enhances the vibrational (Stokes or anti-Stokes) signal of the molecule. A number of recent implementations of Raman experiments in plasmonic nanocavities appear to provide results which escape the standard description of the Raman process based on the classical treatment of the electromagnetic fields enhancement inside the cavity.

We establish a novel analogy between non-resonant SERS in molecular spectroscopy and typical optomechanical processes. By adopting an optomechanical hamiltonian which describes the interaction between cavity plasmons and molecular vibrations, we are able to trace the quantum dynamics of both plasmons and vibrations in a SERS process. The solution of the master equation of this optomechanical hamiltonian allows to identify novel quantum effects such as the existence of different regimes of molecular vibrational build-up: a thermal vibrational regime, a vibrational pumping regime, and a strongly nonlinear vibrational regime, which emerge as a consequence of the quantum dynamics induced by the optomechanical

interaction. Correlations between the Stokes and anti-Stokes Raman signals can also be traced for different temperatures and pumping powers.

The presence of strong optomechanical effects in Raman has been recently addressed experimentally in special "picocavities" formed by a few metallic atoms in a plasmonic cavity. The strong optomechanical coupling achieved in this situation is found to activate the pumping regime in the Raman signal, thus corroborating the validity of this description.

10359-18, Session 5

Towards optomechanics with one-dimensional gallium phosphide photonic crystal cavities

Katharina Schneider, Pol Welter, Yannick Baumgartner, Herwig Hahn, Lukas Czornomaz, Paul F. Seidler, Simon Hönl, IBM Research - Zürich (Switzerland)

We describe the design, fabrication and characterization of one-dimensional photonic crystal cavities made of gallium phosphide (GaP). The large band gap (2.26 eV) and high refractive index (n≈3.1) make GaP a promising candidate for optomechanical devices. Compared to silicon, a reduced two-photon absorption is expected, which should mitigate heating of the devices in optical experiments.

We have developed a process flow for GaP devices that allows device integration on silicon dioxide (SiO2). GaP is grown by metal-organic chemical vapor deposition (MOCVD) on a bulk GaP wafer with an intermediate aluminum-gallium-phosphide (AlGaP) layer. A GaP-on-insulator substrate is then obtained by bonding the GaP-AlGaP-GaP stack on an oxidized silicon wafer. The sacrificial layers are removed with wet etch and dry etch processes selective to AlGaP or GaP. Finally, the device designs are transferred into the GaP by dry-etching. Structures, which are meant to be freestanding, are released by removal of the underlying SiO2.

Optical components such as grating couplers, waveguides and one-dimensional photonic crystal cavities have been designed for the GaP-on-SiO2 system. Photonic crystal cavities optimized with finite-element simulations yield optomechanical coupling strengths as high as g/2ϖ=900 kHz and optical quality factors Q>?10?^6. The optical performance of the fabricated devices is characterized and the optomechanical coupling of the trapped optical mode with the mechanical motion of the beam determined.

10359-19, Session 5

Optomechanical quantum non-demolition measurement of optical field fluctuations

Antonio Pontin, Univ. College London (United Kingdom); Michele Bonaldi, Istituto Nazionale di Fisica Nucleare (Italy) and Istituto per la Fisica Fondamentale e Applicazione, Istituto Nazionale di Fisica Nucleare (Italy); Antonio L. Borrielli, Istituto dei Materiali per l'Elettronica ed il Magnetismo (Italy) and Istituto per la Fisica Fondamentale e Applicazione, Istituto Nazionale di Fisica Nucleare (Italy); Lorenzo Marconi, Istituto Nazionale di Ottica, Consiglio Nazionale delle Ricerche (Italy); Francesco Marino, Istituto Nazionale di Fisica Nucleare (Italy) and Istituto Nazionale di Ottica, Consiglio Nazionale delle Ricerche (Italy); Gregory Pandraud, Technische Univ. Delft (Netherlands); Giovanni Andrea Prodi, Istituto Nazionale di Fisica Nucleare (Italy) and Univ. degli Studi di Trento (Italy); Pasqualina M. Sarro, Technische Univ. Delft (Netherlands); Enrico Serra, Istituto Nazionale di Fisica Nucleare (Italy) and Technische Univ. Delft (Netherlands); Francesco Marin, Univ. degli Studi di Firenze (Italy) and Istituto Nazionale di Fisica Nucleare (Italy) and Lab. Europeo di Spettroscopie Non-Lineari, Univ. degli Studi di Firenze (Italy)

In the framework of quantum mechanics there exists a class of observables for which is possible to confine the perturbation of a continuous measurement to the conjugate variable.

Experimental schemes exploiting this concept are referred to as quantum nondemolition measurements (QND) and can provide the means to estimate the observed variable with arbitrary accuracy or to prepare it in a well-known state. Among these observables there is the amplitude of the light field. Already in the mid-90s, it was proposed to exploit a movable mirror to implement a QND scheme(1). Indeed, intensity fluctuations of an optical field impinging on a mirror are not affected by the interaction. However, if the mirror is movable it can be excited by radiation pressure. The displacement of the mirror, in turn, affects the phase of the field. Thus, by measuring phase fluctuations of the optical field after its interaction with the movable mirror it is possible to gather information on the intensity quadrature.

We present an optomechanical experiment, in which the movable mirror is a high Q micro-mechanical device(2) and is the end mirror of Fabri-Pérot cavity. We have simultaneously measured intensity fluctuations of the field reflected by the cavity and the mirror motion imprinted in the phase fluctuations. By exploiting the correlations between these variables, we demonstrate a reduced uncertainty on intensity fluctuations actually reaching a sub-shot noise level.

10359-20, Session 6

Towards integrated plasmonic quantum devices *(Invited Paper)*

Simeon Bogdanov, Mikhail Y. Shalaginov, Justus C. Ndukaife, Oksana A. Makarova, Purdue Univ. (United States); Alexey V. Akimov, Texas A&M Univ. (United States); Alexei S. Lagutchev, Alexander V. Kildishev, Alexandra Boltasseva, Vladimir M. Shalaev, Purdue Univ. (United States)

Integrated quantum photonics imposes very stringent and often contradictory requirements on the design of integrated optical components. Many material platforms have been proposed and developed to host the future quantum optical systems. All of them feature fundamental limitations that invite to consider more complex, hybrid platforms. In this talk, we focus on the use of plasmonic materials for realizing quantum devices that possess properties not available with only dielectric materials. We present our work on fast room-temperature single-photon sources and specifically address the problem of efficient outcoupling of the plasmonic modes to the far-field. We demonstrate optical spin-state readout from nitrogen-vacancies in nanodiamonds through surface plasmon-polaritons and show that quantum registers and sensors based on these color centers can operate within nanoscale optical circuits. We also discuss how our novel approach combining plasmonics with optofluidics helps achieving fast and deterministic positioning of nanodiamonds in the vicinity of plasmonic antennas. This result promises scalable assembly techniques for more complex nanophotonic systems. With these new functionalities, plasmonic devices could play a decisive role in the engineering of tomorrow's quantum photonic systems.

10359-21, Session 6

Inelastic-scattering tunnel electrons towards an electrically driven single-photon light source *(Invited Paper)*

Hasan Goktas, The George Washington Univ. (United States) and Harran Univ. (Turkey); Fikri Serdar Gökhan, Alanya Alaaddin Keykubat Üniv. (Turkey); Volker J. Sorger, The George Washington Univ. (United States)

We show that inelastically-scattering tunnel electrons are a source for electric plasmon generation. We experimentally demonstrate such electrically-driven light-emitting tunnel junction by forward biasing a Fermi sea against a doped semiconductor across a nanometer-thin tunnel oxide gap. Light emission at room temperature is found in the visible frequency range corresponding to a spectral power dependency of the tunnel current and the plasmonic mode. Light outcoupling, however is fundamentally weak since a top metal blocks emission. We studied the improvement in outcoupling in two ways; a) by gradually reducing the top-metal film thickness, and b) by introducing a grating coupler. Results show that the optimum metal thickness corresponds to the skin-depth of the metal at the emission frequency, while the grating allows for n 400x times increased relative to metal-blocking case. For the ~1-2eV observed emission, Heisenberg's uncertainty principle dictates an upper limit time response of the junction in the fs-range. Solving the current equation for both thermionic and tunnel event contributions, gives a response time (speed) scaling inverse exponentially with the tunnel gap thickness, approaching Tpbs for <0.5nm thin gaps. Lastly, since tunnel allows for single-charge events, the possibility for single-photon generation is expected.

10359-22, Session 6

Theory directions in excited-state quantum plasmonics *(Invited Paper)*

Prineha Narang, Harvard Univ. (United States)

The limits of electronic, optical and thermal performance of devices are determined by atomic-scale dynamics in their constituent materials. To enable technologies of the future, high-performance exascale computing, next factor-of-100 cost-effective capacity increases in optical networks and integrated quantum devices, conventional device concepts are insufficient. Non-equilibrium and excited state device architectures offer a fundamentally new pathway toward these technologies.

Surface plasmons, electromagnetic modes confined to the surface of a conductor-dielectric interface, have sparked recent interest because of their quantum nature and their broad range of applications in integrated nanophotonics, biosensing, photovoltaic devices, single photon transistors and single molecule spectroscopy. Despite more than a decade of intensive scientific exploration, new plasmonic phenomena continue to be discovered, including quantum interference of plasmons, observation of quantum coupling of plasmons to single particle excitations, and quantum confinement of plasmons in single-nm scale plasmonic particles.

Decay of surface plasmons to hot carriers is a new direction that has attracted considerable fundamental and application interest, yet a detailed theoretical understanding of ultrafast plasmon decay processes and the underlying microscopic mechanisms remain incomplete. In this talk I will provide a fundamental understanding of plasmon-driven hot carrier generation and relaxation dynamics in the ultrafast regime. I will report the first ab initio calculations of phonon-assisted optical excitations in metals as well as calculations of energy-dependent lifetimes and mean free paths of hot carriers, accounting for electron-electron and electron-phonon scattering, lending insight towards transport of plasmonically-generated carriers at the nanoscale. I will also discuss recent experimental observations of the injection of these nonequilibrium carriers into molecules tethered to the metal surface and into wide bandgap nitride semiconductors.

An unconventional direction in excited state quantum devices that I will discuss is based on quantum mechanical phenomena in natural energy conversion systems, namely photosynthesis. I will show recent results that probe the fundamental optical physics of cavities coupled to the elaborate topology of light-harvesting complexes. This understanding will enable rational control of photonic energy transfer at the molecular scale using spatially programmable nanoscale materials inspired by natural photosynthetic systems.

Finally I will give an outlook on the potential of excited state and non-equilibrium phenomena to deliver integrated quantum-engineered systems with diverse applications in quantum sensing and metrology, ultra-low power optoelectronic and electronic devices as well as energy conversion.

10359-23, Session 6

Plasmonic hot-carriers in the UV-VIS regime: experimental study of the internal quantum efficiency of generation and injection into GaN

Giulia Tagliabue, California Institute of Technology (United States); Ravishankar Sundararaman, Rensselaer Polytechnic Institute (United States); Adam S. Jermyn, Univ. of Cambridge (United Kingdom); Prineha Narang, Harvard Univ. (United States); Harry A. Atwater Jr., California Institute of Technology (United States)

The decay of surface plasmon resonances is usually a detriment in the field of plasmonics, but the possibility to capture the energy normally lost to heat has open new opportunities in photon sensors and energy conversion devices. In particular, the large extinction cross-section at a surface plasmon resonance enables nanostructures to absorb a significant fraction of the solar spectrum in very thin films and generate energetic carriers which could be exploited to drive photochemical processes.

Previously, we analyzed theoretically the quantum decay of surface plasmon polaritons, with and without phonons, and found that the prompt distribution of generated carriers is extremely sensitive to the energy band structure of the plasmonic material. In particular, the onset of interband transitions, occurring in the VIS regime (around 2 eV) for most common plasmonic metals (Au, Cu, Ag), is expected to significantly modify the hot-carriers distribution. Based on the theoretical work, we have designed an experimental system using GaN/noble-metal nanoscale heterostructures to investigate the photocurrent generated upon plasmon decay across the extended UV-visible regime. We indeed fabricated planar Schottky diodes where the Schottky contact was patterned with e-beam lithography to concurrently serve as plasmonic resonator. Using a super continuum Fianium laser as light source to cover the energy range from 3 eV to 1.2 eV, we measured the photocurrent as a function of photon energy. Thanks to the use of an optically transparent substrate which allows a direct experimental quantification of the absorption spectrum of our plasmonic structures, we can determine the internal quantum efficiency (IQE) spectrum of each device. By direct comparison with ab-initio calculations, we aim at assessing the contribution of direct and indirect transitions and identifying guidelines for engineering the generation of plasmonic hot-carriers in the UV-VIS regime.

10359-24, Session 6

Quantum phenomena with graphene plasmons *(Invited Paper)*

F. Javier García de Abajo, ICFO - Institut de Ciències Fotòniques (Spain)

Plasmons in atomic-scale structures exhibit intrinsic quantum phenomena related to both the finite confinement that they undergo and the small number of electrons on which they are supported. Their interaction with two-level emitters is also evidencing strong quantum effects. In this talk I will discuss several salient features of graphene plasmons in this context, and in particular their ability to mediate ultrafast heat transfer, the generation of high harmonics, their interaction with molecules and quantum emitters, and their extreme nonlinearity down to the single-photon level.

Conference 10360: Light Manipulating Organic Materials and Devices IV

SPIE. OPTICS+ PHOTONICS ORGANIC PHOTONICS+ ELECTRONICS

Sunday - Monday 6 –7 August 2017

Part of Proceedings of SPIE Vol. 10360 Light Manipulating Organic Materials and Devices IV

10360-1, Session 1

Light-induced plasmonic properties of organic materials: surface polaritons, bistability and switching waves *(Invited Paper)*

Boris D. Fainberg, Holon Institute of Technology (Israel) and Tel Aviv Univ. (Israel) and ITMO Univ. (Russian Federation); Nikolay N. Rosanov, ITMO Univ. (Russian Federation) and Vavilov State Optical Institute (Russian Federation); Nikolay Veretenov, ITMO Univ. (Russian Federation)

Recently Noginov et al. and Gentile et al. demonstrated that purely organic materials characterized by low losses with negative dielectric permittivities can be easily fabricated. And even the dramatic laser-induced change of the dielectric permittivity of organic dyes may be realized [1] that can enable us to control their "plasmonic" properties. Here we develop a theory of non-steady-state organic "plasmonics" with strong laser pulse excitation [2,3]. Our theory contains experimentally measured quantities that makes it closely related to experiment. The bistability response of the electron-vibrational model of organic materials in the condensed phase has been demonstrated [2]. Intermolecular interactions give rise to the excitation transfer along organic thin films. If the film transverse size exceeds the characteristic diffusion length, transverse phenomena such as switching waves (SW), known in optical bistability [4], should take place. We present the alternating-sign dependence of the SW velocity on pump intensity and the conditions for the spatial hysteresis realization [5]. As a mater of fact, in the case under consideration SW represents the wave of dramatic change of the dielectric permittivity of organic dye films that may have many applications. In particular, the SWs enable us to observe the bistability of surface polaritons.

Reverse saturable absorption (RSA) in fluorinated iridium derivatives

Michael J. Ferry, Ryan M. O'Donnell, Neal Bambha, Trenton R. Ensley, William M. Shensky III, Jianmin Shi, U.S. Army Research Lab. (United States)

Cyclometallated iridium compounds are widely studied in the organic light-emitting diode (OLED) community because of the large spin-orbit coupling constant of iridium which leads to efficient triplet state population. These photophysical properties are also advantageous for non-linear applications, such as the design of reverse saturable absorption (RSA) materials. We report on the photophysical characterization of a family of compounds of the form [Ir(pbt)2(LX)], where pbt is 2-phenylbenzothiazole and LX is a beta-diketonate ligand. Beta-diketonate ligands are referred to in the literature as "ancillary" ligands as they do not generally affect the photophysical properties of the material but allow for chemical manipulation. In particular, we investigate the effects of trifluoromethylation on compound solubility and photophysics compared to the parent acetylacetonate (acac) version. The non-linear optical properties, such as the singlet and triplet excited-state cross sections, of these compounds were measured using the Z-scan technique. We also round out the characterization with determination of the excited-state lifetimes and visible transient absorption spectroscopy from the picosecond to microsecond time scales.

10360-3, Session 1

Nonlinear management of the optical angular momentum of light from liquid crystals

Nina Kravets, Etienne Brasselet, Univ. Bordeaux 1 (France) and Ctr. National de la Recherche Scientifique (France)

Nowadays, complex light beam shaping is routinely achieved by the use of various kinds of linear optical devices enabling intensity, phase and polarization structuring of an incident light field. Less common are the situations where structured light results from a nonlinear process. Here we present recent experimental progress on the nonlinear management of the orbital angular momentum of light via spin-orbit interactoin of light. This is done by exploiting the self-induced light-driven generation of locally structured liquid crystal materials assisted by the photorefractive phenomenon. Two options are considered, namely the use of photorefraction under static and quasistatic applied voltage, while their application potential will be discussed.

10360-4, Session 1

On photochemical tweezing and photoassisted holography in azo dye containing polymers *(Invited Paper)*

Zouheir Sekkat, Moroccan Foundation for Advanced Science, Innovation and Research (Morocco)

Holographic storage is one of the most important applications in the field of optics, especially for recording and retrieving data, and information storage by interference patterns in photosensitive materials are no exception in this regard. In this talk, I will discuss the impact of photochemical tweezing on light-induced macroscopic movement in azopolymers whereby the photoisomerization force opposes the optical trapping force to form surface relief gratings, and I will give evidence that holograms recorded by interference of two coherent laser beams in azo dye doped polymer films can be controlled by a third incoherent assisting laser beam, and light diffraction can be increased or decreased by the assisting beam depending on the respective orientation of the polarizations of the recording and the assisting beams.

10360-5, Session 2

Dynamic amplification of light signals in photorefractive ferroelectric liquid crystal blends containing photoconductive chiral dopant *(Invited Paper)*

Takeo Sasaki, Tokyo Univ. of Science (Japan)

Effect of ferroelectricity on the photorefractive effect of ferroelectric liquid crystal blends was investigated. The photorefractive effect of ferroelectric liquid crystal blends is strongly dependent on the ferroelectricity of the blend. We have prepared a series of ferroelectric liquid crystal blends that contains several concentrations of a chiral compound while keeping a constant concentration of a photoconductive moiety. The photorefractive

properties of the ferroelectric liquid crystal blends were discussed with relations to the ferroelectric properties of the blends.

10360-6, Session 2

Silicon-organic hybrid devices for THz generation based on difference frequency generation

Manfred Eich, Technische Univ. Hamburg-Harburg (Germany) and Helmholtz-Zentrum Geesthacht (Germany); Marvin Schulz, Technische Univ. Hamburg-Harburg (Germany); Alexander Yu. Petrov, Technische Univ. Hamburg-Harburg (Germany) and ITMO Univ. (Russian Federation)

Here, we introduce a paradigm change in phase matching strategy and demonstrate how integrated waveguide optics can be used for wave mixing with large wavelength mismatch.

10360-7, Session 2

Measurement of the dynamics of nonlinear refraction and absorption via nonlinear beam deflection *(Invited Paper)*

David J. Hagan, Peng Zhao, Sepehr A. Benis, Eric W. Van Stryland, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States)

Many materials exhibit nonlinear refraction (NLR) and absorption (NLA) that has multifaceted temporal dynamics. As a result, measurements at one laser pulse width may not be fully predictive of the behavior at other pulse widths. We have recently developed a method, Nonlinear Beam Deflection, (BD) that allows sensitive time-resolved measurement of nonlinear refraction (NLR) and absorption (NLA) by using an excitation beam to create an index gradient deflecting a probe beam onto a quad-cell detector. The method has a demonstrated sensitivity to induced phase changes as small as 1/20,000 of a wavelength, which is sensitive enough to measure NLR in gases. By changing the relative polarization of the beams we can separate the bound-electronic response from the slower and different-symmetry nuclear contributions. In gases and liquids where reorientational nonlinearities are important, measurements at the magic angle allow isolation of the ultrafast nonlinearities. In isotropic solids the bound-electronic symmetry dictates a ratio of 1/3 for parallel to perpendicular polarizations which measurements confirm. This method also allows for measurements of nonlinearities using very different wavelengths for the excitation and probe. We have used this method to characterize the impulse response function for third-order nonlinearities in many transparent organic solvents. This allows accurate prediction of the nonlinear refraction for any pulse width longer than that used for the BD characterization. The method proves to be very useful in organic materials that may show strong nonlinear absorption, as it is able to resolve NLR in the presence of strong NLA better than other methods, such as Z-scan.

10360-8, Session 2

Enhanced optical limiting in 2D materials *(Invited Paper)*

Jitesh Kumar, Jayan Thomas, Sreekanth Varma, Katherine Layne, Univ. of Central Florida (United States); Yang Liu, Jingjie Wu, Pulickel M. Ajayan, Rice Univ. (United States)

Two dimensional (2D) graphene and transition metal dichalcogenides are an emerging class of extremely interesting materials showing unique physical properties, such as large third-order optical nonlinearity, offering potential applications in optical limiting. Materials which show high optical limiting can be used to protect sensors and human eyes against powerful laser irradiations. Here we report the optical limiting properties of graphene, titanium disufide (TiS_2) and molybdenum disulfide (MoS_2) sheets and their respective quantum dots measured using open aperture and photo-acoustic z-scan techniques. Our studies reveal that superior optical limiting is exhibited by 2D sheets and 2D quantum dots of TiS_2 at both low and high fluences compared to their graphene counterparts. Also, TiS_2 sheets and quantum dots show improved shelf life and stability upon irradiation with higher laser powers which demonstrates the feasibility of using them as potential candidates for optical limiting applications.

10360-10, Session 3

Reconfigurable micro-holes array by directional laser manipulation

Federica Pirani, Angelo Angelini, Francesca Frascella, Serena Ricciardi, Politecnico di Torino (Italy); Federico Ferrarese Lupi, Natascia De Leo, Luca Boarino, Istituto Nazionale di Ricerca Metrologica (Italy); Emiliano Descrovi, Politecnico di Torino (Italy)

In recent years, the ability to pattern large areas at the micro- and nano-scale with stimuli-responsive materials has opened the opportunity to engineer surface structures and trigger peculiar properties such as complex optical functionalities or surface properties by laser-matter interactions. The use of light-sensitive materials, such as azobenzene compounds, can open the opportunity to active manipulate in terms of morphology, physical and mechanical properties a pre-patterned architectures, which are intrinsically static once fabricated.

We employ azopolymers, in which the rapid and reversible photoisomerization reaction of azobenzene molecules can actuate mass transport phenomena typically parallel to the light polarization. The azopolymeric film is patterned by soft-imprinting as an array of micro-holes showing a well-defined isotropic round pores. Upon a linearly polarized illumination (365 nm, 150 W/cm2), we observe a deformation of the initial holes along the polarization direction, in such a way that the circular pores are transformed into long closed slits. A rotation of the polarization by 90° triggers a reconfiguration of the pristine round shape, with a good degree of control of the photo-induced pore reshaping. Due to the polarized-directionality of the photo-manipulation we demonstrate the possibility to tune the pristine morphology and properties along specific directions, providing a smart engineered platform with different reshaped micro-patterns. The light-induced contraction and expansion reshaping strategy of a porous polymeric structures shows exciting potential for a number of applications including microfluidics, lithography and tissue engineering. Tuning cells behavior in response to material manipulation cues is a promising goal in biology

10360-12, Session 3

Solution-processed organic bulk-heterojunctions in optical cavities for continuously tunable narrowband photodetection

Zheng Tang, Koen Vandewal, TU Dresden (Germany)

Spectroscopic photodetection, currently achieved through a combination of filters/prisms and broadband photodetectors, is the foundation of many modern technologies, such as environmental monitoring, biomedical materials analysis, imaging and surveillance. Low-cost arrays of filterless photodetectors with a continuously-tunable and selective spectral response would allow miniaturization of the used instrumentation.

Here, we use an organic bulk heterojunction in a resonant optical cavity device architecture to achieve solution-processed narrowband photodetectors. By making use of the weak CT absorption, and through optimizations on the molecular and the device level, we demonstrate a

spectral resolution down to 14 nm and a specific detectivity (over 10^13 Jones) comparable to commercial inorganic photodetectors lacking wavelength selectivity. Moreover, we achieve continuous wavelength tunability over a large part of the NIR spectral range, from 700 to 1700 nm. This excellent performance along with the advantages of organic materials, such as, flexibility, scalability, and easy-processibility makes this class of photodetectors highly demanded for future innovative areas of photodetection.

10360-13, Session 4

Simultaneous 10-fold brightness increase and emitted-light tunability in transparent ambipolar organic light-emitting transistor by integration with inorganic high-k photonic crystal

Stefano Toffanin, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Marco Natali, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Santiago D. Quiroga, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Luca Passoni, Luigino Criante, Istituto Italiano di Tecnologia (Italy); Emilia Benvenuti, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Gabriele Bolognini, Istituto per la Microelettronica e Microsistemi (Italy); Laura Favaretto, Manuela Melucci, Istituto per la Sintesi Organica e la Fotoreattività (Italy); Michele Muccini, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Francesco Scotognella, Politecnico di Milano (Italy); Fabio Di Fonzo, Istituto Italiano di Tecnologia (Italy)

In organic light-emitting transistors the structural properties such as the in-plane geometry and the lateral charge injection are the key elements which enable the monolithic integration of multiple electronic, optoelectronic and photonic functions within the same device [1]. In this contribution, we report on the realization of hybrid highly-integrated multifunctional optoelectronic organic device by introducing an inorganic high-capacitance photonic crystal [2] as a gate dielectric into a transparent single-layer ambipolar OLET. By engineering the photonic crystal multistack and band gap, we show that the integration of the inorganic photonic structure has a twofold effect on the optoelectronic performance of the device, i.e. (i) to modulate the spectral profile and outcoupling of the emitted light and (ii) to enhance the transistor source-drain current by a 25-fold factor. Consequently, the photonic-crystal integrated OLET showed an order-of-magnitude higher brightness with respect to the corresponding polymer-dielectric device, while presenting as-designed electroluminescence spectral and spatial distribution. Our results validate the efficacy of the proposed approach that is expected to unravel the technological potential for the realization of hybrid highly-integrated optoelectronic smart systems based on organic light-emitting transistors.

A highly sensitive pyroresistive all-organic infrared bolometer

Raphael Pfattner, Victor Lebedev, Elena Laukhina, Institut de Ciència de Materials de Barcelona (Spain); Majid Ebrahim-Zadeh, Gerasimos Konstantatos, ICFO - Institut de Ciències Fotòniques (Spain); Vladimir Laukhin, Marta Mas-Torrent, Concepció Rovira, Jaume Veciana, Institut de Ciència de Materials de Barcelona (Spain)

The development of intelligent materials that can respond to the application of an external stimulus is of major interest for the fabrication of artificial sensing devices able to sense and transmit information about the physical, chemical and/or biological changes produced in our environment. In addition, if these materials can be deposited or integrated on flexible and transparent substrates and processed employing low-cost techniques their appeal is greatly increased. It is well known that single crystals of molecular conductors, consisting of ion-radical salts (IRSs), typically based on tetrathiafulvalene (TTF) derivatives, exhibit striking conducting properties. Such properties can be further tuned by choosing the nature of the IRSs enabling high sensitivity in sensors under applied pressure or temperature variations[1,2].

Bilayer (BL) films, composed of a thin-layer of pyroresistive submicrometer-sized crystals on top of a polymeric matrix can be used both as direct-contact thermometer and as passive infrared sensor (bolometer). These materials are capable of detecting, radiation of a wide range of wavelengths, from 532 to 6960 nm, very rapidly and reversibly, as well as recognizing distant objects[3].

This sensor platform enables the combination of high electrical performance of single crystals with the processing properties of polymers towards a simple, low-cost and highly sensitive sensor platform for applications in robotics, bio-medicine and human health care.

Organic crystals with long-period diffraction gratings engraved directly on their surfaces by focused ion beam lithography *(Invited Paper)*

Takeshi Yamao, Kyoto Institute of Technology (Japan)

Laser oscillations need a combination of gain media and optical cavities. We have used as the gain media crystals of thiophene/phenylene co-oligomers (TPCOs) that are composed of inline thiophene and benzene rings, and combined them with diffraction gratings acting as the optical cavities. We have fabricated these diffraction gratings on substrates as an external cavity.

Recently, we have directly engraved one-dimensional (1D) diffraction gratings on the surface of TPCO crystals by using focused ion beam (FIB) lithography. We regarded these diffraction gratings as a built-in cavity, and expected to be effective for producing narrowed emission peaks. However, the engraved parts of the crystals were quenched because the ion beam damaged the molecules. Engraving the diffraction gratings with a short period that is comparable in size to the beam spot caused weak emissions from the crystal.

In the present studies, we tried to keep wide unprocessed parts on the TPCO crystals with the FIB lithography. To this end, we fabricated diffraction gratings having a long period on the crystals. We chose one of the TPCOs that shows emission maxima at around 605 and 650 nm. We laminated vapor-phase-grown crystals on substrates. We engraved the equally-spaced 300 grooves with a period of 501 nm by precisely controlling FIB process conditions. We observed the emissions perpendicular to the grating grooves as well as parallel to the crystal surface under ultraviolet light illumination from a mercury lamp. We succeeded in observing a narrowed peak at 662 nm with the crystal with the 1D diffraction grating.

10360-16, Session 4

Low power optical switching by use of long-lived room-temperature triplet excitons *(Invited Paper)*

Toshiyuki Watanabe, Kenro Totani, Tokyo Univ. of Agriculture and Technology (Japan)

In general, all optical switching can be achieved under high-power pulsed laser irradiation. In this presentation, we will demonstrate low power all optical switching by use of metal free chromophore embedded into special polymer backbone. Persistent excited triplet state with a long lifetime (> 1 s) in special polymer can only be observed at a low temperature, because of the significant nonradiative deactivation pathway that occurs at room-temperature (RT). If polymer with persistent excited triplet state in air could be developed, they could potentially be utilized for optical modulation. Here, polymeric materials having long life time of excited triplet state are developed by minimizing the nonradiative deactivation pathway of triplet excitons. The nonradiative deactivation pathway is dependent on both nonradiative deactivation of chromophores and quenching by diffusional motion of the polymer. The rigidity and oxygen barrier properties of polynorbornene derivatives suppressed the quenching, and minimize nonradiative deactivation of chromophores. Accumulation by photosensitization of long-lived room-temperature triplet excitons with a large triplet–triplet absorption coefficient allows a nonlinear increase in absorbance also under low-power irradiation conditions that induce relatively large refractive index change in polymeric materials.

As a consequence, continuous exposure to weak light significantly decreases the transmittance of thin films fabricated with these compounds. Although, the response time of these systems are extremely slow, all optical modulation in these systems can be achieved under laser illumination in the intensity range between1 mW cm-2 to 100 mW cm-2.

Flexible thin film polarizer with perylene-based reactive mesogens

Seok-in Lim, Ja-hyeon Koo, Seohee Park, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

Because the self-assembled lyotropic chromonic liquid crystal phase (LCLC) nanocolumns in LC phases can be uniaxially oriented in the macroscopic length scales, their applications have been dramatically magnified and expanded in various fields, such as dichroic light-polarizing materials, biosensing active materials, and electro-optic devices. However, LCLC water-based system have several disadvantages. To overcome this problem, we newly designed and synthesized a perylene-based reactive mesogen (PBRM) introducing the diacrylate functional groups at the both ends of perylene-diimide. Phase diagram of PBRM-H2O with different composition and temperature are observed by cross-polarized optical microscope (POM). The isotropic state (I) is observed under POM below 10 wt % at room temperature. Between 10 to 30 wt % at room temperature, it transforms to a typical columnar nematic (ColN) phase. Upon increasing the temperature of PBRM-H2O solutions between 10 and 30 wt %, its phase turns into the I phase by passing the biphase (ColN + I) state and it is the distinctive characteristic of LCLC compounds. After mechanically shearing the PBRM LCLC aqueous solution on the flexible polymer substrates, we successfully fabricated the patterned PBRM polarizer by etching the unpolymerized regions selectively blocked by a photomask during the photopolymerization process. The surface morphology was further investigated by optical microscopy, atomic force microscopy, and three-dimensional (3D) surface nanoprofiler. The fabrication of thin film polarizer on the flexible substrate may open the possibility of applications for the flexible devices. This work was supported by the BK21 Plus, the BRL 2015042417, Mid-Career Researcher Program (2016R1A2B2011041).

10360-17, Session PMon

To enhance OLED brightness by an extraction glass layer

Wei-Cheng Chien, Tatung Univ. (Taiwan); Chuang-Hung Chiu, Chunghwa Picture Tubes, Ltd. (Taiwan); Chao-Heng Chien, Yueh-Hao Chen, Tatung Univ. (Taiwan)

OLED has many advantages. For example, it is very thin, it can be self-luminous and has a fast reaction rate and so on. However, OLED has low life and optical loss and other issues. In organic light-emitting diodes (OLEDs), there are two major optical loss are related with glass layer. The two optical loss are waveguide mode and substrate mode, respectively. So the glass layer with the OLED light loss has a great impact.

In this research, an extraction layer is developed to enhance OLED brightness. The extraction layer could improve waveguide mode and substrate mode. A concave micro structure array was made on the glass substrate surface. A micro metal oxide particles was mixed with a transparent organic solution, which was filled into concave micro structure array. After baking process the transparent organic solution was cured. The cured glass layer was polished to get flat surface. Finally, the extraction layer was completed. The extraction glass layer was bonded on the OLED emitting surface to enhance luminance over 50 %.

10360-18, Session PMon

A remote-controllable light shutter by photochromic liquid crystalline amphiphile containing azobenzene

Ja-hyeon Koo, Seok-in Lim, Seohee Park, Kwang-Un Jeong, Chonbuk National Univ. (Korea, Republic of)

Systems showing photo-reversible phase transition have been considered to be promising in optical devices. By considering intramolecular conformations and intermolecular interactions, a photochromic liquid crystalline amphiphile containing a photo-isomerizable azobenzene (abbreviated as PLCA) is designed and synthesized for a remote-controllable light shutter. We investigated PLCA for demonstrating a remote-controllable light shutter by the photo-reversible isothermal phase transition induced by photo-isomerization of azobenzene. On the basis of diffraction results combined with thermal and microscopic ones, we confirmed the molecular packing structures of PLCA are transformed quickly upon alternating ultra-violet and visible lights. According to this, the direct photo-reversible phase transition between opaque crystalline solid and transparent isotropic liquid occur in 20 seconds at 25?. Therefore, PLCA films could be used as a remote-controllable light shutter. PLCA films were further investigated by transmittance test. The transmittance intensity of liquid state is about 40 times higher than that of solid state. The transmittance of solid state and liquid state is almost same under repeated and alternate irradiation of ultra-violet and visible lights. It is concluded that the relationship among the chemical structure, molecular packing structure and optical properties is very important to design the advanced photo-responsive materials for the practical applications in optical devices. This work was supported by the BK21 Plus, the BRL 2015042417, and Mid-Career Researcher Program (2016R1A2B2011041).

Electronic structure at various substrates/ perovskite interface

Myung Joo Cha, Dong-A Univ. (Korea, Republic of)

The electronic properties of the interface formed between Au and organometallic triiodide perovskite (CH3NH3PbI3) were investigated using ultraviolet photoelectron spectroscopy (UPS) and X-ray photoemission spectroscopy (XPS). The CH3NH3PbI3 films were prepared onto the Au,

ITO and ITO / PEDOT:PSS surfaces by spin casting with various solution concentrations to control the film thickness and their morphology was examined using atomic force microscopy (AFM). The $CH_3NH_3PbI_3$ film exhibited a band gap of 1.70 eV and the maximum valence band edge of 6.31 eV. The best energy levels shift on Au downward by 0.26 eV with a perovskite coverage of 50 wt% upon it, indicating the band bending at the interface. The observed energy level shift means the presence of the interface dipole exists at the Au/$CH_3NH_3PbI_3$ interface. These findings are important for understanding how the perovskite materials function in electronic devices, and the design of new materials for use in perovskite-based optoelectronic devices.

The study of polyelectrolyte-containing photoanisotropic compositions

Irakli Chaganava, Barbara N. Kilosanidze, George Kakauridze, Institute of Cybernetics (Georgia)

This paper presents the experiments on photoanisotropic organic media films based on the hydrophilic composition of the azo dye and polymer matrix with introduced different polyelectrolytes. In our previous works, we have repeatedly been observing that improved photoanisotropic properties of polarization-sensitive materials on the basis of azochromophores and polymers are essentially related to the integration of the material component molecules. As a part of an experiment to strengthen the cohesion of the matrix macromolecules, we individually added to the test compositions polyelectrolytes with a variation of quantity and with the different nature: polycation, polyanion and polyampholyte. The kinetic curves of the inducing photoanisotropy in the developing organic polarization-sensitive composition films are shown. According to our observations, the addition of the electrolyte to the composition of this type of materials contributes to an early manifestation of vector polyphotochromic effect at much lower exposures compared to the control samples without electrolytes, which in turn is a sign of improved photoanisotropic properties as this effect appears exclusively in high-performance polarization-sensitive materials.

10361-1, Session 1

Electro-optics of cholesterics with oblique helicoidal director *(Keynote Presentation)*

Oleg D. Lavrentovich, Olena Iadlovska, Kent State Univ. (United States); Sergij V. Shiyanovskii, Kent State Univ. (United States)

Liquid crystal materials with tendency to bend are capable of forming a unique type of a helicoidal structure in which the director is titled with respect to the helicoidal axis rather than orthogonal to it, as in regular cholecterics. The new state occurs in presence of an electric or magnetic field. It is called a cholesteric with oblique helicoidal structure or simply a twist-bend cholesteric, since both twist and bend deformations are characteristic of the ground state supported by the external field. Tilted configuration of the director and absence of density modulation makes the twist-bend cholesterics a unique material for various electro-optical applications. The presentation discusses electrically and magnetically tuned selective reflection of light as well as tunable lasing enabled by these materials. It is demonstrated that the electro-optical performance of the twist-bend cholesterics depends strongly on the type of anchoring conditions imposed by the boundaries of the cell. The work is supported by NSF grant DMR-1410378.

10361-2, Session 1

Self-assembly in chiral nematic LC *(Invited Paper)*

Julian S. Evans, Zhejiang Univ. (China); Nan Wang, Zhejiang Univ. (China); Sailing He, Zhejiang Univ. (China); Iam-Choon Khoo, The Pennsylvania State Univ. (United States)

Chiral nematic LC often contains a variety of defect lines which can cause aggregation of nanoparticles and other materials such as fluorescent dyes. While normal dyes suffer aggregation induced quenching a class of propeller-like dyes display aggregation induced emission (AIE), which makes them an ideal material for cholesteric lasers. Nanoparticle dispersion is necessary for switchability, while aggregation can be used as a tool to produce assembled structures. I will discuss strategies to promote or inhibit aggregation of various materials in chiral nematics.

10361-3, Session 1

Conditions for the formation of a uniformly lying helix structure induced by the electrohydrodynamic effect *(Invited Paper)*

Yu-Lin Nian, Po-Chang Wu, Wei Lee, National Chiao Tung Univ. (Taiwan)

The uniformly lying helix (ULH) state constitutes a class of cholesteric textures, showing unidirectionally aligned helices with their axes parallel to the plane of substrates. Unlike the generation of the well-known planar (P) and the focal conic (FC) states, a specific means is required to obtain a defect-free ULH structure in a cholesteric liquid crystal (CLC) cell. In this invited talk, we intend to discuss several key experimental conditions required to electrohydrodynamically induce a stable and well-aligned ULH state in CLC. Here the generation of the ULH structure stems from the low-frequency-electric-field-induced electrohydrodynamic (EHD) instability, attributable to the ionic movement. By means of dielectric spectroscopy and optical texture observation, clarified are the optimal frequency regime and three other significant parameters—field strength, ambient temperature and ion density and temperature—determining the formation of a well-structured ULH state.

10361-4, Session 1

Controlling optical phase in cholesteric and dye-doped liquid crystals *(Invited Paper)*

Stefania Residori, Aurélie Jullien, Umberto Bortolozzo, Institut Non Linéaire de Nice Sophia Antipolis (France); Jean-Pierre Huignard, Jphopto (France); Anis Alayet, Univ. of Tunis El Manar (Tunisia); Raouf Barboza, Tampere Univ. of Technology (Finland); Marcel G. Clerc, Univ. de Chile (Chile); Dong Wei, Beijing Genomics Institute (China)

We study the phase properties of dye-doped nematic and cholesteric liquid crystals. By using different mixtures and relative concentrations of chiral and dye dopants, we explore and characterize the phase shift as a function of the different relevant parameters : applied voltage, light-induced reorientation and optical phase shift, light polarization state. We study the dynamical response and degenerate two-wave mixing in both cw and pulsed regimes and we characterize the phase shift both in reflection and in transmission configuration. Then, by using cholesteric liquid crystals (CLC), which act as twisted Bragg reflectors, we demonstrate a novel type of geometric phase where the light-matter interaction is limited to the surface of reflection and the polarization state of the reflected light is unchanged. Even though planar CLC layers reflect circular polarized light with the same handedness as the helix without changing the polarization state, we demonstrate that the reflected light exhibits a geometric phase, ?(?)=??, where ? is the angle of the optical axis at the input face and ? the handedness of the polarization. The analytical predictions, derived from coupled wave theory in CLC, have been validated numerically and experimentally with planar CLC reflectors with piecewise uniform optical axis at the input interface. These findings open new routes to reflective geometric phase optical elements, with the possibility of designing asymmetric devices, as the front and the back reflective faces can have different optical axis patterns, as well as planar reflectors, refractive elements and gratings.

10361-5, Session 2

Optoelectronic applications of functional materials with aggregation-induced emissions *(Keynote Presentation)*

Ben Zhong Tang, Hong Kong Univ. of Science and Technology (Hong Kong, China)

Aggregation-induced emission (AIE) has drawn continuously growing attention due to its great potential in material science and biological techniques. The AIE effect is expected to conquer the notorious aggregation-caused quenching (ACQ) encountered by conventional luminescent materials, and thus realize the high-performance organic light-emitting diodes (OLEDs) without complicated doping method. Our recent studies have demonstrated that it is feasible. The solid-state luminescent materials created by melting AIEgens with conventional chromophores that suffer from ACQ problem at the molecular levels exhibit high photoluminescence efficiency up to unity, and function efficiently as light-emitting layers in non-doped OLEDs. Tunable electroluminescence colors from blue to red and excellent efficiencies approaching theoretical limit are attained by the devices. In addition, rational modifications on AIEgens with carrier-transporting functional groups can endow the luminescent materials with not only high solid-state emission efficiencies but also good hole- or electron-transporting abilities. The non-doped bilayer OLEDs fabricated by utilizing these multifunctional materials as light-emitting and hole-transporting (electron-transporting) simultaneously afford remarkably high efficiencies. These results clearly manifest the practical utility of the AIE effect in development of active materials for OLEDs.

10361-6, Session 2

Waveguiding with liquid crystal structures *(Invited Paper)*

Miha Ravnik, Univ. of Ljubljana (Slovenia) and Jo?ef Stefan Institute (Slovenia); Anja Bregar, Univ. of Ljubljana (Slovenia)

The birefringence of liquid crystal materials allows for the microscopic control of the-flow-of light. Here, we explore waveguiding by selected liquid crystal structures, including escaped nematic profiles and double-twist cylinders, by using numerical modelling. In order to realise stable waveguiding, these structures generally require negative liquid material birefringence, which is a notable materials' challenge. Methodologically, we use a combination of analytical approaches and Finite Difference Time Domain numerical calculations. Structure and properties of the waveguiding modes and their characteristics –especially polarization- are discussed. More broadly, this work is an attempt towards the development of soft matter photonics.

10361-7, Session 2

Functionalized liquid crystal polymers generate optical and polarization vortex beams *(Invited Paper)*

Moritsugu Sakamoto, Yuki Nakamoto, Tran Minh Tien, Kotaro Kawai, Kohei Noda, Tomoyuki Sasaki, Nagaoka Univ. of Technology (Japan); Nobuhiro Kawatsuki, Univ. of Hyogo (Japan); Hiroshi Ono, Nagaoka Univ. of Technology (Japan)

Optical and polarization vortex (OV and PV) beams, which have phase and polarization singularities, have much attracted attention from various research fields due to their unique physical properties. In general, for the study of vortex beams, a spatial light modulator is required to control the phase and polarization pattern of light waves between homogeneous into inhomogeneous, and advancement in the functions of them should be lead to evolution in photonics applications of vortex beams. In this presentation, we report our attempts for the vortex beam generation based on the photo-alignment technique of functionalized liquid crystal (LC) polymers.

We first report OV beam generation by using azo-dye-doped LC polymer (ADDLC). Due to the photo-isomerization of azobenzene molecules, LC director of ADDLC can be controlled by polarization illumination. Hence, when homogeneously aligned ADDCL is illuminated by the PV beam, three-dimensional helical LC alignment structure is formed since polarization states of light is continuously modulated in a propagation direction by an initial anisotropy. This LC structure shows OV generation properties. Phase singularity of generated OV can be temporally controlled by changing polarization pattern of illuminating PV. In addition, it has a potential for broadband OV generation with low dispersion.

Second, we also report PV beam generation by using photocrosslinkable polymer LC. Basic principle of this approach is based on the polarization holography. Proposed hologram spatially modulates not only polarization but also phase patterns of incident light, so that PV beam with helical phase is generated. Also, polarization, phase, and amplitude pattern of generated PV beam can be controlled by changing a polarization state of incident light.

10361-9, Session 2

Role of the order parameter, electric field, and geometric confinement on the dynamics of the photoinduced nematic-isotropic transition

Jayalakshmi Vallamkondu, National Institute of Technology, Warangal (India); Krishna Prasad Subbarao, Geetha G. Nair, Ctr. for Nano and Soft Matter Sciences (India); Gurumurthy Hegde, BMS College of Engineering (India)

The photoinduced phase transitions that we describe here are brought about by the photoisomerization driven shape transformation of photoactive molecules. The photoactive group is either covalently attached to the molecule or doped in a non-photoactive LC host material. The latter type, have the advantage of a wide choice of host materials that can be employed, the selection criterion being the required phase sequence, physical properties, etc. The guest photoactive material, present as a minority, adds the photoisomerization functionality to the system. Before presenting the results, the apparatus employed to investigate the photoinduced effects, is described in the thesis.

The thermal back relaxation of the photoinduced Z conformation of the photoactive molecule to its equilibrium E conformation is a matter of significant importance from the view point of basic as well as applied sciences. While the photochemical transition involving the change from E to Z form is fast, the TBR recovering the equilibrium phase is generally very slow ranging from few tens of minutes to as long as days although very fast (sub microsecond) time scales can be achieved with a pulsed laser source. In this chapter, we describe systematic studies of the influence of three different parameters, namely, (a) the nematic order parameter, (b) applied electric field and (c) geometric confinement, on the photochemical as well as TBR response times. The photoactive molecule serving as the guest dopant in all these studies is the 4-(4-ethoxyphenylazo)phenyl hexanoate (EPH). This compound also exhibits the nematic phase, a feature useful in obtaining homogeneous mixtures with host nematogenic compounds. The experiments were performed using an intensity-stabilized uv radiation with a peak wavelength of 365 nm and intensity of 1 mW/cm2.

10361-10, Session 3

Nano slippery interfaces in nematic gels -localization and lubrication of director motions *(Keynote Presentation)*

Jun Yamamoto, Kyoto Univ. (Japan); Isa Nishiyama, Dainippon Ink and Chemicals, Inc. (Japan)

We designed the fast switching & low driving voltage principle with nano slippery interfaces in nematic gels. Confinement effect by the gel network can accelerate the response time of nematic due the localization of director motion as similar way to the cholesteric blue phase. However, the anchoring of the director on the gel network induces the driving voltage. Slippery effect on the nano interface of the gel network can reduce the driving voltage due to the lubrication of the director motion. Since azo dye acrylates are co-polymerized with nematic gels (Azo-NGel), we can demonstrate the UV-switchable nano-slippery interface on the nematic gels.

Dynamic Light Scattering (DLS) provides us the information of the dynamics of director rotation. Dispersion relation of the pure 7CB-T15 mixture completely satisfies the prediction of hydrodynamic modes in the nematic. On the contrary, the relaxation frequency of the Azo-NGel keeps fast response in the low wave-number region due to the confinement effect.

Electro-Optic response (EO) of the Azo-Ngel without UV illumination shows the serious increase of the driving voltage compared to the pure 7CB-T15 mixture. When the Azo-Ngel is illuminated by UV-light Slippery interfaces can be created by the trans-cis isomerization of the Azo dye of the side-chain on the nano network of nematic gels. EO under UV illumination shows the drastic reduction of the driving voltage keeping the fast response time. We have also confirmed that the dispersion relation of the UV illuminated Azo-Ngel is almost the same as that of Azo-Ngel without UV illumination by the DLS measurement. Thus, the confinement effect for the nematic gels is still effective after the slippery interface is created by the UV illumination.

We success to demonstrates that the acceleration of the response time is compatible with reduction of the driving voltage by the localization and lubrication of director motions due to the design of the nano-slippery interfaces in the nematic gels.

10361-11, Session 3

Optically robust photoalignment materials for liquid crystal device applications in the near-UV region *(Invited Paper)*

Kenneth L. Marshall, Debra J. Saulnier, Tanya Z. Kosc, Univ. of Rochester (United States); Oleg Didovets, Optimax Systems, Inc. (United States); Shaw-Horng Chen, Univ. of Rochester (United States)

Photo-alignment technology is important for liquid crystal (LC) device applications where both high resistance to incident optical energy and spatially distributed alignment states over the device clear aperture are required. Coumarin-based photo-alignment materials developed at the Laboratory for Laser Energetics (LLE) possess near-IR laser damage resistance approaching that of fused silica and have been employed in the development and fabrication of a wide variety of LC high-peak-power laser optics. One example is a photo-patterned LC beam shaper, developed for use in LLE's four-beam, petawatt-peak-power OMEGA EP laser, that has demonstrated 1054-nm, 1 ns laser-damage thresholds approaching those of dielectric thin-film Brewster's angle polarizers (30 to 40 J/cm2). Achieving similar performance levels in LC devices for near-UV applications is challenging due to a scarcity of both UV-transparent LC materials and polymer alignment layers that can withstand repeated exposure to intense pulsed- or CW UV irradiation without degradation. Previously-employed alignment materials for UV-LC devices such as buffed polyvinyl alcohol (PVA) or Nylon 6/6 have limited usefulness; buffing embeds particulates and scratches into the alignment layer that reduce its UV damage thresholds to only a few J/cm2 and is incapable of producing highly resolved and spatially-distributed LC alignment states. In recent experiments, we have found that coumarin photoalignment materials are remarkably more resistant to damage from both incident 351 nm, 1 ns high-energy laser pulses [~11.42 J/cm2 (1-on-1) and ~15.70 J/cm2.(N-on-1)] and broad-band, continuous wave (CW) UV-visible light than would be expected due to their highly conjugated aromatic electronic structures. This finding opens a new chapter in the development of LC devices for UV applications in high-peak-power lasers (e.g. wave plates, polarization rotators, radial polarization converters, photo-patterned beam shapers) and other areas of optics and photonics where UV stability is important (e.g., space-based applications).

10361-12, Session 3

Template effect of twist structure liquid crystal and its photonic application *(Invited Paper)*

Jiangang Lu, Shanghai Jiao Tong Univ. (China)

The template effect of self-assembly twist structure liquid crystal (LC) is investigated. The anchoring energy of blue phase (BP) template containing different concentration of conventional polymer has been investigated that every different polymer system had its own threshold concentration to reconstruct the blue phase. The anchoring energy of the BP template increased with the polymer concentration resulting in the improvement of the reconstruction capacity. No matter with the same-handed or reverse-handed chiral materials refilling, there was a concentration range for the chiral dopant to reconstruct the blue phase by the polymer template. And the reconstruction range of the templates was extended as the polymer concentration of the template increased. It was demonstrated that the template anchoring energy has a threshold value to reassemble the double twist cylinder structure of BPLC by either refilling same-handed chiral materials or reverse-handed chiral materials which may help to improve the driving capacity of the polymer stabilized BPLC. Similar to the BPLC, a sphere phase template was proposed to improve the temperature range of sphere phase (SP) to more than 175?.By template processing, a wavelength tunable random lasing was demonstrated with dye doped SPLC. With different polymer concentrations, the reconstructed sphere phase random lasing may achieve more than 40nm wavelength shifting by electrical field modulation. And the threshold energy of SPLC random laser can be lowered to about 30% of that from the chiral nematic phase LC.

10361-14, Session 3

Fabrication of nearly-millimeter thick well aligned cholesteric liquid crystals for ultrafast pulsed laser modulation

Chun-Wei Chen, Iam-Choon Khoo, The Pennsylvania State Univ. (United States); Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan)

We describe a technique that enables fabrication of nearly mm-thick stable well-aligned cholesteric liquid crystals (CLC) that possess very small scattering loss, large operating temperature range [~ 100 degrees Centigrade] and well-defined 1-D photonic crystal properties. Owing to the enhanced optical nonlinearity and dispersion near the photonic band-edges that result in velocity slow down, pulse chirping and nonlinear phase shifts, theory and experiments have been have shown that these CLC's can be used for femtoseconds -picoseconds laser pulse modulation [compression, stretching, variable pulse delay] purposes in compact photonic systems.

10361-24, Session 3

Smectic layer origami based on preprogrammed photoalignment *(Invited Paper)*

Yan-Qing Lu, Wei Hu, Nanjing Univ. (China)

Mesoscopic hierarchical superstructures bridge the micro and macro worlds and play vital roles in natural materials. To mimic hierarchical organization in nature, one promising strategy is the convergence of top-down microfabrication and bottom-up self-assembly. Much efforts have been devoted to this field, but till now, the precise realization and rational control of large-area perfect hierarchical superstructures is still challenging. On the other hand, Smectic liquid crystals (SLCs) are formed by flexible molecular layers of constant thickness. If the nanometer-thin smectic layers can be manipulated in an origami manner, a Japanese art that constructs various 3D objects via folding pieces of papers, brand new hierarchical superstructures possessing exceptional features then could be realized. In this work, the smectic layer origami is accomplished via preprogrammed photoalignment. The principle is rooted in the anisotropy of molecular interactions at interfaces, which makes the preset patterned alignment favoring a certain layer bending of adjacent SLCs, and subsequently dominating the configuration of entire family of smectic layers. Thanks to the excellent flexibility of photoaligning, the unit geometry (shape, size and orientation) as well as the clustering characteristic (lattice symmetry) of fragmented TFCDs can be rationally designed and freely manipulated over square centimeters. The obtained fragmented toric superstructures break the rotational symmetry while maintain the radially gradient director field, enabling metasurface-like direction-determined-diffraction. We believe this work is an important step toward extending the fundamental understanding of self-assembled soft materials and enhancing the construction of possible hierarchical superstructures. It may inspire extra possibilities in advanced functional materials and fantastic photonic applications.

Single crystal blue-phase photonic crystal *(Keynote Presentation)*

Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan); Iam-Choon Khoo, The Pennsylvania State Univ. (United States); Timothy J. Bunning, Air Force Research Lab. (United States); Chun-Wei Chen, The Pennsylvania State Univ. (United States)

Photonic crystals are one of the most attractive optical materials, in which the inherent periodic undulations of refractive indices give rise to novel reflection, transmission and emission characteristics. Blue Phase Liquid Crystal (BPLC), is introduced because of its self-assembled 3D photonic crystal make-up and controllable lattice spacing. Besides, the uniqueness of BP lies in their high susceptibility to external stimuli, opening up a new door of adaptive photonics.

Although BPLCs have been widely studied, the conventional approach to crystal growth of BP, normally results in polycrystalline texture with crystal size ranging from submicron (in diameter) to ~ 300 ?m at most. This is because, in such an approach, nuclei form at arbitrary positions in the isotropic melt and grow in almost all directions, eventually terminating when meeting the others. To break the limit of the size of a BP single crystal, we have developed new ways of growing single-crystal BPLC of macroscopic sizes by introducing spatial variations of temperature into crystal growth. Fabrication procedure, characterization and applications of millimeter-sized BP monocrystals will be reported at the meeting.

10361-16, Session 4

Ultrafast nonlinear photonic in cholesteric liquid crystals *(Invited Paper)*

Yikun Liu, Jianying Zhou, Sun Yat-Sen Univ. (China); Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan); Iam-Choon Khoo, The Pennsylvania State Univ. (United States)

Cholesteric liquid crystals (CLC) has the advantage of large nonlinearity and fast response. This brings great convenience to its applications in ultrafast nonlinear photonic. Here, several kinds of nonlinear phenomenon and applications are reported, such as optical soliton, modulation instability, optical diode effect and pulse compression of cascade CLC samples.

10361-17, Session 4

Liquid-crystalline simple cubic blue phase stabilized via polymer networks *(Invited Paper)*

Suk-Won Choi, Kyung Hee Univ. (Korea, Republic of)

A polymer-stabilized siple cubic blue phase (BPII) possessing a wide temperature range has been scarcely reported. Here, we report a polymer-stabilized BPII over a temperature range of 50 °C including room temperature. The fabricated polymer-stabilized BPII is confirmed via polarized optical microscopy, Bragg reflection, and Kossel diagram observations. Furthermore, we demonstrate reflective BP liquid-crystal devices utilizing the reflectance–voltage performance as a potential application of the polymer-stabilized BPII. Our work demonstrates the possibility of practical application of the polymer-stabilized BPII to photonic crystals.

10361-18, Session 4

Investigation of polarization-independent optical phases in polymer-dispersed liquid crystals originating from Kerr effect and molecular orientations *(Invited Paper)*

Yi-Hsin Lin, Chia-Ming Chang, Jing Yi Wang, Po-Ju Chen, National Chiao Tung Univ. (Taiwan); Eunjeong Shin, Ramesh Manda, Seung Hee Lee, Chonbuk National Univ. (Korea, Republic of)

The anisotropic properties of nematic liquid crystals result in polarization dependency which leads to requirement of at least a polarizer in liquid crystal photonic devices; however, polarizer reduces optical efficiency. We have been developed many polarization-independent liquid crystal (LC) phase modulators. In 2015, we found that the optical phases in nano-PDLC(size~250 nm) come from LC molecular orientations and Kerr effect-induced birefringence. However, optical phase from Kerr effect is much smaller than the one from LC molecular orientations. As a result, in this paper, we would like to continue investigating that in nano-PDLC, is it possible to have optical phase from Kerr effect is comparable to the optical phase from LC molecular orientation or even larger? The experimental results show that the polarization-independent optical phases in nano-PDLC come from both of LC molecular orientation and Kerr effect as the droplet size is around 200 nm. At a small applied voltage, Kerr phase dominates. With an increase of voltages, optical phase from LC molecular orientation dominates. For droplet size larger than 350nm, the optical phases come from LC orientation, without any Kerr phase. In our study and optical analysis, we conclude that Kerr phase depends on the droplet size in nano-PDLC. Kerr phase and orientational phase indeed can be comparable. Experimental results also indicates that Kerr phase occurs as applied voltage (V) is less than the threshold voltage(Vth). At V> Vth. orientational phase increases and Kerr phase reduced.

10361-19, Session 4

Azo-blue phase liquid crystals for high efficiency holographic Bragg grating with optically prolonged memory

Tsung-Jui Ho, Chun-Wei Chen, Iam-Choon Khoo, The Pennsylvania State Univ. (United States)

We present the results of recent studies of holographic Bragg grating formation and relaxation dynamics in mm-thick azo-dye doped Blue phase liquid crystals (a-BPLC). Unlike their nematic counterparts which generally yield low efficiency in this regime due to strong nonlocal anchoring forces, we have observed [Sci. Rep. 6, 36148; doi: 10.1038/srep36148 (2016)] that these mm-thick a-BPLC ware capable of yielding polarization-independent grating diffraction efficiency as high as 50% for grating constant as small as ~ 1 micron. Furthermore, we have discovered a simple all-optical means of prolonging the lifetime of the written grating; by keeping the reference beam on when the other beam (input signal) is turned off, the lifetime of the written grating/hologram can be prolonged from its natural relaxation time of a few seconds to several minutes. The underlying mechanism is attributed to local and nonlocal BPLC lattice distortions following laser induced trans-cis isomorphism of the azo dopant molecules. Our studies show that these 'performance' characteristics can be optimized with appropriate choice of the a-BPLC constituent materials, sample thickness, azo-dye concentration, and many other material and optical parameter, thus making a-BPLC a highly promising candidate material for updateable holographic recording and display application.

10361-13, Session 5

Magneto-optical properties of liquid crystal dimers *(Invited Paper)*

Seyyed M. Salili, Matthew Murachver, Samuel N. Sprunt, James T. Gleeson, Antal I. Jákli, Kent State Univ. (United States)

We studied magneto-optical properties of various liquid crystal dimers with both odd and even number carbon atoms in their flexible linkages. Dimers with even and odd numbered carbons in their linkages have I-N-Cr and I – N –Ntb –Cr or I – N –Ntb –SmCmod-Cr phase sequences, respectively.

Measurements of the Iso-N-Ntb transition temperature as a function of applied magnetic field found to show an unprecedented magnetic field enhancement of the nematic order. At 25T magnetic induction the transition temperature is shifted by up to 15ºC for the odd-dimers1 and up to 8ºC for the even-dimers. The field induced birefringence is much weaker for the even-dimers and show anomalous temperature dependences. The shift of the N-Ntb transition for the odd-dimers can be both positive and negative depending on the material. The effect of the chiral dopants also had been studied and was found to enhance the field induced transition shift. Possible microscopic models will be considered to consistently explain the experimental observations.

10361-20, Session 5

High quality alignment of the helical nanofilament phase by micro-confinement in polymer channels *(Keynote Presentation)*

David M. Walba, Eric Carlson, Lee M. Foley, Edward Guzman, Eva D. Korblova, Rayshan Visvanathan, Univ. of Colorado Boulder (United States); SeongHo Ryu, Min-Jun Gim, Dong Ki Yoon, KAIST (Korea, Republic of); Noel A. Clark, Univ. of Colorado Boulder (United States)

The helical nanofilament (HNF) phase is one of a small family of “low temperature dark conglomerate” phases seen in bent-core mesogens, exhibiting low birefringence and very high optical rotatory power in the visible. The HNF phase is unique, however, per our hypothesis that the phase is composed of twisted nanocrystals, approximately 30 nm in diameter, and up 100s of μm in length.

Several research groups have reported on somewhat successful efforts to align the HNF phase. To our knowledge, however, none of the known methods for HNF alignment has led to alignment quality approaching that achievable for more conventional molecular LC phases.

Here we report unprecedentedly high quality alignment of the HNF phase of NOBOW (P-9-O-PIMB) by simply allowing the isotropic liquid to cool to room temperature in microchannels of polydimethylsiloxane (PDMS) on glass. Removal of the PDMS “mold” leaves well-defined and indefinitely stable stripes of HNFs showing excellent extinction by polarized optical microscopy (crossed polarizer and analyzer) with the polarizer parallel or perpendicular to the stripes, and strong visible light transmission with the polarizer at 45 deg. 2-D X-ray scattering on these samples corroborates the proposed structure, where the HNFs run parallel to the microchannels, with the twisted smectic layers perpendicular to the HNF long axis (this requires negative Gaussan curvature of the layers).

This method is a form of lithography, and should provide an approach for obtaining well-aligned HNF “stripes” of arbitrary shape in one dimension (parallel to the HNF long axis).

10361-21, Session 5

Shape and size effects in chirality transfer from chiral-ligand-capped nanomaterials to nematic liquid crystals *(Invited Paper)*

Torsten Hegmann, Lin Li, Leah E. Bergquist, Ahlam Nemati, Kent State Univ. (United States)

To probe how chirality propagates from a chiral nanoscale surface, we studied gold nanoparticles functionalized with chiral ligands. To do so, we synthesized series of chiral ligand-capped gold nanoparticles (Au NPs) differing in size, shape, curvature, and ligand density that allowed us to tune the chirality transfer from these nanoscale solid surfaces to a bulk nematic liquid crystal medium.[1] Ultimately, we tested how far the chirality from a NP surface reaches into the bulk N-LC material.[2] The helical pitch values of the induced N*-LC phase were determined, and the helical twisting power (HTP) of the chiral Au NPs and nanorods calculated to elucidate the chirality transfer efficiency of the chiral ligand-capped Au NPs. Remarkably, the HTP increases with increasing diameter for the smaller nanoclusters (~1 to 2 nm in core diameter) and increase for larger nanoparticles (~5 nm in core diameter), i.e. the efficiency of the chirality transfer of the chiral ligands bound to the NP surface is size dependent. However, in comparison to the free ligands, per chiral molecule, all tested Au NPs induce helical distortions in a 10- to 50-times larger number of N-LC host molecules surrounding each NP, indicating a significantly enhanced chiral correlation length, which appears to be the largest for chiral ligand-capped gold nanorods as expected from their largest anisotropy factors.[3] We propose that both the helicity and the chirality transfer efficiency of chiral ligands can be efficiently and elegantly controlled at NP surfaces by adjusting the NP size, shape, and curvature as well as the number and density of the chiral ligands to ultimately measure and tune the chiral correlation length.

10361-22, Session 5

Light-melt adhesive based on a columnar liquid crystal *(Invited Paper)*

Shohei Saito, Kyoto Univ. (Japan)

Liquid crystal (LC) provides a suitable platform to exploit structural motions of molecules in a condensed phase. Amplification of the structural changes enables a variety of technologies not only in LC displays but also in other applications. Until very recently, however, a practical use of LCs for removable adhesives has not been explored, although a spontaneous disorganization of LC materials can be easily triggered by light-induced isomerization of photoactive components. The difficulty of such application derives from the requirements for simultaneous implementation of the following essential requisites: (i) adequate strength for a temporary bond (more than 1 MPa) even under heating conditions, (ii) significant reduction of the bonding strengths by light irradiation, and (iii) quick photoresponse for the separation of bonded materials. Here we present a liquid crystal (LC) material that satisfies all of the above-mentioned requisites for the light-melt adhesives, namely, (i) a shear strength over 1 MPa up to 110 °C for bonding glass plates, (ii) an 85% reduction of the strength by ultraviolet (UV) irradiation, and (iii) an instant photomelting of the LC film in a few seconds. Moreover, this material is reusable as an adhesive, and the transformation between the LC and melted phases is associated with an informative color change in fluorescence. We envision that composite materials with the light-melt function will further improve the performance in manufacturing processes, which will accelerate the on-demand photoseparation technology complementary to the other switchable adhesion approaches.

10361-23, Session 5

Structure modifications directed towards obtaining SmAPf phases with broad temperature ranges *(Invited Paper)*

Eva D. Korblova, Edward Guzman, Edgardo Garcia, Joseph E. Maclennan, Matthew A. Glaser, Ren-Fan Shao, Rayshan Visvanathan, Noel A. Clark, David M. Walba, Univ. of Colorado Boulder (United States)

The first successful design of SmAPF mesogens came from modification of structural elements of known SmAPA mesogens. Specifically, bent-core smectics with orthogonal director orientation and ferroelectric interlayer order were achieved by suppression of out of layer fluctuations, leading to anticlinic layer interfaces. Thus, placement of a tricarbosilane moiety at the end of the single tail of a known SmAPA structure produced the SmAPF mesogen known as W586. [1] In typical LC cells, these materials exhibit electrooptic phase only modulation with optical latching. [2]

In order to optimize the properties of SmAPF materials for a wide range of exciting applications, a search for new mesogens providing industrial grade phase temperature ranges and improved phase modulation depth is in progress.

Here, we present the design, synthesis, and characterization of new materials with fluorinated tails. The original SmAPF mesogens possess one long tricarbosilane-terminated alkyl tail, and one "short tail" (a cyano group or trifluoromethyl group). Synthesis and properties of new structures showing the SmAPF phase, where the tricarbosilane-terminated tale of the classic system is replaced by fluorinated oligoethyleneglycols or oligoethyleneglycol esters, will be discussed.

10361-25, Session 6

Photoalignment control of dye-doped and dye-free liquid crystal systems *(Keynote Presentation)*

Atsushi Shishido, Tokyo Institute of Technology (Japan)

Photoalignment control of liquid crystals has been developed for optical, photonic, mechanical and display applications. Photophysical molecular alignment based on nonlinear optical effect was reported first, and photochemical control due to axis-selective photoresponse of anisotropic dye molecules was developed. The photophysical process was enhanced in dye-doped liquid crystals around the same time. In this study, recent progress on photochemical and photophysical molecular alignment control in dye-doped liquid crystals are presented. Dye-free liquid crystal systems can be also controlled by masked photopolymerization.

Intrinsic and photo-induced optical properties of photoaligning azo-based materials coupled with liquid crystal systems *(Invited Paper)*

Nina Podoliak, Elena Mavrona, Univ. of Southampton (United Kingdom); Sakellaris Mailis, Optoelectronics Research Ctr., Univ. of Southampton (United Kingdom); Jordan R. E. Gill, Giampaolo D'Alessandro, Vasilis Apostolopoulos, Univ. of Southampton (United Kingdom); Nelson V. Tabirian, BEAM Engineering For Advanced Measurements Co. (United States); Malgosia Kaczmarek, Univ. of Southampton (United Kingdom)

Recent developments in photoalignment of liquid crystals (LCs) brought to the market photoreversible materials such as azobenzene-based PAAD complex dyes [1], which quickly found broad photonics applications for constructing diffraction elements and waveplates [2,3]. Despite extensive investigations of photoaligned LC systems, there is little information on the optical properties such thin PAAD layers.

Here we report an experimental investigation of optical properties, such as refractive indices and absorption coefficients for different PAAD materials, namely PAAD-22D, 22E and 22N. Photoinduced phase gratings were recorded in 20-50 nm thick PAAD layers with no evidence of a corresponding surface relief, which is a typical feature in thicker azobenzene films. Therefore, the formation of the gratings is attributed to optically induced birefringence. The investigated materials exhibited different values of birefringence, reaching 0.025, and significantly different temporal response to laser irradiation. Moreover, the diffracted power was observed to be very sensitive to the polarisation of the probe beam with respect to that of the pump beam.

We also studied photoinduced diffraction in PAAD-LC systems, where we observed the formation of a stable and strong diffraction pattern. The gratings can be rewritten by illumination with another light pattern or switched off by reorienting liquid crystals with a bias voltage. A diffraction efficiency of more than 5% was measured in a cell containing PAAD-22D in combination with 8?m thick LC-E7 layer. Finally, we compare the dynamics of light induced response in the PAAD layers and PAAD-LC cells and investigate their respective memory effects.

Computational chemistry modeling and design of photoswitchable alignment materials for optically addressable liquid crystal devices II: Transition state modeling in azobenzene and spiropyran oligomers

Kenneth L. Marshall, Unni Kurumbail, Akif Hosein, Univ. of Rochester (United States)

Computational chemistry tools such as density functional theory (DFT) have seen increasing application in the design and development of new organic optical materials, organic light emitting diodes (OLED) and liquid crystals. In previous work, we employed DFT to model the trans–cis isomerization state energies in a series of methacrylate and acrylamide photoswitchable polymer alignment materials functionalized with azobenzene pendants connected through a flexible alkyl chain (tether). Such photoswitchable alignment materials are of interest for LC devices for beam shaping due to their remarkable 1054 nm, 1 ns laser damage thresholds (28 to 67 J/cm2) and their ability to support spatially-varying write-erase capability. These modeling efforts were confined to a small representative section of the photoaligment polymer (an oligomer) composed of one tethered chromophore and four repeat backbone segments to reduce the large amounts of computational resources and time that would be required to accurately model a complete polymer system. Twenty-two different terminal functional groups were evaluated computationally to determine their individual effects on the trans and cis isomerization-state energies of the methacrylate and acryamide oligomers when used as substituents on azobenzene cores linked through a four-carbon tether to methacrylate and acrylamide backbones. The contribution of the alkyl tether to the isomerization-state energies of the methacrylate and acrylamide oligomers was also investigated computationally. This work extends the previous study by using DFT to evaluate the effect of molecular structure and tether length on the transition state energy barrier separating the pendant's isomeric switching states, which can have a large effect on bistability, write-erase fatigue, and switching energy requirements. Both oligomers containing azobenzene and spiropyran photoswitchable pendants were modeled in this study.

10361-28, Session 6

Liquid crystal elastomers presenting a homochiral building block

Elda Hegmann, Liquid Crystal Institute, Kent State Univ. (United States); Marianne Prévôt, Kent State Univ. (United States)

We have previously synthesized SmA LCEs using D,L-lactide as one of the building blocks. This resulted in a biodegradable and biodegradable scaffold for supporting the attachment and growth of cells. Here we present the use of enantiomically pure L-lactide, which is found naturally abundant in the human body, as a replacement to the previously used racemic D,L-lactide to affect its chirality. These racemic new biocompatible liquid crystal elastomers (LCE) showed enhanced mechanical properties promoting superior, stimuli-responsive surface properties for cell attachment and growth. LCE properties can also be tuned to vary in hydrophobicity, tensile strength, surface properties, biodegradation rate, cell adhesion, and response to external stimuli. We will discuss how this chirality change can affect the morphology as well as the mesomorphic behavior, and could potentially affect cell-elastomer interactions.

10361-29, Session 6

Relative permittivity imaging based on a liquid crystal sensor

Amir Aizen, Ibrahim Abdulhalim, Ben-Gurion Univ. of the Negev (Israel)

A new method and system for sensing and imaging objects based on sensing their relative permittivity values at low frequencies of a few kHz is presented. To the best of our knowledge, there is no system that can provide an image of an object's relative permittivity values at frequencies below the microwaves regime. The system's sensor is a parallel plate capacitor made from three main layers: a liquid crystal cell, a buffer layer and a cavity into which the imaged samples are inserted. When applying AC voltage of a few kHz on the sensor, the relative permittivity values of the samples will cause a unique voltage drop pattern on the liquid crystal cell. The voltages will create a retardation pattern in the liquid crystal cell that is then read by a light beam and being imaged. An image of the relative permittivity values of the samples can then be calculated using a few images taken at different voltages.

10361-30, Session 7

High power 4G optics *(Keynote Presentation)*

Nelson V. Tabiryan, David E. Roberts, Sergiy Kaim, Svetlana V. Serak, Sarik Nersisyan, Haiqing Xianyu, BEAM Engineering For Advanced Measurements Co. (United States); Timothy J. Bunning, Air Force Research Lab. (United States); Diane M. Steeves, Brian R. Kimball, U.S. Army Natick Soldier Research, Development and Engineering Ctr. (United States)

The optical power of diffractive waveplate structures is limited not as much by fabrication technology issues as by the fundamental features of light propagation in complex anisotropic structures. The infinitely thin two-dimensional film approximation does not apply, and the efficiency of 4G lenses, prisms, etc., is reduced for geometries corresponding to sharp focusing lenses and large diffraction angles. Due to thin-film nature, these films can be combined to reduce effective focal length, increase effective diffraction angle, topological charge, etc. Along with this, we will discuss the opportunity of increasing optical power of 4G lenses, prisms, etc. without compromising efficiency.

10361-31, Session 7

The Nematicon: A highly nonlocal regime wave singularity with ultra-sharp profile and random walk trajectory *(Invited Paper)*

Hélène Louis, Lab. de Physics des Laser, Atomes, et Molécules (France); Mustapha Tlidi, Univ. Libre de Bruxelles (Belgium); Eric Louvergneaux, Univ. des Sciences et Technologies de Lille (France)

We investigate light propagation within liquid crystals with focusing-like reorientational nonlinearity. This medium is "an excellent playground" for the study of spatiotemporal dynamics [1] such as localized states or modulational instability. Applications such as all optical routing is also a subject of intense research.

We focus here on the highly nonlocal regime (transverse beam extension "smaller" than the transverse nonlocality length). This regime is well known to depict solitary-like wave state [2]. We show experimentally that this state (known as "nematicon") has a "cusp"-like profile together with a trajectory that continuously wanders erratically with time [4]. In addition, we demonstrate that the highly nonlocal regime avoid wave collapse [3].

10361-32, Session 7

Nonlinear optical measurement of the twist elastic constant in thermotropic and lyotropic chiral nematics *(Invited Paper)*

Liana Lucchetti, Univ. Politecnica delle Marche (Italy); Tommaso Fraccia, Univ. degli Studi di Milano (Italy) and Univ. Telematica San Raffaele (Italy); Fabrizio Ciciulla, Univ. Politecnica delle Marche (Italy); Tommaso Bellini, Univ. degli Studi di Milano (Italy)

We show that by adopting a simple geometry we can readily extract the twist coefficient for known thermotropic N*, obtaining the value expected from literature. In the geometry here adopted the optical field induces a pure twist deformation, enabling a direct comparison between optical and elastic coupling. Furthermore, due to the planar geometry in which chiral nematic planes are stacked parallel to the cell walls, the characteristic length entering the energy balance is not the cell thickness but the pitch periodicity of the N* phase. This successful test opens the possibility to extend this strategy to lyotropic N* phases, in which coupling with external fields is typically more difficult to exploit. In particular, we focused on the N* phase of oligomeric DNA.

While the thermodynamics of DNA LC has been extensively characterized and modeled, no data is so far available on their elastic properties. This lack of information is the result of a combination of difficulties: DNA LC are

intrinsically chiral, making it difficult to use typical light scattering based analysis; no strategy has emerged yet to control the surface alignment of DNA LC phases; coupling with electric fields is weak and disturbed by the large density of intrinsic counterions present in the solution. The strategy that we describe here bypasses these limitations by using an optical field and by exploiting a geometry in which surface alignment is not crucial.

10361-33, Session 7

Self-induced structured light transformations using liquid crystal topological defects *(Invited Paper)*

Nina Kravets, Etienne Brasselet, Univ. Bordeaux 1 (France)

We discuss the use of self-engineered liquid crystals topological defects as soft spin-orbit photonic tools for that may find application in various fields such as opto-mechanics, optical metrology, information coding, and optical imaging. Here we will present recent results based on the use of a liquid crystal light valve that is known to enable the light-assisted electrical generation of localized umbilic defects acting as vectorial phase masks. Several examples emphasizing the self-induced interplay between structured light and structured matter will be presented.

10361-34, Session 8

Responsive optical filters prepared from polymer stabilized cholesteric liquid crystals *(Keynote Presentation)*

Timothy J. White, Kyung Min Lee, Vincent P. Tondiglia, Air Force Research Lab. (United States)

This presentation will summarize the opportunities to reconfigure the selective reflection inherent to the cholesteric liquid crystal phase. Adjustments to the materials or preparation conditions can enable either red- or blue-shifting reflection tuning, asymmetric or symmetric bandwidth broadening, dynamic scattering, or combinations thereof.

10361-35, Session 8

Liquid crystal 3D periodic gratings based on photo-alignment *(Invited Paper)*

Kristiaan Neyts, Inge Nys, Varsenik Nersesyan, Jeroen Beeckman, Univ. Gent (Belgium)

By illuminating a photo-alignment layer with two interfering UV laser beams with opposite circular polarization, a periodic alignment pattern is obtained for nematic liquid crystal. In a liquid crystal cell two substrates are used with periodic photo-alignment, with the periodicities perpendicular to each other. After filling with nematic liquid crystal the director obtains a 3D pattern with period twice that of the photo-alignment. The resulting 3D structure depends on the cell thickness (between 3 and 20 ?m) and the periodicity of the photo-alignment (also between 3 and 20 ?m). The director pattern can be estimated by performing numerical simulation with a Q-tensor method. The simulation results can be verified by polarization optical microscopy or by observing the diffraction properties of the structure. For a long range periodicity combined with a small period, the light is efficiently distributed over a small number of diffraction orders. The director pattern can be reoriented by applying a potential difference between the two substrate electrodes. Optical and electrical steering is investigated for devices with different dimensions.

10361-36, Session 8

Intra-ocular accommodative implant using liquid crystal lenses *(Invited Paper)*

Tigran Galstian, Ctr. d'Optique, Photonique et Laser (Canada)

Loss of distance accommodation is a common disease and many approaches have been considered to solve this problem. Some of them are based on the use of mechanical force. However, we have developed an alternative approach using motion-free focusing based on liquid crystal lenses. Electrical distance triggering mechanism was also developed. The optical, energy and size characteristics will e presented.

10361-37, Session 8

Confined photovoltaic fields in a photo-responsive liquid crystal test cell *(Invited Paper)*

Atefeh Habibpourmoghadam, Lin Jiao, Faissal Omairat, Univ. Paderborn (Germany); Dean R. Evans, Air Force Research Lab. (United States); Liana Lucchetti, Univ. Politecnica delle Marche (Italy); Viktor Y. Reshetnyak, Taras Shevchenko National Univ. of Kyiv (United Arab Emirates); Alexander Lorenz, Univ. Paderborn (Germany)

Exciting experimental results on the response properties of hybridized photo responsive liquid crystal test cells are reported, where iron doped lithium niobate substrates were used to photo generate electric fields and indium tin oxide coated cover glasses were used to confine these photo generated fields in a liquid crystal layer.

Samples were investigated in a modified inverted optical polarizing microscope with white probe light (crossed polarizers) and exposed with a Gaussian laser beam focused to a small spot (14 μm FWHM).

Test cells filled with nematic LC showed homeotropic director alignment. Upon exposure, this alignment was maintained at the exposure spot center and the LC director was selectively realigned in a surrounding single ring. This ring had a thickness of a few microns and its diameter increased with increasing exposure intensity (112 μm at 0.7 mW, 204 μm at 1.1 mW). This characteristic director realignment was traced back to the optically generated electric field distributions by simulations.

In samples filled with chiral nematic LC, uniformly standing helix alignment was found. Textural transitions were induced at the focus position, which again led to the formation of well-defined circular defects. We could show that these defects can be permanently stored within the chiral nematic LC. Polarized optical microscopy of a rotated sample revealed that a point like defect with +1 topological charge was enclosed in each of these defects.

Photovoltaic fields generated in small lithium niobate particles dispersed in a LC were found to cause promising optical responses and particle movement.

Chromatic-aberration correction in geometric-phase lenses, for red, green, and blue operation *(Invited Paper)*

Jihwan Kim, Kathryn J. Hornburg, Michael J. Escuti, North Carolina State Univ. (United States)

All diffractive lenses manifest chromatic aberration/dispersion. If the focal length f0 at a given wavelength ?0 is known, then the focal length f(?) = f0 ?0 / ? at other wavelengths ?. This can be considerable, even for lenses of a few diopters. Geometric-phase lenses (GPLs), are no exception, which manipulate incident light's wavefront by the Pancharatnam-Berry phase

effect. Several years ago, we developed achromatic coatings based on photo-aligned chiral liquid crystals that achieve nearly 100% efficiency into the primary and conjugate waves, and more recently we demonstrated fast, defect-free GPLs down to F/1.5 for red light. Until now, no one has reported how to generally reduce chromatic aberration and ensure that two or more wavelengths can have the same focal length. Here, we report on a new approach to correct for chromatic aberration using a stack of GPLs and retarders to arrange red, green, and blue wavelengths to have precisely the same focal length. A simple arrangement of these elements results in a thin, monolithic, and flat GPL, which can either converge or diverge three wavelength sources (R/G/B) with the same focal length, positive or negative, depending on the handedness of the circular input polarization. Here, we describe the concept and characterize our first prototypes by evaluating focal lengths, efficiency, and polarization contrast. We also discuss the realistic opportunities and limitations for this approach.

10361-39, Session PMon

Compact optical device for measuring liquid crystal elastic and dynamic properties

Nina Podoliak, Elena Perivolari, Thomas P. Bennett, Matthew B. Proctor, Univ. of Southampton (United Kingdom); Thomas Regrettier, Thomas Heiser, Univ. de Strasbourg (France); Giampaolo D'Alessandro, Malgosia Kaczmarek, Univ. of Southampton (United Kingdom)

We present a prototype of compact device for all-optical measurements of the elastic and dynamic properties of nematic liquid crystals (LC). The device is based on a standard cross-polarized optical set-up and uses a combination of both amplitude and frequency of the driving AC electrical signal. Using a three-step measurement protocol and a corresponding fitting procedure, it simultaneously determines the following LC parameters: the splay and bend elastic constants, K1 and K3, the rotational viscosity ?1, and the combination of Leslie viscosity coefficients ?4+ ?5. Moreover, by taking sampled measurements across the area of a LC cell, the map profile of the LC layer thickness and average pre-tilt on the surfaces can be determined. All measurements are conducted using the same LC sample, which simplifies the measurement procedure and allows LC parameter testing in already assembled LC devices. We demonstrate the device performance using standard LC cells with commercially available nematic LCs such as E7 and TL205, as well as more complex LC-polymer samples containing photoconductive polymers such as C60 doped polyvinylcarbazole (PVK: C60), or poly(3-hexylthiophene) and phenyl-C61-butyric acid methyl ester (P3HT:PCBM).

10361-40, Session PMon

Light-driven liquid crystalline elastomeric devices: From micro-robotics to micro-photonics

Sara Nocentini, Daniele Martella, Lab. Europeo di Spettroscopie Non-Lineari (Italy); Dmitry Nunhdin, Lab. Europeo di Spettroscopie Non-Lineari (Italy) and Karlsruher Institut für Technologie (Germany); Simone Zanotto, Istituto Nazionale di Ottica (Italy); Camilla Parmeggiani, Lab. Europeo di Spettroscopie Non-Lineari (Italy) and Consiglio Nazionale delle Ricerche (Italy); Diederik S. Wiersma, Lab. Europeo di Spettroscopie Non-Lineari (Italy) and Univ. degli Studi di Firenze (Italy)

Liquid crystals have been recognized as a state of matter that characterize the technological applications of the last century not only in the display technology but also in the bio-medical field, photonic devices and robotic research. If the liquid crystalline molecules are combined with cross-linking units, a polymeric liquid crystalline elastomeric (LCE) material is formed. Polymer deformation controlled by the molecule alignment opens to bending, twisting or more complex movements. Light has been chosen as the external stimulus since it figures out as one of the more appealing energy source for micro and nano-robot actuation, enabling the remote spatial and temporal control on the material responses up to the nano-scale. In order to obtain a photoresponsive material, a dye, an azobenzene molecule, is added in the monomeric formulation. Moreover the possibility to pattern LCE in the microscale thanks to the lithographic technique of direct laser writing allows to design with nanometric precision different kind of photo-responsive micro-structure.

Depending on the photonic structure that should be addressed, the property tuning is achieved both on the chemical point of view and on the physical side, acting on the lithographic parameters. It has already been demonstrated how this optimized technique, based on a two-photon polymerization, leads to 3D walking and swimming micro-structures. We show here how the chemical and physical knowledge merged into the realization and characterization of optically tunable photonic devices as a grating beam steerer and micro-robots as a self-activated gripper of absorbitive nanoparticles.

10361-41, Session PMon

High resolution all-optical image processing with azobenzene-doped blue-phase liquid crystals

Tsung-Jui Ho, Chun-Wei Chen, Iam-Choon Khoo, The Pennsylvania State Univ. (United States)

In this presentation, we show by theory and experiment that dye-doped BPLCs are capable of all-optical edge enhancement, intensity conversion, hologram recording as well as optical wave front conjugation with aberration correction capability. Generally, these image processing operations can be performed with arbitrary polarization state of the light, and only requires low optical input powers. The underlying mechanism is laser induced lattice distortion that result from trans-cis isomorphism of the azo-dye molecules which, unlike laser induced crystalline axis reorientation in other LC phases, allow very high resolution [~ 1micron] image processing capabilities.

10361-42, Session PMon

Nonlinear optical logic circuits enabled by dye-doped twisted nematic liquid crystals

Cheng-Yu Wang, Chun-Wei Chen, The Pennsylvania State Univ. (United States); Hung-Chang Jau, National Sun Yat-Sen Univ. (Taiwan); Iam-Choon Khoo, The Pennsylvania State Univ. (United States); Tsung-Hsien Lin, National Sun Yat-Sen Univ. (Taiwan)

All-optical transistors and diodes enable a wide range of applications, such as direct logic processing of optical image, that were previously unachievable by traditional linear optical elements. In this presentation, we demonstrate how all-optical transistor and diode actions (including cascadability, signal fan-out, logic restoration) using dye-doped twisted nematic liquid crystals (DTN) by exploiting their non-reciprocal transmission responses enabled by the anisotropic absorption, polarization-rotation property, and collective optical nonlinearity of the DTN. By integrating these nonlinear optical elements, we have also demonstrated various logic-gate operations such as OR, AND, and NOT. It is noteworthy that these devices can be designed to fit a wide range of operation power owing to the controllable absorbance of DTN.

10361-43, Session PMon

The alignment of liquid crystalline nanowires using micropatterned elastomer molds

Eric Carlson, Lee M. Foley, Edward Guzman, Eva D. Korblova, Rayshan Visvanathan, Univ. of Colorado Boulder (United States); SeongHo Ryu, Min-Jun Gim, Dong Ki Yoon, KAIST (Korea, Republic of); Noel A. Clark, David M. Walba, Univ. of Colorado Boulder (United States)

The helical nanofilament (HNF) liquid crystal (LC) phase of NOBOW (9-O-PIMB) forms chiral nanofilaments, driven by a torsional strain between molecular halves within smectic layers that causes a saddle-splay deformation. Due to the high levels of crystallinity within each filament, the HNF phase can be described as a LC phase of nanowires—potentially perfect for use in organic electronics. Various methods have been used to align the HNF phase, yet effective alignment within an electronic device framework remains elusive. In this study, we use a lithographic technique, template assisted self-assembly, to align HNFs in microchannels. Polydimethylsiloxane (PDMS) molds containing channels ca. 5μm wide, 10μm high, and 1cm long are fabricated from an etched silicon master. These PDMS molds are placed on a glass substrate and the resultant cell is subsequently filled with isotropic NOBOW and cooled to room temperature. Removing the mold from the substrate reveals high quality alignment of HNFs within now free-standing channels as studied by polarized light microscopy, 2-D SAXS, and SEM. SAXS data also suggests the B2 and B3 phases of NOBOW are perfectly aligned in the molds, and thus their alignment is at least partially responsible for the alignment of HNFs. Mixtures with 8CB in the molds, unlike glass cells, promote the formation of the B2 phase, highlighting the influence PDMS has on phase formation. Not only does this study aid in the development of new organic electronic motifs using liquid crystal nanowires, but it also helps to better understand how HNFs and other LCs might align in this bulk system.

Conference 10362: Organic Light Emitting Materials and Devices XXI

SPIE. OPTICS+ PHOTONICS ORGANIC PHOTONICS+ ELECTRONICS

Sunday - Tuesday 6 –8 August 2017

Part of Proceedings of SPIE Vol. 10362 Organic Light Emitting Materials and Devices XXI

10362-1, Session 1

The design and synthesis of n-dopants and TADF materials for OLED applications *(Invited Paper)*

Seth R. Marder, Georgia Institute of Technology (United States)

Organic semiconductors have attracted interest for electronic applications due to their potential for use in low-cost, large-area, flexible electronic devices. In this talk I will discuss the development of metallocenes-based dimers as n-dopants for use in semiconductors, 2D materials and electrodes, and their resulting impact on material properties and device performance. In particular I will focus on the application of photo-induced doping of low electron affinity compounds using air-stable organometallic compounds. The mechanism of doping and the application of the doping for fabrication of organic light emitting diodes (OLEDs) will be discussed. I will also briefly discuss recent work on the development of materials that have small excited state singlet-triplet energy gaps, which may be of interest as hosts or emitters for OLED applications.

10362-2, Session 1

Highly efficient pure blue-to-green emission from pyrimidine-based TADF emitters *(Invited Paper)*

Hisahiro Sasabe, Ryutaro Komatsu, Tatsuya Ohsawa, Kohei Nakao, Yuya Hayasaka, Junji Kido, Yamagata Univ. (Japan)

A series of pyrimidine-based pure blue-to-green emitters are developed, and investigated the structure–property relationships. A pure blue emitter realized a PE of 20 lm W–1 at CIE of (0.16, 0.15), and a green emitter exhibited a PE of over 110 lm W?1 at CIE of (0.36, 0.58).

10362-3, Session 1

Vibrational coupling in TADF and how molecular structure can control this complex triplet harvesting process *(Invited Paper)*

Andrew P. Monkman, Durham Univ. (United Kingdom)

The process of triplet harvesting is by thermally activated delayed fluorescence, 'TADF', i.e. E-type delayed fluorescence, is now well established. In this talk I shall discuss how this triplet harvesting mechanism is affected by molecular architecture.

Detailed photophysical measurements of intramolecular charge transfer (ICT) states have been made both in solution and solid state. Temperature dependent time resolved emission, delayed emission and photoinduced absorption are used to map the energy levels involved in molecule decay, and through detailed quantum chemical modelling, true electron exchange energies and other energy barriers of the systems are determined with the real states involved in the reversed intersystem crossing mechanism elucidated.

Using the vibronic coupling second order spin orbit interaction we go on to show how both D-A-D molecule structure and conformation control TADF and efficiency in a TADF OLED. By confirming the vibronic coupling mechanism of rISC (and ISC) we can now start to think about true molecular design for TADF emitters.

10362-4, Session 1

Efficient TADF OLEDs using active materials with both efficient internal generation and external extraction *(Invited Paper)*

Chung-Chih Wu, National Taiwan Univ. (Taiwan)

To achieve ultimately high external quantum efficiencies of OLEDs, OLED materials and device architectures that can achieve high internal quantum efficiencies and high optical out-coupling efficiencies are equally important. In this paper, we will present some of our recent works on OLED materials and devices that can provide high internal and optical out-coupling efficiencies. For instance, extremely efficient blue organic EL with external quantum efficiency (EQE) of ~37% is achieved in a conventional planar device structure, using a highly efficient TADF emitter based on the spiroacridine-triazine hybrid that simultaneously possesses nearly unitary (100%) photoluminescence quantum yield and strongly horizontally oriented emitting dipoles (with a horizontal dipole ratio of 83%). On the other hand, judicious use of low-index active organic materials in OLEDs can also effectively enhance optical coupling efficiency and EQEs of OLEDs even with isotropic emitters. This was demonstrated by efficient and tunable blue-green to yellow TADF OLEDs (with EQEs of >31%) based on TADF emitters having acridine donor units and CN-substituted pyridine/pyrimidine acceptor units.

10362-5, Session 1

High efficiency thermally activated delayed fluorescence through an excited-state intramolecular proton transfer *(Invited Paper)*

Masashi Mamada, Ko Inada, Takeshi Komino, William J. Potscavage Jr., Hajime Nakanotani, Chihaya Adachi, Kyushu Univ. (Japan)

Thermally activated delayed fluorescence (TADF) materials have shown great potential for highly efficient organic light-emitting diodes (OLEDs). While the current molecular design of TADF materials primarily focuses on combining donor and acceptor units, we present a novel system based on the use of excited-state intramolecular proton transfer (ESIPT) to achieve efficient TADF without relying on the well-established donor-acceptor scheme. In an appropriately designed acridone-based compound with intramolecular hydrogen bonding, ESIPT leads to separation of the highest occupied and lowest unoccupied molecular orbitals, resulting in TADF emission with a photoluminescence quantum yield of nearly 60%. High external electroluminescence quantum efficiencies of up to 14% in OLEDs using the material prove that efficient triplet harvesting is possible with ESIPT-based TADF materials. This work will expand and accelerate the development of a wide variety of TADF materials for high performance OLEDs.

10362-6, Session 2

Conventional fluorescent OLEDs toward EQE of 30% *(Invited Paper)*

Jang-Joo Kim, Seoul National Univ (Korea, Republic of); Hyun-Gu Kim, Seoul National Univ. (Korea, Republic of)

Harnessing triplet excited states resulting from electrical pumping by conventional fluorophores in organic light emitting diodes (OLEDs) is very attractive to overcome low stability and high-efficiency roll-off at high current density of phosphorescent and thermally activated delayed fluorescence (TADF) OLEDs. Here we demonstrate a method to increase the fraction of singlet excitons on a conventional fluorescent material by reverse intersystem crossing (RISC) of exciplex and sensitization effect. As a result, we realise a fluorescent OLED with the external quantum efficiency (EQE) of 26% and predict that EQE of 30% may be expected if all singlet excitons in the fluorescent emitter decay radiatively.

10362-7, Session 2

Molecular design and device architectures for high performance thermally activated delayed fluorescent OLEDs *(Invited Paper)*

Chun-Sing Lee, City Univ. of Hong Kong (Hong Kong, China)

Thermally activated delayed fluorescence (TADF) has attracted much recent attention for it application in high performance organic light-emitting devices (OLED). In this talk, approaches for enhancing performance of TADF based OLED in term of both molecular design and device architecture will be discussed.

10362-8, Session 2

High efficiency OLEDs based on exciplex *(Invited Paper)*

Ken-Tsung Wong, National Taiwan Univ. (Taiwan)

Organic materials with efficient thermally activated delayed fluorescence (TADF) are emerging as attractive OLEDs emitters because of the achievable 100% internal quantum efficiency. TADF can be achieved by the manipulation of HOMO-LUMO overlap by tailor-made molecular structure with subtle intramolecular charge transfer (ICT) between the electron donor and acceptor.

Many efficient TADF emitters have been reported, paving the way to make high efficiency OLEDs in much cost-effective ways. Alternatively, TADF can be achieved by an exciplex formed through the intermolecular charge transfer between a hole-transporting (HT) material and an electron-transporting (ET) material. The uses of exciplex as emitting layer or host for high efficiency phosphorescent or fluorescent OLEDs have been successfully demonstrated, indicating the potential of exciplex in OLEDs. The selection of suitable HT and ET materials not only can generate efficient exciplex but also can reduce the complexity of device structures. In this conference, our recent developments of new carbazole-based HT and triazine-based ET materials for high efficiency exciplex and their uses to achieve blue to yellow and tandem white OLEDs will be reported.

10362-9, Session 3

Blue OLEDs based on thermally activated delayed fluorescent emitters with improved stability *(Invited Paper)*

Lian Duan, Dongdong Zhang, Tsinghua Univ. (China)

Much effort has been devoted to boost the performance of thermally activated delayed fluorescence (TADF) devices; however, the stability of blue TADF emitters remains a constraint for their potential applications in displays and lightings. In our previous work, we have successfully added bulky substituents to protect the chromophore of blue TADF emitters and improved lifetime is attained. Here, we will also show some other methods to further improve their stability. The first one is to use host materials with TADF properties together with TADF emitters. Reduced STA, TTA, and also TPA can be achieved. The second one is to utilize stable transporting materials, especially electron transporting materials with extended conjugations. By incorporating all these techniques into one device, we have demonstrated blue OLEDs with EQE of over 20% and a T50 up to 1200 hrs at an initial brightness of 500 cd/m2, pushing the performance of blue TADF OLEDs closer to the requirements of real applications.

10362-10, Session 3

Towards commercialization: Blue TADF emitter materials for next-generation AMOLED-displays *(Invited Paper)*

Thomas Baumann, Daniel Volz, cynora GmbH (Germany)

Thermally activated delayed fluorescence (TADF) is an upcoming key technology for organic light-emitting diodes (OLEDs).

For the first time, OLED materials that combine efficiency, stability and a deep blue color point are available.

In this work, we introduce the TADF technology and give a status update and development roadmap towards commercialization. As a highlight, we will especially feature a status update for deep-blue emitters with high stability and good color point, which are useful for efficient OLED displays.

10362-11, Session 3

Understanding spin-dependent processes in TADF light-emitting materials based on magneto-optical studies *(Invited Paper)*

Bin Hu, The Univ. of Tennessee Knoxville (United States)

This presentation reports our recent studies on the understanding of spin-dependent processes in TADF (Thermally Activated Delayed Fluorescence) light-emitting materials based on magneto-optical studies. Recently, we have performed magneto-optical studies on TADF light-emitting molecules (DMAC-TRZ) by using magneto-photoluminescence (magneto-PL). Our magneto-PL studies provide the first evidence that the TADF is a spin-dependent process occurring in charge-transfer states. Essentially, the key spin-dependent process, namely spin mixing, necessarily required to activate the TADF, is determined by the competition between two critical parameters: (i) exchange interaction which functions as a resistance force to the TADF and (ii) spin-orbital coupling which acts as a driving force to the TADF. Therefore, controlling the exchange interaction and spin-orbital coupling becomes a critical issue in the development of highly efficient TADF light-emitting materials. By using magneto-PL studies, we further found that, doping soluble magnetic nanoparticles (surface-modified Fe_3O_4) can conveniently change the exchange interaction and spin-orbital coupling, and consequently alters the TADF rate. At low doping concentrations, the spin-orbital coupling is enhanced, leading to an increase on TADF rate. However, at high doping concentrations, the exchange interaction is increased, causing a decrease on the TADF rate. Furthermore, we studied the polarization effects of spin mixing in liquid TADF materials by using various solvents with different polarities. We observed that increasing the host polarization can directly weaken the spin mixing and leads to a decrease on the TADF rate. This experimental observation indicates that host polarization can weaken the spin-orbital coupling and thus decreases the driving force to TADF. Clearly, the magneto-PL studies provide an insightful understanding on the spin-dependent process to control the TADF rate in organic light-emitting materials.

10362-12, Session 3

Device approach for extended lifetime in triplet exciton harvesting organic light-emitting diodes *(Invited Paper)*

Wook Song, Si Hyun Han, Jeong Min Choi, Jun Yeob Lee, Sungkyunkwan Univ. (Korea, Republic of)

Lifetime of organic light-emitting diodes has been a challenging issue because of intrinsic instability of organic light-emitting materials. In particular, the lifetime of high efficiency organic light-emitting diodes such as phosphorescent organic light-emitting diodes and thermally activated delayed fluorescent organic light-emitting diodes is still shorter than that of conventional fluorescent organic light-emitting diodes. Therefore, the lifetime extension of those triplet exciton harvesting organic light-emitting diodes is important. There have been many material and device approaches to extend the lifetime of the triplet harvesting organic light-emitting diodes and one of effective methods was to manage triplet-polaron annihilation in the emitting layer. In this presentation, we discuss several methods to control the triplet-polaron annihilation in the phosphorescent and thermally activated delayed fluorescent devices

10362-13, Session 3

Enhanced photoluminescence from a molecular tunneling junction

Alfred J. Meixner, Kai Braun, Eberhard Karls Univ. Tübingen (Germany); Xiao Wang, Hunan Univ. (China); Dai Zhang, Eberhard Karls Univ. Tübingen (Germany)

We demonstrate enhanced photoluminescence (PL) from an optically pumped bias driven molecular tunneling junction (Au-substrate/self assembled molecular monolayer/Au-tip) with molecules chemically bound to the Au substrate. The gap between a sharp gold tip and a flat gold substrate covered with a self-assembled monolayer (SAM) of 5-chloro-2 mercaptobenzothiazole (Cl-MBT) molecules can be used as an extremely small optical gain medium. When a bias-voltage is applied between tip and sample such that electrons tunnel from the Cl-MBT's highest occupied molecular orbital (HOMO) to the tip, holes are left behind in the molecules. These can be repopulated by hot electrons that are created by the laser-driven plasmon oscillation on the metal surfaces enclosing the molecule. Emission of photons occurs from the recombination of plasmon excited hot electrons with holes in the HOMO of surface bound molecules below the tip. Varying the laser pump power or alternatively the applied bias voltage shows in both cases a distinct threshold above which enhancement of the optical signal occurs. Solving the rate equations for this system shows that optical feed-back by the gap mode's near field can efficiently stimulate the emission process. The system reflects many essential features of a superluminescent organic light emitting diode.

10362-14, Session 4

Highly efficient flexible OLEDs with the extraction enhancement *(Invited Paper)*

Jianxin Tang, Yanqing Li, Soochow Univ. (China)

Flexible organic light-emitting diodes (OLEDs) hold great promise for future bendable display and curved lighting applications. One key challenge of high-performance flexible OLEDs is to develop new flexible transparent conductive electrodes with superior mechnical, electrical and optical properties. The second is to extract the confined light in the devices due to different loss mechanisms. Herein, an effective nanostructured metal/dielectric composite electrode (NMDCE) on plastic substrate is applied to flexible OLEDs with an ultrathin metal alloy film for optimum optical transparency, electrical conduction and mechanical flexibility. By combining an light-extraction structure for broadband and angle-independent outcoupling of white emission, the waveguided light and surface plasmonic loss can be remarkably reduced in white flexible OLEDs, resulting in a substantial increase in the external quantum efficiency and power efficiency to ~70% and >160 lm/W.

10362-15, Session 4

Efficient light extraction of organic light-emitting diodes *(Invited Paper)*

Qibing Pei, Univ. of California, Los Angeles (United States)

Organic light-emitting diodes (OLEDs) typically suffers from limited light outcoupling efficiencies despite high internal quantum efficiencies because of light loss in the surface plasmon, waveguide and substrate modes. Using a nanocomposite substrate with embedded silver nanowire network to replace ITO/glass, the waveguide and substrate modes can be out-coupled from the device. White OLEDs were fabricated on the nanocomposite substrates, achieving a power efficacy external quantum efficiency significantly higher than control devices on ITO/glass. Furthermore, the reported nanocomposite substrate was fabricated by solution processes and are mechanically flexible, allowing them to be readily adaptable in the low-cost production of flexible OLEDs.

10362-16, Session 4

Enhanced outcoupling of light from OLEDs fabricated on corrugated polycarbonate and PET substrates *(Invited Paper)*

Chamika Hippola, Rajiv Kaudal, Eeshita Manna, Iowa State Univ. of Science and Technology (United States); Thomas Trovato, Trovato Mfg., Inc. (United States); Dennis Slafer, MicroContinuum, Inc. (United States); Rana Biswas, Joseph Shinar, Ruth Shinar, Iowa State Univ. of Science and Technology (United States)

Extracting the "internally waveguided" light from OLEDs, which together with losses to plasmons at the metal cathode typically account for > 50% of the light generated in the emission zone, has proven to be a particularly challenging problem. To address this problem, we fabricated devices on nano-patterned plastic substrates that disrupt the internal waveguiding. We describe thermally evaporated small molecule fluorescent and phosphorescent OLEDs fabricated on corrugated polycarbonate (PC) and polyethylene terephthalate (PET) substrates nanopatterned in a roll-to-roll process. We compare the devices fabricated on plastic/ITO to those on plastic/PEDOT:PSS and the effect of adding a μm-scale Cu honeycomb mesh to the integrated substrate/anode as well. Depending on the height and pitch of the pattern, up to a 2.5 fold increase in the outcoupling factor is observed relative to the flat substrate. Issues related to the fidelity of the conformal deposition of the various layers on the patterned plastic are also discussed, particularly the effect of the nanopatterns on device stability.

10362-17, Session 4

Molecular orientations and energy levels *(Invited Paper)*

Yiying Li, Zheng-Hong Lu, Univ. of Toronto (Canada)

The relative molecular orientation between two adjacent molecules plays an important role in device performance. For example, a horizontally orientated emitter molecule leads to a surface-aligned transition dipole moment which yields a much higher optical out-coupling efficiency than a vertically oriented dipole, and hence, it significantly improves the external quantum efficiency of the organic light emitting diode. Molecular orientation has significant influence on energy levels at organic heterojunctions. In this talk, we will discuss our recent experimental findings on correlations between energy levels and molecular orientation. The impact of molecular orientation on interface energy level alignment and on interface charge transfer will be discussed. The influence of a material's glass transition temperature on molecular orientation will also be discussed.

10362-18, Session 4

OLED light extraction with corrugated substrate and hemispherical lens

Xiangyu Fu, Cheng Peng, Univ. of Florida (United States); Dong-Hun Shin, Monica Samal, Franky So, North Carolina State Univ. (United States)

While the internal quantum efficiency of an OLED can reach 100%, its external quantum efficiency (EQE) is limited to 30% because of light trapped in waveguided mode, SPP mode and substrate mode. In this study, we achieve more than 2X enhancement in EQE by using a corrugated substrate and a hemispherical lens. Polarized angle-resolved electroluminescence spectroscopy is used to analyzed the EL data, and the results are compared with optical simulation. We find the efficiency enhancement mainly comes from the diffraction of the SPP mode towards air mode due to the corrugated substrate, and the hemispherical lens assists the light extraction by extending the air cone into the substrate mode.

10362-19, Session 4

Vacuum nanohole array embedded organic light emitting diodes for enhanced light extraction *(Invited Paper)*

Sohee Jeon, Jun-Ho Jeong, Korea Institute of Machinery & Materials (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

High-efficiency organic light emitting diode (OLED) approaching the theoretical limit was produced by using the highly effective extraction layer based on a vacuum nanohole array (VaNHA). A novel process called robust reverse-transfer was developed to transfer a nanohole array defined on a dielectric layer onto a substrate. The nanohole array remains vacant between the dielectric layer and the substrate after the transfer process, maximizing the refractive index (RI) contrast of the extraction layer for the dielectric material as the selected high RI. The extraction enhancement confirmed that VaNHA extracts the entire waveguide loss into the air by comparing experimentally measured results with those produced from optical modeling analysis. We will show that EQEs approaching 80% is achievable by extracting all the waveguided and substrate confined modes with a VaNHA structure and a half spherical lens as internal and external light extraction layers, respectively, and by minimizing surface plasmon polariton loss with increasing the thickness of the electron transporting layer.

10362-20, Session 5

Extending the lifetime of blue phosphorescent OLEDs *(Keynote Presentation)*

Stephen R. Forrest, Univ. of Michigan (United States)

Since its first demonstration in 1998, electrophosphorescence has yielded 100% internal quantum efficiency OLEDs (PHOLEDs) across the color gamut. This advance has given birth to a huge global OLED display industry, now estimated to be >$15B, or more than 10% of all displays made. While red and green devices have shown extraordinary operational lifetimes, blue PHOLEDs have had unacceptably short lifetimes. In this talk I discuss the fundamental origins of this deficiency1, and approaches to extending the lifetime of blue PHOLEDs. Indeed, recent results in our laboratory have already yielded a 10 fold improvement in lifetime, the first such major improvement in almost a decade2. The understanding gained from these experiments suggest that much longer lifetimes, even for very deep blue emitting PHOLEDs, is possible. In particular, I will discuss the use of hot excited state managers as a means to greatly extend the lifetime of blues for both displays and lighting.

10362-21, Session 5

Blue emitting square planar metal complexes for displays and lighting applications *(Invited Paper)*

Jian Li, Arizona State Univ. (United States)

The successful development of alternate low cost technology for current solid state lighting devices will have a significant impact on the U. S. economy and national security. White organic light emitting diodes (OLEDs) with potentially high power efficiency are considered as strong candidate for the next generation of illumination devices. Moreover, the use of environmentally benign organic materials in white OLEDs and their potentially low fabrication cost makes them an attractive technological prospect. In this presentation, we will discuss our continuing efforts on the design, synthesis and characterization of novel platinum complexes for displays and lighting applications. The photo-physics, electrochemistry, electroluminescent properties and operational stability of these novel metal complexes, including deep blue narrowband emitters, blue emitters with 6-membered chelate rings and blue MADF emitters, will be discussed, particularly including our 10-year effort in the design of blue emitting phenyl-pyridine based metal complexes. The rational molecular design enables us to develop cyclometalated metal complexes with both photon-to-photon (in thin film) and electron-to-photon (in device settings) conversion efficiency close to 100% for OLED applications. Our approaches to achieve high efficiency white OLED using a single emitter will be also included.

10362-22, Session 5

Recent advances in phosphorescent OLEDs: Molecular design for long lifetime and high color purity *(Invited Paper)*

Hirohiko Fukagawa, Takahisa Shimizu, Yukiko Iwasaki, Taku Oono, Toshihiro Yamamoto, NHK Japan Broadcasting Corp. (Japan)

OLEDs are key devices for realizing next-generation displays such as flexible displays. Although the emission mechanism along with new luminescence materials have been intensively studied with the goal of harvesting all excitons as emission, it has not been uncommon to hear of devices with internal quantum efficiencies of approximately 100% that use phosphorescent or thermally activated delayed fluorescent (TADF) emitters in recent years. Thus, the device performances directly related to practical applications, such as operational lifetime and color purity, have begun to attract much attention. Here, we report on recent advances in phosphorescent OLEDs (PHOLEDs) related to these two device performances. First, the molecular design of the host material to obtain an operationally stable PHOLED is clarified. By analysing the device characteristics of several PHOLEDs utilising similar TADF materials as hosts, a TADF material with a small molecular size is found to be suitable for the phosphorescent host. Second, we demonstrated efficient green OLEDs with high color purity utilising a platinum complex with a rigid molecular structure. A current efficiency of 84 cd/A was obtained from a bottom-emitting OLED with CIE x-y coordinates of (0.27, 0.67), which is much greater than that of a bottom-emitting green OLED using conventional iridium complexes with CIE x-y coordinates of (0.33, 0.62). Furthermore, the CIE x-y coordinates reached (0.18, 0.74) upon employing a top-emitting structure.

Realizing high-performance and low-cost fluorescent OLEDs *(Invited Paper)*

Shi-Jian Su, South China Univ. of Technology (China)

Organic light-emitting diodes (OLEDs) are being increasingly applicable in flat-panel displays, such as television and mobile phone, and have a great potential to become the next generation solid-state lighting sources. One of the most attractive strategies is to construct OLEDs with low cost purely organic materials, where high cost phosphorescent materials containing rare or noble metals are not involved in the device fabrication. We have proposed a simple strategy towards high-performance fluorescent OLEDs. The designed devices are merely composed of stacked p-type hole-transport layer and n-type electron-transport layer, resulting in a planar pn heterojunction configuration similar to their inorganic counterparts, namely light emitting diodes (LEDs). In this novel device, the excitons are generated and decay at the pn junction interface due to the synergetic interaction of p-type and n-type materials, finally giving the light emission. In addition, a novel strategy towards simultaneously low-driving voltage and high efficiency fluorescent OLEDs was also proposed using an active planar pn heterojunction as the exciton generation region and conventional fluorescent dye or thermally activated delayed fluorescence (TADF) material as the emitter. The current findings highlight the significance of the role of the organic active planar pn heterojunction in fabrication of high-performance and structure-simplified OLEDs with conventional fluorescent and TADF emitters, and also enlighten that organic active pn heterojunction should play a much more important role in electric-to-light conversion devices as it has done in the light-to-electric photovoltaic devices.

10362-24, Session 5

Active control of OLED beam shapes *(Invited Paper)*

Sebastian Reineke, Felix Fries, Markus Fröbel, Pen Yiao Ang, Simone Lenk, TU Dresden (Germany)

Organic light-emitting diodes (OLEDs) are scalable area light sources, allowing for highly efficient mono- or polychromatic emission. In standard configuration of the OLED architecture, the emission pattern can be approximated well with an Lambertian intensity distribution. Patterns deviating from this distribution can be achieved by fine-tuning of the interplay between emitter location and the strength of the micro-cavity. Here, we demonstrate a concept for an OLED-based concept that allows for actively controlled, variable beam shapes. This is achieved using a cavity optimized tandem architecture, comprising two red-emitting phosphorescent OLED units, which is driven with a pulse-width modulation to achieve the desired beam shapes. For an optimized side-emission, this device shows a 2.7 times higher emission at 56° with respect to the normal emission. The discussion of our experimental results is supplemented with state-of-the-art optical simulations. We also include geometrical considerations that are important to evaluate the potential of this concept. Finally, we demonstrate qualitatively, how external optical elements can be incorporated the alter the emitted beam shape.

10362-25, Session 6

Investigating the causes of the lower stability of solution-coated versus vacuum-deposited small-molecule organic light emitting devices *(Invited Paper)*

Hany Aziz, Yong Joo Cho, Hyeong Hwa Yu, Yingjie Zhang, Univ. of Waterloo (Canada)

Although the promise of realizing lower cost fabrication by means of solution-based processing techniques, such as spin coating, web coating or inkjet printing, has been one key driver behind the interest in OLEDs for the last two decades, the lower stability of devices made by these techniques has been a long standing issue. With recent advances in developing solution-processable small molecule materials, it is now possible to make OLEDs of the same small molecule materials by either solution coating or vacuum deposition. Despite this, there continues to be an intriguing stability gap.

In this work, we investigate this phenomenon with the purpose of identifying its root causes. Electroluminescence, delayed electroluminescence and photoluminescence measurements are used to study and compare between the aging behavior in OLEDs made by spin-coating versus vacuum-deposition. Hole-only devices are also utilized, and employed to study the effects of charges and excitons, separately and combined. The results reveal that the faster degradation of solution-processed devices relative to their vacuum-deposited counterparts under electrical stress is due to a faster molecular aggregation process. Excitons and interactions between them and polarons appear to play a leading role in inducing this phenomenon. Results from these investigations will be presented and discussed.

10362-26, Session 6

Addition of lithium 8-quinolate into polyethylenimine/zinc oxide electron-injection layer improving driving voltage and lifetime of OLEDs *(Invited Paper)*

Yong-Jin Pu, Takayuki Chiba, Takafumi Ide, Satoru Ohisa, Hitoshi Fukuda, Tatsuya Hikichi, So Kawata, Junji Kido, Yamagata Univ. (Japan)

Solution-processed electron injection layers (EILs) comprising lithium 8-quinolate (Liq) and polyethylenimine ethoxylated (PEIE) are highly effective for enhancing electron injection from ZnO to organic layers and improving device lifetime in organic light-emitting devices (OLEDs). Doping of Liq into PEIE further reduces the work function of zinc oxide (ZnO) by enhancing dipole formation. The intermolecular interaction between Liq and PEIE was elucidated by UV-vis absorption measurement and quantum chemical calculation. The OLEDs with ZnO covered with PEIE:Liq mixture exhibited lower driving voltage than that of the device without Liq. Furthermore, as doping concentration of Liq into PEIE increased, the device lifetime and voltage stability during constant current operation was successively improved.

10362-27, Session 6

Electroluminescent polymers for solution-processed PLEDs *(Invited Paper)*

Lixiang Wang, Changchun Institute of Applied Chemistry (China)

Polymer light-emitting diodes (PLEDs) is fabricated by solution process, and should be cheaper enough, however their performance so far remains inferior to that of the best vacuum deposited organic light-emitting diodes (OLEDs), such as power efficiency and stability, so the further research for PLED will be on the materials issue and device structure for improving the efficiency and stability.

This presentation will discuss two topics with most updated results: (1) Solution-processed multilayer polymer light-emitting diodes for high-efficiency blue, green, red and white emission; (2) Power efficient solution-processed white organic light-emitting diodes with high energy level blue-emitting iridium complexes and carbazole-based dendritic host.

Based on the solvent resistance tests for the dendritic dopants with different emission color and dendritic hosts, the multilayer polymer light-emitting diodes are fabricated by using alcohol-soluble electron-transporting materials. It is found that their performances are quite comparable with that of the corresponding device with the electron-transporting layer by vacuum-deposition process, which is favorable to construct white polymer light-emitting diodes with multilayer structure.

To reduce the driving voltage and realize high power efficiency, solution processed white OLEDs with the power efficiency of 64.5 lm W-1 are achieved by using high energy level blue-emitting iridium complexes to replace low energy level FIrpic and carbazole-based dendritic host H2 instead of the traditional PVK. This result represents an important progress in solution-processed WOLEDs, for the development of the next-generation WOLEDs device using the active layer with the barrier-free hole/electron injection features.

10362-28, Session 7

Highly efficient solution-processed small-molecule organic light-emitting diodes using novel electron transporting host *(Invited Paper)*

Tae-Woo Lee, Tae-Hee Han, Seoul National Univ. (Korea, Republic of); Mi-Ri Choi, Pohang Univ. of Science and Technology (Korea, Republic of); Chan-Woo Jeon, Yun-Hi Kim, Soon-Ki Kwon, Gyeongsang National Univ. (Korea, Republic of)

Multilayered small-molecule organic light-emitting diodes (OLEDs) have been commonly used for balanced charge transport and exciton confinement. However, standard method that uses high-vacuum deposition for multilayered OLEDs entails high material and fabrication cost, and it has been a critical impediment to low-cost production. Solution-processing of small-molecule OLEDs has been considered as a promising method, but limited luminous efficiency of solution-processed OLEDs have also been a hurdle for practical use. Therefore, high-efficiency in solution-processed small-molecule OLEDs with a simple device structure should be developed. Here, we report highly efficient solution-processed simplified OLEDs using novel electron-transporting host materials based on tetraphenylsilane with pyridine moieties. These host materials have high triplet energy levels (> 2.8 eV), wide band gaps (> 4.0 eV), and high glass transition temperature. We additionally used multifunctional polymeric hole injection layer and mixed-host emitting layer to achieve simple device architecture without hole transporting or electron blocking layer. Our novel electron transporting host materials which have higher electron transporting ability and triplet energy levels than that of conventional electron transporting host material (2,2?,2''-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole)) provided more balanced charge transport and efficient energy transfer preventing backward energy transfer from phosphorescent dopants to host. Orange-red (~97.5 cd/A), green (~101.5 cd/A), and white (~74.2 cd/A) solution-processed phosphorescent OLEDs with simple device structure showed the highest recorded electroluminescent efficiencies of solution-processed OLEDs without additional light outcoupling structure reported to date. We also demonstrated a solution-processed flexible solid-state-lighting device as a potential application.

10362-29, Session 7

Elucidating the film structure in organic light-emitting diodes *(Invited Paper)*

Paul L. Burn, Claire Tonnele, Martin Stroet, Tom Lee, Andrew J. Clulow, Jake A. McEwan, Ian R. Gentle, Alan Mark, Ben J. Powell, The Univ. of Queensland (Australia)

Advances in light-emitting materials design and device manufacturing have brought the first organic light-emitting diodes (OLEDs) to market. The most efficient devices are a combination of layers within the active film designed to: 1) balance charge injection and transport; 2) maximise recombination of the singlets and triplets generated in the device; 3) achieve an emissive layer with a high PL quantum yield; and 4) provide enhanced out-coupling of the light generated in the device. Furthermore, during their lifetime time devices undergo electrical and thermal stress and hence it is important to understand what happens within a device during its lifetime. In this presentation we will discuss our approach to understanding the structure of films typically used in OLEDs and their fate under thermal stress. In particular we will focus on a computational approach to understand film structure as well as neutron reflectometry (NR) with in situ photoluminescence measurements for elucidating the relationship between physical structure and emissive properties under thermal stress.

10362-30, Session 7

Unified analysis of transient and steady-state electrophosphorescence: Establishing an analytical formalism for OLED charge balance *(Invited Paper)*

Kyle W. Hershey, Russell J. Holmes, Univ. of Minnesota, Twin Cities (United States)

Under steady-state operation, organic light-emitting devices (OLEDs) often suffer from a reduction in luminescence efficiency. This "efficiency-roll-off" has been previously considered by invoking losses due to bimolecular processes including exciton-exciton annihilation and exciton-polaron quenching. While these efforts have successfully reproduced the steady-state efficiency roll-off, the corresponding transient electroluminescence behavior has not been modeled as effectively using the same approach. Here, we examine steady-state and transient electroluminescence from the archetypical green phosphor tris[2-phenylpyridinato-C2,N]Iridium(III) (Ir(ppy)3). Both the steady-state and transient (rise and decay) behaviors are successfully reproduced by considering a dynamic polaron population in addition to conventional exciton dynamics. Injected polarons may form excitons or leak through the device emissive layer, reducing efficiency. This formalism permits a rigorous connection between exciton and polaron dynamics and OLED charge balance, with the charge balance defined as the exciton formation efficiency. In the devices considered here, charge leakage through the emissive layer dominates the roll-up in efficiency at low current density, while bimolecular quenching is responsible for the majority of the roll-off. This model thus provides a complete picture of the dynamics present during the electrical operation of an OLED, while elucidating the rate and efficiency of exciton formation. Both of these parameters will be of use in more quantitative analyses of device efficiency and operation lifetime.

10362-31, Session 7

Multiscale hopping-type charge transport simulation: the prediction and molecular-level analysis *(Invited Paper)*

Hironori Kaji, Kyoto Univ. (Japan)

Charge transport is one of the most important factors for various devices. However, for organic devices, such as organic light-emitting diodes, charges are transported in amorphous molecular aggregates, and the prediction and detailed analysis has been difficult so far. Here, we show our recent study on multiscale charge transport calculations based on our preceding works[1,2]; the combination of quantum chemical calculations, molecular dynamics simulations, and kinetic Monte Carlo simulations. The calculations are performed by explicitly considering organic molecules, which allows detailed molecular level analysis.

10362-32, Session 8

Highly efficient perovskite LEDs from nanoscale perovskite crystallites *(Invited Paper)*

Barry P. Rand, Princeton Univ. (United States)

Hybrid organic-inorganic perovskite materials such as methylammonium lead iodide (CH3NH3PbI3 or MAPbI3) or methylammonium lead bromide (CH3NH3PbBr3 or MAPbBr3) have garnered significant interest in the thin film optoelectronics community due to their outstanding optical and electrical properties. However, solution processed perovskites commonly suffer from poor thin film quality, reproducibility, stability, and scalability. Our work has determined that the fabrication of perovskite thin films displays all of the hallmarks of sol-gel processing, an aspect that we exploit to improve the quality of spin coated thin films. In particular, we realize films with roughness on the order of 1 nanometer that consist of nanoscale crystallites, formed by incorporating a bulky organoammonium halide in addition to the stoichiometric 3D perovskite precursors. These bulky ligands passivate the 3D crystal, lead to considerably enhanced luminescence quantum yields, and increase stability. LEDs produced in this way are capable of exceeding 10% external quantum efficiency and exhibit significantly improved stability.

10362-33, Session 8

Continuing to explore the unusual properties of hybrid perovskites

Jinsong Huang, Univ. of Nebraska-Lincoln (United States)

There have been many unique and unusual properties been discovered for organic–inorganic halide perovskites which explain the high performance and many unusual characteristics of hybrid perovskite electronic devices. Here I will present our recent advance in studying the several hypothesized properties of hybrid perovskite materials including photon-recycling and ferroelectricity. I will qualify the photon recycling efficiency in hybrid perovskite single crystals by studying the reabsorption and remission efficiency. The recent first observation of abnormal photovoltaic effect in the perovskite solar cells will also be presented, and its origin will be discussed. I will also discuss the verification of ferroelasticity property of hybrid perovskite, but not ferroelectricity.

10362-34, Session 8

Tunable light emitting diodes utilizing quantum-confined layered perovskite emitters

Dan Congreve, Massachusetts Institute of Technology (United States) and Harvard Univ. (United States); Mark Weidman, Michael Seitz, Watcharaphol Paritmongkol, Nabeel Dahod, William A. Tisdale, Massachusetts Institute of Technology (United States)

Organic-inorganic perovskites have revolutionized the optoelectronics field, providing materials with a wide range of properties for solving numerous applications. Indeed, much recent work has been focused on nanostructured perovskites, with quantum dots, nanowires, and nanoplatelets showing tremendous potential. Here, we utilize the unique tunability of 2D perovskite nanoplatelets to build LEDs that span the visible spectrum. Quantum confinement in the z direction drives a significant blueshift, allowing for blue devices utilizing the bromide system and orange devices utilizing the iodide system. We demonstrate that excess ligand addition is crucial to achieving this blueshift in thin films that otherwise suffer from energy funneling. We build devices that show electroluminescence from 440 nm to 650 nm, although they still suffer from low efficiencies due to low photoluminescence quantum yields. We finally demonstrate that these materials suffer from reversible degradation with an applied electric field, further limiting the efficiency. The favorable optoelectronic properties of perovskite materials, combined with the blueshift due to quantum confinement, shows the promise of these materials as a new class of low cost emitters.

10362-35, Session 8

Hybrid perovskite light-emitting field-effect transistors

Francesco Maddalena, Xin Yu Chin, Daniele Cortecchia, Annalisa Bruno, Cesare Soci, Nanyang Technological Univ. (Singapore)

We demonstrate AC-driven, top-contact methylammonium lead iodide perovskite light-emitting field-effect transistors (PeLEFETs) with large electron mobility, high electroluminescence efficiency, uniform emission across the channel area, and operating near room temperature.

Field-effect transistors provide a versatile architecture to increase charge carrier density, mobility and radiative recombination efficiency of light-emitting devices. Using this concept, we recently demonstrated PeLEFETs with balanced ambipolar charge transport and stable electroluminescence at low temperature (below 200 K) [1]. Ionic screening and poor charge transport are the critical issues affecting efficiency and reliability of these devices. Here we prove a tenfold improvement of the field-effect electron mobility (~0.1 cm2V-1s-1) by employing a top-contact FET architecture, and significant reduction of ionic drift/screening by applying AC-driven gate bias, resulting in brighter and more uniform electroluminescence respect to DC-driven PeLEFETs at comparable applied voltages. Most significantly, high-frequency AC operation enables electro-luminescence emission at significantly higher temperatures, approaching room temperature. These results constitute a significant leap forward toward the realization of stable perovskite PeLEFET devices with controllable emission pattern, to be used in active-matrix displays and solid state lighting.

10362-36, Session 8

Halide perovskite/polymer composites for fully printed and multifunctional LEDs

Zhibin Yu, Florida State Univ. (United States)

Recently, astounding optoelectronic properties have been discovered in a group of halide perovskite materials. They share a general ABX3 chemical formula, in which A is a cesium (Cs+) or an aliphatic ammonium (RNH3+) cation, B is a divalent Pb2+ or Sn2+ cation and X is an anion such as Cl-, Br- or I-. Their crystal structures resemble the one commonly found in conventional oxide based perovskite (BaTiO3). The halide perovskites can be processed like polymeric semiconductor materials using solution based processes; and can be coated into large area thin films on arbitrary substrates; they can also be crystallized into three-dimensional periodic structures and behavior like conventional inorganic semiconductors including the superior charge transportation properties.

In this talk, our recent work of developing perovskite/polymer composites towards the realization of fully printable light-emitting diodes (LEDs) will be presented. The perovskite/polymer composites possess all the remarkable optoelectronic characteristics of pure perovskites. For instance, we have demonstrated their use for blue, green and red LEDs. In addition, the device efficiencies exceeded those of pure perovskite LEDs. The perovskite/polymer composites have shown advantages in improving the processability and quality of the perovskite thin films; and enhancing the structural stability of the perovskites especially at highly humid fabrication and service environments. By embedding the perovskite crystals inside a polymer matrix, the perovskites can be less toxic and more environmentally benign compared to pure perovskites. Applications of the perovskite/polymer composites will be discussed towards multifunctional LEDs with ultra-high luminance intensities.

Quantitative analyses of photophysical processes in thermally activated delayed fluorescent emitters

Wei-Kai Lee, Kuan-Chung Pan, Shiu Yi Jiun, Chung-Chih Wu, National Taiwan Univ. (Taiwan)

In addition to phosphorescent transition metal complexes, metal-free luminophores showing efficient thermally activated delayed fluorescence (TADF) are also emerging as attractive and promising alternatives for harvesting both singlet and triplet excitons in organic electroluminescence (EL) to achieve ideal 100% internal quantum efficiency. In order to fully evaluate potentials of a TADF emitter, quantiative analyses of their rate constants for various photophysical processes are essential. In this work, by solving rate equations involving both singlet and triplet states, quantitative relationships between various photophysical rate constants of a TADF emitter and photophysical quantities (such as prompt and delayed fluorescence quantum yields and decay rates) experimentally determined from steady-state and transient photoluminescence measurements, are derived. These quantitative relationships are then used comprehensively to study and establish the correlation of photophysical properties with molecular structures for a few series of TADF emitters, and to provide further insights in design of more effective TADF materials.

10362-49, Session PMon

Conjugation-induced highly efficient thermally activated delayed fluorescence in polymer emitters

Qiang Wei, Leibniz-Institut für Polymerforschung Dresden e.V. (Germany); Paul Kleine, TU Dresden (Germany); Yevhen Karpov, Xianping Qiu, Hartmut Komber, Karin Sahre, Anton Kiriy, Leibniz-Institut für Polymerforschung Dresden e.V. (Germany); Ramunas Lygaitis, Simone Lenk, Sebastian Reineke, TU Dresden (Germany); Brigitte Voit, Leibniz-Institut für Polymerforschung Dresden e.V. (Germany)

Nowadays, thermally activated delayed fluorescence (TADF), used as a novel, efficient concept for light-emitting materials in organic light-emitting diodes (OLEDs) has seen tremendous research efforts. It is widely discussed as an alternative to phosphorescent emitter materials, assuring 100% internal quantum efficiency via effective reverse intersystem crossing (RISC) of barely radiative triplet to emissive singlet states. While many small molecules have been reported to show efficient TADF, reports on polymers sporting TADF are rare. Still, compared with small-molecules, the conjugated polymers excel in low-cost and large-area applications as they allow for “wet“ processability via ink-jet printing, roll-to-roll coating, etc. at low temperatures. However, so far the dominating and simultaneously restrictive strategy in designing of TADF polymers involves the incorporation of known TADF-active building blocks into polymer structures either as pendant groups, as main chain constituents or as core units.

By contrast, we report a novel strategy unlocking an additional molecular design rule reserved exclusively for polymeric materials. A TADF ϖ-conjugated cyclic polymer composed of non-TADF building blocks was developed. Conjugation induced HOMO destabilization leads to a decreased singlet-triplet splitting and efficient TADF in the polymer, while the repeating unit itself shows only inefficient phosphorescence. In comparison to known concepts for TADF-polymers, our work shows for the first time a methodology to design TADF polymers based on non-TADF building units, which significantly enlarges the chemical space for material development. Our research comprises synthesize, detailed quantum chemical calculations and considerations paired with an in-depths time resolved photophysical characterization.

10362-50, Session PMon

Highly efficient fluorescent organic light emitting diodes using a novel blue TADF dopant

Min Hyeong Hwang, Chil Won Lee, Byung-Doo Chin, Dankook Univ. (Korea, Republic of)

Highly efficiency blue organic Light Emitting Diodes (OLEDs) has been researched actively for an achievement of low power consumption at the application of full color display. Conventional fluorescent materials, which can only utilize singlet excitons, exhibit low efficiency characteristics due to the quantum mechanical probability limit of electron excitation. Thermally activated delay fluorescence (TADF) can provide higher efficiency by a management of energy gap between singlet and triplet excitons ; TADF materials with donor-acceptor moieties have a small singlet-triplet energy gap (ΔEST) below 0.3eV. In this study, we designed novel donor-acceptor structure for blue TADF emitters. We have employed carbazole derivative, 7,7-dimethyl-5,7-dihydroindeno[2,1-b]carbazole (DMICz), which has high triplet energy and electron donating properties. 2,4-diphenyl-1,3,5-triazine, 2,4-bis(4-(tert-butyl)phenyl)-1,3,5-triazine and 2,4-bis(4-fluorophenyl)-1,3,5-triazine were used as acceptor units and were connected with DMICz through the para position of the phenyl spacer to produce DMICzTrz, DMICztBTrz and DMICzFTrz, respectively. tert-butyl substituent weakens the electron withdrawing effect of the triazine, and fluorine atom is the substituent that enhances the electron withdrawing property. We synthesized structures that DMICz combined with modified triazine through Buchwald-Hartwig coupling reaction. Also, Optical and electrochemical properties of three TADF materials were examined by Uv-vis, photoluminescence (PL with transient data) and cyclicvoltammetry (CV). We have fabricated the blue OLED device with dopant system using Bis[2-(diphenylphosphino)phenyl]etheroxide (DPEPO) as a host material. As a result, device performance showed the maximum external quantum efficiency of 14.8% and luminous efficiency of 27.0cd/A. Our investigation might provide more chance to develop the high performance OLED device based on TADF blue dopants.

10362-51, Session PMon

Identification of degradation mechanism of organic light emitting diodes based on cyan color thermally activated delayed fluorescence emitter

Cheng Peng, Univ. of Florida (United States); Amin Salehi, Ying Chen, North Carolina State Univ. (United States); Georgios Liaptsis, cynora GmbH (Germany); Franky So, North Carolina State Univ. (United States)

Degradation mechanism is studied on organic light emitting diodes (OLEDs) based on a cyan color thermally activated delayed fluorescence (TADF) emitter with a hole dominant host and hole blocking layer. Photoluminescence (PL) intensity degradation of the OLED is measured during electrical operation at a constant driving current density. A difference is observed between the degradation in PL intensity and electroluminescence (EL) intensity. This difference is attributed to the smaller exciton formation zone compared to the emitting layer thickness. Based on the fitting of the PL and EL losses in a theoretical model, the exciton formation zone length is estimated and compared to same type of OLEDs based on common commercially available TADF emitter. Our results show that the device operational stability in these OLEDs is found to be limited by the narrow exciton formation zone near the emitting layer and hole blocking layer interface due to a poor electron injection or transport property of the emitter.

10362-52, Session PMon

Development of new dopant materials for OLED

Yun-Hi Kim, Soon-Ki Kwon, Gyeongsang National Univ. (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Organic light emitting diodes (OLEDs) have evolved because of their low power consumption and the possibility to fabricate large flat panel displays. Recently, fluorescent dopants are used for blue light emission, and phosphorescent dopants are used for green or red light. In the case of the phosphorescent material as compared with the fluorescent material, both singlet and triplet excitons can be harvested for light emission, and the internal quantum efficiency can achieve 100 %. Recently, the efficient fluorescene blue emitters have been developed by using TTA and TADF. Our group developed various blue emitters. For example, we designed fluorescent emitters with horizontal emitting dipoles using interconnecting units between chromophores. As a result, the new blue fluorescence emitter showed EQE of 6.6% and CIE color coordinates of (0.145, 0.068). We also developed azasiline-based TADF blue emitters. A blue OLED based on azasiline derivatives display CIE coordinates of (0.149, 0.197) with EQE of 22.3%. In addition, we developed high efficient deep blue phosphorescene with EQE of 21.4% and CIE color coordinates of (0.152, 0.148). In here, we will introduce the design strategies for dopant materials for high-efficient and high-color pure OLED.

10362-53, Session PMon

A new class of hole-transporting material for simple-structured phosphorescent OLEDs

Jaemin Lee, Hyejin Na, Korea Research Institute of Chemical Technology (Korea, Republic of); Byung-Jun Jung, The Univ. of Seoul (Korea, Republic of)

With the growth of the OLED industry, there is a growing market demand for various types of organic materials, and development of good hole-transporting materials (HTMs) is still an important issue in OLED research. Especially, in order to prepare effective HTMs for phosphorescent OLEDs, a high enough triplet energy level that can block triplet exciton quenching as well as a well-aligned HOMO energy level with adjacent emitting layer (EML) to facilitate hole-injection/transport should be considered. We have therefore introduced relatively less-explored phenoxazine moiety in designing new HTMs in this work. By adjusting the connection of such phenoxazine moieties, a new HTM candidate, HJ-01, could be successfully prepared. The basic chemical and physical properties of the new HTM were thoroughly investigated by NMR, UV-Vis./PL spectroscopy, cyclic voltammetry and etc. Finally, a series of phosphorescent OLED devices with a configuration of [ITO/HTL/CBP:Ir(ppy)2(acac)/BPhen/LiF/Al] with different HTLs, NPB, TAPC and HJ-01, have been fabricated and characterized. The device using NPB showed low efficiency due to exciton quenching at HTL/EML interface. On the other hand, despite the relatively simple device structure with a single HTL, devices using either TAPC or HJ-01 showed a sufficiently high efficiency of about 60 cd/A. But the maximum luminance of a device containing TAPC was less than one-tenth of that of HJ-01. These results show the superiority and potential of such phenoxazine derivatives including HJ-01 as a HTL. We believe our presentation about experimental procedures and detailed results and discussions can facilitate the development of new OLED materials.

10362-54, Session PMon

Highly efficient solution processed organic light emitting diode using low refractive index electron transport layer

Amin Salehi, North Carolina State Univ. (United States); Szuheng Ho, Univ. of Florida (United States); Ying Chen, North Carolina State Univ. (United States); Cheng Peng, Univ. of Florida (United States); Franky So, North Carolina State Univ. (United States); Daniel Volz, cynora GmbH (Germany); Hartmut Yersin, Univ. Regensburg (Germany)

A low refractive index electron transporting layer (ETL) can be very effective to enhance the out-coupling efficiencies of an organic light emitting diode (OLED). However, most organic films show a high refractive index close to 1.8. In this work, we discovered that tris-[3-(3-pyridyl)mesityl]borane (3TPYMB) has a low refractive index of 1.65 (at 550 nm), which is, to the best of our knowledge, the lowest refractive index among common used ETLs up to date. Using 3TPYMB as an ETL, we demonstrated a solution processed OLED using a novel copper based thermally-activated delayed florescence (TADF) emitter [(2-(Diphenylphosphino)-4-isobutylpyridine)(PPh3)2Cu2I2] (CuI-iBuPyrPHOS), resulting in nearly 80% enhancement in external quantum efficiency (EQE).

Stable core-shell copolymer-perovskite nanohybrids

Shaocong Hou, The Rowland Institute at Harvard (United States); Yuzheng Guo, The Rowland Institute at Harvard (United States) and Swansea Univ. (United Kingdom); Qimin Quan, The Rowland Institute at Harvard (United States)

The stability issue of the emerging lead halide perovskites has placed a grand challenge in their way to practical applications as optical and optoelectronic materials. Here, we demonstrate a facile synthesis approach to achieve core-shell perovskite nanocrystals at nanoscale via copolymer micelle template. In the nanosized micelle of copolymer ligands, the coordinating blocks of copolymer in the core uptake lead precursors and passivate the surface of as-reacted perovskite nanocrystals via multidentate coordinate bonds, while the hydrophobic blocks in the shell provide excellent colloidal stability and resistance from attacks from unfavorable environments.

10362-57, Session PMon

Optical and electric properties of lead iodide-based layered perovskite with self-organized quantum-well structure

Masanao Era, Saga Univ. (Japan); Kazuhiro Ema, Sophia Univ. (Japan); Yasunori Yamada, Saga Univ. (Japan); Kento Mori, Ryoka Systems Inc. (Japan); Norio Tomotsu, Idemitsu Kosan Co., Ltd. (Japan)

In our previous work1, we found that a lead iodide-based layered perovskite with cyclohexenylethyl ammonium molecular cation as an organic layer exhibits highly efficient PL originated from an exciton having large binding energy of several hundred meV. Further, efficient EL was observed in a device having emissive layer of the layered perovskite Here, we would like to present detailed optical properties, electric properties of the layered perovskite.

Kramers-Kronig transformation of reflection spectrum measured using a crystal sample of the layered perovskite demonstrated that an exciton band locates at 2.452 eV at RT. Polarization dependencies of its PL at 4 K revealed that emission bands assigned to singlet-dominant exciton and triplet-dominant exciton are located at 2.408 eV and 2.398eV, respectively. The PL excitation spectrum measured by detecting emission of the triplet-dominant exciton demonstrated the formation of an exciton-polariton in the crystal sample; L-T splitting = 94 meV, transverse exciton energy ET = 2.410 eV, and longitudinal exciton energy EL =2.504 eV. From the values, oscillator strength of the exciton band was estimated to be 0.74, and band gap Eg and binding energy Eb of the exciton were estimated to be 2.68 eV and 282 meV, respectively. The PL quantum efficiency was evaluated to be about 0.7 at 110 K from the quantum efficiency measurement using integrated optical sphere.

We also report electronic properties and properties expected from its band structure calculated by quantum mechanical calculation in this presentation.

Charge-exciton interaction rate in organic field-effect transistors by means of transient photoluminescence electromodulated spectroscopy

Stefano Toffanin, Istituto per lo Studio dei Materiali Nanostrutturati (Italy); Wouter A. Koopman, Univ. Potsdam (Germany); Marco Natali, Giovanni P. Donati, Michele Muccini, Istituto per lo Studio dei Materiali Nanostrutturati (Italy)

Charge-exciton interaction is the main dominating mechanisms limiting the efficiency in Organic Light-emitting Transistors (OLETs). Thus, a comprehensive physical understanding of this detrimental process in charge accumulation devices is mandatory in order to unlock the technological potentiality of OLETs in real-setting applications. We have recently introduced a novel confocal microscopy method for mapping the charge density spatial distribution in OFETs based on the photoluminescence electro-modulation (PLEM) [1]. Here, we implement time-resolved PLEM spectroscopy on the picosecond timescale to investigate throughout the charge-exciton interaction in organic transistors [2]. The results show that the injected charges reduce the exciton radiative recombination in two ways: (i) charges may prevent the generation of excitons and (ii) charges activate a further non-radiative channel for the exciton decay. Moreover, the measurements clearly reveal that not only trapped charges, as it was already reported in literature, but rather the entire injected charge density contributes to the quenching of excitons. Finally, the kinetic model that we propose can be generalized to all the devices based on the field-effect transistor platform given that it relies on generic description of the charge accumulation and charge-exciton interaction processes.

Based on these insights we suggest possible measures to achieve high exciton density in OLETs, which might foster the development of high brightness OLETs.

Universal charge carrier generation layers for all-solution processed, highly efficient tandem OLEDs

Stefan Höfle, Min Zhang, Christian Kayser, Alexander Colsmann, Karlsruher Institut für Technologie (Germany)

Common tandem OLEDs comprise charge carrier generation layers (CGLs) from high-work function PEDOT:PSS and low-work function ZnO, only allowing the implementation of inverted device architectures (bottom cathode). Any attempt to incorporate a ZnO/PEDOT:PSS CGL into tandem OLEDs with regular architecture (bottom anode) would inevitably lead to a dissolution of ZnO in the acidic PEDOT:PSS. In this work, we developed novel CGLs based on solution processed metal oxides that simultaneously form a barrier for subsequently used processing agents and are robust towards the use of acidic components. Therefore, they can be universally employed in regular and inverted tandem OLEDs comprising fluorescent polymers as well as small-molecule triplet and TADF emitters. In total, 11 layers were sequentially processed from solution, including charge carrier injection, transport and blocking layers, yielding maximum current efficiencies of 200 cd/A.

Since every injected electron-hole pair generates two photons, the luminance and the current efficiency of the tandem OLED at a given device current are doubled (versus a reference single OLED) while the power efficiency remains constant. At a given luminance, the lower operating current in the tandem device reduces electrical stress and improves the device life-time.

Transparent electrode of silver network fabricated by using cracks of polymers as templates

Beom Sun Choy, Jeong Hui Lee, Oh Young Kim, Ho Jong Kang, Dong Hyun Lee, Dankook Univ. (Korea, Republic of)

A highly transparent electrode was fabricated using silver networks embedded in an elastomeric substrate. To prepare the porous templates of silver(Ag) inks, a brittle silica-like layer was initially produced by UV/ozone treatment and sequentially bent with certain strain to create well-controlled cracks. Average crack spacing could be accurately controlled by changing bending strains. It was found that the crack spacing was influenced by relative thickness of the brittle layer to the flexible layer, UV/ozone dose and moduli of substrates. Then, conductive silver inks were filled into the cracks by sliding a glass blade on the surface and thermally sintered to create silver networks, which were directly used as electrodes. In addition, the silver networks were simply transferred to flexible substrates by placing adhesive tapes on the silver networks and immediately peeling them off. Finally, AC voltage-driven light-emitting devices based on an ECL electrolyte consisting of $Ru(bpy)_3^{2+}$ (ECL luminophore) and [EMI][TFSI] (ionic liquid) were demonstrated by applying the silver networks as electrodes.

Organic light-emitting diodes with polyethylenimine as a solution-processed electron injection layer: Operational stability and degradation mechanisms

Sebastian Stolz, Karlsruher Institut für Technologie (Germany) and InnovationLab GmbH (Germany); Yingjie Zhang, Univ. of Waterloo (Canada); Ulrich Lemmer, Karlsruher Institut für Technologie (Germany); Gerardo Hernandez-Sosa, Karlsruher Institut für Technologie

(Germany) and InnovationLab GmbH (Germany); Hany Aziz, Univ. of Waterloo (Canada)

The fabrication of organic light-emitting diodes (OLEDs) by printing techniques requires the development of solution-processable electron injection layers (EILs). Over the last few years, amine-based EIL materials like Polyethylenimine (PEI) have received a lot of attention as they can be used with a multitude of electrode materials.1–3

In this work, we investigate the operational stability of OLEDs, which use PEI as EIL, and we show that the cathode metal that is in contact with the EIL plays a crucial role for the device lifetime. In case of Al, the primary degradation mechanism during electrical driving is caused by excitons which reach and subsequently degrade the emitter/PEI interface. At a current density of 20 mA cm-2, an LT50 lifetime of ~ 200 h is achieved. In contrast, in case of Ag, an additional mechanism degrades the OLEDs; during operation holes accumulate at the emitter/PEI interface and as a result the emitter quantum yield drops. Consequently, the operational lifetime of such OLEDs is significantly shorter with an LT50 value of < 10 h. Finally, we show that the degradation by excitons can be significantly slowed down by the use of a PEI:ZnO composite EIL. As a result, the LT50 lifetime of OLEDs with an Al cathode is increased by a factor of five, without adversely affecting OLED performance.

To eliminate coffee ring effect during Inkjet printing of functional polymers for PLED

Yanchun Han, Changchun Institute of Applied Chemistry (China)

Organic/polymer light emitting diodes (O/PLEDs) have been attracting much attention due to their high brightness, wide viewing angle, low power consumption and good contrast. Inkjet printing is considered one of the most promising technology in the field of controlled deposition of polymers and functional materials in well-defined patterns, especially in relation to the fabrication of multicolor OLED displays. For OLED displays, the accuracy and uniformity of organic layer thickness is an important manufacturing issue. This talk will attempt to answer questions about how to eliminate coffee ring effect and improve film uniformity of inkjet printed films by low surface tension of PEDOT inks, suppression the outer-flow and edge deposition of poly (spirobifluorene) by the addition of co-solvent with high boiling point and high viscosity. By improving the uniformity of the film thickness, the performance of devices with ink-jet printed poly (spirobifluorene) film can reach 70% of the spin-coated devices.

Simulation of exciton effects in OLEDs based on the master equation

Weifeng Zhou, Christoph Zimmermann, Christoph A. Jungemann, RWTH Aachen Univ. (Germany)

The luminous efficiency of OLEDs greatly depends on the doping profile in the emission layer (EL). To investigate this effect, occupancies of singlets and triplets are calculated with an extension to our numerical bipolar master equation model. Both Foerster and Dexter energy transfer of excitons are included and exciton energy equals the bandgap between LUMO and HOMO reduced by a binding energy. Exciton dissociation into free carriers involves an escape of the bound electron or hole at a donor-acceptor pair. Radiative and non-radiative decay, inter-system crossing, exciton-polaron quenching and triplet-triplet annihilation are all included with respective lifetimes. Based on appropriate parameters, the IV measurements of OLEDs, with a PH1 EL doped by Irppy and sandwiched between NPB and Alq as hole and electron transport layer (HTL and ETL) respectively, are well simulated in the space-charge-limited-current regime. For the OLEDs with higher constant dopant concentrations, excitons are produced in a broader region at the anode side of the EL, leading to lower exciton diffusion into the adjacent HTL and higher efficiencies. The efficiency roll-off of the OLED with 30% constant dopant may originate from exciton diffusion into the ETL and dopant-assisted dissociation. The best luminous performance is achieved by a graded dopant concentration from 30% at the anode to 0% at the cathode side of the EL with the merits of broad exciton distribution within and confined to the EL.

Monte Carlo simulation of OLEDs by hopping conduction in the distributed density of state

Mun Chae Yoon, Il Hoo Park, Jinyoung Yun, Gyutae Kim, Korea Univ. (Korea, Republic of)

The light emission from organic light emitting diodes (OLEDs) is closely related to the electrical characteristics of the organic layers constituting OLEDs. Therefore, it is important to investigate and analyze the electrical parameters of the organic layers for improving the performance of OLEDs.

Unlike crystalline materials in conventional semiconductors, organic materials hardly form a continuous energy band. The analysis methods in conventional inorganic semiconductors cannot be applied to organic devices, requiring properly modified method considering the physical and chemical characteristics of organic materials.

However, carrier injection and transport mechanisms determining the electrical characteristics of OLEDs are not clearly confirmed. Especially, space charge limited conduction (SCLC) and hopping conduction are referred as dominant transport mechanism in organic materials. But, those studies are lack of enough explanation on the distribution of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO), which are closely related to electrical characteristics of organic materials.

In this paper, a Monte Carlo simulation model based on the hopping transport through organic layers is suggested. This model considers the distribution of HOMO/LUMO levels in OLEDs for the realistic disordered states. The tunneling event is considered as carrier injection or extraction with hopping of carriers among the HOMO/LUMO levels as carrier transports in the organic materials.

The validity of the model will be verified by comparing I-V curve, light spectrum and noise characteristic of the model with the real OLED devices.

Boosting OLED efficiency by blending: spectroscopic identification of reduced charge trapping

Elham Khodabakhshi, Gert-Jan Wetzelaer, Paul W. M. Blom, Jasper Michels, Max-Planck-Institut für Polymerforschung (Germany)

Many polymeric semiconductors of use in organic light-emitting diodes (OLEDs) are known to suffer from a strongly suppressed electron current due to the presence of trap states within the bandgap. As a consequence, the electron current density may well be several orders of magnitude lower than the holes current density. This unbalanced charge transport limits the efficiency of the device. An important loss process is so-called trap-assisted recombination, where holes non-emissively recombine with trapped electrons. Very recently, we have experimentally shown that if the traps are distributed in energy or sufficiently deep, their negative effect can be eliminated by spatially separating the charge accommodation sites via dilution of the semiconductor in an insulating host material, such as polyvinyl carbazole (PVK) or polystyrene (PS). The observed increase in electron current and luminous efficiency validates long standing theoretical predictions. In this contribution, we present an analogous study based on the blue emitter poly(9,9-dioctylfluorene) (PFO), as it provides the possibility of directly visualizing the reduction of charge trapping green emission upon blending. This feature is obtained when the PFO contains a small fraction of fluorenenone monomers, which represent emissive trap states whilst integrated in the polymer backbone. Our results show that by blending disordered emitters with affordable insulating materials, electron and hole transport become balanced, leading to increased OLED efficiency by reducing both the radiative and non-radiative trap assisted recombination. Hence, our method may pave the way to cost-effective large scale production of highly efficient OLEDs.

Effect of dopant polarity on the recombination mechanism in organic light-emitting diodes

Chang-Heon Lee, Jeong-Hwan Lee, Kwon-Hyeon Kim, Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

The recombination of charges is an important process in photonic devices such as organic light-emitting diodes (OLEDs) and organic photovoltaics because the process influences characteristics such as the driving voltage, efficiency and lifetime. Until now, trap depth has been considered the most important factor determining the recombination mechanism. Recombination at dopant becomes dominant if the dopant acts as deep trap site. Therefore, trap-assisted recombination is known as the dominant mechanism in phosphorescent dye-doped OLEDs (PhOLEDs) because the energy levels of the dopants are located deep compared with the host energy levels and act as trap sites. By contrast, there have been reports that some PhOLEDs with deep trap depths have Langevin-dominant characteristics. Unfortunately, the reason why Langevin recombination is dominant in these devices has not been determined. Here we report that the dipole moment of the dopant is a major factor influencing the recombination mechanism in dye-doped organic light-emitting diodes(OLEDs). Introducing dipole trap theory into the drift-diffusion model revealed that dipole moment becomes a major factor determining the recombination mechanism if trap depth is > 0.3 eV where any detrapping effect becomes negligible. Our experimental results showed that homoleptic Ir complexes possessing large dipole moments, exhibited trap-assisted recombination-dominant characteristics and that heteroleptic Ir complexes with small dipole moments exhibited Langevin recombination-dominant characteristics. Dopants with larger dipole moments can readily trap a charge with stronger Coulomb attraction, which in turn boosts trap-assisted recombination.

Electrical degradation model of OLEDs depending on driving conditions

Ilhoo Park, Korea Univ. (Korea, Republic of)

OLEDs are widely used in display application because they are cheap and efficient in power consumption. By optimizing the materials and the designs, manufacturers can tune the electrical and opto-electronic properties of OLEDs. The opto-electronic properties of OLEDs are also changed by external conditions such as temperature, DC bias, defects, etc..

Reliability and lifetime are important issues in OLEDs, which have been improved by managing cleanliness and evaporation circumstance in fabrication. However, degradations occurs with the appearance of dark spots initiated by small pinholes, which is still the important problem to overcome. Therefore accurate evaluation of performance and lifetime is still required.

The researches on the degradation of OLEDs with secondary effects of dark spots were reported. The size of dark spot were reported linearly increase with the constant current through the OLEDs. The pinholes made during the process of the manufacture is known to play a major role in degradation phenomena owing to the possible intrusion of water and oxygen through the pinholes.

In this paper, we investigated the correlation of the degradation of OLEDs with the growth of dark spots under different conditions such as drive current, temperature, etc. By impedance analysis, the resistance and the capacitance of OLEDs are extracted depending on the bias condition. The resistance increased and the capacitance decreased as time increased.

We suggest more realistic model with environmental and time dependent parameters in the equivalent circuit model of OLEDs. By considering the growth effects of dark spots, we can evaluate and design the performance and lifetime more accurately.

Achievement of long device lifetime by decreasing dipole moment of hole-blocking layer

Ko Inada, OPERA Ctr. for Organic Photonics and Electronics Research (Japan) and Japan Science and Technology Agency (JST), ERATO, Adachi Molecular Excton Engineering Project (Japan); Hiroshi Fujimoto, i3-OPERA (Japan) and OPERA Ctr. for Organic Photonics and Electronics Research (Japan); Masayuki Yahiro, Institute of Systems, Information Technologies and Nanotechnologies (ISIT) (Japan) and i3-OPERA (Japan) and OPERA Ctr. for Organic Photonics and Electronics Research (Japan); Satoshi Yukiwaki, i3-OPERA (Japan); Keiko Kusuhara, OPERA Ctr. for Organic Photonics and Electronics Research (Japan) and Japan Science and Technology Agency (JST), ERATO, Adachi Molecular Exciton Engineering Project (Japan); Nozomi Nakamura, OPERA Ctr. for Organic Photonics and Electronics Research (Japan) and International Institute for Carbon Neutral Energy Research (WPI-I2CNER) (Japan); Atula S. D. Sandanayaka, OPERA Ctr. for Organic Photonics and Electronics Research (Japan) and Japan Science and Technology Agency (JST), ERATO, Adachi Molecular Excton Engineering Project (Japan); Chihaya Adachi, OPERA Ctr. for Organic Photonics and Electronics Research (Japan) and International Institute for Carbon Neutral Energy Research (WPI-I2CNER) (Japan) and Japan Science and Technology Agency (JST), ERATO, Adachi Molecular Excton Engineering Project (Japan)

We applied extremely pure 2,4,6-tris(biphenyl-3-yl)-1,3,5-trazine (T2T) as the hole-blocking layer in organic light-emitting diodes (OLEDs) with an emission layer of 3,3-di(9H-carbazol-9-yl)biphenyl (mCBP) as host and (4s,6s)-2,4,5,6,-tetra(9H-carbazole-9-yl)isophthalonitrile (4CzIPN) as guest. Even though the current-density–voltage characteristics and external quantum efficiencies were the same as for devices using T2T with typical purities, the lifetimes were approximately nine-times longer for OLEDs with the extremely pure T2T. The dominant impurities affecting lifetime were determined to be chlorine-containing T2T derivatives having large dipole moments, which cause the charging of host and guest molecules in the emission layer near the interface with the hole-blocking layer. Density function theory calculations support that the degradation occurs through the charged host and guest molecules.

High thermal stability OLEDs

Jared S. Price, Baomin Wang, Yufei Shen, Noel C. Giebink, The Pennsylvania State Univ. (United States)

Reliability remains an ongoing challenge for organic light emitting diodes

(OLEDs) as they expand in the marketplace. The ability to withstand operation and storage at elevated temperature is particularly important in this context, not only because of the inverse dependence of OLED lifetime on temperature, but also because high thermal stability is fundamentally important for high power/brightness operation as well as applications such as automotive lighting, where interior car temperatures often exceed the ambient by 50°C or more. Here, we present a strategy to significantly increase the thermal stability of small molecule OLEDs by co-depositing an additive that stabilizes their morphology and prevents crystallization. Using this approach, we demonstrate that the thermal breakdown limit of common electron and hole transport materials can be increased from typical temperatures of ~100°C to more than 200°C with minimal impact on their electrical transport properties. Similar enhancements are demonstrated in complete OLEDs ranging from simple bilayer fluorescent to multilayer phosphorescent devices. The generality of our approach points toward a new class of thermally robust and morphologically-stable organic electronic devices that are capable of operating or being stored in extreme thermal environments.

Kirigami-based three-dimensional OLED concepts for architectural lighting

Taehwan Kim, Jared S. Price, Alex Grede, Sora Lee, Thomas N. Jackson, Noel C. Giebink, The Pennsylvania State Univ. (United States)

Dramatic improvements in white organic light emitting diode (OLED) performance and lifetime over the past decade are driving commercialization of this technology for solid-state lighting applications. As white OLEDs attempt to gain a foothold in the market, however, the biggest challenge outside of lowering their manufacturing cost arguably now lies in creating an architecturally adaptable form factor that will drive public adoption and differentiate OLED lighting from established LED products. Here, we present concepts based on kirigami (the Japanese art of paper cutting and folding) that enable intricate three-dimensional (3D) OLED lighting structures from two dimensional layouts. Using an ultra-flexible, encapsulated OLED device architecture on 25 ?m thick clear polyimide film substrate with simple cut and fold patterns, we demonstrate a series of different lighting concepts ranging from simple pyramidal shapes to more complex artistic designs such as stretchable window blind-like panels, multi-element globes, and candle flames. We only find slight degradation in OLED electrical performance when these designs are shaped into 3D and, because they naturally pack more OLED active area into the footprint of a traditional flat panel, these 3D OLED designs effectively enable higher luminance to be achieved at a given device current density. Our results point to an alternate paradigm for OLED lighting that moves beyond traditional 2D panels toward 3D designs that deliver unique and creative new opportunities for lighting.

How to distinguish scattered and absorbed light from re-emitted light for solid-state lighting?

Maryna L. Meretska, Ad Lagendijk, Henri N. Thyrrestrup, Allard P. Mosk, Univ. Twente (Netherlands); Wilbert L. IJzerman, Philips Lighting B.V. (Netherlands); Willem L. Vos, Univ. Twente (Netherlands)

Energy efficient generation of white light has become an important issue in recent years. Technology of white-light emitting diodes (LEDs) is one of the promising directions. The main challenges in the LED production are understanding scattering, absorption and emission from ab-initio, and obtain chromaticity independent emission directions. Physical understanding of multiple light scattering in the LED can provide us with simple tools for extracting optical parameters of this system.

We have studied the transport of light through phosphor diffuser plates that are used in commercial solid-state lighting modules (Fortimo). These polymer plates contain YAG:Ce+3 phosphor particles that both elastically scatter light and Stokes shift light in the visible wavelength range (400-700 nm). We excite the phosphor with a narrowband light source, and measure spectra of the outgoing light. The Stokes shifted light is spectrally separated from the elastically scattered light in the measured spectra. Using this technique we isolate the elastic transmission of the plates. This result allows us to extract the transport mean free path ltr over the full wavelength range by employing diffusion theory. Simultaneously, we determine the absorption mean free path labs in the wavelength range 400 to 530 nm where YAG:Ce+3 absorbs. The diffuse absorption (μ_a=1/l_abs) spectrum is qualitative similar to the absorption coefficient of YAG:Ce+3 in powder, with the diffuse spectrum being wider than the absorption coefficient. We propose a design rule for the solid-state lighting diffuser plates.

10362-72, Session PMon

Semi-transparent vertical organic light emitting transistors based on a perforated indium-tin-oxide source electrode

Szuheng Ho, Univ. of Florida (United States); Hyeonggeun Yu, Nilesh Barange, Ryan Larrabee, Franky So, North Carolina State Univ. (United States)

Transparent or semi-transparent devices have found more versatile applications with the growing interest in smart gadgets. Vertical organic light emitting transistors (VOLETs), whose architecture features a vertical integration of a light emitting unit and the switching transistor, stand out as a novel device for transparent displays with high aperture ratio and low power consumption. However, the transparent VOLET hasn't been demonstrated because it is difficult to control the suitable roughness and obtain high transmittance from the thin metal source electrode. Herein, we for the first time fabricate semi-transparent VOLETs using indium tin oxide (ITO) source electrode. The maximum luminance and current efficiency are 500 cd/m2 and 8.8 cd/A on the bottom side, and 250 cd/m2 and 4.6 cd/A on the top side, which are the highest among the reported transparent organic light emitting transistors. With a porous ITO source electrode, the enhanced light extraction is observed and confirmed with a finite-difference time-domain simulation. Furthermore, the correlation between channel layer thickness and luminance ratio of bottom to top is investigated. The results presented here offer a new device approach for transparent displays.

Experimental investigating distinguishable and non-distinguishable grayscales applicable in active-matrix organic light-emitting diodes for quality engineering

Henglong Yang, Wen-Cheng Chang, Yu-Hsuan Lin, Ming-Hong Chen, National Taipei Univ. of Technology (Taiwan)

The distinguishable and non-distinguishable grayscales of green and red organic light-emitting diode (OLED) with 64 (6-bit) grayscale control were experimentally investigated by using high-sensitive photometric instrument. The feasibility of combining external detection system for quality engineering to compensate the grayscale loss based on preset grayscale table as OLED degraded during operation was also investigated by SPICE simulation. Although active-matrix organic light-emitting diode (AMOLED) has been used in smart phones and TV, degradation phenomena caused by thin-film transistor (TFT) circuitry or OLED itself are major quality issues. The degradation loss of OLED deeply affects image quality as grayscales become inaccurate. The brightness of OLED is linearly dependent on driving current in general. The distinguishable grayscales are indicated as those brightness differences and corresponding current increments are differentiable by instrument. The grayscales may become non-distinguishable as current or voltage increments are in the same order of noise level in circuitry. The distinguishable grayscale tables for individual

red, green, blue, and white colors can be experimentally established as preset reference for quality engineering (QE) in which the degradation loss is compensated by corresponding grayscale numbers shown in preset table. The degradation loss of each OLED colors is quantifiable by comparing voltage increments to those in preset grayscale table if precise voltage increments are detectable during operation. The QE of AMOLED can be accomplished by applying updated grayscale tables. Our preliminary simulation result revealed that it is feasible to quantify degradation loss in terms of grayscale numbers by using external detector circuitry.

10362-74, Session PMon

White emission based on excimer emission control of triple core chromophores

Hyocheol Jung, Kyung Hee Univ. (Korea, Republic of); Jaehyun Lee, Kyoto Univ. (Japan); Hwangyu Shin, Joonghan Kim, The Catholic Univ. of Korea (Korea, Republic of); Daisuke Yokoyama, Yamagata Univ. (Japan); Hidetaka Nishimura, Atsushi Wakamiya, Kyoto Univ. (Japan); Jongwook Park, Kyung Hee Univ. (Korea, Republic of)

Three triple-core chromophore derivatives based on anthracene and pyrene or chrysene moieties were synthesized and characterized. All three materials showed highly twisted core structures and exhibited excimer emission when prepared as a film. Excimer emission makes single molecular white emission possible, and can be interpreted by anisotropic intermolecular alignment (orientation effect). The maximum wavelength of excimer emission was controlled by varying the core chromophore at the center position of the triple-core chromophore, with excimer emission of 1,6 DAP-TP, DAC-TP, and 2,7 DAP-TP occurring at 591 nm, 556 nm, and 537 nm, respectively. When the three materials were used as an OLED emitting layer, the CIE coordinate values of 1,6 DAP-TP, DAC-TP, and 2,7 DAP-TP were (0.37, 0.31), (0.30, 0.37), and (0.32, 0.44), respectively, indicating white emission. Especially, the device based on 2,7 DAP-TP acted as a WOLED with a high efficiency of 6.01 cd A-1 at 10 mA cm-2. The present findings demonstrate that triple-core chromophores composed of various chromophores can be applied in OLED lighting applications.

10362-75, Session PMon

High-efficiency orange-red organic electrophosphorescent devices with excellent operational stability

Pang-Chi Huang, Meng Hao Chang, Jin-Sheng Lin, Mei-Rurng Tseng, Industrial Technology Research Institute (Taiwan)

A novel orange-red phosphorescent iridium complex PR-24 has been successfully synthesized and characterized. By using this material, we demonstrated the high-efficiency OLED devices. The best efficiency was achieved for a device using PR-24 as the dopant, exhibiting 25.8 cd/A current efficiency, 20.0 lm/W power efficiency and 15.9% EQE at 1000 cd/m2. Moreover, when using the optimized co-host configuration, PR-24 shows a remarkable lifetime T50 of 211,000 h for an initial luminance of 1000 nits.

10362-76, Session PMon

White electroluminescence from single polymers with high power efficiency

Shiyang Shao, Changchun Institute of Applied Chemistry (China)

White electroluminescence from a single polymer represents an approach to realize low-cost plastic-based lighting application without the risk of phase segregation that is observed for the conventional physical blend systems. However, the molecular design of single white-emitting polymers (SWPs) is challenging and their performance is yet far from practical application.

This presentation will discuss some new design concepts toward high power efficiency SWPs: (1) non-conjugated polyarylether hosts showing both high triplet energy and bipolarity; (2) all-phosphorescent SWPs with power efficiency comparable with that of fluorescent lamps.

Different from the conventional conjugated polymer hosts (PFs, PCzs and so on) and PVK host, non-conjugated polyarylether hosts, namely poly(arylene ether phosphine oxide) hosts are designed for white phosphorescent OLEDs. These hosts feature a triarylphosphine oxide-containing main chain and carbazole-containing side chain, giving both high triplet energy (2.96 eV) and bipolarity.

On the basis of the polyarylether hosts, all-phosphorescent SWPs are designed by combining a high-energy-level blue phosphor with a high HOMO-level polyaryl ether host to achieve power efficiency comparable with that of fluorescent lamps (>40 lm/W). The role of the high-energy-level blue phosphor is to eliminate the hole scattering between the blue phosphors and polymer hosts, while the high HOMO-level polyaryl ether host is to reduce the hole injection barrier from the anode to the host, which both lead to a low driving voltage of <3.0 V.

Controlling preferential alignment of heteroleptic phosphors in organic guest-host systems via film preparation parameters

Thomas Lampe, Philippe Linsmayer, Tobias D. Schmidt, Wolfgang Brütting, Univ. Augsburg (Germany)

The preferential alignment of organic small molecules in thin films is a very promising approach to increase the efficiency of organic light emitting devices. In this work we focus on the molecular orientation of heteroleptic Ir-complexes embedded in different organic host systems. While the underlying mechanism for the horizontal alignment in films prepared from evaporation techniques has already been described[1], we have recently performed experiments suggesting various contributing interactions, which can be identified from the preparation via solution processing. The results indicate dependence not only on the preparation technique itself but also on the dopant concentration as well as thermal post-deposition treatments. From the experiments we conclude on the contribution of three alignment mechanisms[1–3] to the film morphology, having different effects on the dye orientation. While the interaction of the heteroleptic complexes with the aromatic film surface is dominant during step-by-step deposition such as thermal evaporation[1], in solution processed films the alignment seems to be determined by host-dopant[2] and dopant-dopant[3] related processes. The results provide a better understanding of the orientation of heteroleptic Ir-complexes, thus having important impacts on the improvement of device efficiency.

Probing molecular orientation of organic molecules for organic light-emitting diode applications

Johnny K. W. Ho, Hong Kong Baptist Univ. (Hong Kong, China); Sai Wing Tsang, City Univ. of Hong Kong (Hong Kong, China); Shu Kong So, Hong Kong Baptist Univ. (Hong Kong, China)

Molecular orientation is found to be one of the factors in the out-coupling efficiency in organic light-emitting diodes. Studies based on optical methods are commonly used to measure the orientation order parameter and the preferred orientation, but the origin of such orientation is yet clear. We present here probing the preferred orientation with electrical approach by organic thin-film transistors (OTFTs). The carrier mobility of OTFT is dominated by the orientation of first few monolayers of the active layer in contact with the gate dielectric, which can be used to study the impact of molecular orientation. The interfacial dipoles of the gate dielectic plays a significant role in altering the molecular orientation. The influence of carrier mobility between different organic and iridium-based molecules with controlled ordered and random orientation was studied and the negative correlation between the carrier mobility ratio and degree of preferred molecular orientation was demonstrated.

Controllable random nano-structures for organic light-emitting diodes

Yungui Li, TU Dresden (Germany); Milan Kova?i?, Univ. of Ljubljana (Slovenia); Paul-Anton Will, TU Dresden (Germany); Jasper Westphalen, Fraunhofer-Institut für Organische Elektronik, Elektronenstrahl- und Plasmatechnik (Germany); Manuela Junghähnel, Fraunhofer-Institut für Organische Elektronik, Elektronenstrahl- und Plasmatechnik FEP (Germany); Steffen Oswald, Leibniz-Institut für Festkörper- und Werkstoffforschung Dresden (Germany); Simone Lenk, Sebastian Reineke, TU Dresden (Germany)

Here, we report on controllable random nano-structures for light outcoupling in bottom-emitting organic light-emitting diodes (OLEDs). Wrinkle structures are generated by reactive ion etching (RIE) on polydimethylsiloxane (PDMS) and are randomly distributed on the entire surface with a periodicity distribution from 60 nm to more than 1000 nm. By optimizing the PDMS pretreatment conditions and RIE treatment recipes, we can reliably control the wrinkle geometry both in periodicity distribution and depth. We will discuss the physical reason why we can control the random wrinkle structures by using X-ray photoelectron spectroscopy of the RIE treated surface composition and dynamic mechanical analysis of various PDMS pretreatment conditions. We further obtain structures with a fixed periodicity distribution peaking at around 300 nm and different depth from 60 nm to 140 nm. OLEDs on wrinkle structures provide a better color stability with increasing viewing angle. To analyze the OLED emission, we bring together finite element method for thin organic films in the thick incoherent layers and at the structured surface. Therefore, the wrinkle structures are assumed to be a combination of sinusoidal wave patterns with different periodicity. OLEDs based on these wrinkle structures show enhanced light outcoupling. Simulation shows external quantum efficiency increases from about 20% for the planar device to 47% for buckled device.

How high can the external quantum efficiency of OLEDs become by a scattering approach?

Jinouk Song, KAIST (Korea, Republic of); Kwon-Hyeon Kim, Seoul National Univ. (Korea, Republic of); Eunhye Kim, KAIST (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of); Seunghyup Yoo, KAIST (Korea, Republic of)

Increasing the external quantum efficiency (EQE) of OLEDs is a key agenda not only for display and general lighting but also for emerging applications such as automotive and wearable electronics. Several efforts have been made to realize OLEDs with high EQE by, for instances, using emitters with preferred horizontal dipole orientation or by taking advantage of cavity resonant effect [1,2]. However, these EQE values are still smaller than those of inorganic counterparts. In order to accomplish ultimately high EQEs yet without incurring too high fabrication cost, it is essential to introduce a light extraction structure that is practically viable and cost-effective. In this regard, an approach based on light-scattering layers has been of significant interest and proven quite effective. Nevertheless, there have been few studies that try to predict the maximum-achievable efficiency by considering both a base OLED structure and the effect of a scattering layer. Such study would be important because it is often challenging, even with a light-extraction structure, to further improve the EQE of already efficient OLEDs, which calls for more delicate and systematic design.

Hence, we here adopt a trans-scale simulation [3] to provide one with a global, bird-eye view on the EQE of OLEDs equipped with a scattering layer. The trans-scale simulation is done by combining a classical dipole model for a base, multilayer structure and a radiative transfer theory for the optical effect of a scattering layer. The latter, in particular, is based on equations rather than Monte-Carlo approach [3], making it easy to integrate two different domains and enable a fast, global simulation. Our study reveals that EQE over 50% is feasible when a scattering medium with forward-intensive scattering particles is combined with an emitter having a high horizontal dipole ratio.

Inkjet-printed polymer-based scattering layers for enhanced light outcoupling from top-emitting organic light-emitting diodes

Armin Heinrichsdobler, OSRAM OLED GmbH (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Manuel Engelmayer, OSRAM OLED GmbH (Germany) and Univ. Augsburg (Germany); Daniel Riedel, OSRAM OLED GmbH (Germany) and Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Christoph J. Brabec, Friedrich-Alexander-Univ. Erlangen-Nürnberg (Germany); Thomas Wehlus, OSRAM OLED GmbH (Germany)

High refractive index polymer-based scattering layers used as internal light extraction layers are a promising low-cost approach to enhance the luminous efficacy of organic light-emitting diodes (OLEDs). In order to avoid damaging of the OLED layers a structured and contactless deposition method for the polymer-based scattering layers is required. For enhanced lifetime of the devices water diffusion through the scattering layer has to be eliminated by a structured patterning technique. Inkjet printing offers both a contactless and structured deposition.

In this study we evaluate inkjet printing of nanocomposite polymer-based scattering layers for OLEDs. A detailed view on the material and process development is given. This involves an optimization of ink formulation, printing parameters as well as layer formation. The resulting haze values of the scattering layers vary between 40% and 90% for different layer thicknesses. The gain in external quantum efficacy of top-emitting OLEDs induced by light scattering compared to reference devices peaks at a factor of 2.3

The obtained results are discussed and verified by an optical volume scattering simulation model which will be presented in full detail. Also a parameter variation study and its impact on extraction efficiency will be shown.

Complex 3D photonic films used as external diffractive layer to improve blue OLEDs

Michal Mruczkiewicz, Univ. Bordeaux 1 (France); Frederic Dumur, Aix-Marseille Univ. (France); Mathias Perrin, Univ. Bordeaux 1 (France); Arthur Bertrand, Univ. de Pau et des Pays de l'Adour (France); Stéphane Reculusa, Institut des Sciences Moléculaires-NSysA (France); Christine Dagron-Lartigau, Antoine Bousquet, Univ. de Pau et des Pays de l'Adour (France); Lurence Vignau, Univ. Bordeaux 1 (France); Laurent Billon, Univ. de Pau et des Pays de l'Adour (France); Sophie Fasquel, Univ. Bordeaux 1 (France)

Blue OLEDs are essential to fabricate efficient color displays, but have a relatively low efficiency. Indeed, the produced light is strongly coupled to the optical modes of the metallo-dielectric stack waveguide, and tend to remain inside the medium of high optical index. Typically, only 20% of the electrogenerated photons are coupled to free space. To extract more light, several methods have been proposed, from the internal structuration of the organic layers, to the addition of an external diffractive layer made of micro-lenses or disordered structures.

Internal structuration of the OLED yields high improvements of the external quantum efficiency, but is complicate and costly to set up. We will present low cost techniques that can be easily scaled up to large surface OLEDs. These later uses dielectric films made either with the Langmuir-Blodgett technique [1], either using Breath Figure techniques [2]. We measured an improvement up to 40% of the EQE for a blue OLED emitting at 480 nm.

Besides, we will present a numerical model of this three-dimensional optical OLED cavity. This later extends the well-known one-dimensional formalism that is commonly used to model OLED stacks. It permits to link simply the electrical properties (exciton distribution) to the optical gain in an OLED caped with 3D photonic crystal, what enables global optimisation of 3D-OLED architectures. Eventually, we derive a simple criterion to optimize the photonic crystal shape and size, knowing the architecture of the planar OLED stack.

Cavity dependent Bragg scattering in red top-emitting organic LEDs

Paul-Anton Will, Elisabeth Schwarz, Cornelius Fuchs, Reinhard Scholz, Simone Lenk, Sebastian Reineke, TU Dresden (Germany)

We present a study of red top-emitting organic light-emitting diodes (OLEDs) comprising one dimensional nanoimprinted Bragg gratings beneath the opaque bottom electrode. The scattering of the trapped waveguide (WG) and surface plasmon polariton (SPP) modes is experimentally investigated and compared to results of a new sophisticated a-priori simulation of corrugated OLEDs. While the gratings properties are kept constant, a systematic variation of the cavity length is performed. Angular dependent spectral radiant intensity (SRI) measurements reveal that the cavity thickness strongly influences the occurring interference between the scattered non-radiative WG and SPP modes and the radiative cavity mode. Since an azimuthal symmetry of the corrugated OLED pixel is not given, an integrating sphere is used to determine the external quantum efficiencies (EQE). Compared to planar references, we find a decreased EQE for the 1st and 2nd optical maxima, but an eightfold enhanced EQE in the optical minimum for the OLED with Bragg grating. The enhancement originates mainly from a single scattered WG mode, which can be identified by comparing the SRI of the corrugated OLED to the simulated power dissipation spectra of the planar reference. Furthermore, we can qualitatively predict the SRI of the corrugated OLED in the optical minimum with our new simulation tool. We discuss the agreement between experiment and simulation in dependence of simulation parameters. Crucial quantities arise from the Bragg grating like period, height, and profile shape as well as from the OLED like layer thicknesses, coherence length, and optical constants.

Towards continuous-wave operation of organic semiconductor lasers

Atula S. D. Sandanayaka, Toshinori Matsushima, Fatima Bencheikh, Kou Yoshida, Munetomo Inoue, OPERA Ctr. for Organic Photonics and Electronics Research (Japan); Takashi Fujihara, Institute of Systems, Information Technologies and Nanotechnologies (ISIT) (Japan); Kenichi Goushi, Jean-Charles Ribierre, Chihaya Adachi, OPERA Ctr. for Organic Photonics and Electronics Research (Japan)

The demonstration of continuous-wave lasing from organic semiconductor films is highly desirable for practical applications in the areas of spectroscopy, data communication and sensing but still remains a challenging objective. Here, we report low-threshold surface-emitting organic distributed feedback lasers operating in the quasi-continuous-wave regime at 80 MHz as well as under long pulse photoexcitation of 30 ms. This outstanding performance was achieved using an organic semiconductor thin film with high optical gain, high photoluminescence quantum yield and no triplet absorption losses at the lasing wavelength combined with a mixed-order distributed feedback grating to achieve low lasing threshold. A simple encapsulation technique greatly reduced the laser-induced thermal degradation and suppressed the ablation of the gain medium taking place otherwise under intense continuous-wave photo-excitation. Overall, this study provides evidence that the development of a continuous-wave organic semiconductor laser technology is possible via the engineering of the gain medium and the device architecture.

High quality white OLEDs with LED efficiencies

Kyung-Hoon Han, Seoul National Univ. (Korea, Republic of); Sohee Jeon, Korea Institute of Machinery & Materials (Korea, Republic of); Sunghun Lee, Kwon-Hyeon Kim, Hyun Shin, Seoul National Univ. (Korea, Republic of); Jun-Ho Jeong, Korea Institute of Machinery & Materials (Korea, Republic of); Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

White OLEDs (WOLEDs) are considered as more attractive lighting sources than LEDs in terms of the quality of light, mechanical and design flexibility, free of blue hazard, and so on. However, WOLEDs with high luminous efficacy (LE) overcoming LEDs at high luminance are believed to be a distant goal at present even with large advances in light extraction during the last couple of decades. Here, we report novel WOLEDs approaching the theoretical limit by using the highly effective extraction layer based on a randomly dispersed vacuum nano-hole array (VaNHA). To obtain isotropic emission similar to the Lambertian emission profile, a random VaNHA was designed by dispersing the position of holes. The randomness of vacuum nanoholes is controlled not to show any symmetric emission patterns in the unit cell of 10*10 μm2. The WOLEDs in combination with a half spherical lens exhibited comparable performance with LED lighting with unprecedentedly high LE of 164 lm W–1 at 1,000 cd m–2 originating from high EQE (75.9%), low operating voltage (3.51 V) and low efficiency roll-off. In addition, the WOLEDs showed the maximum EQE of 78%, high color rendering index (CRI) around 80 and no color variation with viewing angle.

10362-86, Session PMon

Simulation and optimization for the optical performance of top emitting OLED

Shuwei Fan, Nana Chen, Zhaoxin Wu, Shenli Jia, Xi'an Jiaotong Univ. (China)

Top emitting Organic light-emitting diode(TEOLED) has been demonstrated to be suitable for next generation lighting and display application for high performance such as high efficiency and flexibility etc. The paper 's main work about TEOLED is as follow:

First, different anode structures of the TEOLED device was studied and the complex structure of Al (120nm) /MoO3 (4nm) /Al (4nm) was chosen as a reflective anode.

Second, with the help of software FDTD, the optimization design of the TEOLED device structures was completed. The light out coupling layer of the TEOLED had been modified to improve the light out coupling efficiency. The simulation of TEOLED with different microstructures on the surface of light out coupling layer was developed. And then the optimization design of TEOLED was carried out, which demonstrated that the average coupling-out efficiency could reach 75.8% near the wavelength of 525nm.

Down-conversion white OLEDs with high performance color-conversion light outcoupling structures.

Joo Won Han, Siti Aisyah Nurmaulia Entifar, Pukyong National Univ. (Korea, Republic of); Chul Woong Joo, Jonghee Lee, Electronics and Telecommunications Research Institute (Korea, Republic of); Yong Hyun Kim, Pukyong National Univ. (Korea, Republic of)

White organic light-emitting diodes (OLEDs) have attracted considerable attention due to their important applications in flat panel displays, general lighting. The biggest challenge of conventional OLEDs is the limited light outcoupling efficiency about 20 % while the internal quantum efficiency of OLEDs approaches almost 100 %. In this respect, numerous light outcoupling techniques have been investigated to enhance the device efficiency. In contrast to most internal outcoupling structures, external outcoupling structures do not deteriorate the electrical functions of devices and can be readily introduced to the back side of substrate as a form of films. For external outcoupling, microlens array films and micro-sphere scattering layers have been extensively used. However, these external outcoupling structures typically need complex and expensive lithography process to form micro-shape patterns.

In this work, we develop a high performance down-conversion microlens array (DC-MLA) films for white OLEDs. The DC-MLA films are fabricated by a soft imprinting method with breath figure patterns, which are low-cost, simple and quick solution process. Blue OLEDs employing the DC-MLA films exhibit highly enhanced light outcoupling efficiency and high quality of white light. The DC-MLA films improve the external quantum efficiency (EQE) of white OLEDs by a factor of 1.45. In addition, high quality white light with a color rendering index of 84.3 is achieved for the white OLEDs with DC-MLA films. We anticipate that the novel solution-processable DC-MLA films based on breath figure patterns can be a simple, cost-effective approach to realize high performance down-conversion white OLEDs.

The analysis of working mechanism for organic heterojunction charge generation layer

Feiping Lu, Tianshui Normal Univ. (China)

No Abstract Available

10362-89, Session PMon

The study of working mechanism of organic heterojunction charge generation layer

Feiping Lu, Tianshui Normal Univ. (China); Bo Yao, Yan Li, Shaoxing Univ. (China); Qin Liu, Yinglong Shi, Tianshui Normal Univ. (China)

The tandem organic light-emitting diodes (tandem OLEDs), which having two or more electroluminescence (EL) units vertically stacked in series through charge generation layer, were widely used in flatpanel displays and solid state lighting because of their advantages of enhanced current efficiency and luminance at low current densities, as well as their prolonged lifetime as compared to the conventional single unit devices. In a tandem OLED, the charge generation layer plays an important role, serving as the charge generation layer, and it is critical for the performance of tandem OLEDs. So the deep understanding the working mechanism of charge generation layer is the basis of fabrication high efficiency OLEDs. Organic heterojunction thin film layers were widely used in tandem OLEDs as charge generation layer, in order to undersdand the working mechanism of organic heterojunction charge generation layer, the device with the structure of glass/ITO/ tris(8-hydroxyquinoline) aluminum (Alq3) (60 nm)/C60(x nm)/ pentaence((40- x) nm)/ N,N'-bis(naphthalen-1-yl)-N,N'-bis (phenyl)-benzidine (NPB) (40 nm)/Al (100 nm) were successfully fabricated, here the organic heterojunction C60/pentaence was used as charge generation layer. The experiment results demonstrated that the organic heterojunction charge generation layer with the structure of C60(15 nm)/pentaence(25 nm) with the most effective charge generation ability. By the analysing the carrier transport characteristics in device, the device current can be attributed to the organic heterojunction charge generation layer. By numerical analysing the current-voltage (J-V) characteristics of devices, the results showed the charge generation mechanisem of organic heterojunction was in accord with quantum tunneling. The obtained results can help ones deeply understand the working mechanism of organic heterojunction charge generation layer and fabricat high efficiency OLEDs.

Conductivity and injection ability enhancing of nickel (II) oxide hole injection layer for organic light-emitting diodes

Moohyun Kim, KAIST (Korea, Republic of); Chul Woong Joo, Byoung-Hwa Kwon, Electronics and Telecommunications Research Institute (Korea, Republic of); Wonseok Choi, Dodam Kim, Duk Young Jeon, KAIST (Korea, Republic of)

Sol-gel processed nickel (II) oxide (NiOx) is the one of the p-type metal oxide semiconductor materials which has widely used for hole transport layer (HTL) or hole injection layer (HIL) in optoelectronic devices. The NiOx film which fabricated with sol-gel process has many attractive electronic, optical and chemical properties. Based on these advantages of NiOx and disadvantages from PEDOT:PSS, NiOx is considered as great alternative for PEDOT:PSS. Consequently, NiOx film used optoelectronic devices like organic photovoltaic (OPV), organic light emitting diodes (OLEDs) and quantum-dot light emitting diodes (QLEDs) were demonstrated.

We introduce that the co-doping in NiOx with same Cu element but also different Cu oxidation number (Cu (I) and Cu (II)). There are only few studies in co-doping method for NiOx and that was limited to using distinct elements. The Cu2O (Cu (I)) and CuO (Cu (II)) have different crystal structures which are known as cubic structure and monoclinic structure. We assumed that Cu doping with two different lattice parameter led NiOx to more off-stoichiometric NiOx and this CuNiOx generates Ni2+ vacancies more effectively. Their modified chemical composition enhance conductivity and hole injection properties.

10362-92, Session PMon

The facile synthesis of 1,8-dibromo-9-heterofluorenes

Jinzhu Cao, Chuanhao Sun, China Electronics Standardization Institute (China); Yijiang Jiang, Beijing University of Technology (China)

The linking pattern of conjugated polymers was found to greatly influence their properties both in single molecular and aggregated states. For example, poly(1,8-carbazole) has been synthesized and has quite different properties in comparison with poly(2,7-carbazole) and poly(3,6-carbazole). Our previous theoretical investigations reveal that poly(1,8-silafluorene)s are very interesting optoelectronic materials with high bandgap, good hole and electron transport balance, and modest effective conjugation length for high-performance blue or deep-blue OLEDs. However, other poly(1,8-heterofluorenes) have not been synthesized due to the difficulties in the preparation of the monomers of 1,8-dibromo-9-heterofluorenes.

Recently,we successfully developed the critical premonitory compound of 1,8-dibromo-9-heterofluorenes via a new and facile synthetic route. The prepared compounds were fully characterized by NMR, GC-MS, and element analysis (EA).The successful preparation of 1,8-dibromo-9-heterofluorenes opens a door for a new kind of materials with high triplet state energy as excellent host materials and unique optical properties with tremendous potential in the field of organic electronics.

10362-93, Session PMon

Optical materials based on organometallic complexes and quantum dots loaded in solid matrices

Leandro P. Ravaro, Univ. of California, Santa Barbara (United States) and Univ. of São Paulo (Brazil); Peter C. Ford, Univ. of California, Santa Barbara (United States); Andrea S. S. de Camargo, Univ. of São Paulo (Brazil)

Optical materials based on organometallic copper (I) complexes and/or CdTe quantum dots displays rich photophysics properties that make them suitable candidates for technological applications including catalysis, OLEDs, cellular imaging, optical sensors, Photodynamic Therapy (PDT) and others. Due to the effect of quantum confinement, the CdTe semiconductor nanoparticles exhibit narrow and symmetrical fluorescence covering a broad spectrum of excitation and emission as a function of nanoparticle size. Many studies are focused on the characterization of these materials in solid state and solution, however there are few studies of them loaded into solid matrices. This work reports the photophysical properties of copper (I) complexes and CdTe QDs loaded in a mesoporous silica matrix obtained by sol-gel method with an average pore diameter of 10 nm. The colloidal suspension of CdTe, synthesized in aqueous phase, presents maximum excitation at 375 nm, maximum emission at 520 nm with full width at half maximum (FWHM) of 46 nm. While loaded into the solid SiO2 matrix, the QD emission had small shift, according to the type of incorporation strategy. The complexes Cu4I4py4 (1) and C30H28N2O2PCuI (2) incorporated on mesoporous silica showed a shift in emission of 580 nm to 720 nm and 660 nm to 575 nm, respectively. This shift of the emission is caused by distortion of the molecular complex, in the MLCT excited state, inside the matrix, known as rigidochromic effect [1]. Also, a sensitivity of these hybrids materials (1@SiO2 and 2@SiO2) was observed to oxygen. The mesoporous matrix dispersed the molecules of the complex, so as to enable a reversible interaction with oxygen in the center of the metal that quenches of luminescence[2] and provides a new functionality to the complex[3].

Already, the new complex C30H28N2O2PCuI (2) presented interesting properties. Exposed to dichloromethane its color alters from yellow to orange with shift the emission and returns the original color on exposure to acetone, indicating a reversible process. This color change was also observed for the complex 2 incorporated into a mesoporous silica matrix (2@SiO2). The x-ray data demonstrates that both compounds (yellow and orange) have the same crystalline structure (monoclinic), but with different lattice parameters and distorted angles. For example, for the yellow compound, the lattice parameter found was a = 17.769 Å, angle ? = 114.05 o and a smaller distance between Cu···Cu centers of 9.174 Å. While the orange compound, the lattice parameter found was a = 11.555 Å, angle ? = 92.70 o and a smaller distance between Cu···Cu centers of 7.197 Å. The change of color and shift of the emission must be related to the change of molecular packings after its recrystallization with referred organic solvent. The new functional materials proposed in this study have great potential for applications in optical materials devices.

Unraveling origin of phosphors doped in organic semiconducting layers

Chang-Ki Moon, Kwon-Hyeon Kim, Jang-Joo Kim, Seoul National Univ. (Korea, Republic of)

Emitting dipole orientation (EDO) is an important issue of emitting materials in organic light-emitting diodes (OLEDs) for an increase of outcoupling efficiency of light. The origin of preferred orientation of emitting dipole of spherically shaped iridium-based heteroleptic phosphorescent dyes doped in organic layers is revealed by simulation of vacuum deposition using molecular dynamics (MD) along with quantum mechanical (QM) characterization of the phosphors for a direct comparison with experimental observations of EDO. Consideration of both the electronic transitions in a molecular frame and the orientation of the molecules interacting with the environment at the vacuum/molecular film interface allows quantitative analyses of the EDO depending on host molecules and dopant structures. Interaction between the phosphor and nearest host molecules on the surface, minimizing the non-bonding energy determines the molecular alignment during the vacuum deposition. Parallel alignment of the main cyclometalating ligands in the molecular complex due to host interactions rather than the ancillary ligand orienting to vacuum leads to the horizontal EDO.

10362-38, Session 9

Charge transport and light emission in anisotropic media: the liquid-crystalline light-emitting diode

Changmin Keum, Shiyi Liu, Akram Al-Shadeedi, Vikash Kaphle, Robert J. Twieg, Antal I. Jákli, Björn Lüssem, Kent State Univ. (United States)

Alignment of emitter or transport molecules can have a profound influence on the efficiency of Organic Light-Emitting Diodes (OLEDs). A horizontal alignment of the emitter molecule is known to increase the overall external quantum efficiency (EQE) [Phys. Status Solidi 210, 44–65 (2013)]; an optical anisotropy in the transport layers can be used to tune the OLED microcavity [Opt. Express 23, 21128–21148 (2015)]; and finally, an increased order in the organic film enhances charge and exciton transport [Adv. Mater. 22, 1233–1236 (2010)].

Liquid-Crystalline (LC) semiconductors [Appl. Mat. & Interf. 7, 16374 (2015)] provide for new ways to control the orientation of functional molecules in organic thin films. In this presentation, a novel blading process is presented, which allows to change the orientation of the organic semiconductor C8-BTBT. Applying the blading process at elevated temperatures, i.e. in the LC phases of C8-BTBT, induces a more tilted alignment. The influence on the alignment of the semiconductor on electron and hole transport is studied in n-i-n and p-i-p devices and it is shown that the charge carrier mobility increases for a more tilted orientation.

To realize light emission inside the C8-BTBT layer, the semiconductor is doped by a red phosphorescent emitter. P-i-n type OLEDs show a promising EQE of up to 8%. Most importantly, both, annealing and blading lead to an increase in EQE. Hence, the presented results present a first step toward OLEDs employing LC layers, which opens new design possibilities to optimize OLEDs further.

10362-39, Session 9

Polymer gating white flexible field-induced lighting device

Junwei Xu, Wake Forest Univ. (United States); David Loren Carroll, Ctr. for Nanotechnology and Molecular Materials (United States)

The development of field induced electroluminescence (EL) devices holds great promise for the production of extremely flexible and efficient large-area light sources. Here, a novel flexible polymeric gate layer for alternating current (AC) driven organic electroluminescence (AC-OEL) devices is presented. The charge-valve mechanism of carrier manipulation in forward and reversed bias of the applied AC cycles is fully detailed. With a low-doping strategy of two phosphors in the fluorescent host, a flexible PET-based AC-OEL device with poly[(9,9-bis(3'-((N,N-dimethyl)-N-ethylammonium)-propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)] (PFN-Br) gate exhibits incredible stability on EL performance with a superior color rendering index (CRI), over 81 at 2800K color temperature and a power efficiency of 2.8 lm/W at 1,000 cd/m2 with high bending ability (-90° to +90°).

10362-40, Session 9

Alternating current polymer electroluminescence for dynamic interactive display *(Invited Paper)*

Cheolmin Park, Yonsei Univ. (Korea, Republic of)

Field induced electroluminescence of either organic or inorganic fluorescent materials under alternating current (AC) has been of great attention as a potential candidate for next generation displays, lightings and sensors. Unique device architecture in which an emitting layer is separated with an insulator from electrode offers a new platform for designing and developing a variety of types of ELs. Here, we demonstrate high-performance field-induced AC polymer electroluminescence (AC-PEL) devices with high brightness, high efficiency and color-tunability. We also present a non-volatile EL memory in which arbitrarily chosen EL states are programmed and erased repetitively with long EL retention. Our memory is based on utilizing the built-in electric field arising from the remanent polarization of a ferroelectric polymer which in turn controls the carrier injection of an AC-PEL device. The device exhibits two distinctive non-volatile EL intensities at constant reading AC voltage, depending upon the programmed direct current (DC) voltage on the ferroelectric layer. DC programmed and AC read EL memories are also realized with different EL colors of R, G and B. Finally, we show that simultaneous sensing and visualization of the conductive substance is achieved when the conductive object is coupled with the light emissive material layer on our novel parallel-type AC-PEL device. A variety of conductive materials can be detected regardless of their work functions, and thus information written by a conductive pen is clearly visualized, as is a human fingerprint with natural conductivity.

10362-41, Session 9

Universal ohmic electron and hole contacts for organic light-emitting diodes and electronics *(Invited Paper)*

Peter Ho, Rui-Qi Png, Lay-Lay Chua, National Univ. of Singapore (Singapore)

An ohmic electrical contact is one that allows the largest possible current density limited by space-charge effects to be injected into the adjoining semiconductor. This is key to maximizing device efficiency and reliability, and thus fundamental to all semiconductor devices. A long-standing challenge for organic (and other solution-based) electronics is the lack of a general solution-based compatible strategy to fabricate ohmic contacts at will. To overcome these challenges, we have recently developed self-compensated heavily-doped polymers with ultrahigh and ultralow workfunctions, and polyelectrolyte interlayers for 2D interface doping. Unprecedented p- and n-doped conductive polymer films over an ultrawide work function range of 3.0 eV to 5.8 eV have been obtained, enabling solution-processed ohmic contacts for light-emitting diodes, solar cells, photodiodes and transistors. Self-aligned doped contacts have also become possible. We anticipate that these strategies will enable ohmic contacts to also be made to other advanced semiconductors, including quantum dots, nanotubes and 2D materials, and open up new and technologically interesting device architectures for various photonic and non-photonic applications. Using these materials, we have developed new understanding of the physics of work function and ohmic contacts relating to doped organic semiconductors. The localization of charge carriers in organic semiconductors, different from conventional band semiconductors, leads to important differences in the essential physics.

Recent advances in OLEDs on unconventional substrates *(Invited Paper)*

Bernard Kippelen, Xiaoqing Zhang, Canek Fuentes-Hernández, Felipe A. Larrain, Georgia Institute of Technology (United States)

The printed electronics industry offers a paradigm change in manufacturing, cost and environmental impact when compared to the conventional semiconductor industry. Printed electronic devices are expected to be mass-produced from less-energy-demanding processes over large areas and on flexible substrates with techniques that closely resemble the well-known mass production of printed media on paper. Organic light-emitting diodes (OLEDs) offer great versatility in the design of application-specific light sources; yet examples of OLEDs fabricated on exotic substrates that differ from glass and plastic are still scarce. In this talk we will present recent examples of OLEDs fabricated on unconventional substrates, including nanocellulose and shape memory polymers.

Thermally-activated delayed fluorescent (TADF) emitters have been successfully used in organic light-emitting diodes (OLEDs) with up to 100% internal quantum efficiencies and are now considered as the third generation of OLED materials.[1

]Here, we report on the fabrication of NIR TADF OLEDs with a maximum electroluminescence external quantum efficiency (EQE) of nearly 10%. The devices used a solution-processable heavy-metal-free do-nor-acceptor-donor borondifluoride curcuminoid derivative[2] as NIR emitter. This compound shows a rather high photoluminescence quantum yield (up to 69%) in solid matrices with an emission maximum wavelength typically in the range between 720 and 750 nm. Time-resolved photophysical measurements show that the TADF mechanism of this NIR emitter is due to a reverse intersystem crossing from triplet charge transfer (CT) to singlet CT excited states. In addition, the TADF emission wavelength and efficiency are found to strongly depend on the dye concentration in the emissive layer due to the large dipole moments of this compound. In the last part of this talk, we will demonstrate that this new TADF material exhibits amplified spontaneous emission in the NIR region, suggesting the possibility to harvest triplet excitons for stimulated emission.

Würzburg (Germany); Jana Zaumseil, Ruprecht-Karls-Univ. Heidelberg (Germany)

Organic materials offer attractive properties for solid-state lasers, including large oscillator strength, high exciton binding energy, spectral tunability, and compatibility with low-cost fabrication processes. However, despite impressive proof-of-principle demonstrations and dramatic improvements in performance, important fundamental limitations remain. Particular challenges are concentration quenching and bi-molecular exciton recombination which limit the available gain under practical pumping conditions. For electrical pumping, there are further restrictions, including the low charge carrier mobility of most organic materials. Recently, it has been suggested that lasers operating in the regime of strong exciton-photon coupling may address some of these challenges.

Here, we will summarize key results from two current collaborations that both look at unconventional nano-scale organic materials for solid-state lasers: Biologically produced fluorescent proteins and single walled carbon nanotubes.

We found that the barrel-like molecular structure of fluorescent proteins prevents concentration-induced quenching of fluorescence and drastically reduces singlet-singlet annihilation at high exciton densities. This facilitates low-threshold lasing in various configurations and has recently enabled the realization of the first organic polariton laser that can be pumped in a quasi-continuous ns-regime.

In another collaboration, we have shown that the special photophysical properties of polymer-sorted semiconducting single-walled carbon nanotubes render them well-suited for strong light-matter coupling, possibly up to the ultra-strong coupling regime. Most recently, we found that the high charge carrier mobility and stability also enable efficient electrical generation of exciton polaritons. Using a light-emitting field effect transistor geometry, we achieved current densities up to 18,000 A/cm2 while maintaining strong coupling conditions.

10362-46, Session 10

Tunable solution processed metal organic perovskite distributed feedback lasers *(Invited Paper)*

Ulrich Lemmer, Philipp Brenner, Florian Mathies, Dorothee Kapp, Gerardo Hernandez-Sosa, Ian A. Howard, Karlsruher Institut für Technologie (Germany)

The use of metal halide perovskites for optoelectronic devices beyond solar cells is gaining growing attention.

Perovskites with different compositions are promising as tuneable light emitters for the whole visible spectral region [1]. We report solution processed perovskite laser devices that show amplified spontaneous emission and lasing. We have fabricated surface emitting perovskite distributed feedback lasers by spin-coating CH3NH3PbI3 precursor solutions in ambient atmosphere on nanoimprinted grating substrates [2]. These lasers exhibit narrow lasing linewidths below 0.2 nm and an excellent stability of more than 5?10^7 pulses at 1 kHz repetition rate. Lasing at different wavelengths could be achieved on a single substrate by integrating different grating periods on the same substrate. While the emission wavelength of CH3NH3PbI3 is in the deep red to infrared spectral region, the lasing emission can be shifted into the visible by a gradual exchange of iodine to bromine. By adapting the grating period to the emission spectra of the mixed halide perovskite, we achieved lasing in the visible. Furthermore, we demonstrate high-quality perovskites fabricated by ink-jet printing on flexible substrates. Such films show strong amplified spontaneous emission with a clear ASE intensity threshold.

Electrical simulation of organic light emitting diode under high current injection *(Invited Paper)*

Fatima Bencheikh, Atula S. D. Sandanayaka, Toshiya Fukunaga, Toshinori Matsushima, Chihaya Adachi, OPERA Ctr. for Organic Photonics and Electronics Research (Japan)

During the last two decades, organic semiconductor lasers (OSLs) have been attracted much attention due to their advantageous properties such as wavelength tunability in visible range [1], low cost, flexibility and large area fabrication [2]. These properties make them good candidates for a range of applications including sensing, spectroscopy and optical communication. However, only optically pumped organic lasers have been realized so far and the demonstration of an electrically-driven organic laser diode still remains a very challenging task. To achieve electrically pumped OSLs, much effort has been focused on the reduction of the energy threshold of optically pumped organic lasers by enhancing the gain media properties and optimizing the resonant cavities. The injection of high current density involves Joule heating which causes degradation and breakdown of the device. Moreover, the presence of high charge density induces multiple annihilation processes such as exciton-polaron quenching, polaron absorption and electric field dissociation which are ones of the causes of device external quantum efficiency rolloff. A fundamental understanding of the physical mechanisms governing the device operation is crucial to optimize the device performance and overcome the limitation processes to the achievement of an electrically driven OSLs. Electrical simulation of an organic light emitting diode under high current density is performed in order to predict the current at high voltage. The influence of the various annihilation processes is investigated by solving the exciton continuity equation.

2D compact model to characterize phase separation in organic solar cell bulk heterojunctions

Franklin L. Lee, Amir Barati Farimani, Kevin L. Gu, Stanford Univ. (United States); Hongping Yan, Stanford Synchrotron Radiation Lightsource (United States); Zhenan Bao, Stanford Univ. (United States); Vijay S. Pande, Stanford Univ. (United States) and Andreessen Horowitz (United States)

The phase separation between donor and acceptor molecules within the active layer of an organic solar cells dictates the morphology and hence is key to the recombination rate and ultimately the performance of the organic solar cell. Molecular dynamics (MD) simulation is a suitable technique to understand this phenomenon; however, conventional all-atom MD simulations cannot reach the appropriate length and time scales to compare with macroscopic observation. Even with the many available coarse-grained MD models, it is difficult to reach these scales. Therefore, we introduce here a 2D compact model to overcome this challenge, built by multiscale coarse-graining. First, we simulate systems including conjugated polymers, fullerenes, and organic solvents using all-atom MD to extract information about molecular conformation and packing. This includes an analysis of polymer solution behavior, fullerene clustering, and binary and tertiary mixing properties. These results are then used to systematically parameterize the molecules used in 2D coarse-grained MD simulations. The 2D simulations probe experimentally relevant length scales that were previously intractable to sample by other MD simulation methods. Using this model, we explore ternary systems including polymer, fullerene, and solvent molecules to investigate the phase separation process between polymer donors and fullerene acceptors. In this scheme, we additionally introduce explicit solvent evaporation to emulate realistic processing conditions. We quantify phase separation domain sizes that are comparable to experimentally observed values from resonant soft x-ray scattering. In addition, we extend this framework to other chemical species to demonstrate the flexibility of the approach.

10363-2, Session 1

Quantitative structure-function relations in PSCs from soft x-ray scattering *(Invited Paper)*

Harald W. Ade, North Carolina State Univ. (United States)

Polymer Solar Cells (PSCs) continue to be a promising third generation, low energy-budget, lead-free PV technology. Efficiencies have now improved to over 12% and a new class of materials (small molecule acceptors) have recently provided rapid improvements that promise further advances. Significant effort in the field is being spent on synthetic efforts to tune the electronic structure and in understanding charge generation. In contrast, we explore the correlation of fill factor to the purity of domains as measured with soft x-ray scattering, and how said purity is controlled by thermodynamically metastable morphologies. We will argue that ideal materials systems will have a Flory Huggins interaction parameter ? that naturally leads to mixed domains that have a composition close the fullerene/SMA percolation threshold. Systems that are too miscible will have excessive bimolecular recombination. Systems too immiscible need to be quenched for best performance, are thus unstable and eventually produce fullerene islands that trap charges. Although some of these concepts are known and are indirectly referred to as "miscibility", quantitative relations remained largely elusive. Understanding molecular interactions is even more important for conventional ternaries devices. In some cases, the two donor polymer used can have unfavorable thermodynamic interactions (? = - 0.56 at 296 °C) that prevent improved performance due to lack of phase separation and alloying of the two donors. Overall, we advocate a program to measure ?(T) in model systems in order to develop a frame-work that will eventually lead to computational approaches that allow predictions of ? as a function of molecular tuning before synthesis of a targeted compound is attempted.

10363-3, Session 2

Triplet energy transfer and triplet exciton recycling in singlet fission sensitized organic heterojunctions

Ajay Pandey, Queensland Univ. of Technology (Australia)

Organics semiconductors such as tetracene, rubrene and pentacene have the unique ability of efficiently producing two electron-hole pairs per absorbed photon. This occurs due to the physical process of singlet fission where the excited singlet state breaks into two low energy triplets [1]. In this paper, we will present novel "triplet exciton management" strategies that are aimed at enhancing the yield of photocurrent generation and reduction of recombination losses in singlet fission active/sensitized organic photovoltaic diodes. Some latest results on ultrafast triplet exciton dynamics in donor-acceptor heterojunctions of rubrene and tetracene with C60 will be presented.

Example of squaraine as a triplet exciton reflecting layer in enhancing the photocurrent yield in pentacene/C60 diodes to values above 100% and triplet energy transfer (TET) from DCV3T to pentacene will be discussed. A successful case of triplet exciton recycling in the low optical gap polymer-fullerene bulk-heterojunctions of PCPDTBT:70-PCBM will be discussed where we have been successful in suppressing bimolecular recombination losses via TET that progresses through charge transfer intermediate and transfers its energy to the adjacent layer of pentacene.

In summary, through carefully designed experiments on operational photodiodes, we will discuss successful examples of Dexter type TET process in the organic photovoltaic cascades. We will make a strong case for strategic management of the triplet excitons in organic donor-acceptors and pitch new strategies for the material and device designs for realisation of next generation of organic photovoltaics.

Ultrafast terahertz snapshots of excitonic Rydberg states and electronic coherence in an organometal halide perovskite

Liang Luo, Long Men, Zhaoyu Liu, Yaroslav Mudryk, Xin Zhao, Yongxin Yao, Joong-Mok Park, Ruth Shinar, Joseph Shinar, Kai-Ming Ho, Iowa State Univ. of Science and Technology (United States) and Ames Lab. (United States); Ilias E. Perakis, The Univ. of Alabama at Birmingham (United States); Javier Vela, Jigang Wang, Iowa State Univ. of Science and Technology (United States) and Ames Lab. (United States)

How photoexcitations evolve in time into Coulomb-bound electron and hole pairs, called excitons, and unbound charge carriers is a key cross-cutting issue in photovoltaic and optoelectronic technologies. Until now, the initial quantum dynamics following photoexcitation remains elusive in the organometal halide perovskite system. Here we reveal excitonic Rydberg states with distinct formation pathways by observing the multiple resonant, internal quantum transitions using ultrafast terahertz quasi-particle transport. Nonequilibrium emergent states evolve with a complex co-existence of excitons, unbound carriers and phonons, where a delayed build-up of excitons under various pumping conditions allows us to distinguish between the loss of electronic coherence and hot state cooling processes. The terahertz transport with rather long dephasing time and scattering processes due to discrete terahertz phonons in perovskites are distinct from conventional photovoltaic materials. In addition to providing implications for ultrafast coherent transport, these results break ground for a perovskite-based device paradigm for terahertz and coherent optoelectronics.

Study the effects of thickness variation of different layers on the light spectrum reaching active layers of organic solar cells

Ronak Rahimi, Intel Corp. (United States)

Significant progress in fabrication and optimization of organic photovoltaics (OPVs) has been made during the last decade. The main reason for popularity of OPVs is due to their low production cost, large area devices and compatibility with flexible substrates. Various approaches including optimizing morphology of the active layers, introducing new materials as the donor and acceptor, new device structures such as tandem structure have been adapted to improve the efficiency of the organic photovoltaics. Power conversion efficiency of OPVs are affected by various parameters such as light absorption and charge carrier extraction. Among these parameters, light absorption strongly depends on the optical properties of the layers and the device structure. Solar cells with CuPC/PTCDI-C8 active layers were fabricated and their reflectivities were measured. Transfer matrix formalism was used to simulate the reflectivities of each layer and the final device structure. Simulated and measured reflectivities were compared and studied to determine the effects of thickness variation of different layers on the light spectrum reaching the active layers.

10363-58, Session PMon

EDOT-diketopyrrolopyrrole copolymers for polymer solar cells

Chao Wang, Christopher R. McNeill, Monash Univ. (Australia)

The photovoltaic properties of a series of diketopyrrolo[3,4-c]pyrrole (DPP) copolymers containing 3,4-ethylenedioxythiophene (EDOT) as a comonomer are reported. With use of different aryl flanking units on the DPP core, namely thiophene, pyridine or phenyl, optical gaps ranging from 1.91 eV to 1.13 eV are achieved. When blended with the fullerene derivative [6,6]-phenyl C71-butyric acid methyl ester (PC71BM), the thiophene-flanked copolymer PDPP[T]2-EDOT with an optical gap of 1.13 eV was found to have the best photovoltaic performance, with an efficiency of 2.5% in an inverted device architecture. Despite having the lowest open circuit voltage of the three polymers studied, PDPP[T]2-EDOT-based devices were able to achieve superior efficiencies due to the high short circuit current of up to ~ 15 mA/cm2. PDPP[T]2-EDOT-based devices also exhibit higher external quantum efficiencies which are associated with a superior microstructure as revealed by transmission electron microscopy (TEM) and grazing incidence wide-angle X-ray scattering (GIWAXS). In particular PDPP[T]2-EDOT:PC71BM blends were found to have a finer phase separated morphology with superior thin-film crystallinity. Surface morphology was also investigated with atomic force microscopy and near-edge X-ray absorption fine-structure spectroscopy.

10363-59, Session PMon

Modeling of trap assisted interfacial in planer heterojunction perovskite solar cells

Behzad Bahrami, Qiquan Qiao, South Dakota State Univ. (United States)

Based on our model, diffusion of electrons from compact TiO2 into the Mesoporous-TiO2 and electron injection from TiO2 into perovskite through the trap assisted processes have role in the case of dark current. Trap assisted mechanisms dominates the current flow at low defect densities. In contrast, at high defect density regime, diffusion through TiO2, overcomes the current flow. This explains the nearly higher sensitivity of J0 to NT in low defect density regime. In both the low and high defect density regimes VOC is sensitive to NT but Jsc is only sensitive to NT in the high defect density regime. The VOC and JSC of the simulated perovskite solar cell are dependent upon Dn and NT. These parameters, respectively, govern dispersive diffusion of electrons through shallow defect states in mesoporous TiO2 and trap-assisted injection of electrons into the perovskite. The simulation results show that VOC and JSC are independent of Dn at the low defect density regime. This means that the diffusion of electrons through the mesoporous TiO2 is much faster than the process of injection of electrons into perovskite through trap states for the entire range of Dn. VOC shows a weak decrease by increasing in Dn, at higher defect density regime because a smaller quasi-Fermi level separation due to fast diffusion leads to a lower density of electrons in the conduction band of TiO2. In contrast, JSC shows an important sensitivity to the Dn values because in the low diffusion coefficient and high defect density regime, injection time of photoelectrons into the perovskite is less than the time scale of their transit to reach the contact. This causes to too much recombination and decrease of JSC.

10363-60, Session PMon

Thick film high performance bulk-heterojunction solar cells retaining 90% PCEs of the optimized thin film cells

Hang Yin, Shu Kong So, Hong Kong Baptist Univ. (Hong Kong, China)

Amid looming concerns over the deteriorating environment and energy problems, organic photovoltaic (OPV) devices have gained considerable attention because of their high flexibility, light weight, and capability for large-area fabrication. Most optimized, high performance, bulk-heterojunction polymer solar cells have an active layer thickness of about 100nm. The thin active layer is unfavorable for optical absorption and film coating. This contribution employs a ternary cell to address this problem. We show that thick film BHJ cells can be fabricated that retain 90% of the optimized thin film cells. The BHJs under investigations are PTB7:PC71BM, PTB7-Th:PC71BM and P3HT:PCBM. Into these BHJs, a ternary component, p-DTS(fbtth2)2 (~5% for PTB7, PTB7-Th, and ~10% for P3HT by weight) is introduced. Without p-DTS(fbtth2)2, the binary BHJ devices have PCEs of 6.3%, 7.3% and 3.2% in thick films (~200nm, ~200nm and ~400nm). With p-DTS(fbtth2)2, the corresponding BHJs have markedly improved PCEs of 7.6%, 8.3% and 4.0%, respectively. The results are more than 90% the PCEs of the optimized binary BHJs. The origins of the improvement are investigated. Addition of the ternary component p-DTS(fbtth2)2 enhances hole mobility and reduces trap states. Both observations are well correlated with improved FFs of the ternary BHJ cells. We use 1H nuclear magnetic resonance (NMR) to trace the nano-scale interactions of the p-DTS(fbtth2)2 with the polymer and fullerene. Our results suggest the p-DTS(fbtth2)2 behave as conducting bridges in between two neighboring polymer segments.

10363-61, Session PMon

Enhanced photovoltaic performance of PTB7:PCBM bulk heterojunction solar cells with Al doped TiO2 interfacial layer

Jun Young Kim, Korea Institute of Industrial Technology (Korea, Republic of)

In inverted polymer solar cell, several n-type buffer layers such as cesium carbonate (Cs2CO3), titanium dioxide (TiO2), zinc oxide (ZnO) were used as an electron transport layer due to their relatively high electron mobility, environmental stability, and high transparency. Recently, in order to increase the device performance of inverted polymer solar cells, several groups have studied the use of metal doped n-type buffer layer. The metal doping is an effective procedure to modify the grain size, orientation, conductivity and could greatly influence the structural, optical and electrical properties of the n-type buffer layer. Especially, TiO2 films doped with impurities such as Al, Ga and In exhibit not only higher conductivities but also better stabilities compared to those of TiO2 films. In this work, we have investigated the effect of Al doping and properties of Al doped TiO2 thin films and have fabricated inverted polymer solar cells with doped TiO2 interfacial layer based on PTB7:PCBM bulk hetrojunction.

10363-62, Session PMon

Cationic dibenzothiophene-S,S-dioxide-bispyridinium-alt-fluorene copolymer as an efficient cathode modifier for polymer solar cells

Wei Yang, Zhicai He, Yong Cao, South China Univ. of Technology (China)

A novel n-type alcohol-soluble conjugated polymer containing dibenzothiophene-S,S-dioxide (FSO), bispyridinium, and fluorene scaffolds in the backbone (PFSOPyCl) was synthesized and used in the cathode interfacial layers (CILs) of conventional polymer solar cells (PSCs). The high electron affinities and large planar structures of the FSO and bispyridinium units endowed this polymer with good energy level alignments with [6,6]-phenyl-C71 butyric acid methyl ester (PC71BM) and metal cathode, and excellent electron transport and extraction properties. The bispyridinium salt donated to the polyelectrolyte nice solubility and processability in highly polar solvents, as well as versatile tunability of the cathode work function (WF). As a result, PSCs based on the poly[N-9''-heptadecanyl-2,7-carbazole-alt-5,5-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PCDTBT):PC71BM system with PFSOPyCl CIL exhibited simultaneous enhancements in open-circuit voltage, short-circuit current density, and fill factor, while the power conversion efficiency increased from 5.47% to 6.79%, relative to that of the bare Al device.

Morphological effects of ZnO electron-collecting interlayers on the performance of organic solar cells

Jisoo Goo, Dongguk Univ. (Korea, Republic of); Do Kyung Hwang, Ju Won Lim, Korea Institute of Science and Technology (Korea, Republic of); Jae Won Shim, Dongguk Univ. (Korea, Republic of)

Organic solar cells (OSCs) with an inverted geometry, wherein transparent electron-collecting electrodes (ECEs) with a low work function (WF) sit at the bottom of the device, have been proposed to improve the air stability of OSCs. In such a structure, ITO, which is commonly used as a transparent electrode, is modified with low WF electron-collecting interlayers (ECIs) to serve as an efficient ECE. ZnO has been considered as a promising candidate for ECIs because of its electrical and optical properties. Even though many studies focusing on the characterization of inverted OSCs with various types of ZnO ECIs have been reported, only a few studies have been conducted to investigate the influence of the morphology-dependent effects of ZnO ECIs on the performance of OSCs.

Here, we examined the influence of the morphology-dependent effects of ZnO on the performance of PTB7:PC70BM-based inverted OSCs. To investigate the electrical, morphological, and optical properties of the ZnO layers in the OSCs, three different ZnO layers, sol-gel, nanoparticles, and nanorods, were employed as the ECI on the top of a glass/ITO substrate. All the ZnO layers showed a comparable WF value with the electron affinity of the PC70BM acceptor, allowing the ZnO-modified ITO electrode to function as an effective ECE. Among the ZnO layers, ZnO nanorods showed the strongest scattering effects and the most effective electron-collecting properties, resulting in an enhanced external quantum efficiency, and consequently, the highest efficiency (8.38±0.09%) under simulated AM 1.5G illumination. The optical effects were simulated by using a finite-difference time-domain method.

10363-66, Session PMon

Fluorinated PCPDTBT and its efficient polymer solar cells from sequential solution processing

Yong Zhang, Harbin Institute of Technology (China)

We reported a partially fluorinated low bandgap polymer, poly[2,6-(4,4-bis(2-ethylhexyl)-4H-cyclopenta [2,1-b;3,4-b?]dithiophene)-alt-4,7-(5-fluoro-[2,1,3]-benzothiadiazole)] (PCPDTFBT) was synthesized through a microwave-assisted Stille polymerization. It was found that PCPDTFBT has better ϖ–ϖ stacking in solution than its nonfluorinated analogue PCPDTBT, resulting in 2 times higher hole mobility. Power conversion efficiency (PCE) of the device using PCPDTFBT/PC71BM as active layer (5.51%) is much higher than the device using PCPDTBT/PC71BM (2.75%) that was fabricated under the same condition without using any solvent additive to modify the morphology. Further, by utilizing the solubility difference of PCPDTFBT and PC71BM in cold xylene and/or xylene/DCB mixture solvent, we are successfully fabricated the conventional and inverted solar cells by a sequential processing (SqP) method. With appropriate orthogonal solvents and thermal treatment, the SqP film can form an inter-diffused layer, and the SqP devices show efficient photovoltaic performance in both conventional and inverted layouts. The SqP inverted device was firstly demonstrated and the highest power conversion efficiency (PCE) of 5.84% with the enhanced Jsc of 16.4 mA cm-2 was able to be achieved with the high internal quantum efficiency (IQE). Photoluminescence quenching shows the SqP films can provide efficient exciton quenching. X-ray photoemission spectroscopy (XPS) and ellipsometry analysis shows a polymer-rich surface in SqP films after thermal annealing. The charge mobilities in the SqP films were significantly enhanced as measured by SCLC method. We believe that these results inspire a new way of forming the active layer with controllable morphology, efficient charge separation and collection in polymer solar cells.

10363-67, Session PMon

Fabrication of heterojunction film of lead halide perovskites by vacuum deposition using single crystal sources

Senku Tanaka, Natsuki Ueyama, Takuya Yoshitomi, Kindai Univ. (Japan); Toshihiko Kaji, Tokyo Univ. of Agriculture and Technology (Japan)

Vacuum deposition method is able to apply for the fabrication of a heterojunction film of lead halide perovskites. However, when the vacuum deposition is done by the co-deposition or the 2-step deposition of organic molecules and lead halides, the control of organic molecule deposition is relatively difficult because of the high vapor pressure of organics. As an alternative method to preparing perovskite films by vacuum deposition, we used single crystals as the deposition source. Using the single crystals of perovskite as the source of vacuum deposition improved controllability of vacuum deposition method significantly. The simplification of vacuum deposition conditions allows to fabricate various combinations of heterojunction films. As an example, we prepared a CH3NH3PbI3 (MAPbI3)/ CH3NH3PbBr3 (MAPbBr3) hetero-junction film. The MAPbI3 and the MAPbBr3 layer were deposited sequentially by the vacuum deposition using single crystal. The formation of heterojunction was confirmed by X-ray diffraction pattern of film. We observed the superimposed pattern of the MAPbI3 and the MAPbBr3 phase. However, the results of X-ray photoelectron spectroscopy indicated that a part of film surface was composed by a mixture of MAPbI3 and MAPbBr3 phase. We also explored the effect of deposition conditions and post-preparation on the physical and the chemical properties of perovskite films. The photovoltaic properties of solar cells with heterojunction perovskite layer will also be presented.

Impact of 3D morphology on the performance of all-polymer solar cells processed by environmentally benign non-halogenated solvents

Hyeseung Jung, A-Ra Jung, Ewha Womans Univ. (Korea, Republic of); Seon-Mi Jin, Eunji Lee, Chungnam National Univ. (Korea, Republic of); Myung Hwa Kim, BongSoo Kim, Ewha Womans Univ. (Korea, Republic of)

Recently organic solar cells using halogenated solvents such as chlorobenzene and o-dichlorobenzene have recorded high efficiencies over 10%. However, halogenated solvents are very toxic to human health and environment. These solvents must be replaced with environmentally friendly non-chlorinated solvents. In addition, commonly-used n-type fullerene derivatives such as PC71BM are quite expensive, which spurred researchers to develop new soluble n-type organic materials. N-type polymers are a good alternative to fullerene derivatives because they renders many advantages including strong light absorption, good energy level tunability, and high mechanical stability. In these regards, we have investigated all polymer solar cells employing p-type PTB7-Th and n-type PNDI2OD-T2 polymers to find the dependence of photovoltaic properties on the processing solvent. We find that toluene and xylene are better processing solvents than halogenated solvents for the photovoltaic performance of PTB7-Th:PNDI2OD-T2 based devices. 3D TEM demonstrated that more ideal blend morphology in toluene and xylene-used active layer films was responsible for the solvent-property relationship.

Interfacial engineering of hybrid perovskite solar cells via fullerene derivatives

Ka Kan Wong, Azhar Fakharuddin, Philipp Ehrenreich, Eugen Zimmermann, Michael Seybold, Carola Ebenhoch, Univ. Konstanz (Germany)

Extensive research activities on emerging organic-inorganic halide perovskite solar cells (PSCs) over the past few years brought them to deliver a certified photo-conversion efficiency (PCE) ~ 22 %, which is comparable to market dominating silicon and thin film solar cells. This remarkable improvement in PSCs, from 3.8% since their inception in 2009, has been due to unique optical (bandgap, high absorption coefficient) and electronic (high electron and hole mobility, low trap density) properties, their improved films processing and composition engineering, e.g., from a single cation to mixed cations that further broadened their optical absorption, and or eliminating charge-carrier recombination at the device interfaces via modification of electron/ hole transporting materials. Interface engineering has shown to significantly improve the charge carrier dynamics within the device as well as its stability. It is of particular importance as typical PSCs (those employing a low mobility electron transporting material, TiO2) results in notable interfacial recombination due to surface trap states and inferior electronic properties of TiO2. This not only limits the photovoltaic performance in PSCs but also induces a change in their current voltage profile dependent on voltage sweep directions. A remedy to resolve the trap-assisted recombination is to employ interfacial modifiers of high electronic mobility, e.g., fullerene-derivatives, where the fullerene, embedded into perovskite active layer, facilitates electron transfer to the TiO2. Herein, we employ two fullerene derivate such as fullerene-based PCBM-, and the self-assembling PCBA molecule, which anchors to TiO2 via a COOH-group. Additionally, benzoic acid has been used as interfacial modifiers to improve the charge carrier dynamics. Unlike the fullerene-based self-assembled molecules where anchoring group is chemically bonded to TiO2, PCBM is not, directly attached to TiO2 surface due to the absence of such an anchoring group. We investigate such different interactions with TiO2 surface via solar cells performance, steady-state and time-resolved spectroscopy studies, to understand charge extraction, and interfacial charge recombination.

Driving intramolecular charge transfer by tuning molecular orbitals and dielectric constant

Melissa P. Aplan, Youngmin Lee, Jason M. Munro, Christopher Grieco, Ismaila Dabo, Qing Wang, John B. Asbury, Enrique D. Gomez, The Pennsylvania State Univ. (United States)

Fully conjugated block copolymers, consisting of an electron donor and an electron acceptor block, can serve as the active layer in organic photovoltaic devices. Incorporating the donor-acceptor interface within the chemical structure enables model studies of energy and charge transfer. We synthesized a series of block copolymers consisting of a P3HT electron donor and three different push-pull polymer electron acceptors, either poly-((9-(9-heptadecanyl)-9H-carbazole)-1,4-diyl-alt-[4,7-bis(3-hexylthiophen-5-yl)-2,1,3-benzothiadiazole]-2',2''-diyl) (PCT6BT), poly-((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthiophen-5-yl)-2,1,3-benzothiadiazole]-2',2''-diyl) (PFT6BT), or poly-((2,5-dihexylphenylene)-1,4-diyl-alt-[4,7-bis(3-hexylthiophen-5-yl)-2,1,3-benzothiadiazole]-2',2''-diyl) (PPT6BT). By altering only the electron rich unit of the acceptor, we adjust the driving force for intramolecular charge transfer by tenths of an eV. Dynamic light scattering confirms that the synthesized block copolymers can be fully dispersed in dilute solutions, enabling studies of photoluminescence quenching within individual chains. The absorption and emission spectra of the block copolymers can be deconvoluted to extract the contributions from each of block, enabling us to quantify the yield of intramolecular charge transfer states. Taking the data from all block copolymers together, we find a critical driving force required to generate charge transfer states that depends on the dielectric constant of the solvent.

Polarized soft x-ray scattering reveals chain orientation within block copolymer structures

Joshua H. Litofsky, Melissa P. Aplan, Thinh P. Le, Youngmin Lee, Enrique D. Gomez, The Pennsylvania State Univ. (United States)

Fully conjugated block copolymers, consisting of covalently bonded donor

and acceptor blocks, can serve as the active layer in organic photovoltaics (OPV) and other organic electronic devices. The use of Resonant Soft X-Ray Scattering (RSoXS) allows for studies into the molecular orientation and domain spacing of the polymers within lamellae by tuning the X-ray energy and polarization to examine various components of block copolymers. Using the conjugated block copolymer system of poly(3-hexylthiophene)-block-poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(thiophen-5-yl)-2,1,3-benzothiadiazole]-2?,2?-diyl), P3HT-b-PFTBT, and PFTBT derivatives, we can examine the effects of various polymer blocks on the differences of morphology between the donor and acceptor. Polarized Soft X-Ray Scattering (PSoXS) allows us to quantify the type and the degree of orientation of chains within block copolymer domains in thin films. Our work suggests that within our conjugated block copolymers, the P3HT chains orient parallel to the block copolymer interface. Furthermore, examining the anisotropy in PSoXS data provides a clear signature of the block copolymer microstructure. Fourier transform calculations of ideal polymer structures corroborate this concept of block copolymer domains. Thus, we confirm that the domain spacing extracted from PSoXS scales with the end-to-end distance of the blocks. Based on our early findings, we believe that within our P3HT-b-PFTBT block copolymer films, the crystalline P3HT blocks orient parallel to the block copolymer interface.

Photoluminescence dynamics in perovskites with different grain sizes

Hyung Do Kim, Yasunari Tamai, Hideo Ohkita, Kyoto Univ. (Japan)

Solution-processed organic–inorganic perovskites based on metal halides have shown considerable potential in application of photovoltaic devices because of their excellent properties, such as direct bandgap with high absorption coefficient, high charge carrier mobility, long diffusion length, and Wannier–Mott exciton. Currently, the power conversion efficiency (PCE) of perovskite solar cells has been improved dramatically from 3.8% in 2009 to more than 22% in 2016. Recently, we have fabricated highly efficient planar heterojunction CH3NH3PbI3 devices with different grain sizes by the fast deposition–crystallization procedure. All the photovoltaic parameters were improved as the grain size of perovskites increases.[1] The best PCE of 19.4% was obtained for a grain size of 500 nm: a short-circuit current density of 23.9 mA cm?2, an open-circuit voltage of 1.08 V and a fill factor of 0.750. In this study, we discuss the photoluminescence (PL) dynamics of perovskites with different grain sizes by measuring the time-resolved PL spectroscopy. As a result, we found that the lifetime is increased with increasing grain size of perovskites. By analyzing the lifetime dependence of excitation intensity, we also found that trap density is decreased with increasing grain size of perovskites. On the basis of these experimental data, we further discuss the relationship between the photovoltaic performance and the grain size of perovskites in terms of the charge carrier recombination dynamics.

Dual Förster resonance energy transfer and morphology control to boost the power conversion efficiency of all-polymer OPVs

Jiangang Liu, Changchun Institute of Applied Chemistry (China)

Broadening the absorption spectrum and efficiently harvesting photogenerated excitons are crucial tasks to realize high-efficiency polymer solar cells (PSCs). Recently, ternary PSCs with complementary absorptions into a single junction device have been emerging as a promising strategy to enhance the absorption of binary PSCs. However, the effect of ternary PSCs critically depends on the location of the third component according to different principles. Due to the hard control of the third component location, only limited high-performance ternary systems have been demonstrated previously. Here, we develop a new concept of dual Förster resonance energy transfer (dual-FRET), in which the third component acts as “energy donor” and the donor and acceptor act as “energy acceptor”. Thus, exciton energy of the third component could transfer energy to both the donor and the acceptor through the FRET principle. Consequently, the third component should only be dispersed uniformly in the binary film regardless of its location. Using this concept, the performance of ternary PSCs, i.e., PTB7-Th (donor) / P(NDI2OD-T2) (accepter) / PF12TBT (the third component), reaches to 6.07%, more than about 30% compared to the corresponding binary PSCs (4.70%). Our work provides a novel way for designing the ternary structure to boost the efficiency of PSCs.

Proton radiation effects of conjugated polymer composite thin films

Sam-Shajing Sun, Harold O. Lee, Norfolk State Univ. (United States)

Polymeric thin film based electronic and optoelectronic materials and devices appear attractive for potential space and certain radiation related applications due to their inherent features such as lightweight, flexible, biocompatible, etc. Proton radiation is a major form of ionizing radiation in space, particularly in the so-called inner Van-Allen belt region where most near-earth satellites are orbiting, yet very few literature or data are available on proton radiation effects on conjugated polymer systems. In this study, the proton radiation effects on the electronic/optoelectronic properties of several conjugated polymers and their composites are briefly evaluated. Specifically, UV-Vis absorption spectra of several conjugated polymers and/or their composite thin films were studied and compared before and after the proton radiations at different dosages. The results revealed that proton radiation has very little or insignificant impact up to 800 Rads (corresponding to a dosage over an intense solar event in solar system) on the optoelectronic properties of P3HT, P3HT:PC60BM blend, a light harvesting donor-bridge-acceptor (DBA) and a novel donor-bridge-fluorinated-acceptor (DBfA) type block copolymer thin films. Results imply these conjugated polymers or their composites appear stable and durable for potential space and proton radiation related device applications.

Dimethyl sulphoxide vapor annealing assisted morphology control for hysteresis-free organometal halide perovskite solar cells

Yu Wang, Ping Liu, Dongwei Han, Dongying Zhou, Feng Lai, Soochow Univ. (China)

Realizing high performance perovskite solar cells (PeSCs) requires that photons absorbed in the active layer and charges collected by the electrode be maximized. To this end, morphology control of perovskite films is very essential. Previous reports have revealed that dense pinhole-free perovskite films via one-step fabrication, having less recombination defects, generally contribute to high efficiency and negligible current-voltage hysteresis PeSCs. For such one-step fabrication of PeSCs, thermal annealing is routinely conducted to produce the crystallization of perovskite layers. However, due to their heterogeneous nucleation growth nature, discontinuous perovskite films are generally induced by the only treatment with thermal annealing. As an alternative method, solvent vapor annealing has been impressed for morphology control of perovskite films. For example, DMF and DMSO vapor annealing applied pre-/post- thermal annealing have been demonstrated for crystallization improvement of CH3NH3PbI3 films, respectively. In this regard, effects of solvent annealing onto the CH3NH3PbIxCl3-x based perovskite films still remain less studied.

In this work, we report that the use of DMSO vapor annealing followed by thermal annealing increases remarkedly the crystallinity and coverage of CH3NH3PbIxCl3-x film. Due to elimination of the film voids, DMSO solvent annealing effectively improves the electronic properties of CH3NH3PbIxCl3-x perovskite films by reducing recombination defects. Particularly, the perovskite solar cell using the DMSO vapor annealing yields a power conversion efficiency (PCE) of 13.14% under air mass global (AM 1.5 G) spectrum illumination, which shows a 14% improvement in PCE compared to the counterpart only treated by the thermal annealing (ca. a PCE of 11.51%).

10363-77, Session PMon

Inverted polymer solar cells with zinc oxide-modified vanadium-doped indium oxide as the electron-collecting electrode at room temperature

Sung-Jin Lim, Min-Jun Choi, Dongguk Univ. (Korea, Republic of); Keun Yong Lim, Korea Institute of Science and Technology (Korea, Republic of); Jisoo Goo, Young-Jun You, Dongguk Univ. (Korea, Republic of); Do Kyung Hwang, Korea Institute of Science and Technology (Korea, Republic of); Kwun-Bum Chung, Jae Won Shim, Dongguk Univ. (Korea, Republic of)

Recently, polymer solar cells (PSCs) with an inverted structure have received considerable attention for their improved air stability. In such a structure, tin-doped indium oxide (ITO)-modified with low-work function interlayers commonly serves as an electron-collecting electrode. However, a thermal annealing process is inevitable for high conductivity of ITO, which limits versatile use of ITO. Vanadium-doped indium oxide (IVO) is an attractive material for an alternative transparent conducting electrode (TCE), because of the excellent optical and electrical properties, and a variety of stoichiometric compositions of oxides VOX.

Here, we examined optical, electrical, and surface properties of the IVO films deposited by a radio frequency (RF) co-sputtering system using dual targets of V2O5 and In2O3 at room temperature as a function of V2O5 target RF power. The IVO film with the V2O5 target RF power of 8 W showed the optimal transparent conducting properties with the sheet resistance of 74.83 Ohm/square and an average transmittance of 89.4%. The energy band offset between Fermi level and conduction band minimum decreased to 1.02 eV without changes in the physical structure or surface property. The inverted PTB7:PC70BM-based PSCs with the IVO TCE fabricated at the V2O5 target RF power of 8 W yielded the highest power conversion efficiency of 4.7 ± 0.4 % under simulated air mass (AM) 1.5 global (G), 100 mW/cm2 illumination, which was above that of the reference PSCs fabricated using the ITO as the TCE.

Perylene-3,4,9,10-tetracarboxylic acid tetracesium salt (Cs4PTA) as efficient and inexpensive cathode interfacial layer for inverted planar perovskite solar cells

Chen Wang, Ping Liu, Dongwei Han, Dongying Zhou, Lai Feng, Soochow Univ. (China)

Currently, perovskite solar cells (PeSCs) have attracted tremendous attention due to their boosting power conversion efficiency (PCE) up to 21%, allowing a promising application for solar-energy conversion in industry. Efforts have been devoted to developing efficient perovskite materials with improved photon absorption and exciton separation. More importantly, charge extraction from the perovskite to the electrodes also plays a critical role in the performance of PeSCs. Since diffusion length of electrons is generally shorter than that of holes, cathode interfacial layers (CILs) are very essential. For the inverted planer PeSCs, the electron transport layer, fullerene derivatives typically used, have the mismatch lowest unoccupied molecular orbitals with the work function of the cathode. Therefore, cathode interfacial layers (such as ZnO, BPhen, etc.) have been usually utilized between the fullerene derivatives and the cathode to reduce the electron extraction barriers.

In this work, we first report the use of perylene-3,4,9,10-tetracarboxylic acid tetracesium salt (Cs4PTA) as effective and low-cost cathode interfacial layer for perovskite solar cells. As a proof of concept, we impressed Cs4PTA to PeSCs having an inverted configuration of ITO/PEDOT:PSS/CH3NH3PbIxCl3-x/PCBM/CIL/Ag as the CIL. The PeSC with Cs4PTA yields a PCE of 12.55%, which is increased by 20% in comparison to the reference device without the CIL (ca. a PCE of 10.42%). The PCE value of PeSC with Cs4PTA is also higher than that of device with BPhen as the CIL (ca. a PCE of 11.94%).

Controlling hybrid charge transfer exciton properties at nitride-organic semiconductor heterojunctions

Anurag Panda, Stephen R. Forrest, Univ. of Michigan (United States)

Analogous to polaron-pair states at excitonic HJs, hybrid charge transfer excitons (HCTEs) are at the heart of exciton-to-charge conversion and charge recombination processes at organic-inorganic heterojunctions (OI-HJs). In this work, we study HCTE formation and dissociation kinetics at junctions between inorganic semiconductors, gallium nitride ((In)GaN) with varying indium compositions, and organic semiconductors, boron subphthalocyanine chloride (SubPc), and tris(4-(5-phenylthiophen-2-yl) phenyl)amine (TPTPA). To study the HCTE dissociation efficiency as functions of temperature (T), from T = 294 K to T = 10 K, and voltage (V), from V = 1 V to V = -5 V, we measure external quantum efficiencies (EQE) of the OI devices. We find that nitride semiconductors with appropriate doping can dissociate organic semiconductor excitons with near unity efficiency at room temperature. We explain the voltage and temperature dependence of the EQE using our previously developed theory [1,2] of OI diode operation. We observe the HCTE spectra by electroluminescence, and find that the peak energy closely corresponds to OI-HJ offset energy. Further, we tune the spectra peak energy by changing the indium composition in the GaN layer. We use a quantum mechanical model [3] to elucidate the effects of semiconductor energy levels, dielectric constants, and interface confinement on the binding energy and oscillator strength of the HCTE.

Hybrid tandem solar cells combining PbS quantum dot and organic subcells with complementary near infrared absorption

Taesoo Kim, Ru-Ze Liang, Hanlin Hu, King Abdullah Univ. of Science and Technology (Saudi Arabia); Banavoth Murali, Univ. of Hyderabad (India); Ahmad R. Kirmani, King Abdullah Univ. of Science and Technology (Saudi Arabia); Mingjian Yuan, Univ. of Toronto (Canada); Pierre M. Beaujuge, King Abdullah Univ. of Science and Technology (Saudi Arabia); Edward H. Sargent, Univ. of Toronto (Canada); Aram Amassian, King Abdullah Univ. of Science and Technology (Saudi Arabia)

We demonstrate monolithically integrated hybrid tandem solar cells that combine a solution-processed colloidal PbS quantum dot (CQD) and a solution-processed bulk heterojunction subcells with enhanced complementary absorption in the red and near infrared spectra. The hybrid tandem solar cell is electrically connected in series with a p and n type interconnecting layer (ICL) stack that includes a metal oxide layer and a conjugated polyelectrolyte with the incorporation of Au nano-islands. As the CQD subcell exhibits strong absorption at short wavelength and weaker absorption at longer wavelength (PbS QD; Eg = 1.34 eV), it is complemented with a polymer:fullerene top cell consisting of a blend of the low bandgap polymer (PDPP3T; Eg = 1.56 eV) and PC61BM, which is weakly absorbing in the visible to assure excellent spectral complementarity. The insertion of Au nano-islands into the ICL reduces the series resistance, increases the shunt resistance, enhances the fill factor and then achieves a power conversion efficiency (PCE) of 7.9%, superior to the efficiency of individual single cells. Additionally, we will discuss how QD subcell can be fabricated on the OPV subcell without damaging it and can help us achieve PCE approaching 10%.

10363-81, Session PMon

Optical excitations dynamics at quantum dots-fullerene heterointerface

Marcello Righetto, Alberto Privitera, Renato Bozio, Univ. degli Studi di Padova (Italy)

Colloidal quantum dots (QDs) display intriguing optoelectronic properties, such as broadband absorption, high oscillator strength, and size-tunable energy levels. These properties make them suitable candidates for photon harvesting. Due to generally high exciton binding energies, exciton-separating interfaces lay at heart of QDs photovoltaics.[1] The interaction of CdSe/CdS QDs with organic acceptors, such as PCBM, is complex and results in either exciton migration (energy transfer) or exciton dissociation (charge transfer). [2]

In this work, we exploit surface chemistry tools to tailor and direct QDs/PCBM interaction towards desired charge separation in blends, mimicking bulk hetero-junctions active layers. Indeed, changing ligands' chemical nature and length we achieved higher charge generation yields.

We monitored interaction dynamics on picosecond timescale using ultrafast transient absorption (TA) technique. Bleach signals in TA are associated with conduction band electrons and their dynamics is a quantitative probe of interactions dynamics. Moreover, electron paramagnetic resonance (EPR) provided a broader view on charge dynamics at hetero-interface. Indeed, time resolved and pulsed EPR allows tracking the dynamics of paramagnetic species on millisecond timescale. The fate of photo-generated charges plays a pivotal role in determining the efficiency of photovoltaic materials.

Noteworthy, short chain thiols ligands appear to greatly enhance charge generation and suppress geminate recombination of charges. The outcomes of this work suggest possible strategies for the implementation of QDs in hybrid organic-inorganic solar cells.

Tuning charge transfer at organic/metal interfaces

Afaf El-Sayed, Al Azhar Univ. (Egypt); Elizabeth Goiri, Donostia International Physics Ctr. (Spain); Patrizia Borghetti, Institut des NanoSciences de Paris (France); Dimas G. de Oteyza, Donostia International Physics Ctr. (Spain); Enrique Ortega, Univ. del País Vasco (Spain)

Energy-level alignment at hetero-interfaces plays an essential role in the functionality of charge injection devices, such as organic solar cells, where the efficiency is largely determined by the relative band edge positions of all its constituents. In fact, an appropriate level alignment may drive the formation of hybrid interface states at the Fermi energy, trigger significant charge transfer and lower interface potential barriers. 1

In this work, we report how the electronic level alignment of fluorinated copper-phthalocyanines (F16CuPc) on metal surfaces [e.g. Au(111), Cu(111), and Ag(111)] can be tailored by changing the substrate work function. By doing this we show how the charge transfer into empty molecular levels can be triggered across the metal-organic interface. Remarkably, we report how we can finely tune the charge transfer within the very same organic-metal interface by making use of the supramolecular environment-dependent work function in molecular blends. 1-3

These intriguing observations are the outcome of a combination of surface-sensitive electron spectroscopies, e.g. x-ray photoemission spectroscopy (XPS), ultra-violet photoemission spectroscopy (UPS), and near edge x-ray absorption fine structure (NEXAFS). Such powerful techniques reveal a number of characteristic spectroscopic fingerprints that provide a fully coherent picture of the physical chemistry phenomena occurring at these relevant interfaces.

Fabrication of high coverage lead-free CH3NH3SnI3 perovskite films using modified solvent bathing method

Takashi Fujihara, Institute of Systems, Information Technologies and Nanotechnologies (ISIT) (Japan); Shinobu Terakawa, Toshinori Matsushima, Chuanjiang Qin, Masayuki Yahiro, Chihaya Adachi, OPERA Ctr. for Organic Photonics and Electronics Research (Japan)

Developing lead-free organic–inorganic perovskite absorbers for solar cells is a crucial issue for commercial use. Tin halide perovskites are alternative candidates for lead perovskites. However, they show unstable properties due to the low quality of their films. The film quality strongly depends on the formation speed of precursor solution to perovskite in a solution process. In this work, a modified solvent bathing method was used to fabricate MASnI3 perovskite films. The formation speed of the perovskite films was controlled by combining anti-solvents with miscibilities different from those of the precursor solvent. The coverage of the perovskite films was significantly improved by employing a mixed solvent in an appropriate ratio and at an appropriate temperature. The power conversion efficiency of a planar perovskite solar cell with a film prepared using this method was 2.1 ± 0.4%, which is higher than that of solar cells with a conventionally prepared active layer. Notably, an open-circuit voltage of 0.45 ± 0.01 V was obtained, which is relatively high for tin halide perovskites. Additionally, significant reproducibility was achieved in comparison with previously reported devices. Further, an unexpectedly long lifetime of over 200 h was observed for encapsulated solar cells under simulated 1 sun (AM1.5, 100 mW/cm2) continuous irradiation, which is in contrast to the expectation that tin perovskites degrade quickly. The high surface coverage of our tin halide perovskite film results in relatively high open-circuit voltage and stable photovoltaic properties.

Practically viable strategy for efficient and reliable semi-transparent organic solar cells: Face-seal encapsulation embedded with color-filter functionality

Hyunwoo Lee, Jaewon Ha, Hyeonwoo Lee, Seunghyup Yoo, KAIST (Korea, Republic of)

Semitransparent solar cells are regarded as a photovoltaic (PV) technology in which organic solar cells (OSCs) can have a competitive edge over other PV technologies mainly due to their thin-film nature. Furthermore, the compatibility of OSCs with plastic substrates can even lead to semitransparent PV films that can be easily integrated with the existing building infrastructure at low cost, making semitransparent OSCs (ST-OSCs) even more attractive. To deploy ST-OSCs in real-world application such as solar windows in building-integrated or vehicle-integrated PV (BIPV or VIPV) applications, it is essential to establish an encapsulation method that effectively prevents water vapor or oxygen from infiltrating into cell active layers and interfaces while keeping the low manufacturing cost. From the efficiency perspectives, on the other hand, it will be highly useful if one can recycle a significant portion of the light that usually passes through ST-OSCs without being absorbed in active layers.

In this work, we propose an architecture for semi-transparent organic solar cells (ST-OSCs), wherein the cells are “face-seal” encapsulated with color-filtering barrier films. The color-filtering barrier film is designed based on transfer matrix formalism so that spectral components corresponding to major absorption band of active layers can be selectively reflected while the other spectral components are transmitted for see-through capability. Preparation of these color filters being independent of cell fabrication, the best material/ process composition can be utilized without worrying about damaging the organic active layers. By integrating the proposed plastic films having the embedded color filters with semi-transparent organic solar cells, we demonstrate ST-OSCs with power conversion efficiency of 7.3% under 100mW/cm2 (AM 1.5G) and with transmittance over 10% in the spectral range of 450-600 nm. Furthermore, we show that these devices can maintain over 90% of the initial efficiency even after being kept under highly damp condition (30°C, 90% relative humidity) for 120 hours.

Stability enhancement of organic-inorganic perovskite solar cells via thin film encapsulation

Nochang Park, Korea Electronics Technology Institute (Korea, Republic of); Jincheol Kim, Jae S. Yun, The Univ. of New South Wales (Australia)

This paper details an thin film encapsulation of perovskite solar cells to improve the stability from moisture. The perovskite solar cells were encapsulated with alumunum oxide (Al2O3) via atomic layer deposition (ALD) process. The process was performed at low temperatures (110°C, 150°C) to minimize thermal degradation. We achieved the 6.3 nm and 6.6 nm in thickness at 110°C and 150°C, respectively. There were little changes in electrical properties of perovskite solar cells after ALD process at 110°C. However, the power conversion efficiency (PSC) was decreased to about 10 % compared to initial PSC at 150°C. The encapsulated samples showed good stability at 25 °C, 50% RH for 2,000 hours. In addition, More than 200 hours in 45 °C, 85% RH testing has been observed without significant PSC decrease caused by moisture.

Perovskite thin films on insulators and in thin-film transistors applications

Johnny K. W. Ho, Rocky K. H. Chan, Jenner H. L. Ngai, Sin Hang Cheung, Shu Kong So, Hong Kong Baptist Univ. (Hong Kong, China)

Methylammonium (MA)-based perovskite compounds are generally grown on conducting or semiconducting substrates. In this study, we explore the growth of these compounds on insulators. The key challenge is to find a surface that favors crystal growth of perovskites, but without compromising the adhesion of the crystals. A family of methacrylate-based polymers has been identified as the insulators. Onto these insulators, Pb-based MA iodide polycrystalline thin films are successfully grown. We found that PPMA, a derivative of a common commercial plastic poly(methyl methacrylate), produces the best perovskite films. To test the electronic quality of these films, we perform photothermal deflection spectroscopy to look into its subgap optical absorptions. The relation between the crystal quality and the hydrophobicity as well as microscopic interactions is investigated. Furthermore, we employ these films for thin-film transistor applications. Under optimal conditions, the thin-film transistors fabricated on PPMA produces the best device with electron mobility in excess of 0.1 cm2 V-1 s-1.

Optoelectronic properties of CuO-Cu2O complex layers in MAPbI3 perovskite solar cells

Kuan-Lin Lee, Lung-Chien Chen, Kai-Chieh Liang, National Taipei Univ. of Technology (Taiwan)

The perovskite-based solar cells have high performance for power conversion efficiencies. The scientists had been searching new materials to fabricate a new structure of solar cells over the past 5 year. In this work, we report the optoelectronic properties of CuO-Cu2O complex layers in CH3NH3PbI3 (MAPbI3) perovskite solar cells. The nanostructured CuO-Cu2O films are made on the ITO-coated glass from cupper (Cu) target by AC sputtering. The CuO-Cu2O films were formed by oxidation method at different annealing temperature from 300 to 500° C. The CuO-Cu2O films were also applied into the MAPbI3 perovskite solar cells as a hole transport layer. In the cell structure, the C60 (Fullerene) is a n-type material that helps to inject electrons into the electrode. The BCP (Bathocuproine) not only is an exciton block layer but also the electron transport layer and active layer of the protective layer in the device. The evaporation method was employed to deposited C60 and BCP. The device structure is Ag / BCP / C60/ CH3NH3PbI3 / CuO-Cu2O / ITO / Glass which the C60 and BCP play electron transport layers (ETLs) and buffer layers, respectively. When the annealing temperature is 350° C, the PCE of the cell is the best value for 8.53%. With optimized annealing temperature and conditions, the solar cells have the highest efficiency, low J?V hysteresis and excellent stability. Therefore, the low-cost processed and stable nanostructured CuO-Cu2O will be an alternative hole transport layer materials for industrial production of the perovskite solar cells.

Plasmon enhanced power conversion efficiency in inverted bulk heterojunction organic solar cell

Minu Mohan, Ramkumar Sekar, Manoj A. G. Namboothiry, Indian Institute of Science Education and Research Thiruvananthapuram (India)

P3HT:PCBM is one of the most studied polymer-fullerene system. However the reported power conversion efficiency (PCE) values falls within the range of 4% to 5%. The thin film architecture in OPVs exhibits low PCE compared to inorganic photovoltaic cells. This is mainly due to the low exciton diffusion length that limits the active layer thickness which in turn reduces the absorption of incident light. Several strategies are adapted in order to increase the absorption in the active layer without increasing the film thickness. Inclusion of metal nanoparticles into the polymer layer of BHJ solar cells is one of the promising methods. Incorporation of metal nanostructures increases the absorption of organic materials due to the high electromagnetic field strength in the vicinity of the excited surface plasmons.

In this work, we used ~ 60 nm Au plasmonic structures to improve the efficiency of organic solar cell. The prepared metal nano structures were characterized through scanning electron microscopy (SEM), and UV-Visible spectroscopy techniques. These prepared metallic nanoparticles can be incorporated either into the ETL or into the active P3HT:PC71BM layer. The effect of incorporation of plasmonic gold (Au) nanoparticle in the inverted bulk heterojunction organic photovoltaic cells (OPVs) of P3HT:PC71BM fabricated in ambient air condition is in progress. Initial studies shows an 8.5% enhancement in the power conversion efficiency (PCE) with the incorporation of Au nanoparticles under AM1.5G light of intensity 1 Sun.

The intrinsic photoproducts and their dynamic balance revealed by density-resolved spectroscopic method

Shufeng Wang, Peking Univ. (China)

The highly efficient organolead trihalide perovskite based solar cells are the top interests in photovoltaics for the recent years. It is well known that their high efficiencies benefit from the rich photo-induced free carriers. It is also know that excitons co-exist with the free carriers. Are these two photoproducts has a fixed ratio after excitation, or they are of dynamic balance depending on the density? This fundamental question decides whether the exciton can convert to free carriers to improve the cell efficiency. It also decides the excited state dynamics since the ratio follows the total density, which decays in time. In addition, the dynamic balance of exciton and free carriers should be a very general question in many widely studied semiconductors. However, no method can be applied to see such density-dependent behavior until now. We developed a density-resolved spectroscopic method to directly observe the photoproduct types and their density-dependent interconversion. In perovskite, the dynamic co-existence of excitons and free carriers was experimentally verified for the first time. It is also revealed a exciton binding energy of 24±2 meV and an effective mass of electron-hole pair. Surprisingly, with the method, we found that the photoproduct system could be more complicated than above exciton-carrier system. Our spectroscopic method and the results profoundly enrich the understanding of the photophysics in perovskite materials for photovoltaic applications. In addition, our method can be widely applied to other semiconductors. (Ref: Physical Review B 94, 140302 (2016)).

High efficiency printable polymer solar cell modules with a new simplified series connection architecture

Eunhag Lee, Jinho Lee, Soonil Hong, Kwanghee Lee, Gwangju Institute of Science and Technology (Korea, Republic of)

Despite the recent dramatic improvements in power conversion efficiencies resulting in values exceeding 12%, the fabrication of polymer solar cell modules (PSMs) via printing process is the important challenges. Conventional module architecture consisting of serially interconnected stripe-shaped patterned subcells requires highly sophisticated patterning techniques that significantly increase the complexity of manufacture process and lead to reduction in module efficiency due to so-called 'aperture loss' in series connection areas (SCAs). Here, we demonstrate the highly efficient PSM architecture without any patterning process by introducing innovative electric field-induced metal-nanofilament concept. To produce vertically connected metal nanoelectrodes within SCAs between the bottom indium tin oxide and top silver electrodes, we introduce the silver-nanoparticles (SNPs) and nonconjugated polyelectrolyte (NPE) into the photoactive bulk-heterojunction solar inks. The SNPs facilitate the formation of metal-nanofilament while amine-containing NPE performs dual function to construct simplified solar module architecture: (i) Self-assembly: NPE molecules are spontaneously migrate onto ITO surface and act as a work function modifier, thereby allowing ohmic contact. (ii) Stabilizer: amine group of NPE help to form and stabilize the SNP in solution. With the loss-free geometrical and electrical connection of subcells, we achieve a high module efficiency over 6.6% with a geometric fill factor of 90%.

Femtosecond transient absorption spectroscopy of planar CH3NH3PbI3 perovskite films

In-Sik Kim, Cheol Jo, Gwangju Institute of Science and Technology (Korea, Republic of); Rira Kang, Korea Atomic Energy Research Institute (Korea, Republic of); Dong-Yu Kim, Do-Kyeong Ko, Gwangju Institute of Science and Technology (Korea, Republic of)

As an alternative to conventional inorganic solar cells, organo-metal halide perovskites (OMHPs) have caught considerable attention due to a high absorption coefficient, allowing photovoltaic devices to be thin and flexible, as well as low-cost solution processing methods. As a matter of fact, solution-processed perovskite solar cell technologies have reached power conversion efficiencies (PCEs) of over 20% in the past few years. This rapid progress in OMHP solar cells have realized by several approaches: a material development through varying consistent components of the perovskites, an optimization of device structure, and a development of sample preparation methodology. However, understanding of photo-induced carrier dynamics in the OMHPs remains still unclear.

We have fabricated methylammonium lead halide (CH3NH3PbI3) perovskite films using various methods for the solution processing, which affect crystal orientation, charge transfer in presence of electron transport layer, and PCE of planar perovskite solar cell devices. In this work, we demonstrate photo-generated dynamics in planar CH3NH3PbI3 perovskite films using a femtosecond transient absorption (TA) spectroscopy. The TA dynamics of perovskite shows a dependence on the preparation methods of the perovskite films.

Crystalline MoOx thin-films as hole transport layer in organic photovoltaics

André L. F. Cauduro, Mehrad Ahmadpour, Univ. of Southern Denmark (Denmark); Roberto Moreno Souza dos Reis, Gong Chen, Lawrence Berkeley National Lab. (United States); Andreas K. Schmid, Lawrence Berkeley National Lab. (United States) and Univ. of Southern Denmark (Denmark); Christophe Méthivier, Léo Bossard-Giannesini, Hervé Cruguel, Nadine Witkowski, UPMC Sorbonne Univ. (France); Horst-Günter Rubahn, Morten Madsen, Univ. of Southern Denmark (Denmark)

Molybdenum-oxide (MoOx) thin-films have attracted a lot of attention in the past years due to their unique ability to act as interfacial layers in electronics and energy applications. In the work presented here, large tuning possibilities in the electronic and optoelectronic properties of MoOx thin-films deposited by reactive sputtering are demonstrated, along with the implementation of the films in organic photovoltaics. A large tuning range in the conductivity of thin MoOx films of around 10 orders of magnitude is demonstrated via tuning of the oxygen partial pressures during the growth process, which also lead to drastic changes in the optical absorption (0.60 eV - 2.50 eV) of the films. The observed effects are attributed to changes in the electron density at the defect band: as the oxygen partial pressure increases, electrons are released and empty out the defect band [1].

Ultraviolet (UPS) and X-Ray (XPS) Photoelectron Spectroscopy investigations are conducted for accessing information about the work function and surface composition of the thin-films. Importantly, the work function of the films increase strongly with annealing temperature, and span a tuning range of almost 2 eV. Low Energy Electron Microcopy (LEEM) is applied to extract the spatially resolved work function values from the sputtered MoOx thin-films [2]. Application of the MoOx thin-films in novel organic optoelectronic devices is demonstrated by employing them as hole transport layers in DBP:C70 based small molecule solar cells.

Role of energy transfer for charge generation at organic-inorganic interfaces

Philipp Ehrenreich, Eugen Zimmermann, Lukas Schmidt-Mende, Univ. Konstanz (Germany)

Hybrid solar cells promise large potential for solar cell application by bringing together mechanical as well as chemical stability of an inorganic metal-oxide on the one hand, with unlimited design possibilities for organic semiconductors on the other hand. For efficient charge generation, not only comprehensive light absorption is needed but also charge separation and charge collection should take place efficiently. These properties, however, have turned out to be limited for hybrid interfaces compared to their fully organic opponents. In this contribution we highlight major challenges that are responsible for such limitations. Beside the role of trap states in the metal oxide we focus on the influence of polymer morphology and the role of Förster resonant energy transfer in a charge generation process. Both electronic measurements on solar cell devices as well as spectroscopic results with respect to exciton dynamics are presented and reveal design rules for future developments on hybrid solar cell materials.

10363-95, Session PMon

Multiscale study of the formation of the PFI:PSS:PEDOT super structure and its HOMO-LUMO energies

Min Huang, Tongji Univ. (China)

The vertically self-organized concentration profile of the PSS:PEDOT:PFI layer from mesoscale DPD simulations presented in the previous contribution were inversely mapped back into atomistic scale. DFT quantum calculations were then performed to understand the nature of the formation of the PFI:PSS:PEDOT complex. Hydrogen bond bonding energy and deprotonation energy were obtained accordingly. The charge states of PSS polymer chain in this complex and its effects on the HOMO-LUMO (the work function) were discussed. The DFT quantum calculation revealed the formation of complex hydrogen bonding networks leading to the formation of super PFI:PSS:PEDOT structure. PFI was found to be a stronger H donor than PSS. The adding of PFI was found to have the effect of lowering the energy of deprotonated PSS chain, as the result pushing HOMO, LUMO of the PFI:PSS:PEDOT ternary structure to lower than those of the original PSS:PEDOT binary structure. The increasing of the work function from the bottom to the top of the film can therefore be understood as the result of the combining effects of increasing PSS:PEDOT and PFI:PSS ratio in the vertical direction induced by PFI led phase segregation.

Design of novel triphenylamine-based donor-acceptor oligomers for stable organic photovoltaics

Sergey A. Ponomarenko, Institute of Synthetic Polymeric Materials (Russian Federation) and M.V. Lomonosov Moscow SU (Russian Federation); Yuriy N. Luponosov, Alexander N. Solodukhin, Institute of Synthetic Polymeric Materials (Russian Federation); Artur L. Mannanov, M.V. Lomonosov Moscow SU (Russian Federation) and Institute of Synthetic Polymeric Materials (Russian Federation); Oleg V. Kozlov, Zernike Institute for Advanced Materials (Netherlands) and M.V. Lomonosov Moscow SU (Russian Federation); Dmitry Y. Paraschuk, M.V. Lomonosov Moscow SU (Russian Federation) and Institute of Synthetic Polymeric Materials (Russian Federation); Maxim S. Pschenichnikov, Zernike Institute for Advanced Materials (Netherlands); Christoph J. Brabec, i-MEET (Germany)

A library of linear and star-shaped donor-acceptor oligomers having triphenylamine (TPA)-based electron-donating unit linked through (oligo) thiophene ϖ-conjugated spacers to 1, 2 or 3 terminal alkyl- or phenyl-substituted dicyanovinyl (DCV) or 3-ethylrhodanine electron-withdrawing groups was designed, synthesized and investigated [S.A. Ponomarenko et al., Faraday Discuss., 2014, 174, 313; Y.N. Luponosov at al., Organic Electronics, 2016, 32, 157]. Systematic variations of the number and chemical nature of the acceptor units, length of both the solubilizing alkyl chains and oligothiophene ϖ-bridges allowed elucidating the structure-properties relationships in this series of organic semiconductors. We have shown that the analog of TPA with methoxy-substitutes (m-TPA) increases solubility and crystallinity of the star-shaped molecules, making m-TPA as attractive intramolecular donor unit [Y.N. Luponosov at al., J. Mater. Chem. C, 2016, 4, 7061]. Our studies revealed that oligomers with alkyl- or phenyl- substituted DCV groups demonstrate significantly better solubility, electrochemical and oxidation stability as compared to their analogues with common H-containing DCV groups. Ultrafast photoinduced absorption spectroscopy, using a visible pump to mimic the sun photons and broadly tunable IR probe to monitor concentration of hole polarons at the conjugated system allowed to study the charge separation dynamics [O.V. Kozlov et al., Adv. Energy Mater., 2015, 5, 1401657]. Right choice of TPA-based oligomers as donors and fullerene-based acceptors allowed preparation of bulk heterojunction organic solar cells achieving PCE of 4.0 – 5.4% with high (0.9 - 1.0 V) open circuit voltage, which are fairly stable without any encapsulation. This work was supported by Russian Science Foundation (grant 14-13-01380).

Single phase high mobility Cu2O film as efficient and robust hole transporting layer for organic solar cells

Yaxiong Guo, GuoJia Fang, Wuhan Univ. (China); Gang Li, The Hong Kong Polytechnic Univ. (Hong Kong, China)

Carrier transport material plays critical role in solution processed advanced solar cells such as organic polymer solar cell and hybrid perovskite solar cells. Comparing to "standard" PEDOT:PSS hole transporting material (HTM)/ layer, inorganic HTMs such as MoO3, V2O5, NiOx etc. showed improved environmental stability and also high performance. High mobility, earth-abundant, environmentally-stable and nontoxic are the focus of HTMs research. This presentation will show highly transparent, high mobility and phase pure Cu2O nano-crystal films, which are synthesized by reactive magnetron sputtering at room temperature, are promising HTMs for efficient OSC applications.

In classical PTB-7 based solar cell system, we show that polymer solar cell with phase pure Cu2O HTM layer has over 10% enhancement in PCE, comparing to that with standard PEDOT:PSS solar cell. Better energy level alignment and reduced series resistance are believed to responsible for the improvement. The improved photovoltaic performance suggest Cu2O is a promising HTM for future low temperature roll to roll organic polymer solar fabrications.

Minimizing beam damage in the electron microscope to enable new imaging approaches for conjugated polymers

Brooke Kuei, Enrique D. Gomez, The Pennsylvania State Univ. (United States)

Transmission electron microscopy (TEM) of conjugated polymers has remained a challenge because resolution is limited by the electron dose the sample can handle. We have characterized the effects of beam damage on poly(3-hexylthiophene) (P3HT) and poly[(5,6-difluoro-2,1,3-benzothiadiazol-4,7-diyl)-alt-(3,3’’’-di(2-octyldodecyl)-2,2’;5’,2’’;5’’,2’’’-quaterthiophene-5,5’’’-diyl)] (PffBT4T-2OD) via electron diffraction and scanning TEM electron energy-loss spectroscopy (STEM-EELS). Critical dose DC values were calculated from the decay of diffraction and low-loss EELS peaks as a function of dose rate, accelerating voltage, and temperature. Importantly, DC increases with dose rate in the low dose rate regime, likely due to the limited diffusion of ions. This diffusion-limited argument is further explored by studying beam damage in P3HT with the antioxidant butylated hydroxytoluene (BHT), as well as through beam blanking experiments in which ions are given time to move between short exposures to the beam. STEM-EELS spectrum imaging also revealed that damage occurs even in areas untouched by the beam, likely due to a local rise in temperature caused by the beam. Altogether, our results suggest that although local heating can be important, other factors such as the dose rate must also be tuned to minimize beam damage. This improved understanding of beam damage in conjugated polymers will allow for new TEM techniques that were previously difficult for this class of beam sensitive materials, such as low-loss electron energy loss spectroscopy imaging and high resolution imaging.

On the ferroic properties of methylammonium lead iodide thin-films

Tobias Leonhard, Holger Röhm, Alexander Colsmann, Karlsruher Institut für Technologie (Germany)

The quest for alternative, non-toxic and long-term stable Perovskites is partly hampered by a lack of fundamental understanding of the MAPbI3 properties and energy conversion mechanisms. As part of this process, the scientific community controversially discusses the importance of ferroic properties for the exceptional performance of MAPbI3, including claims of non-ferroelectricity, anti-ferroelectricity, ferroelectricity and ferroelasticity. Some simulations have predicted ferroelectricity in MAPbI3 with alternating polarized domains ruling the vertical charge carrier transport. Any experimental evidence towards ferroelectricity will therefore provide helpful guidance for the quest to find non-toxic MAPbI3 replacements.

We explore the ferroic properties of methylammonium lead iodide (MAPbI3) perovskite solar cells by Piezoresponse Force Microscopy. We find domains of alternating polarization with a diameter of 90 nm which we identify as in-plane polarized ferroelectric domains. High-resolution photo-conductive atomic force micrographs under illumination also show an alternating charge carrier extraction pattern which we attribute to a small vertical polarization component. The correlation of the sample properties with Atomic Force and Kelvin Probe Force Micrographs evidence the piezo-electric nature of the domains.

Porphyrin-based donor materials for highly efficient organic photovoltaics

Xunjin Zhu, Hong Kong Baptist Univ. (China)

To mimic the natural photosynthetic systems utilizing chlorophylls to absorb light and store light energy, a series of symmetrical ϖ-conjugated small molecules have been constructed from meso-alkyl substituted porphyrins as the central unit and rhodanine derivatives as the terminal group. At first, we synthesized three new unsymmetrical push-pull A-D-A small molecules (CS-I, CS-II and CS-III) consisting of meso-alkyl substituted porphyrins 5,15-bis(2-octylundecyl)-porphyrin, 5,15-bis(3-octyl-1-tridecyl)-porphyrin and 5,15-bis(4-octyl-1-tetradecyl)-porphyrin as electron rich donor (D) units, ethynylbenzene as ϖ-linkage, and 3-ethylrhodanine (RH) as electron deficient acceptor (A), and applied them as electron donors in solution-processed bulk-heterojunction solar cells, leading to high power conversion efficiencies up to 6.49%.[1] And further detailed studies indicated that small molecules based 10,20-bis(2-hexylnonyl) aliphatic peripheral substituted porphyrin core performed much better than those with aromatic peripheral substituted porphyrin cores (4a, 4b and 4c), mainly due to the decreased steric hindrance and increased intermolecular ϖ-ϖ interactions.[2] Very recently, to extend the backbone conjugation and enhance intermolecular ϖ-ϖ interaction, we designed and prepared two porphyrin-based small molecules (PTTR and PTTCNR) in which 3,3’’-dihexyl-terthiophene were symmetrically conjugated to 10,20-bis-(2-octylundecyl)-porphyrin core. The conjugation of terthiophene and 2-octylundecyl peripheral substitutions on porphyrin-core, can not only effectively increase the solar flux coverage, but also can simultaneously facilitate stronger intermolecular ϖ-ϖ stacking and higher charge transfer mobility in the film. The processing engineering for their blend films with PC71BM afforded the highest power conversion efficiency of 8.21%, corresponding to a JSC of 14.30 mA cm?2, VOC of 0.82 V, and FF of 70.01%.[3]

Effect of Cu2O inorganic hole conducting material in flexible perovskite based heterojunction solar cell

Md. Asaduzzaman, Ali Newaz Bahar, Mawlana Bhashani Science and Technology Univ. (Bangladesh); Mohammad Maksudur R. Bhuiyan, Univ. Grants Commission of Bangladesh (Bangladesh)

The device modeling of a methyl ammonium lead iodide (CH3NH3PbI3) perovskite sensitized heterojunction solar cell has been carried out in this study. Cuprous oxide (Cu2O), an inorganic hole conducting material (HCM) has been proposed to use in the device structure consisting of Sn2O: F (FTO)/TiO2/perovskite absorber/HCM/Au stack. The thicknesses of the p-type Cu2O HCM, the n-type FTO, and the perovskite absorber have been optimized the crucial performance parameters including short circuit current density (Jsc), open circuit voltage (Voc), fill factor (FF), and energy conversion efficiency (?) of the perovskite solar cell have been computed using ADEPT 2.1 simulator. In addition, the effects of hole mobility and doping concentration of the HCM in corporations with the defect states of the Cu2O/interface have been analyzed. A higher open circuit voltage of 937.64 mV and a high energy conversion efficiency outstripping 23% have been recorded from the simulation. Moreover, the use of Cu2O as a hole transport layer substantiates the enhancement of the cell performance by reducing the degradation occurred due to using conventional Spiro-OMeTAD organic hole conducting layer. In addition, the replacement of moisture sensitive and costly Spiro-OMeTAD hole conducting material by Cu2O layer can provide double benefits to reduce the cost and to improve the stability.

Role of morphology in exciton dissociation and charge extraction in dilute donor-acceptor blend organic heterojunctions

Kan Ding, Univ. of Michigan (United States)

The performance of mixed-heterojunction (HJ) organic photovoltaic (OPV) cells show a significant dependence on device morphology. Here, we study HJs comprising blends of tetraphenyldibenzoperiflanthene (DBP) and C70. OPVs with this material combination is maximum at a very low (< 10%) DBP concentration in C70[1][2]. It is unclear how hole polarons in DBP

created on the dissociation of excitons at donor-acceptor junctions can be extracted from such a dilute system, yet the high efficiencies achieved suggests that charge extraction is unimpeded in the dilute mixtures. By studying the photoluminescence emission of two discrete charge transfer (CT) states [3] in structures comprising alternating, ultrathin layers of C70 and DBP, we precisely control the layer morphology, and it influence on the charge dissociation process. A kinetic Monte Carlo (KMC) simulation model is applied to understand the nanoscopic morphology of the multilayers and blends. The model quantitatively explains the charge extraction process and the CT emission spectra in the dilute active regions. We find that planar DBP molecules form ϖ-ϖ stacks that result in continuous percolation pathways to enable hole extraction even in the most dilute blends. We provide an explanation to the high performance of DBP/C70 photovoltaics at surprisingly low donor concentrations.

Hybrid solar cell based on a-Si/polymer flat heterojunction on flexible substrates

Antonio J. Olivares-Vargas, Svetlana Mansurova, Ismael Cosme-Bolaños, Andrey Kosarev, Carlos Alberto Ospina, Hiram Enrique Martinez, Instituto Nacional de Astrofísica, Óptica y Electrónica (Mexico)

An alternative to pure organic PVs is the class of organic-inorganic hybrid solar cells, where heterojunction is formed between inorganic semiconductors and organic compounds. An advantage of hybrid PVs over organics PVs lies in the high carrier mobility of the semiconductor and the light absorption at longer wavelengths than for organic compounds. In addition, band gap engineering can be a useful instrument in the design of the hybrid solar cell architecture since rather developed deposition process of inorganic semiconductors allows to tune the important structural and electronic parameters such as optical gap, Fermi level position, localized states distribution, etc. On the other hand, the chemical functionalizing of the organic component (by introduction of reducing or oxidizing groups in the chemical structure) is capable of significantly affecting their performance.

In this work, we present the results of investigation of thin film hybrid organic-inorganic photovoltaic structures based on flat heterojunction hydrogenated silicon (Si:H) and poly(3,4 ethylene dioxythiophene):poly(4-styrenesulfonate) (PEDOT:PSS) fabricated on different types of flexible substrates, namely, polyethylene naphthalate (PEN) and poly (4,4'-oxydiphenylene-pyromellitimide) (Kapton). Scanning electron microscopy (SEM) and atomic force microscopy (AFM) imaging have been used in order to study morphological characteristics of different layers in the structure. Spectral dependence of short circuit current has been analyzed aiming to reveal contribution of substrate on the electrical properties of the films grown on it. Performance characteristics of fabricated photovoltaic structures have been measured and analyzed for different thicknesses of the transparent electrodes and different substrate types.

10363-104, Session PMon

Investigation of charge generation and transport in fullerene-free ITIC-based organic solar cells

Xueping Yi, Iordania Constantinou, Erik D. Klump, Bhoj Gautam, Sofia Garakyaraghi, Franky So, North Carolina State Univ. (United States)

Over the past several years, considerable efforts have been dedicated to the synthesis of new non-fullerene small molecule acceptors but device efficiencies remained low compared to PC71BM-based devices. Recently, polymer solar cells using a non-fullerene acceptor, ITIC, reached efficiencies over 11%. In fullerene devices, it has been well understood that a large LUMO-LUMO offset (> 0.3 eV) between the donor polymer and the acceptor molecule is necessary for efficient exciton dissociation. On the other hand, devices using ITIC have been able to perform efficiently with much smaller LUMO-LUMO offsets.

To understand the difference between ITIC and traditional fullerene acceptors, we fabricated PTB7-Th devices with either ITIC or PC71BM. We found that these devices had similar performances, with a smaller short circuit current in the ITIC devices resulting from less short wavelength absorption. Surprisingly, while the LUMO of ITIC is 3.8 eV and PC71BM's LUMO is 4.3 eV, the open circuit voltage (VOC) observed in the devices was almost identical, indicating a larger voltage loss in the PTB7-Th:ITIC devices. To understand this difference, we probed the charge transfer state dynamics via transient photoluminescence. In this we found that the exciton lifetime was comparable in both ITIC and PC71BM systems, indicating that charge dissociation was efficient in both systems. Additionally, we measured sub-bandgap external quantum efficiency spectra in order to determine the energy level of the CT states. From these results, we found that despite the shallower LUMO energy of ITIC, both ITIC and PC71BM devices have the same CT energy level. Therefore, we conclude that while a smaller LUMO-LUMO offset is needed in ITIC based devices to achieve efficient exciton dissociation, the CT states form at a lower energy than the predicted energy level resulting in a significant VOC loss.

10363-105, Session PMon

Effect of polar sidechains on high efficiency organic solar cells

Xueping Yi, North Carolina State Univ. (United States); Bing Xu, Georgia Institute of Technology (United States); Erik D. Klump, Franky So, North Carolina State Univ. (United States); John R. Reynolds, Georgia Institute of Technology (United States)

It is commonly believed that a high dielectric constant is required to lower the exciton binding of a photovoltaic polymer. A common strategy is to add a polar side group to the polymer, as it will not affect the energy levels of the backbones. In this study, we compare the device performance of two polydithienosilole-thienopyrrolodione (DTS-TPD) based donor polymers. These two polymers are identical except DTS-TPD-CN has a side chain containing a cyano group while DTS-TPD does not. Surprisingly, despite the measured higher dielectric constant due to the polar cyano group, the device characteristics of the cyano containing devices were significantly worse than those of the devices made with the cyano polymer.

Atomic force microscopy images revealed very similar domain sizes for the two polymer-fullerene blends and suggested polar groups does not impair the intermixing of the polymer and fullerene. The measured space charge limited current mobilities showed the hole mobility of DTS-TPD-CN was two magnitudes lower than that of DTS-TPD indicating the cyano groups hinder the hole transport, contributing to a significant reduction in JSC and fill factor for the DTS-TPD-CN device. The energetic disorder of the hole transport was investigated by temperature dependent mobility measurements. It was found that the energetic disorder of DTS-TPD-CN:PC71BM was higher compared to that of DTS-TPD:PC71BM. We believe the high energetic disorder is due to local variations in the potential caused by the permanent dipoles on the cyano group.

Ultrashort pulsed laser-dicing of silicon wafers for the decollating of conventional and hybrid solar cells

Christian J. Hördemann, Christian Fornaroli, Arnold Gillner, Fraunhofer-Institut für Lasertechnik (Germany)

In order to cut and to decollate silicon for the manufacturing of solar cells and electronic components, commonly blade sawing or nanosecond-based laser processes are used. If the cut needs to be carried out with high precision and without causing thermal damage to the surrounding material, ultrashort pulsed laser cutting can deliver a fine and small cutting kerf. The reduction of the kerf width leads to a higher yield per wafer, if single elements need to be cut out. By this, marginal heat affected zones and minimal edge damaging are attainable.
