We report here on our team's early efforts in defining a scientifically compelling HabEx mission that is technologically executable, affordable within NASA's expected budgetary envelope, and timely for the next decade. In particular, we present preliminary architectures trade study results, quantifying technical requirements and predicting scientific outcome for a small number of design reference missions, all with broad capabilities in both exoplanet science and cosmic origins science.

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

10398-2, Session 1

Habitable Exoplanet Imaging Mission (HabEx) initial flight system design

Farah Alibay, Gary M. Kuan, Keith R. Warfield, Jet Propulsion Lab. (United States)

The Habitable Exoplanet Imaging Mission (HabEx) is a concept for a mission to directly image planetary systems around Sun-like stars, being studied as part of a number of mission concepts for the upcoming 2020 Astrophysics Decadal Survey. HabEx would help assess the prevalence of habitable planets in our galaxy, searching in particular for potential biosignatures in the atmospheres of planets in habitable zones. More generally, HabEx would image our neighboring solar systems and characterize the variety of planets that inhabits them. Its direct imaging capability would also enable the mission to study the structure and evolution of debris disks around nearby stars, and their dynamical interaction with planets.

These science goals lead to a mission with a requirement for high contrast imaging requirements and the continuous spectral coverage. The baseline for HabEx is a 4-meter diameter off-axis telescope designed to both search for habitable planets and perform general astrophysics observations, possibly combined with a starshade. We present the initial flight system design for both the telescope and the starshade, focusing on the key and driving requirements and subsystems, as well as the trajectory and station keeping and formation flying technique. Furthermore, we discuss some of the initial design trades undergone, as well as the key challenges and enablers. Finally, we explore some of the future design and architecture trades to be performed within the flight system as part of the continuing effort in the HabEx study.

10398-3, Session 1

HabEx yield modeling with for systems engineering

Rhonda M. Morgan, Michael Bottom, Michael Turmon, Bertrand P. Mennesson, Keith R. Warfield, Jet Propulsion Lab. (United States); Dmitry Savransky, Christian Delacroix, Space Imaging and Optical Systems Lab., Cornell Univ. (United States) and Carl Sagan Institute (United States)

We present yield modeling results for the HabEx concept study using EXOSIMS. EXOSIMS (Exoplanet Open-Source Imaging Mission Simulator) provides a parametric estimate of science yield of mission concepts using contrast curves from physics-based diffraction model codes and Monte Carlo simulations of design reference missions using realistic observing constraints.

Two baseline architecture configurations and two extended configurations are compared. We compare a configuration with a coronagraph to a configuration with a starshade for both detection and spectral characterization. The input parameters, including astrophysical assumptions, are detailed. We show sensitivity to key design parameters around design space local to the point designs. The yield results provide an analysis of the relative performance of telescope and instrument design that enable system engineering decisions.

10398-4, Session 1

HabEx space telescope optical system

Stefan R. Martin, Mayer Rud, Daniel K. Stern, Jet Propulsion Lab. (United States); Paul A. Scowen, Arizona State Univ. (United States)

The HabEx study is defining a concept for a new space telescope with the primary mission of detecting and characterizing planetary systems around nearby stars. The telescope is designed specifically to operate with both a high contrast coronagraph and a starshade enabling the direct optical detection of exoplanets as close as 70 mas from their star. The telescope will be equipped both with cameras for exoplanetary system imaging and with spectrometers capable of characterizing exoplanet atmospheres. Gases such as oxygen, carbon dioxide, water vapor and methane have spectral lines in the visible and near infrared part of the spectrum and may indicate biological activity.

In addition to the study of exoplanets, HabEx enables general astrophysics with two dedicated instruments. One instrument is a camera enabling imaging on a 3 arc minute field of view in two bands stretching from the UV to the near infrared. The same instrument can also be operated as a multi-object spectrograph, with resolution of 2000. A second instrument will be a high resolution UV spectrograph operating near 100 nm with up to 60,0000 resolution. We discuss the preliminary designs of the telescope and the optical instruments for the observatory.

This work was conducted at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

10398-5, Session 1

Overview of a telescope concept design for the Habitable-zone Exoplanet Direct Imaging Mission

H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States)

The Habitable-Exoplanet Imaging Mission (HabEx) engineering study team has been tasked by NASA with developing a compelling and feasible exoplanet direct imaging concept as part of the 2020 Decadal Survey. This paper summarizes a design concept for a 4-meter off-axis monolithic aperture HabEx telescope including launch vehicle accommodation, optical, structural and thermal design.

10398-6, Session 2

Science and architecture drivers for the HabEx Ultraviolet Spectrograph (UVS)

Paul A. Scowen, Arizona State Univ. (United States); Daniel K. Stern, Jet Propulsion Lab. (United States); Rachel Somerville, Rutgers, The State Univ. of New Jersey (United States); Mayer Rud, Stefan R. Martin, Jet Propulsion Lab. (United States); Matthew Beasley, Planetary Resources, Inc. (United States)

We have worked to define the compelling next generation General Astrophysics science that the 4m implementation of the HabEx mission concept might enable. These science drivers have been used to define requirements for a far ultraviolet (FUV) spectrograph design for the telescope design that meets the needs of these programs. We describe both the drivers and the baseline design for the instrument, the modes it might support, and the choices that were made to optimize the performance. The operational performance of the instrument in cooperation with the rest of the telescope design is also discussed.

10398-7, Session 2

Structural design of a 4-meter off-axis space telescope for the Habitable-zone Exoplanet Direct Imaging Mission

William R. Arnold Sr., a.i. solutions, Inc. (United States) and NASA Marshall Space Flight Ctr. (United States); Brent Knight, Jacqueline M Davis, H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States)

The Habitable-Exoplanet Imaging Mission (HabEx) engineering study team has been tasked by NASA with developing a compelling and feasible exoplanet direct imaging concept as part of the 2020 Decadal Survey. This paper details the structural design for a 4-meter off-axis monolithic aperture HabEx telescope including primary mirror substrate and support system, ability to survive launch, telescope optical bench structure, and dynamic analysis of the structures ability to maintain stable optical alignment and wavefront error.

10398-8, Session 2

ATHENA: System design of the ATHENA x-ray telescope

Mark R. Ayre, Marcos Bavdaz, Ivo Ferreira, Eric Wille, David H. Lumb, Martin Linder, Alexander Stefanescu, European Space Research and Technology Ctr. (Netherlands)

ATHENA, Europe's next generation x-ray telescope, is currently under Assessment Phase study with parallel candidate industrial Prime contractors, after selection for the 'L2' slot in ESA's Cosmic Vision Programme, with a mandate to address the 'Hot and Energetic Universe' Cosmic Vision science theme. This paper will consider the main technical requirements of the mission, and their mapping to resulting design choices at both mission and spacecraft level.

The reference mission architecture and current reference spacecraft designs from each of the candidate Primes will then be described, with particular emphasis given to a detailed description of the Science Instrument Module (SIM) design, currently under the responsibility of the ESA Study Team. The SIM is a very challenging item due primarily to the need to provide to the instruments (i) a soft ride during launch, and (ii) a very large (~3 kW) heat dissipation capability at varying interface temperatures and locations.

Finally, a programmatic overview will be given of the on-going Assessment Phase leading up to adoption of the mission.

10398-9, Session 3

The Large UV/Optical/Infrared (LUVOIR) Surveyor: Decadal Mission concept design update *(Invited Paper)*

Matthew R. Bolcar, NASA Goddard Space Flight Ctr. (United States)

In preparation for the 2020 Astrophysics Decadal Survey, NASA has commissioned the study of four large mission concepts, including the Large Ultraviolet / Optical / Infrared (LUVOIR) Surveyor. The LUVOIR Science and Technology Definition Team (STDT) has identified a broad range of science objectives including the direct imaging and spectral characterization of habitable exoplanets around sun-like stars, the study of galaxy formation and evolution, the epoch of reionization, star and planet formation, and the remote sensing of Solar System bodies. NASA's Goddard Space Flight Center (GSFC) is providing the design and engineering support to develop executable and feasible mission concepts that are capable of delivering the identified science objectives. We present an update on the first of two architectures being studied: a 15-meter-diameter segmented-aperture telescope with a suite of serviceable instruments operating over a range of wavelengths between 100 nm to 2.5 ?m and beyond. Four instruments are being developed for this architecture, including: an optical / near-infrared coronagraph capable of delivering 10?10 contrast at inner working angles as small as 2 ?/D; the LUVOIR UV Multi-object Spectrograph (LUMOS), which will provide medium resolution multi-object spectroscopy in addition to near-UV imaging and high-resolution point-source spectroscopy; the High Definition Imager (HDI), a high-resolution wide-field-of-view NUV-Optical-IR imager; and a UV spectro-polarimeter being contributed by Centre National d'Etudes Spatiales (CNES). A fifth, empty instrument bay will also be available for future contributions. We provide an update on this architecture, as well as plans for the second architecture to be studied in late 2017.

10398-10, Session 3

The Large UV/Optical/Infrared (LUVOIR) surveyor: Decadal Mission concept technology development overview

Matthew R. Bolcar, NASA Goddard Space Flight Ctr. (United States)

The Large Ultraviolet / Optical / Infrared (LUVOIR) Surveyor is one of four large mission concept studies being developed by NASA for consideration in the 2020 Astrophysics Decadal Survey. LUVOIR will support a broad range of science objectives, including the direct imaging and spectral characterization of habitable exoplanets around sun-like stars, the study of galaxy formation and evolution, the epoch of reionization, star and planet formation, and the remote sensing of Solar System bodies. The LUVOIR Science and Technology Definition Team (STDT) has tasked a Technology Working Group (TWG), with more than 60 members from NASA

centers, academia, industry, and international partners, with identifying technologies that enable or enhance the LUVOIR science mission. The TWG has identified such technologies in the areas of Coronagraphy, Ultra-Stable Opto-mechanical Systems, Detectors, Coatings, Starshades, and Instrument Components, and has completed a detailed assessment of the state-of-the-art. We present here a summary of this technology assessment effort, as well as the current progress in defining a technology development plan to mature these technologies to the required technology readiness level (TRL). We also comment on the role these technology assessments and the technology development plan play in the overall mission concept study.

10398-12, Session 3

Dynamic stability with the disturbance-free payload architecture as applied to the Large UV/Optical/Infrared (LUVOIR) mission

Larry D. Dewell, Raymond M. Bell, Nelson Pedreiro, Richard L. Kendrick, Lockheed Martin Space Systems Co. (United States)

The need for high payload dynamic stability and ultra-stable mechanical systems is an overarching technology need for large space telescopes such as the Large Ultraviolet / Optical / Infrared (LUVOIR) Surveyor. Wavefront error stability of less than 10 picometers RMS of uncorrected system WFE per wavefront control step represents over a factor of 1000 improvement over current space-based telescopes being fielded. Previous studies of similar telescope architectures have shown that passive telescope isolation approaches are hard-pressed to meet dynamic stability requirements and usually involve complex actively-controlled elements and sophisticated metrology. To meet these challenging dynamic stability requirements, an innovative non-contact vibration isolation technology called Disturbance Free Payload (DFP) is applied to and analyzed for LUVOIR. In a non-contact DFP architecture, the payload and spacecraft fly in close proximity, and interact via non-contact actuators to allow precision payload pointing and isolation from spacecraft vibration. Because disturbance isolation through non-contact, vibration isolation down to zero frequency is possible, and high-frequency structural dynamics of passive isolators are not introduced into the system. In this paper, the performance of a DFP non-contact architecture is analyzed for LUVOIR, by quantifying the performance in metrics directly traceable to its science objectives, including astrophysics and the direct imaging of habitable exoplanets. Aspects of the non-contact isolation architecture and how they contribute to system performance are examined and tailored to the LUVOIR architecture and concept of operation.

10398-13, Session 3

First-order error-budgeting for LUVOIR mission

J. Scott Knight, Paul A. Lightsey, Ball Aerospace & Technologies Corp. (United States); Lee D. Feinberg, Matthew R. Bolcar, NASA Goddard Space Flight Ctr. (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States)

Future large astronomical telescopes in space will have architectures that will have complex and demanding requirements in order to meet the science goals. The LUVOIR mission concept being assessed by the NASA/Goddard Space Flight Center is expected to be 9 to 15 meters in diameter, have a segmented primary mirror and be diffraction limited at a 500 nanometer wavelength. The optical stability is expected to be in the picometer range for minutes to hours. Architecture studies to support the NASA Science and Technology Definition teams (STDTs) are underway to evaluate systems performance. JWST is closest analog to this mission concept but requires significant performance improvements to meet the science goals. In order to help define the technology needs and assess performance, a first order error budgets has been developed. Like the JWST error budget, the error budget includes the active, adaptive and passive elements in spatial and temporal domains. JWST performance is scaled using first order approximations where appropriate and includes technical advances in telescope control.

10398-14, Session 3

LUVOIR backplane thermal architecture development through the composite CTE sensitivity study

Sang C. Park, Harvard-Smithsonian Ctr. for Astrophysics (United States); Michael J. Eisenhower, Smithsonian Astrophysical Observatory (United States); Marcel Bluth, SGT, Inc. (United States); Matthew R. Bolcar, Lee D. Feinberg, NASA Goddard Space Flight Ctr. (United States); J. Scott Knight, Ball Aerospace & Technologies Corp. (United States); Joel A. Nissen, David C. Redding, Jet Propulsion Lab. (United States)

The Large UV/Optical/IR Surveyor (LUVOIR) is one of four 2020 Decadal Survey Missions, a concept for 'flag-ship' class space-borne observatory, operating across the multi-wavelength UV/Optical/NIR spectra. An Optical Telescope concept being considered is the segmented primary mirror architecture with composite backplane structure. In order to achieve the high-contrast imaging required to satisfy the primary science goals of this mission would require, roughly, 10 pico-meter wavefront RMS stability over a wavefront control time step of approximately 10 minutes. The LUVOIR primary mirror backplance support structure (PMBSS) requires active thermal management to maintain operational temperature while on orbit. Furthermore, the active thermal control must be sufficiently stable to prevent time-varying thermally induced distortions in the PMBSS. This paper describes a systematic approach to developing a thermal architecture of a modular composite section of the mirror support structure heavily guided by the sensitivity studies of the composite Coefficient of Thermal Expansion (CTE) values. Thermal and finite-element models, sensitivity studies against the absolute values and their variations of the composite CTE, the early findings from the thermal and thermal-distortion analyses are presented.

10398-27, Session 3

Ultra-stable segmented telescope sensing and control architecture

Lee D. Feinberg, Matthew R. Bolcar, NASA Goddard Space Flight Ctr. (United States); J. Scott Knight, Ball Aerospace & Technologies Corp. (United States); David C. Redding, Jet Propulsion Lab. (United States)

Large segmented space telescopes that can achieve 10^10 contrast are under consideration for both the Large Ultraviolet Optical InfraRed (LUVOIR) and Habex mission studies. The key challenge for this type of architecture is how to achieve sufficient stability to support this level of contrast. This paper will survey a few emerging sensing and control architectures and associated technologies that can potentially achieve the required stability. It will also provide a summary of the sensing and control portion of the LUVOIR segmented telescope architecture that has emerged from a recent design study and will provide a first look at the control methods that are being employed.

10398-15, Session 4

The LUVOIR coronagraph instrument: definition and design

Laurent Pueyo, Space Telescope Science Institute (United States)

We present the exo-earth imaging instrument concept for the Large Ultra Violet Optical Infra Red (LUVOIR) surveyor, one for the fours large missions concept studies being developed by NASA for the 2020 astrophysics decadal survey. This paper is an overview of the work of the LUVOIR Science and Technology Definition Team (STDT), working along with the GSFC study office and includes the outcomes of a yearlong discussion with the exoplanet community. It summarizes our group's design and findings regarding the LUVOIR Architecture A (~14 m class aperture). We first review the main science requirements underlying our design choices, and in particular our choice of wavelength coverage. We then present the architecture of the there channels selected for the coronagraph instrument: UV (~200 nm - 400 nm), optical (~0.4 to 1 micron) and near IR (1 to 2.4 microns). For each channel we discuss back end science instrument, coronagraph design and wavefront control. We present our current designs along with their performances based on high fidelity optical simulation. We discuss these performances in the context of their science yield for exo-earth detection, characterization and broader exoplanetary science. We finally summarize the current state of the art for coronagraph technology and discuss avenues towards maturing them.

10398-16, Session 4

Effects of space telescope primary mirror segment errors on coronagraph instrument performance

Mark T. Stahl, H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States); Bijan Nemati, The Univ. of Alabama in Huntsville (United States)

Direct imaging of potentially habitable planets is challenging because of the relative proximity of the planet to the star and the low flux ratio (typically well under 1e-9 in the visible) of the planet relative to the star. Future exoplanet direct imaging telescopes like the Habitable Exoplanet Imaging Mission (HabEx) will hence require large collecting apertures with very low wavefront errors. The feasibility of these missions is in a large part dependent on the sensitivity of the achieved contrast at small working angles to imperfections and motions of the telescope optics. In past studies, we explored the effect of applying specific modes to segmented and monolith telescopes on the contrast leakage of a coronagraph. Here we extend the results to combined modes and incorporate some of the latest coronagraph designs.

10398-17, Session 4

Space technology for directly imaging and characterizing exo-Earths

Brendan P. Crill, Stuart B. Shaklan, Nicholas Siegler, Jet Propulsion Lab. (United States)

The detection of Earth-like exoplanets in the habitable zone of their stars, and their spectroscopic characterization in a search for biosignatures, requires starlight suppression that exceeds the current best ground-based performance by orders of magnitude. The required planet/star brightness ratio of 10^{-10} is obtained by blocking stellar photons with an occulter, either externally (a starshade) or internally (a coronagraph) to the telescope system, so as to directly image the reflected photons from the exoplanet. Coronagraph instruments require advancement with respect to telescope aperture (either monolithic or segmented), aperture obscurations (obscured by secondary mirror and its support struts), and wavefront error sensitivity (e.g. line-of-sight jitter, telescope vibration, polarization). A starshade has never been used in a science application and requires deploying a large structure (tens of meters to greater than 100m in diameter) that must be positioned precisely at a distance of tens of thousands of kilometers from the telescope. We describe in this paper a roadmap to achieving the technological capability to search for life in a Earth-like exoplanet from a future space telescope, in the context of the Decadal Survey mission concept studies. Two of these studies, HabEx and LUVOIR, include the search for habitable exoplanets as a central science theme.

10398-18, Session 4

Laser metrology for ultra-stable space-based coronagraphs

Joel A. Nissen, Alireza Azizi, Feng Zhao, Shannon Kian G. Zareh, Shanti R. Rao, Jeffrey B. Jewell, Jet Propulsion Lab. (United States)

Sensing starlight rejected from a coronagraph is essential in stabilizing the telescope's pointing and wavefront drift, but performance is degraded for dim stars. Laser Metrology (MET) provides a different, complementary sensing method, one that can be used to measure changes in the alignment of the optics at high bandwidth, independent of the magnitude of the host star. Laser metrology measures changes in the separation of optical fiducial pairs, which can be separated by many meters. The principle of operations is similar to the laser metrology system used in LISA-Pathfinder to measure the in-orbit displacement between two test masses to a precision of ~10 picometers. In closed loop with actuators, MET actively maintains rigid body alignment of the front-end optics, thereby eliminating the dominant source of wavefront drift. Because MET is not photon starved, it can operate at high bandwidth and feed-forward secondary-mirror jitter to a fast-steering mirror, correcting line-of-sight errors. In the case of a segmented, active primary mirror, MET provides 6 DOF sensing, replacing edge sensors. MET maintains wavefront control even during attitude maneuvers, such as slews between target stars, thereby avoiding the need to repeat time-consuming speckle suppression. These features can significantly improve the performance and observational efficiency of future large-aperture space telescopes equipped with internal coronagraphs. We evaluate MET trusses for various proposed monolithic and segmented space-based coronagraphs and present the performance requirements necessary to maintain contrast drift below 1e-11.

10398-19, Session 4

Design considerations for future far-IR observatories

Jonathan W. Arenberg, John Pohner, George M. Harpole, Michael B. Petach, Danny Chi, Perry J. Knollenberg, Northrop Grumman Aerospace Systems (United States)

This paper examines the architectural considerations for the development of a future far infra-red (~10-1000 μm) space-based observatory. These missions require their instruments and optics to operate at temperatures less than 10 Kelvin. Achieving these very low temperatures throughout the optical train in an executable and verifiable design is the defining architectural challenge for systems operating in the far-IR. This paper will discuss the necessary elements of the thermal design, cooling, parasitics and verification.

10398-20, Session 5

Technology advancements for future astronomical missions

J. Scott Knight, Paul A. Lightsey, Chip Barnes III, Alex Harwit, Ball Aerospace & Technologies Corp. (United States)

Future astronomical telescopes in space will have architectures have complex and demanding requirements in order to meet the science goals. The missions currently being studied by NASA for consideration in the next Decadal Survey range in wavelength from the X-ray to Far infrared; examining phenomenon from imaging exoplanet and characterizing their atmospheres to detecting gravitational waves. These missions have technical challenges that are near or beyond the state of the art from the telescope to the detectors. This paper describes some of these challenges and possible solutions. Promising measurements and future demonstrations are discussed that can enhance or enable the missions.

10398-21, Session 5

Stray-light field dependence for large astronomical space telescopes

Paul A. Lightsey, Ball Aerospace & Technologies Corp. (United States); Charles W. Bowers, NASA Goddard Space Flight Ctr. (United States)

Future large astronomical telescopes in space will have architectures that expose the optics to large angular extents of the sky.Options for reducing stray light coming from the sky range from enclosing the telescope in a tubular baffle to having an open telescope structure with a large sunshield to eliminate solar illumination. These two options are considered for an on-axis telescope design to explore stray light considerations. The tubular baffle design will limit the sky exposure to the solid angle of the cone in front of the telescope set by the aspect ratio of the baffle length to Primary Mirror (PM) diameter. The illumination from this portion of the sky will be limited to the PM and structures internal to the tubular baffle. The open structure will include direct sky illumination of the PM and Secondary Mirror (SM) and reflected or scattered light from sunshield and other structures onto the PM and SM coming from a large portion of the sky with only the portion of the sky shadowed by the sunshield not contributing. A Radiance Transfer Function (RTF) is calculated for the open architecture that determines the ratio of the stray light background radiance in the image contributed by a patch of sky having unit radiance. The full 4? steradian of sky is divided into a grid of patches, with the location of each patch defined in the telescope coordinate system. By rotating the celestial sky radiance maps into the telescope coordinate frame for a given pointing direction of the telescope, the RTF may be applied to the sky brightness and the results integrated to get the total stray light from the sky for that pointing direction. The RTF data generated for the open architecture may analyzed as a function of the expanding cone angle about the pointing direction. In this manner, the open architecture data may be used to directly compare to a tubular baffle design parameterized by allowed cone angle based on the aspect ratio of the tubular baffle length to PM diameter. Additional analysis has been done to examine the stray light implications for the fields near the image of a bright source. This stray light is shown to be dependent on the Bidirectional Reflectance Distribution Function (BRDF) characteristics of the mirrors in the optical train, with the mirrors closer to the focal plane dominating over the contributions from the PM and SM. Hence the near field stray light is independent of the exterior telescope baffle geometry.

10398-22, Session 5

Cryogenic system for the Origins Space Telescope: cooling a large space telescope to 4K with today's technology

Michael J. DiPirro, David T. Leisawitz, Edgar R. Canavan, Louis G. Fantano, Anel Florez, James W. Kellogg, NASA Goddard Space Flight Ctr. (United States)

The Origins Space Telescope (OST) concept is one of four NASA Science Mission Directorate, Astrophysics Division, observatory concepts being studied for launch in the mid 2030's. OST's wavelength coverage will be from the mid-infrared to the sub-millimeter, 6-600 microns. To enable observations at the zodiacal background limit the telescope must be cooled to about 4 K. Combined with the telescope size (currently the primary is 9 m in diameter) this appears to be a daunting task. However, simple calculations and thermal modeling have shown the cooling power required is able to be met with several already developed cryocoolers. Further, the telescope thermal architecture is greatly simplified, allowing simpler models, more thermal margin, and higher confidence in the final performance values than previous cold observatories. We will describe design principles to simplify thermal modeling and verification. We will argue that the OST architecture and design principles lower its integration and test time and reduce its ultimate cost.

10398-11, Session 6

APERTURE--a precise extremely-large reflective telescope using re-configurable element: a progress report

Melville P. Ulmer, Jian Cao, Yip-Wah Chung, Xiaoli Wang, David B. Buchholz, Northwestern Univ. (United States); Victoria L. Coverstone, Turgut B. Baturalp, Texas Tech Univ. (United States)

One of the pressing needs for the UV-Vis is a design to allow even larger mirrors than the JWST primary at an affordable cost. We report here the results of a NASA Innovative Advanced Concepts first year's Phase II study. Our project is called A Precise Extremely large Reflective Telescope Using Reconfigurable Elements (APERTURE). The idea is to deploy a continuous membrane-like mirror. The mirror figure will be corrected after deployment to bring it into better or equal lambda/20 deviations from the prescribed mirror shape. The basic concept is not new. What is new is to use a different approach from the classical piezoelectric-patch technology. Instead, our concept is based on a contiguous coating of a so called magnetic smart material (MSM). After deployment a magnetic write head will move on the non-reflecting side of the mirror and will generate a magnetic field that will produce a stress in the MSM that will correct the mirror deviations from the prescribed shape. In this progress report we give results of deformation vs in-plane stress, progress toward how long a deformation on Kapton or Mylar can be held in place my a magnetically hard material interacting with a MSM, and designs of a deployment, in-plane stress measurement of deployment and characterization of the deployed surface.

10398-23, Session 6

Highly-adjustable systems: an architecture for future space observatories

Jonathan W. Arenberg, Northrop Grumman Aerospace Systems (United States); Charles R. Lawrence, Robert A. Laskin, David C. Redding, John Steeves, Jet Propulsion Lab. (United States); Alberto Conti, Northrop Grumman Aerospace Systems (United States)

Mission costs for ground breaking space astronomical observatories are increasing to the point of unsustainability. We are investigating the use of highly adjustable or correctable systems as a means to reduce development and therefore mission costs. The paper introduces the promise and possibility of realizing a "net zero CTE" system for the general problem of observatory design. The discussion then introduces the basic systems architecture we are considering. This paper concludes with an overview of our planned study and demonstrations for proving the value and worth of highly adjustable telescopes and systems ahead of the upcoming decadal survey.

10398-24, Session 6

Revolutionary astrophysics using an incoherent synthetic optical aperture

Gerard L. Rafanelli, Susan B. Spencer, Douglas W.

Return to Contents

Wolfe, Raytheon Space and Airborne Systems (United States); Ronald S. Polidan, Polidan Science Systems & Technologies, LLC (United States)

Raytheon Space and Airborne Systems is exploring a paradigm shift for astronomical observatories that would replace circular apertures with rotating synthetic apertures. Rotating Synthetic Aperture (RSA) observatories can enable high value science measurements for the lowest mass to orbit, has superior performance relative to all sparse apertures, can provide the resolution of 20m to 30m aperture with the collecting area of an 8m to 12 m telescope with much less mass, risk, schedule, & cost. RSA is based on current, or near term technology and can be launched on a single, current launch vehicle to L2 (with much larger apertures possible using SLS).

10398-25, Session 6

The crisis in space astronomy: program structure and fatsats as a path to cheaper flagship missions

Martin Elvis, Harvard-Smithsonian Ctr. for Astrophysics (United States)

With an expected $5 B - $6 B to spend on large mission in the decade 2025-2035, NASA Astrophysics has a strategic problem. If JWST-like $9 B costs are the new normal, then the next large mission will launch ~2045, assuming no additional funds, or ~2035 if funding is doubled. No matching missions can join this mission until 10-20 years later yet. Individually impressive, these missions will inevitably narrow the scope of astrophysics for a generation or more. The alternative is to (1) take advantage of technological developments that allow 4 - 5 breakthrough missions to be built for 45 b - $6 B, and so by 3035; (2) take advantage of factor 3 – 5 lower launch costs to cut spacecraft costs, enabling a doubling of the number of breakthrough missions.

To put NASA Astrophysics on this expanding path, and avoid the constriction of the One Big Mission approach, requires policy changes. (1) the Statement of Task to the 2020 Astronomy Decadal should ask for a program that fits sensible design criteria, and avoids a prioritized list of large and medium missions. (2) Program choices should be explicitly tensioned against alternatives so that the opportunity cost is made visible. (3) studies of the gains to be had from using mass to solve problems rather than expensive design/test cycles should be made ahead of the 2020 Decadal. Other potential gains from commercial space on a 2030 timescale should be investigated.

10398-26, Session 6

An evolvable space telescope configured for NASA's Habex mission

Charles F. Lillie, Lillie Consulting LLC (United States); Howard A. MacEwen, Reviresco LLC (United States); James B Breckinridge, Breckinridge Associates, LLC (United States); Ronald S. Polidan, Polidan Science Systems & Technologies LLC (United States)

Previous papers have described our concept for a large telescope that would be assembled in space in several stages (in different configurations) over a period of fifteen to 20 years. Spreading the program cost over 20 years would minimize the impact on NASA's annual budget and drastically shorten the time between program start and "first light" for this space observatory.

The first Stage of that EST would consist of an instrument module located at the prime focus of three 4-meter hexagonal mirrors arranged in a semi-circle to form one-half of a 12-m segmented mirror. After several years three additional 4-m mirrors would be added to create a 12-m filled aperture. Later, twelve more 4-m mirrors will be added to this Stage 2 telescope to create a 20-m filled aperture space telescope. At each stage the telescope will have an unparalleled capability for UVOIR observations, and the results of these observations will guide the evolution of the telescope and its instruments.

This "Stage Zero" configuration will have only one 4-m mirror segment with the same 30-m focal length and a prime focus coronagraph with normal incidence optics to minimize polarization effects. Additional mirror segments and instruments would be added as the telescope evolves.

After augment and checkout in cis-lunar space, the telescope would transfer to a Sun-Earth L2 halo orbit and obtain high sensitivity, high resolution, high contrast UVOIR observations that address the scientific objectives of the UV/Optical/IR Surveyor and Habitable-Exoplanet Imaging Missions that NASA is studying for consideration by the 2020 Decadal Survey.

Active optics for next-generation space telescopes

Vincent Costes, Lionel Perret, David Laubier, Christian Imbert, Laurent Cadiergues, Jean-Marc Delvit, Claude Faure, Ctr. National d'Études Spatiales (France)

High resolution observation systems need bigger and bigger telescopes. The design of such telescopes is a key element for the satellite design. In order to improve the imaging resolution with minimum impact on the satellite, a big effort must be made to improve the compactness of the telescope. Compactness is also important for the agility of the satellite and for the size and cost of the launcher. This paper shows how compact a high resolution telescope can be. A diffraction limited telescope can be less than ten times shorter than its focal length. The compactness impacts drastically the opto-mechanical sensitivity and the optical performances. Typically, a gain of a factor of 2 leads to a mechanical tolerance budget 6 times more difficult. The need to implement active optics for positioning requirements raises very quickly.

Moreover, the capability to compensate shape defaults of the primary mirror is the way to simplify the mirror manufacture, to mitigate the development risks and to minimize the cost. The larger the primary mirror, the more interesting it is to implement active optics for shape compensations .

Our active optics approach is to compensate primary mirror shape defaults with a deformable mirror located in the telescope exit pupil. Telescope positioning errors are corrected thanks to a mechanism located behind the secondary mirror.

Technological developments are ongoing at CNES for active optics demonstration. The aim is to achieve TRL5 for these new technologies and to validate the global performances of such a telescope. The present paper will describe these developments.

10398-29, Session 7

Recent developments in next-generation UV-visible space telescope planning and design

Paul A. Scowen, Arizona State Univ. (United States); Kevin C. France, Univ. of Colorado Boulder (United States); Jason Tumlinson, Space Telescope Science Institute (United States); Stephan R. McCandliss, Johns Hopkins Univ. (United States); Todd Tripp, Univ. of Massachusetts Amherst (United States); Jay C. Howk, Univ. of Notre

Dame (United States)

We discuss the recent input and development of next generation UV-visible space-based observatories, the science they have been designed to achieve, and the technological challenges and potential solutions that have been identified. This talk will cover community-driven needs and strategic goals and hopefully give some insight into what the next UV-visible space telescopes will look like and what they will be able to deliver. The discussion will focus on, but not be exclusive to, the ongoing studies for both LUVOIR and HabEx.

10398-30, Session 7

An innovative UV probe-class mission concept

Sara R. Heap, NASA Goddard Space Flight Ctr. (United States); Anthony B. Hull, The Univ. of New Mexico (United States); Stephen E. Kendrick, Kendrick Aerospace Consulting LLC (United States)

In the 2020's, current and future wide-field telescopes will survey the sky at wavelengths ranging from gamma rays to radio waves. These surveys will be highly synergistic, leading to new, important discoveries. But there is a glaring hole in the emerging global network of survey telescopes: the network lacks a UV-sensitive telescope capable of making surveys and following up on objects discovered in other surveys. We are therefore planning to develop a concept for a probe-class UV survey telescope. Such a telescope must have a wide field of view, high observing efficiency, and a suite of UV-sensitive cameras and spectrographs including a UV multi-object slit spectrograph. These requirements call for innovative telescope and instrument designs and technologies, which we will describe. These designs and technologies will help bridge the technology gap to future large space telescopes such as LUVOIR.

10398-31, Session 7

Medium UV/optical/IR observatory (MUVOIR) concept

Gary W. Matthews, ATA Aerospace, LLC (United States)

In preparation for the 2020 Decadal Survey, NASA has undertaken four general mission areas to assess the potential system configurations and the resulting science. The HabEx and LUVOIR mission concept teams are assessing observatories between 4-meters and 14-meters in size. The MUVOIR mission idea evaluates a modest sized, 6.5-meter mission which includes an additional political component that leverages the JWST investment in the national infrastructure and how that might be used to reduce the lead time for a post-WFIRST Exoplanet/UV and Visible band astrophysics mission. This would include how this new program can leverage the integration support equipment at Goddard Space Flight Center and the optical test facility at Johnson Space Center.

10398-32, Session 7

SYNERGY: An Explorer mission concept for a next-generation ultraviolet survey

John W. MacKenty, Jason Tumlinson, Space Telescope Science Institute (United States); Jonathan W. Arenberg, Craig Elder, Adam Gunderson, Steven Warwick, Terri O'Connell, Carlton Wong, Northrop Grumman Aerospace Systems (United States)

Synergy is an Explorer class mission concept to obtain a large-area, multi-tier near-ultraviolet sky survey with low-resolution, spatially resolved slitless spectroscopy (R = 200-600) and simultaneous arc-second imaging between 210-320 nm. It's Wide and Deep surveys will examine the co-evolution of more than 200 million galaxies, 500,000 AGN, and 30,000 gas halos between $0.8 < z < 2$ to constrain the multi-parameter physical relationships between gas, star formation history, mergers, AGN, and environment at the epoch when star formation peaked, half of galaxies transitioned from star-forming to passive, and the Hubble sequence first emerged. Many facilities in the 2020s will probe galaxies at this epoch, but the key tracers of diffuse gas over the 10 Gyr of cosmic time since $z = 2$ are in the ultraviolet.

Synergy employs a 100 Mpixel CCD focal plane to provide 0.75 arc second pixels over a 4.5 degree field of view. Its reflective optical system uses coatings optimized to pass near-ultraviolet light while rejecting visible light making Silicon CCD detectors ideal for this application. With a 63 cm aperture, this instrument achieves 27.8 AB mag (5 sigma) imaging and 23.8 spectroscopy sensitivity in the Deep Survey and 25.5/21.5 in the Wide Survey. Using a Northrop Grumman Eagle Spacecraft with components from the LCROSS and JWST mission, Synergy would fly in the same orbit as the TESS Explorer mission currently under development. This 100,000 by 400,000 km orbit is phase locked with the Moon and permits an efficient observing plan, cost effective communications, and avoids the geocoronal emission features present in low earth orbit.

10398-33, Session 7

Coatings for large-aperture UV optical infrared space telescope mirrors

Kunjithapatham Balasubramanian, John Hennessy, Shouleh Nikzad, Nasrat A. Raouf, Jet Propulsion Lab. (United States); Manuel A. Quijada, Javier G. Del Hoyo, NASA Goddard Space Flight Ctr. (United States)

Large space telescope concepts aiming for high throughput from far UV to near IR require advanced coating technologies to enable efficient gathering of light with important spectral signatures including those in far UV region down to 90nm. Typical Aluminum mirrors protected with MgF_2 fall short of the requirements below 120nm. New and improved coatings are sought to protect aluminum that oxidizes readily in normal environment causing severe absorption and reduction of reflectance in the deep UV. Besides choice of materials, the process of applying coatings has to be optimized and controlled accurately and reliably to ensure the coatings preserve the expected optical characteristics. This challenge is addressed here with experimental investigations at JPL and at GSFC. We present the progress achieved to date and discuss the path forward to achieve high reflectance in the spectral region from 90 to 130nm without degrading performance in the visible and NIR regions taking into account durability concerns when the mirrors are exposed to normal laboratory conditions. Requirements on other devices such as filters and beam splitters needed for the conceived large space telescope are also discussed.

10398-34, Session 7

Progress towards adding EUV reflectance to broadband Al mirrors for space-based observatories

David D. Allred, R. Steven Turley, Stephanie Thomas, Spencer Willett, Spencer B. Perry, Michael J. Greenburg, Brigham Young Univ. (United States)

We report on progress on vacuum removal of protective layers on aluminum mirror surfaces using hydrogen plasmas and/or heating. One of NASA's flagship astrophysical missions of the 2020's or 30's will likely be a LUVOIR (large, UV-optical-IR) telescope. This space-based observatory will employ the largest mirrors ever flown. The reflective coating will almost certainly be aluminum since such telescopes would profit from truly broad-band mirrors. The top surface of such aluminum mirrors, however, need to be bare without the oxide layers that naturally form in air. (The local space environment for the observatory should be sufficiently oxygen-free that a pristine surface should remain bare for decades.) We discuss protecting as-deposited aluminum mirrors before atmosphere exposure with a robust, protective layer, or layers, that could be deposited to coat the aluminum immediately after its deposition, before it meets air, and cleanly and relatively easily removed once the mirror is in space. This removal must be gentle enough to not roughen the mirror surface nor redepositing material removed from the protective layer on the mirror or other spacecraft components. Thus the choice of hydrogen plasmas. Both organic and inorganic (such as, Si, Cd-containing and Zn) films were evaporated onto the aluminum immediately after its deposition can be removed. Progress could open up the 11-15eV band and an EUV band such as 30.4 nm for space-based astrophysics without sacrificing IR, visible and UV reflectance.

10398-35, Session 7

Improved mirror coatings for use in the Lyman Ultraviolet to enhance astronomical instrument capabilities

Manuel A. Quijada, Javier G. Del Hoyo, NASA Goddard Space Flight Ctr. (United States)

Pure Aluminum (Al) exhibits a high reflectance over the proposed spectral range of the Large Ultraviolet Optical Infrared (LUVOIR) observatory (90-5000 nm). However, the Al has to be protected from the naturally occurring Al_2O_3 oxide layer (when exposed to oxygen) with a thin film of a transparent material for use below 130 nm. Aluminum protected with fluorides such as LiF or MgF_2 have been the most commonly used solutions. But below 102 nm down to 90 nm, no transparent material is available to protect Al and coating mirror reflectance stays well below 30%. But even above 102 nm, the reflectance of protected Al is limited by the residual absorption of the fluoride overcoats and the hygroscopic nature of the LiF overcoat. The low reflectivity of coatings in the Lyman Ultraviolet (LUV) range of 90-130 nm is one of the biggest constraints on FUV telescope and spectrograph design, and it limits the science return of FUV-sensitive space missions. In fact, to achieve high-reflectance in broadband coatings has been identified as an “Essential Goal” in the technology needs for the LUVOIR) surveyor observatory. Improved reflective coatings for optics, particularly in the LUV spectrum, could yield dramatically more sensitive instruments and permit more instrument design freedom. This paper aims at reporting recent developments to produce broadband mirror coatings with high performance that will extend from the infrared spectral region to LUV wavelengths. These mirror coatings would be realized by using a thin AlF_3 overcoat that will protect the aluminum from oxidation and, hence, realize the high-reflectance of this material down to its intrinsic cut-off wavelength of 90 nm. We present the progress achieved to date and discuss the path forward to achieve high reflectance in the spectral region from 90 to 130nm without degrading performance in the visible and NIR regions, taking into account durability concerns when the mirrors are exposed to normal laboratory conditions.

10398-37, Session PMon

James Webb Space Telescope optical simulation testbed IV: linear control alignment of the primary segmented mirror and the secondary mirror

Sylvain Egron, ONERA (France) and Space Telescope Science Institute (United States) and Lab. d’Astrophysique de Marseille (France); Rémi Soummer, Space Telescope Science Institute (United States); Vincent Michau, Aurelie Bonnefois, ONERA (France); Marc Ferrari, Emmanuel Hugot, Lab. d’Astrophysique de Marseille (France); Marshall D. Perrin, Laurent Pueyo, Space Telescope Science Institute (United States); Lucie Leboulleux, Space Telescope Science Institute (United States) and Lab. d’Astrophysique de Marseille (France) and ONERA (France)

The James Webb Space Telescope (JWST) Optical Simulation Testbed (JOST) is a tabletop experiment designed to study wavefront sensing and control for a segmented space telescope, including both initial alignment (commissioning) and maintenance activities. JOST is complementary to existing testbeds for JWST (e.g. the Ball Aerospace Testbed Telescope TBT) given its compact scale and exibility, ease of use, and colocation at the JWST Science & Operations Center. The design of JOST reproduces the physics of JWST’s three-mirror anastigmat (TMA) using three custom spheric and aspheric lenses. It provides similar quality image as JWST (80% Strehl ratio) over a field equivalent to a NIRCam module, but at 633 nm. An Iris AO segmented mirror stands for the segmented primary mirror of JWST. Actuators allow us to control (1) the 18 segments of the segmented mirror in piston, tip, tilt and (2) the second lens, which stands for the secondary mirror, in tip, tilt and x, y, z positions. We present the full linear control alignment infrastructure developed for JOST, with an emphasis on multi-field wavefront sensing and control. Our implementation of the Wavefront Sensing (WFS) algorithms using phase diversity is tested both in simulation and experimentally. The wavefront control (WFC) algorithms, which rely on a linear model for optical aberrations induced by misalignments of the secondary lens and the segmented mirror, are also tested and validated both experimentally and in simulations. The performance of the full active optic control loop is demonstrated by perturbing the testbed and analyzing the quality of the alignment correction.

10398-38, Session PMon

The afocal telescope of the ESA ARIEL mission: analysis of the layout

Vania Da Deppo, CNR-IFN Padova (Italy) and INAF - Osservatorio Astrofisico di Arcetri (Italy); Kevin F. Middleton, STFC Rutherford Appleton Lab. (United Kingdom); Mauro Focardi, INAF - Osservatorio Astrofisico di Arcetri (Italy); Gianluca Morgante, INAF - IASF Bologna (Italy); Emanuele Pace, Univ. degli Studi di Firenze (Italy); Riccardo U. Claudi, INAF - Osservatorio Astronomico di Padova (Italy); Giuseppina Micela, INAF - Osservatorio Astronomico di Palermo Giuseppe S. Vaiana (Italy)

ARIEL (Atmospheric Remote-sensing Infrared Exoplanet Large-survey) is candidate as an M4 ESA mission to launch in 2026. During its foreseen 3.5 years operation, it will observe spectroscopically in the infrared a large population of known transiting planets in the neighborhood of the Solar System. The aim is to enable a deep understanding of the physics and chemistry of these exoplanets.

ARIEL is based on a 1-m class telescope ahead of a suite of instruments: two spectrometer channels covering the band 1.95 to 7.8 microns and four photometric channels (two wide and two narrow band) in the range 0.5 to 1.9 microns.

The ARIEL optical design is conceived as a fore-module common afocal telescope that will feed the spectrometer and photometric channels. The telescope optical design is based on an eccentric pupil two-mirror classic Cassegrain configuration coupled to a tertiary paraboloidal mirror.

The temperature of the primary mirror (M1) will be monitored and finely tuned by means of an active thermal control system based on thermistors and heaters. They will be switched on and off to maintain the M1 temperature within +/-1K thanks to a proportional–integral–derivative (PID) controller implemented within the Telescope Control Unit (TCU), a Payload electronics subsystem mainly in charge of the thermal control of the two detectors owning to the spectrometer. TCU will collect the housekeeping data of the controlled subsystems and will forward them to the Instrument Control Unit (ICU), the main Payload’s electronic Unit linked to the spacecraft On Board Computer (OBC).

Aligning the EUCLID NISP near infrared optics using a multi-zone hologram: stability of the set-up and achieved position readings

Frank U. Grupp, Univ.-Sternwarte München (Germany) and Max-Planck-Institut für extraterrestrische Physik (Germany); Andreas Bode, Jennifer Kaminski, Daniela Penka, Carolin Wimmer, Christof Bodendorf, Norbert Geis, Max-Planck-Institut für extraterrestrische Physik (Germany); Ralf Bender, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany)

We did deeep analysis of our setup. encounterd the unexpected and where able to explainit .. we want to share this experiece with the community

10398-40, Session PMon

Predictive thermal control applied to HabEx

Thomas Brooks, H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States)

The HabEx telescope will focus on directly imaging habitable exoplanets with the use of an internal coronagraph or external starshade. If an internal coronagraph is used, the telescope's wavefront may not change by more than 10pm over 10 minutes. Similarly, the line of sight cannot change by more than 2 mas over the integration time. Stringent pointing and wavefront error requirements result in stringent deflection and thermal stability requirements. Thermal and thermoelastic models of HabEx are used to determine whether requirements may be met with a proposed Predictive Thermal Control (PTC) system.

10398-41, Session PMon

ACCESS: integration, pre-flight performance, and calibration

Mary Elizabeth Kaiser, Matthew J. Morris, Johns Hopkins Univ. (United States); Jeffrey W. Kruk, Randy A. Kimble, Bernard J. Rauscher, NASA Goddard Space Flight Ctr. (United States); Edward L. Wright, Univ. of California, Los Angeles (United States); Robert Kurucz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Stephan R. McCandliss, Russell Pelton, Lauren N. Aldoroty, Paul D. Feldman, H. Warren Moos, Johns Hopkins Univ. (United States); Adam G. Riess, Johns Hopkins Univ. (United States) and Space Telescope Science Institute (United States); Jonathan P. Gardner, NASA Goddard Space Flight Ctr. (United States); Ralph C. Bohlin, Susana E. Deustua, William V. Dixon, David J. Sahnow, Space Telescope Science Institute (United States); Saul Perlmutter, Univ. of California, Berkeley (United States) and Lawrence Berkeley National Lab. (United States)

Using SNeIa to distinguish dark energy models from one another levies a requirement for 1% precision in the cross-color calibration of the SNe Ia flux across a bandpass extending from 0.35 ? 1.7 ?m. The systematic errors in the flux calibration network spanning the visible through the NIR currently exceed 1%. ACCESS, Absolute Color Calibration Experiment for Standard Stars, is a series of rocket-borne sub-orbital missions and ground-based experiments that will leverage the significant technological advances in detectors, instruments, and the precision of the fundamental laboratory standards used to calibrate these instruments to enable improvements in the precision of the astrophysical flux scale through the transfer of absolute laboratory detector standards from the National Institute of Standards and Technology (NIST) to a network of stellar standards with a calibration accuracy of 1% and a spectral resolving power of 500 across the 0.35 to 1.7 micron bandpass. The ACCESS Cassegrain telescope feeds a compact (Rowland circle design) spectrograph with a cross dispersing Fery prism.

The detector, a HST/WFC3 heritage 1024x1024 HgCdTe array, is sensitive across the full 0.35 to 1.7 micron bandpass. Vibration and thermal vacuum testing of the detector have been successful. Ground-based detector characterization is on-going. The thermal vacuum system is being assembled and tested. Integration and alignment of the ACCESS telescope and spectrograph will be described. Calibration strategy and status, ground-based integration, vibration testing and instrument performance results will be presented. Launch is expected within the year. NASA sounding rocket grant NNX14AH48G supports this work.

10398-42, Session PMon

Technology pathways for a habitable-zone exoplanet direct imaging mission

Rhonda M. Morgan, Keith R. Warfield, Bertrand P. Mennesson, Jet Propulsion Lab. (United States); H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States); Shouleh Nikzad, Joel A. Nissen, John E. Krist, Kunjithapatham Balasubramanian, Jet Propulsion Lab. (United States); Dimitri Mawet, California Institute of Technology (United States); Karl Stapelfeldt, Jet Propulsion Lab. (United States); Steven Warwick, Northrop Grumman Aerospace Systems (United States)

HabEx will be optimized for direct imaging and spectroscopy of potentially habitable exoplanets, and will also enable a wide range of general astrophysics science. Exoplanet detection and characterization drives the enabling core technologies. The STDT and Study Design Team have defined the driving technologies for a future HabEx mission, many of which are instrument-focused, and expand upon previous Technology Gap lists initiated by NASA's Exoplanet Exploration Program office. This paper presents initial assessments of these exoplanet-driven technologies, including elements of coronagraphs, starshades, mirrors, jitter mitigation, wavefront control, and detectors. By identifying high technology readiness solutions where ready, and identifying required technology development that can begin early, HabEx will be well position for assessment by the community in 2020.

10398-43, Session PMon

Monitoring solar irradiance from L2 with Gaia

Edmund Serpell, European Space Operations Ctr. (Germany)

Gaia is the European Space Agency's cornerstone astrometry mission to measure the positions of 1 billion stars in the Milky Way with unprecedented accuracy. Since early 2014 Gaia has been operating in a halo orbit around the second Sun-Earth Lagrange point that provides the stable thermal environment, without Earth eclipses, needed for the payload to function accurately. The spacecraft is constructed with a 10m diameter circular sun-shield which is equipped with a number of thermistors that provide a continuous measurement of the local temperature. As a consequence of the spacecraft design and operational conditions the Gaia sun-shield has been observed to behave as a bolometer that is measuring the solar output over a broad wavelength range.

In this paper we present analysis of temperature measurements made of the Gaia sun-shield at frequencies of up to 1Hz for the first 2.5 years of routine operations. We show that the Gaia sun-shield as a bolometer is capable of measuring the changes to the solar irradiance at a level of better than 0.1% with time constants of less than 1 hour.

Conference 10399: Optics for EUV, X-Ray, and Gamma-Ray Astronomy VIII

Tuesday - Thursday 8 –10 August 2017

Part of Proceedings of SPIE Vol. 10399 Optics for EUV, X-Ray, and Gamma-Ray Astronomy VIII

10399-1, Session 1

Cherenkov Telescope Array: the next-generation gamma ray observatory

Jan Ebr, Institute of Physics of the ASCR, v.v.i. (Czech Republic)

The Cherenkov Telescope Array (CTA) is a project to build the next generation ground-based observatory for gamma-ray astronomy at very-high energies in the range from 20 GeV to 300 TeV, which will both surpass the sensitivity of existing instruments in their energy domains and extend the limits of the observed energy spectrum. It will probe some of the most energetic processes in the Universe and provide insight into topics such as the acceleration of charged cosmic rays and their role in galaxy evolution, processes in relativistic jets, wind and explosions and the nature and distribution of dark matter. The CTA Observatory will consist of more than a hundred imaging atmospheric Cherenkov telescopes (IACT) of three different size classes, installed at two premier astronomical locations, one in each hemisphere. It is foreseen that the telescopes will use a variety of optical designs including parabolic primary mirrors, variations of the Davies-Cotton design and two-mirror setups such as the Schwarzschild-Couder telescope, and several camera designs, using both photomultiplier tubes (PMTs) and silicon photomultipliers (SiPMs) for detection of the nanosecond-scale Cherenkov flashes. Each telescope will feature a precise but lightweight and agile mount, allowing even the largest telescopes to change targets within 20 seconds, with systems of sensors and actuators actively controlling the shape of the reflecting surfaces. As an integral part, the Observatory will feature extensive calibration facilities, closely monitoring both the detectors themselves and the surrounding atmosphere. Several telescope prototypes already exist and the installation works at the northern site have started.

10399-2, Session 1

Aplanatic telescopes based on Schwarzschild optical configuration: from grazing incidence Wolter-like x-ray optics to Cherenkov two-mirror normal incidence telescopes

Giorgia Sironi, Paolo Conconi, Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy)

Karl Schwarzschild introduced a method to design large-field aplanatic telescopes introducing radial polynomials in the optics profiles. Couder then refined the Schwarzschild solution correcting for the astigmatic aberration adding a curve focal plane. By the way, the lack of technological solutions to manufacture and test polynomial aspherical mirrors historically limited the applications of the Schwarzschild-like design. In 1952, Wolter extended the polynomial solution of Karl Schwarzschild to grazing incidence telescopes. The obtained design allowed to improve the Wolter-type grazing incidence optics, designed to bee free of spherical aberration, eliminating coma completely.

The resulting Wolter-Schwarzschild design for x-ray optics was adopted for telescopes already flown like the ROSAT WFC and the SOHO X-ray telescope, and for understudy missions like the wide field x-ray telescope (WFXT), designed assuming polynomials numerically optimized to get a flat field of view response. The Schwarzschild-Couder (SC) solution was recently proposed by Vassiliev and collaborators as a solution for Cherenkov telescopes.

The first Cherenkov telescope based on the SC configuration was realized and successfully characterized (the ASTRI telescope) by the Italian institute for Astrophysics (INAF), demonstrating the suitability of the SC configuration for the Cherenkov astronomy requirements. Moreover, another Cherenkov telescope based on a different SC solution is currently under construction at Fred Lawrence Whipple Observatory in southern Arizona, USA. In this paper we will review the Schwarzschild approach applied to grazing incidence and Cherenkov telescopes, discussing on future applications in the field of high energy astronomy.

10399-3, Session 1

The ASTRI SST-2M prototype for the Cherenkov Telescope Array: status after the commissioning phase of the telescope

Rodolfo Canestrari, INAF - Osservatorio Astronomico di Brera (Italy); Enrico Giro, INAF - Osservatorio Astronomico di Padova (Italy); Giorgia Sironi, INAF - Osservatorio Astronomico di Brera (Italy); Elisa Antolini, Univ. degli Studi di Perugia (Italy); Dino Fugazza, INAF - Osservatorio Astronomico di Brera (Italy); Salvatore Scuderi, INAF - Osservatorio Astrofisico di Catania (Italy); Gino Tosti, Univ. degli Studi di Perugia (Italy); Claudio Tanci, INAF - Osservatorio Astronomico di Brera (Italy); Federico Russo, INAF - Osservatorio Astrofisico di Torino (Italy); Daniele Gardiol, INAF - Osservatorio Astronomico di Torino (Italy); Carlos E. Fermino, Univ. de São Paulo (Brazil); Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy); ASTRI collaboration, INAF Osservatorio Astronomico di Brera (Italy); CTA consortium, CTA observatory (Italy); Gianpietro Marchiori, Andrea Busatta, Enrico Marcuzzi, EIE Group s.r.l. (Italy); Ivan Folla, Galbiati Group (Italy)

ASTRI SST-2M is an imaging atmospheric Cherenkov telescope developed by the Italian National Institute of Astrophysics (INAF) in the framework of the Cherenkov Telescope Array (CTA) as an end-to-end prototype for the Small Size array. Large-, medium-, and small-sized telescopes will compose the CTA observatory that represents the next generation of imaging atmospheric Cherenkov telescopes and will explore the very high-energy domain from a few tens of GeV up to few hundreds of TeV.

The ASTRI SST-2M telescope has been installed at the INAF observing station at Serra La Nave, on Mt. Etna (Sicily, Italy) in September 2014. In these 3 years of open-air operations the telescope has been commissioned and its opto-mechanical performance is now well understood. The apparatus was made ready to host its main scientific instrument, the camera with a Silicon-Photomultiplier based detectors.

This contribution is a status report on the complete ASTRI SST-2M telescope assembly including the electro-mechanical structure, the optical system, the control software and on-board instrumentation.

10399-4, Session 1

The GCT small-sized dual-mirror telescopes for CTA

Tim Greenshaw, Univ. of Liverpool (United Kingdom)

The Gamma-ray Cherenkov Telescope (GCT) is one of the Small Size Telescopes (SSTs) proposed for the Cherenkov Telescope Array (CTA). The telescope is a Schwarzschild-Couder design of 2.3 m focal length, with aspherical primary and secondary mirrors of 4 m and 2 m diameter, respectively. It is planned to equip the GCT with Compact High-Energy Camera (CHEC) with about 2000 pixels of physical size about 6 times 6 mm^2, providing a field of view of over 8 degrees. The camera's TARGET-based readout electronics allows the GCT to trigger on and measure the cherenkov light images caused by photons entering the atmosphere of

energies above about 1 TeV. The camera digitises the signals recorded in its pixels at a rate of 1 Gs/s.

The GCT prototype in Meudon, Paris saw first Cherenkov light in late 2015, using a version of CHEC equipped with multi-anode photomultipliers, CHEC-M. This contribution presents the results of these and more recent tests of the prototype with CHEC-M and discusses the modifications to the telescope proposed before the first GCT is installed on CTA's southern site in Paranal, Chile. These include changes which further simplify the installation and maintenance of the telescope. Further, the design of a silicon photomultiplier-based version of the camera, CHEC-S, is presented. This will allow both better sensitivity and more robust operation to be achieved than is possible with CHEC-M.

10399-5, Session 1

First light on a new fully digital camera based on SiPM for CTA SST-1M telescope

Domenico della Volpe, Teresa Montaruli, Matthieu Heller, Victor Coco, Imen Al Samarai, Franck Cadoux, Yannick Favre, Cyril Alispach, Isaac Troyano Pujadas, Andrii Nagai, Theodore R. Njoh Ekoume, Roland Walter, Etienne Lyard, Andrii Neronov, Vitalii Sliusar, Univ. de Genève (Switzerland); Jacek Niemiec, Emil Mach, Jerzy Michalowski, Jacek Blocki, Jakub Rafalski, Krzysztof Skowron, Magdalena Stodulska, Institute of Nuclear Physics (Poland); Marek Stodulski, The Henryk Niewodniczanski Institute of Nuclear Physics (Poland); Marek Jamrozy, Michal Ostrowski, Lukasz Stawarz, Krzysztof Zietara, Jagiellonian Univ. in Krakow (Poland); Jerzy Borkowski, Mateusz Janiac, Adam Frankowski, Rafal Moderski, Nicolaus Copernicus Astronomical Ctr. (Poland); Tomasz Bulik, Mira Grudzi?ska, Univ. of Warsaw (Poland); Pawel Pa?ko, Karol Seweryn, Space Research Ctr. (Poland); Dusan Mandat, Miroslav Pech, Petr Schovánek, Institute of Physics of the ASCR, v.v.i. (Czech Republic); Krzysztof Lalik, Pawel J. Rajda, AGH Univ. of Science and Technology (Poland)

The single mirror small size telescope (SST-1M), one of the proposed solutions to become part of the small-size telescopes of the Cherenkov telescope array (CTA), will be equipped with an innovative camera.

The SST-1M has a Davies-Cotton optics with a mirror dish of 4 m diameter and focal ratio 1.4 focussing the Cherenkov light produced in atmospheric showers onto a 90 cm wide hexagonal camera providing a FoV of ~9 degree.

The camera features 1296 custom designed large area hexagonal silicon photomultipliers (SiPM) coupled to hollow optical concentrators to achieve a pixel size of almost 2.4 cm.

The SiPM is a custom design developed with Hamamatsu and with its active area of almost 1 cm^2 is one of the largest monolithic SiPM existing.

Also the optical concentrators are innovative being light funnels made of a polycarbonate substrate coated with a custom designed UV-enhancing coating.

The analog signals coming from the SiPM are fed into the fully digital readout electronics, where digital data are processed by high-speed FPGAs both for trigger and readout.

The trigger logic, implemented into an Virtex 7 FPGA, uses the digital data to elaborate a trigger decision by matching data against predefined patterns.

This approach is extremely flexible and allows improvements and continued evolutions of the system.

The prototype camera is being tested in laboratory prior to its installation expected in summer 2017 on the telescope prototype in Krakow (Poland).

In this contribution, we will describe the design of the camera, show the performance measured in laboratory and the early operations on the telescope.

10399-6, Session 2

Optics for the Imaging X-ray Polarimetry Explorer

Brian D. Ramsey, NASA Marshall Space Flight Ctr. (United States)

The Imaging X-ray Polarimetry Explorer (IXPE) was recently selected by NASA for flight in late 2020. IXPE features three identical x-ray telescopes each comprised of a 4-m-focal length mirror module assembly, fabricated at MSFC, that focuses x-rays onto a polarization-sensitive, imaging detector, contributed by Italy. Mirrors and detectors are separated by a deployable boom that sits atop a Ball-Aerospace-provided satellite bus. This presentation will give a brief overview of the IXPE mission with particular emphasis on the mirror module assembly design, fabrication approach, and expected performance. Trades performed to optimize the design within mass and launch-vehicle fairing constraints will be discussed, along with finite element analyses run to optimize the mechanical design. The presentation will also touch on modeling of leakage radiation from off-axis sources outside of the field of view.

10399-7, Session 2

The STAR-X X-Ray Telescope Assembly (XTA)

Ryan S. McClelland, Timo T. Saha, William W. Zhang, Peter M. Solly, Joeseph A. Bonafede, NASA Goddard Space Flight Ctr. (United States)

The STAR-X science goals are to discover what powers the most violent explosions in the Universe, understand how black holes grow across cosmic time and mass scale, and measure how structure formation heats the majority of baryons in the Universe. To achieve these goals, STAR-X requires a powerful X-ray telescope with a large field of view, large collecting area, and excellent point spread function. The STAR-X instrument, the XTA, meets these requirements using a powerful X-ray mirror technology based on precision-polished single crystal silicon and a mature CCD detector technology.

The XTA is composed of three major subsystems: an X-ray Mirror Assembly (MA) of high resolution, lightweight mirror segments fabricated out of single crystal silicon; a Focal Plane Assembly (FPA) made of back-illuminated CCDs capable of detecting X-rays with excellent quantum efficiency; and a composite Telescope Tube that structurally links the MA and FPA. The MA consists of 5,972 silicon mirror segments mounted into five subassemblies called meta-shells. A meta-shell is constructed from an annular central structural shell covered with interlocking layers of mirror segments. This paper describes the requirements, design, and analysis of the XTA subsystems with particular focus on the MA.

10399-8, Session 2

Miniature Lightweight X-ray Optics (MiXO) and CubeSat X-ray Telescope (CubeX) for solar system exploration

Suzanne E. Romaine, Jaesub Hong, Harvard-Smithsonian Ctr. for Astrophysics (United States); Brian D. Ramsey, National Space Sciences and Technology Ctr. (United States); Larry Nittler, Carnegie Institution for Science (United States); Keith Gendreau, NASA Goddard Space Flight Ctr. (United States); Daniele Spiga, INAF - Osservatorio Astronomico di Brera (Italy); Martin Elvis, Jonathan Grindlay, Harvard-Smithsonian Ctr. for Astrophysics (United States)

We report the recent progress in development of miniature X-ray optics

(MiXO), which can enable powerful, yet compact lightweight X-ray optics affordable for many future planetary missions.We also introduce a new concept of a CubeSat X-ray telescope (CubeX) capable of both X-ray fluorescence (XRF) imaging and X-ray pulsar timing based navigation (XNAV) by employing the MiXO and a novel focal plane configuration with no moving parts.

Comparative studies of surface variations in the elemental composition of diverse planetary bodies can provide clues to their formation and evolutionary history. XRF, intrinsic to atomic energy levels, carries a unique signature of the elemental composition of the emitting bodies. Unlike optical and infrared spectra that can be altered by space weathering, XRF can probe more than 10–20 ?m deep below the surface, thus it is a powerful diagnostic tool to understand the true chemical and mineralogical composition of the planetary bodies. X-ray Imaging spectroscopy can greatly improve our understanding of the origin and geological history of target bodies by identifying the elemental composition of individual surface features (e.g., boulders versus craters) and activities (e.g., outgassing).

Deep space navigation is a critical issue for small planetary missions. Millisecond pulsars (MSPs), whose spin rates range from a few to a few 10s of milliseconds, provide stable natural clocks in the sky comparable to precise atomic clocks. With recent technological advances of X-ray telescopes and discoveries of many new X-ray MSPs in the last decade, XNAV has become a plausible approach to greatly assist, or even outperform, NASA's Deep Space Network (DSN) or ESA's European Space Tracking (ESTRACK) and to realize low-cost autonomous deep space navigation. For instance, the Station Explorer for X-ray Timing and Navigation Technology (SEXTANT) program plans to test the feasibility of XNAV on the International Space Station (ISS) using the Neutronstar Interior Composition Explorer (NICER) mission.

10399-9, Session 2

The Lynx Optics Working Group: objectives and current status

Mark Schattenburg, MIT Kavli Institute for Astrophysics and Space Research (United States)

Lynx is one of four large mission concepts being developed by NASA for consideration by the 2020 Decadal Survey in Astronomy and Astrophysics. Lynx will observe in the traditional X-ray band (approximately 0.1 to 10 keV) with a sub-arcsecond grazing-incidence telescope of effective area exceeding a square meter.

Such a mission concept was identified in the 2013 NASA Astrophysics Roadmap "Enduring Quests, Daring Visions" and, since early 2016, has been developed by a community-selected Science and Technology Definition Team (STDT). The STDT convened several working groups to refine science objectives and to develop credible plans for maturing technologies needed to axhieve these science objectives. The Lynx Optics Working Group (OWG)---comprising more than 30 technologists from academia, research institutions, and industry---has been assessing current research and development efforts to identify key challenges to be overcome for Lynx to be successful. Here we discuss the OWG organization, its goals, and the current status of its work in support of the Lynx STDT.

10399-10, Session 3

The Athena telescope and optics status

Marcos Bavdaz, Eric Wille, Mark Ayre, Ivo Ferreira, Brian Shortt, Sebastiaan Fransen, European Space Research and Technology Ctr. (Netherlands); Maximilien J. Collon, cosine B.V. (Netherlands); Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Nicolas M. Barrière, Boris Landgraf, cosine B.V. (Netherlands); Jeroen Haneveld, Micronit Microfluidics B.V. (Netherlands); Coen van Baren, SRON Netherlands Institute for Space Research (Netherlands); Karl-Heintz Zuknik, OHB-System AG (Germany); Desirée Della Monica Ferreira, Sonny Massahi, Finn E. (Italy); Dervis Vernani, Thales Alenia Space (Switzerland); Paul Oliver, e2v technologies plc (United Kingdom)

The work on the definition and technological preparation of the ATHENA (Advanced Telescope for High ENergy Astrophysics) mission continues to progress. In parallel to the study of the accommodation of the telescope, many aspects of the X-ray optics are being evolved further.

The optics technology chosen for ATHENA is the Silicon Pore Optics (SPO), which hinges on technology spin-in from the semiconductor industry, and uses a modular approach to produce large effective area lightweight telescope optics with a good angular resolution.

Both system studies and the technology developments are guided by ESA and implemented in industry, with participation of institutional partners. In this paper an overview of the current status of the telescope optics accommodation and technology development activities will be provided.

10399-11, Session 3

Development of Athena mirror modules

Silicon Pore Optics (SPO), developed at cosine with ESA and several academic and industrial partners, provides lightweight, yet stiff high resolution x-ray optics. This technology enables ATHENA to reach an unprecedentedly large effective area in the 0.2 - 12 keV band with an angular resolution better than 5''. After developing the technology for 50 m and 20 m focal length, this year has witnessed the first 12 m focal length mirror modules being produced. The technology development is also gaining momentum with three different radii under study: mirror modules for the inner radii (R_{min} = 250 mm), outer radii (R_{max} = 1500 mm) and middle radii (R = 737 mm) are being developed in parallel.

In this paper, we report on the current state of the Silicon Pore Optics technology, from the manufacturing of the stacks of mirror plates, to the

final characterization of mirror modules taking place at PTB's XPBF with synchrotron radiation and the PANTER test facility.

10399-12, Session 3

Silicon pore optics mirror module assembly process

Nicolas M. Barrière, Maximilien J. Collon, cosine B.V. (Netherlands); Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Boris Landgraf, cosine B.V. (Netherlands); Ramses Günther, Mark Vervest, Roy van der Hoeven, cosine Science & Computing B.V. (Netherlands); David Girou, Marco W. Beijersbergen, cosine B.V. (Netherlands); Marcos Bavdaz, Eric Wille, Sebastiaan Fransen, European Space Research and Technology Ctr. (Netherlands); Coen van Baren, Alexander Eigenraam, SRON Netherlands Institute for Space Research (Netherlands); Peter Müller, Michael Krumrey, Physikalisch-Technische Bundesanstalt (Germany); Giuseppe Valsecchi, Media Lario Technologies S.r.l. (Italy); Karl-Heinz Zuknik, OHB-System AG (Germany)

Silicon Pore Optics are produced as stacks of mirror plates, which are then paired to form X-ray Optics Units (XOUs). For ATHENA, in the current scheme, two XOUs are glued together in a set of brackets, leading to mirror modules (MMs) made of 4 stacks. The requirements regarding the positioning of the brackets with respect to the optical axis of the MM are very tight, in order to make the MMs integration in the mirror structure possible. MMs are integrated at the XPBF beamline of PTB (BESSY II synchrotron, Berlin), using a pencil X-ray beam and dedicated integration jigs. The relative orientation of the secondary stack with respect to the primary stack is fitted using the positions of the reflected beamspots onto the camera. This provides a deterministic way of orienting stacks with respect to each other within a XOU, and allows meeting with the stringent angular accuracy requirements. The same operation is then repeated for the second XOU composing a mirror module, with the additional constraint that it needs to be confocal with the first one. In this paper we review the process that is used to integrate stacks and brackets into mirror modules.

10399-13, Session 3

Optical integration of SPO mirror modules in the ATHENA telescope

Giovanni Bianucci, Giuseppe Valsecchi, Fabio Marioni, Media Lario Technologies S.r.l. (Italy); Daniele Gallieni, Paolo Lazzarini, A.D.S. International S.r.l. (Italy); Giancarlo Parodi, Matteo Ottolini, BCV Progetti S.r.l. (Italy); Maximilien J. Collon, cosine B.V. (Netherlands); Marta M. Civitani, Giovanni Pareschi, Daniele Spiga, INAF - Osservatorio Astronomico di Brera (Italy); Marco Nebiolo, Thales Alenia Space (Italy); Marcos Bavdaz, Eric Wille, European Space Research and Technology Ctr. (Netherlands)

ATHENA is the next high-energy astrophysical mission selected by ESA for launch in 2028. According to the current system studies, the 12 m focal length X-ray telescope is composed of 1062 SPO Mirror Modules (MM), arranged in a 3 m structure. The angular resolution requirement of the telescope is 5 arcsec half energy width, with an error budget allocation of 1.5 arcsec for the alignment and integration step of the entire mirror modules population.

This industrial and scientific team is developing, under an ESA contract, the alignment and integration process of the SPO mirror modules into the mirror structure. Besides the 1.5 arcsec angular resolution budget, the integration process meets the requirement of arbitrary integration sequence and MM exchangeability, independently of the already integrated population.

The integration is based on the 218 nm optical imaging of each MM at the 12 m focal plane, so that each module is precisely aligned in the telescope by measuring the photon counts and centroid position of its point spread function (PSF), and subsequently fixed to the structure by means of three dowel pins. This process does not require any vacuum infrastructure, but only a cleanroom laboratory, and has the great advantage of monitoring the telescope PSF during the 3-year integration time.

In this work, we will report on the design and demonstration of the integration of SPO mirror modules in a simplified mirror structure, including measurements showing that the position of the 218 nm centroid matches perfectly the X-ray values measured at PANTER.

10399-14, Session 3

Integration of the Athena mirror modules: development of indirect and x-ray direct AIT methods

Dervis Vernani, Thales Alenia Space (Switzerland); Thibault Seure, Steffen Blum, Thales Alenia Space (Switzerland); Eric Wille, Marcos Bavdaz, European Space Agency (Netherlands); Uwe Schaeffer, Airbus Deutschland (Germany); Nicolas Lièvre, MICOS (Switzerland); Adeeb Nazeeruddin, Micos Engineering GmbH (Switzerland); Maximilien J. Collon, Nicolas M. Barrière, cosine B.V. (Netherlands); Vadim Burwitz, Max-Planck-Institut für extraterrestrische Physik (Germany); Michael Krumrey, Peter Müller, Levent Cibik, Physikalisch-Technische Bundesanstalt (Germany)

Within the ATHENA optics technology plan, activities are on-going for demonstrating the feasibility of the mirror module integration. Each mirror module has to be accurately attached to the mirror structure by means of three isostatic mounts ensuring minimal distortion under environmental loads. This work reports on the status of one of the two parallel activities initiated by ESA to address this demanding task. In the study awarded to the industrial consortium, the integration relies on opto-mechanical metrology and direct X-ray alignment. For the first or "indirect" method the X-ray alignment results are accurately referenced, by means of a laser tracking system, to optical targets mounted on the mirror modules and finally linked to the mirror module structure coordinate system. With the second or "direct" method the alignment is monitored in the X-ray domain, providing figures of merit directly comparable to the final performance. The integration being designed and here presented, foreseen combining the indirect method to the X-ray direct method. The characterization of the single mirror modules is planned at PTB's X-ray Pencil Beam Facility (XPBF) at BESSY II, and the integration at Panter. It is foreseen to integrate and test a demonstrator with two mirror modules from Cosine. The final testing campaign at Panter shall be completed in December 2017.

10399-15, Session 3

Environmental testing of the ATHENA mirror modules

Boris Landgraf, David Girou, Maximilien J. Collon, cosine B.V. (Netherlands); Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Nicolas M. Barrière, cosine B.V. (Netherlands); Ramses Günther, Mark Vervest, Roy van der Hoeven, cosine Science & Computing B.V. (Netherlands); Marco W. Beijersbergen, cosine B.V. (Netherlands); Marcos Bavdaz, European Space Agency (Netherlands); Eric Wille, Sebastiaan Fransen, Brian Shortt, European Space Research and Technology Ctr.

(Netherlands); Coen van Baren, Alexander Eigenraam, SRON Netherlands Institute for Space Research (Netherlands)

The European Space Agency (ESA) is studying the ATHENA (Advanced Telescope for High ENergy Astrophysics) X-ray telescope, the second L-class mission in their Cosmic Vision 2015 – 2025 program with a launch spot in 2028. The baseline technology for the X-ray lens is the newly developed high-performance, light-weight and modular Silicon Pore Optics (SPO). As part of the technology preparation, ruggedisation and environmental testing studies are being conducted to ensure mechanical stability and optical performance of the optics during and after launch, respectively. At cosine, a facility with shock, vibration, tensile strength, long time storage and thermal testing equipment has been set up in order to test SPO mirror module (MM) materials for compliance with an Ariane launch vehicle and the mission requirements.

In this paper, we report on the progress of our ongoing investigations regarding tests on mechanical and thermal stability of MM components like single SPO stacks with and without multilayer coatings and complete MMs of inner (R = 250 mm), middle (R = 737 mm) and outer (R = 1500 mm) radii.

10399-16, Session 4

Optical simulations for design, alignment, and performance prediction of silicon pore optics for the ATHENA x-ray telescope

Daniele Spiga, INAF - Osservatorio Astronomico di Brera (Italy); FInn E. Christensen, DTU Space (Denmark); Marcos Bavdaz, European Space Research and Technology Ctr. (Netherlands); Giovanni Bianucci, Media Lario Technologies S.r.l. (Italy); Marta M. Civitani, INAF - Osservatorio Astronomico di Brera (Italy); Maximilien J. Collon, cosine B.V. (Netherlands); Paolo Conconi, INAF - Osservatorio Astronomico di Brera (Italy); Desirée Della Monica Ferreira, DTU Space (Denmark); Fabio Marioni, Media Lario Technologies S.r.l. (Italy); Sonny Massahi, DTU Space (Denmark); Giovanni Pareschi, Bianca Salmaso, INAF - Osservatorio Astronomico di Brera (Italy); Brian Shortt, European Space Research and Technology Ctr. (Netherlands); Kashmira Tayabaly, Politecnico di Milano (Italy); Giuseppe Valsecchi, Media Lario Technologies S.r.l. (Italy); Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Niels Joergen S. Westergaard, DTU Space (Denmark); Eric Wille, European Space Research and Technology Ctr. (Netherlands)

The ATHENA X-ray observatory is a large-class ESA approved mission, with launch scheduled in 2028. The technology of silicon pore optics (SPO) was selected as baseline to assemble ATHENA's optic with hundreds of mirror modules, obtained by stacking wedged and ribbed silicon wafer plates onto silicon mandrels to form the Wolter-I configuration. In the current configuration, the optical assembly has a 3 m diameter and a 2 m2 effective area at 1 keV, with a required angular resolution of 5 arcsec. The angular resolution that can be achieved is chiefly the combination of 1) the focal spot size determined by the pore diffraction, 2) the focus degradation caused by surface and profile errors, 3) the aberrations introduced by the misalignments between primary and secondary segments, 4) imperfections in the co-focality of the mirror modules in the optical assembly. A detailed simulation of these aspects is required in order to assess the fabrication and alignment tolerances; moreover, the achievable effective area and angular resolution depend on the mirror module design. Therefore, guaranteeing these optical performances requires: a fast design tool to find the most performing solution in terms of mirror module geometry and population, and an accurate point spread function simulation from local metrology and positioning information. In this paper, we present the results of simulations in the framework of ESA-financed projects (SIMPOSiuM, ASPHEA, SPIRIT), in preparation of the ATHENA X-ray telescope, analyzing the mentioned points: 1) we deal with a detailed description of diffractive effects in an SPO mirror module, 2) we show ray-tracing results including surface and profile defects of the reflective surfaces, 3) we assess the effective area and angular resolution degradation caused by alignment errors between SPO mirror module's segments, and 4) we simulate the effects of co-focality errors in X-rays and in the UV optical bench used to study the mirror module alignment and integration.

10399-17, Session 4

Optical design of the STAR-X telescope

Timo T. Saha, William W. Zhang, Ryan S. McClelland, NASA Goddard Space Flight Ctr. (United States)

Top-level science goals of the Survey and Time-domain Astrophysical Research eXplorer (STAR-X) include: investigations of most violent explosions in the universe, study of growth of black holes across cosmic time and mass scale, and measure how structure formation heats the majority of baryons in the universe. To meet these goals, the field-of-view of the telescope has to be about 1 square-degree, the angular resolution 5 arc-seconds across the field-of-view, and on-axis effective area at 1 KeV about 2,000 cm2.

Telescope design is based on a segmented meta-shell approach we have developed at Goddard Space Flight Center for the STAR-X telescope. The telescope shells are divided into 10-degree or 18-degree segments. Telescopes with meta-shells are nested inside each other in order to meet the effective area requirements in 0.5 – 6.0 KeV range. We consider Wolter-Schwarzschild, and Modified-Wolter-Schwarzschild telescope designs as basic building blocks of the nested STAR-X telescope. These designs offer excellent resolution over a large field of views.

Nested telescopes are vulnerable to stray light problems. We have designed a multi-component baffle system to eliminate direct and single-reflection light paths inside the telescopes. A large number of internal and external baffle vane structures are required to prevent stray rays from reaching the focal plane. We have developed a simple ray-trace based tool to determine the dimensions and locations of the baffles.

In this paper we present the results of our trade studies, baffle design studies, and optical performance analyses of the STAR-X telescope.

10399-18, Session 4

Methods for reducing ghost rays on the Wolter-I focusing figures of the FOXSI rocket payload

Juan Camilo Buitrago Casas, Space Sciences Lab. (United States); Lindsay Glesener, Univ. of Minnesota, Twin Cities (United States); Steven D. Christe, NASA Goddard Space Flight Ctr. (United States); Brian D. Ramsey, Ronald Elsner, NASA Marshall Space Flight Ctr. (United States); Sasha Courtade, Space Sciences Lab. (United States); Juliana Vievering, Univ. of Minnesota (United States); Athiray Subramania, Univ. of Minnesota, Twin Cities (United States); Säm Krucker, Stuart Bale, Space Sciences Lab. (United States)

In high energy solar astrophysics, imaging hard X-rays by direct focusing offers higher dynamic range and greater sensitivity compared to past techniques that used indirect imaging. The Focusing Optics X-ray Solar Imager (FOXSI) is a sounding rocket payload which uses seven sets of nested Wolter-I figured mirrors that, together with seven high-sensitive semiconductor detectors, observes the Sun in hard X-rays by direct focusing. The FOXSI rocket has successfully flown twice and is funded to fly a third time in summer 2018.

The Wolter-I geometry consists of two consecutive mirrors, one paraboloid, and one hyperboloid, that reflect photons at grazing angles. Correctly

focused X-rays reflect twice, once per mirror segment. For extended sources, like the Sun, off-axis photons at certain incident angles can reflect on only one mirror and still reach the focal plane, generating a pattern of single-bounce photons, or 'ghost rays' that can limit the sensitivity of the observation of focused X-rays. Understanding and cutting down the ghost rays on the FOXSI optics will maximize the instrument's sensitivity of the solar faintest sources for future flights. We present an analysis of the FOXSI ghost rays based on ray-tracing simulations, as well as the effectiveness of different physical strategies to reduce them.

10399-19, Session 4

Design and simulations of a short optical baffle for the Lightweight Asymmetry and Magnetism Probe (LAMP)

Yujie Xing, Zhanshan Wang, Tongji Univ. (China); Hua Feng, Tsinghua Univ. (China)

The Lightweight Asymmetry and Magnetism Probe (LAMP) is a micro-satellite based mission concept for soft X-ray polarimetry at 250 eV with a large aperture but a short focal length. Due to the very low energy response of the detector, the solar stray light must be well reduced. However, a long baffle is not favored for a micro-satellite with a limited geometry. In this paper, we propose a novel design of a short optical baffle with effective stray light suppression. With an optical aperture of 700 mm for LAMP, a baffle of 150 mm height can reduce the solar stray light by a factor of smaller than ~10-4 at incidence angles greater than 60?, justified with TracePro ray-tracing software. The design meets the requirement for LAMP and can also be used for other optical/UV/X-ray telescopes.

10399-20, Session 4

Optical design and simulations of the soft x-ray telescope for Einstein Probe mission

Yingyu Liao, Zhengxiang Shen, Qiushi Huang, Zhanshan Wang, Tongji Univ. (China)

The Einstein Probe (EP) mission, which aims at discovering transients and monitoring variable objects in 0.5-4 keV X-rays, is a small scientific satellite dedicated to time-domain high-energy astrophysics. For this purpose, the mission will employ a large instantaneous field-of-view (60°?60°) X-ray telescope (WXT), along with moderate spatial resolution (FWHM ~5') and energy resolution. It will also carry a follow-up observation X-ray telescope (FXT) with a smaller field-of-view (15'x15') — capable of much larger light-collecting power and better energy resolution than the main survey telescope. In this paper, we present the optical design and simulations of the FXT, which include the optimized structure parameters of the FXT and its focusing capabilities. The optical design and simulations are mainly performed based on MATLAB ray-tracing program. In our simulations, the FXT will employ conically-approximated Wolter-I structure with a focal length of 2 m. And the mirrors will employ thin glass with 100 mm in length and 0.3 mm in thickness. To obtain a large collective area, the FXT will consist of 66 shells tightly-nested, whose diameters range from 80 mm to 250 mm based on the center of secondary mirrors and three different kinds of coatings designed by utilizing IMD will be deposited. Based on such a kind of configuration, the effective area can be 238 cm2 at 1 keV and 152 cm2 at 4 keV, with an image quality to be approximately 55'' in half-power diameter (HPD), and with a field of view (FOV) to be approximately 15'.

10399-21, Session 5

Predicting silicon pore optics

Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Marcos Bavdaz, European Space Research and Technology Ctr. (Netherlands); Nicolas M. Barriére, Abdelhakim Chatbi, Maximilien J. Collon, D. Dekker, David Girou, cosine B.V. (Netherlands); Ramses Günther, cosine Science & Computing B.V. (Netherlands); Boris Landgraf, cosine B.V. (Netherlands); Roy van der Hoeven, Mark Vervest, cosine Science & Computing B.V. (Netherlands); Eric Wille, European Space Research and Technology Ctr. (Netherlands)

Continuing improvement of Silicon Pore Optics (SPO) calls for regular extension and validation of the tools used to model and predict their X-ray performance. In this paper we present an updated geometrical model for the SPO optics and describe how we make use of the surface metrology collected during each of the SPO manufacturing runs.

The new geometrical model affords the user a finer degree of control on the mechanical details of the SPO stacks, while a standard interface has been developed to make use of any type of metrology that can return changes in the local surface normal of the reflecting surfaces. Comparisons between the predicted and actual performance of samples optics will be shown and discussed.

10399-22, Session 5

Measuring silicon pore optics

Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Marcos Bavdaz, European Space Research and Technology Ctr. (Netherlands); Nicolas M. Barriére, Abdelhakim Chatbi, Maximilien J. Collon, D. Dekker, David Girou, cosine B.V. (Netherlands); Ramses Günther, cosine Science & Computing B.V. (Netherlands); Michael Krumrey, Physikalisch-Technische Bundesanstalt (Germany); Boris Landgraf, cosine B.V. (Netherlands); Peter Müller, Physikalisch-Technische Bundesanstalt (Germany); Roy van der Hoeven, Mark Vervest, cosine Science & Computing B.V. (Netherlands); Eric Wille, European Space Research and Technology Ctr. (Netherlands)

While predictions based on the metrology (local slope errors and detailed geometrical details) play an essential role in controlling the development of the manufacturing processes, X-ray characterization remains the ultimate indication of the actual performance of Silicon Pore Optics. For this reason SPO stacks and mirror modules are routinely characterized at PTB's X-ray Pencil Beam Facility at BESSYII. Obtaining standard X-ray results quickly, right after the production of X-ray optics is essential to making sure that X-ray results can inform decisions taken in the lab.

We describe the data analysis pipeline in operations at cosine, and how it allows us to go from stack production to full X-ray characterization in 24 hours.

10399-23, Session 5

Testing and calibrating the Athena optics at PANTER

Vadim Burwitz, Max-Planck-Institut für extraterrestrische Physik (Germany)

At the PANTER X-ray test facility of the Max-Planck-Institut für extraterrestrische Physik a lot of effort has and will be devoted to develop, test and calibrate the optics of ESA's Athena X-ray observatory. We will present and discuss the type of measurements that are and will be done at PANTER based on experience of testing and calibrating the optics of ROSAT, XMM-Newton as well as recently eROSITA. This encompasses the testing of single silicon pore optics and mini petals as part of Athena mirror assembly integration and testing efforts. Finally the testing of the complete Athena mirror during different stages of integration as well as the final calibration will have to be performed in a new upgraded X-ray test facility.

10399-24, Session 5

Calibration of the FOXSI sounding rocket x-ray optics

Steven D. Christe, NASA Goddard Space Flight Ctr. (United States); Brian D. Ramsey, Mikhail Gubarev, NASA Marshall Space Flight Ctr. (United States); Juan Camilo Buitrago-Casas, Space Sciences Lab. (United States); Lindsay Glesener, Univ. of Minnesota, Twin Cities (United States); Säm Krucker, Fachhochschule NordWestschweiz (Switzerland); Subramania Athiray, Univ. of Minnesota, Twin Cities (United States); Sasha Courtade, Space Sciences Lab. (United States); Shin-nosuke Ishikawa, The Univ. of Tokyo (Japan); Juliana Vievering, Univ. of Minnesota (United States)

We present the calibration of the Focusing Optics X-ray Solar Imager (FOXSI) sounding rocket X-ray optics. FOXSI consists of 7 telescope modules each with either 7 or 10 nested shells. These monolithic Wolter-I shells are fabricated at NASA MSFC using a nickel replication process wherein thin nickel-alloy shells are electroformed on figured and super-polished aluminum mandrels from which they are separated via differential thermal expansion. Concentric shells are then co-aligned to form a telescope module. FOXSI modules were calibrated at the MSFC Stray Light Facility. Performance metrics such as the point spread function (PSF), the half-power diameter (HPD), and the effective area as a function of energy and position on-axis and at multiple off-axis positions were measured. The PSF was found to have an FWHM of less than 7 arcsec (on-axis). The performance of individual telescope modules is consistent across many modules. The details of the calibration procedure and results are presented.

10399-25, Session 5

The Hitomi (ASTRO-H) Soft X-ray Telescope (SXT): current status of calibration

Yoshitomo Maeda, Institute of Space and Astronautical Science (Japan); Takashi Okajima, Yang Soong, Peter J. Serlemitsos, Hideyuki Mori, Lawrence G. Olsen, David Robinson, Richard G. Koenecke, William S. Chang, NASA Goddard Space Flight Ctr. (United States); Devin J. Hahne, Johns Hopkins Univ. Applied Physics Lab., LLC (United States); Ryo Iizuka, Manabu Ishida, Institute of Space and Astronautical Science (Japan); Toshiki Sato, Sho Kurashima, Nozomi Nakaniwa, Ryota Asai, Tokyo Metropolitan Univ. (Japan); Takayuki Hayashi, Tokyo Metropolitan Univ. (Japan); Takuya Miyazawa, Okinawa Institute of Science and Technology Graduate Univ. (Japan); Kazunori Ishibashi, Kenji Tachibana, Keisuke Tamura, Yuzuru Tawara, Nagoya Univ. (Japan); Akihiro Furuzawa, Fujita Health Univ. (Japan); Satoshi Sugita, Tokyo Institute of Technology (Japan)

We present latest results of the in-flight calibration of the SXT onboard the Hitomi satellite.

10399-26, Session 5

The Hitomi (ASTRO-H) Hard X-ray Telescope (HXT): current status of calibration

Hisamitsu Awaki, Ehime Univ. (Japan); Hideyo Kunieda, Hironori Matsumoto, Kazunori Ishibashi, Keisuke Tamura, Yuzuru Tawara, Ikuyuki Mitsuishi, Nagoya Univ. (Japan); Akihiro Furuzawa, Fujita Health Univ. (Japan); Takuya Miyazawa, Okinawa Institute of Science and Technology Graduate Univ. (Japan); Manabu Ishida, Yoshitomo Maeda, Ryo Iizuka, Institute of Space and Astronautical Science (Japan); Shigeo Yamauchi, Nara Women's Univ. (Japan); Yoshito Haba, Aichi Univ. of Education (Japan); Satoshi Sugita, Tokyo Institute of Technology (Japan); Tessei Yoshida, Ehime Univ. (Japan); Takashi Okajima, Hideyuki Mori, NASA Goddard Space Flight Ctr. (United States); Takayuki Hayashi, Nagoya Univ. (Japan) and NASA Goddard Space Flight Ctr. (United States)

The Japanese X-ray Astronomy Satellite, Hitomi (ASTRO-H) carries two hard X-ray telescopes (HXT), covering the energy band from 5 keV to 80 keV. Several targets were observed during the initial functional verification of the onboard instruments. The preliminary in-flight performance of HXT through the analysis of G21.5-0.9 observation was reported in the previous SPIE meeting.

We have updated the calibration of the Hitomi HXTs with Crab observation. The imaging performance of HXT have been estimated to be about 1.'7 (HPD) with X-ray emission originating from Crab pulsar.

The X-ray image of Crab Pulsar was obtained by subtracting on-pulse image from off-pulse image.

The HPD of HXT is better than those obtained from the extended source, G21.5-0.9. In the calibration of the energy response of HXTs, we found that a fine tuning of energy response of HXTs was required for the case of a bright source such as a Crab. Thus, we introduce a fudge factor to reproduce the effective area obtained from the ground calibration. The X-ray spectrum of Crab nebula is well reproduced with a simple power law model in the energy range from 8 keV to 80 keV.

The energy responses of HXTs are reflected in the latest calibration database of Hitomi.

10399-27, Session 6

Silicon mirror segments, meta-shells, and mirror assemblies for x-ray astronomy

William W. Zhang, NASA Goddard Space Flight Ctr. (United States)

Future X-ray observatories, from small Explorers to flagships, require telescopes of unprecedented performance in terms of angular resolution and effective area. Yet they must still fit under stringent launch and budgetary envelopes, which mean that these telescopes must be lightweight and of very low production cost per unit effective area. In this paper we describe a comprehensive approach to meet those manifold requirements. The approach is based on precision polishing of single-crystal silicon, which has the potential of achieving the highest possible angular resolution and lowest possible weight. In combination with a mass-production process, it also has the potential of achieving the lowest possible cost per unit effective area. Adopting the traditional philosophy of minimizing constraints, we align and bond each mirror segment at four locations, which are optimized for minimal distortion under gravity and after gravity release, to form meta-shells. The salient features of the meta-shells are that they are optically precise and structurally stiff modules and that they preserve the axial symmetry of X-ray optics, affording easy and accurate integration into final mirror assemblies. We will describe the motivation for this approach, its development status, and its prospects for enabling both near-term and long-term X-ray astronomical missions.

10399-28, Session 6

Progress on the fabrication of lightweight single-crystal silicon x-ray mirrors

Raul E. Riveros, NASA Goddard Space Flight Ctr. (United States) and Univ. of Maryland, Baltimore County (United States); Michael P. Biskach, NASA Goddard Space Flight Ctr. (United States); Kim D. Allgood, Marton V. Sharpe, John D. Kearney, Stinger Ghaffarian Technologies, Inc. (United States); William W. Zhang, NASA Goddard Space Flight Ctr. (United States)

Single crystal silicon is an excellent X-ray mirror substrate material due to its high stiffness, low density, high thermal conductivity, zero internal stress, and commercial availability. At NASA Goddard Space Flight Center, we are refining a manufacturing process for producing high resolution and lightweight X-ray mirror segments in a cost and time effective manner. Previous efforts demonstrated the possibility of producing X-ray mirrors that meet the high demands of a future X-ray mission such as STAR-X. Presently, we are producing paraboloidal and hyperboloidal mirror surfaces on the lightweight silicon segments in various optical prescriptions. This paper presents results from these recent investigations.

10399-29, Session 6

Kinematic alignment and bonding of silicon mirrors for high-resolution astronomical x-ray optics

Kai-Wing Chan, NASA Goddard Space Flight Ctr. (United States) and Univ. of Maryland, Baltimore County (United States)

We introduce a method in which a quasi-cylindrical mirror segment is mounted kinematically at 4 points, constrained in the radial direction when placed with its surface facing up or down. The segment is fully statically determined with additional constraints in axial translation and roll. Such alignment procedure is simple and precise when the radial constraints are precisely set. The mirrors are subsequently bonded into place. We address the precision of the process, the accuracy of the constraints, and the technical challenges in building up "meta-shells" of mirrors for lightweight x-ray optics to be used in the proposed STAR-X mission.

10399-30, Session 7

A hybrid concept (segmented plus monolithic fused silica shells) for a high-throughput and high-angular resolution x-ray mission (Lynx/X-Ray Surveyor like)

Giovanni Pareschi, Stefano Basso, Marta M. Civitani, Bianca Salmaso, INAF - Osservatorio Astronomico di Brera (Italy)

Lynx is a large area and high angular resolution X-ray mission concept for the next decade. It is a leap of two orders of magnitude in sensitivity over Chandra and ATHENA. The science of X-ray Surveyor requires a large-throughput mirror assembly with sub-arcsec angular resolution. These future X-ray mirrors have a set of requirements which, collectively, represents very substantial advances over any currently in operation or planned for missions other than X-ray Surveyor. Of particular importance is achieving low mass per unit collecting area, while maintaining Chandra-like angular resolution. Among the possible solutions under study, the direct polishing of both thin monolithic pseudo-cylindrical shells and segments made of fused silica are being considered as viable solutions for the implementation of the mirrors. Fused silica has very good thermo-mechanical parameters (including a very low CTE), making the material very attractive for the production of the Lynx mirrors. It should be noted that the use of close shells is very attractive, since the operations for the integration of the shells will be greatly simplified and the area lost due to the vignetting from the interfacing structures minimized. However the maximum diameter doable for close shells, according to the current technology, is of the order of 1.5 m, i.e. much smaller than the maximum diameter of the Lynx optic (3 m). In this paper we will discuss a possible layout for a hybrid concept (segmented plus monolithic shells made of fused silica) for the Lynx/XRS telescope, discussing preliminary results in terms of optical and mechanical performance.

10399-31, Session 7

Thin fused silica shells for high-resolution and large collecting area x-ray telescopes (like Lynx/XRS)

Marta M. Civitani, Stefano Basso, Oberto Citterio, Joanna Ho?yszko, Mauro Ghigo, Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy); Giancarlo Parodi, BCV Progetti S.r.l. (Italy); Giorgio Toso, INAF - IASF Milano (Italy); Gabriele Vecchi, INAF - Osservatorio Astronomico di Brera (Italy)

The implementation on of a X-ray mission with high imaging capabilities, similar to those achieved with Chandra (< 1arcsec Half Energy Width, HEW), but with a much larger throughput (2.5m2 effective area @1keV), represents a compelling request by the scientific community. To this end the Lynx/XRS mission is being studied in USA, with the participation of international partners. In order to figure out the challenging technological task of the mirror fabrication, different approaches are considered, based on monolithic and segmented shells (possibly combined together). Starting from the experience done on the glass prototypal shell realized in the past years, the direct polishing of thin (2mm thick) fused silica monolithic shells is being investigated as a possible solution. A temporary stiffening structure is designed in order to support the shell during the figuring and polishing operations and to mange the handling up to its integration in the telescope supporting structure. After the grinding and the polishing phases, in order to achieve the required surface accuracy, a final ion beam figuring correction is foreseen. In this paper, we will present the technological process and the results achieved so far on a prototypal shell under development.

10399-32, Session 7

Fused silica segments: a possible solution for x-ray telescopes with very high angular resolution like Lynx/XRS

Bianca Salmaso, Stefano Basso, Marta M. Civitani, Mauro Ghigo, INAF - Osservatorio Astronomico di Brera (Italy); Joanna Holyszko, INAF - Osservatorio Astronomico di Bologna (Italy); Daniele Spiga, Gabriele Vecchi, Giovanni Pareschi, INAF - Osservatorio Astronomico di Brera (Italy)

In order to look beyond Chandra, the Lynx/XRS mission has been proposed in USA and is currently studied by NASA. The optic will have an effective area of 2.5 m2 and an angular resolution of 0.5 arcsec HEW at 1 keV. In order to fulfil these requirements different technologies are considered, with the approaches of both full and segmented shells (that, possibly, can be also combined together). Concerning the production of segmented mirrors, a variety of thin substrates (glass, metal, silicon) are envisaged, that can be produced using both direct polishing or replication methods. Innovative post-fabrication correction methods (such as piezoelectric or magneto-restrictive film actuators on the back surface, differential deposition, ion implantation) are being also considered in order to reach the final tolerances. In this paper we are presenting a technology development based on fused silica (SiO_2) segmented substrates, owing the low coefficient of thermal expansion of Fused Silica and its high chemical stability compared

to other glasses. Thin SiO2 segmented substrates (typically 2 mm thick) are figured by direct polishing combined with final profile ion figuring correction, while the roughness reduction is reached with pitch tools. For the profile and roughness correction, the segments are glued to a substrate with UV glue, thanks to the transparency of the Fused Silica to UV. In this paper we present the current status of this technology.

10399-33, Session 8

Thermal forming of glass substrates for adjustable optics

Vincenzo Cotroneo, Paul B. Reid, Ryan Allured, Vanessa Marquez, Casey T. DeRoo, Eric D. Schwartz, Kenneth L. Gurski, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The proposed Lynx telescope is an X-ray observatory with Chandra-like angular resolution and about 30 times larger effective area. The technology under development at SAO is based on the deposition of piezoelectric material on the back of glass substrates, used to correct longer wavelength figure errors. This requires a large number (about 8000) of figured segments with sufficient quality to be in the range of correctibility of the actuators.

Thermal forming of thin glass offers a convenient approach, being based on intrinsically smooth surfaces (which doesn't require polishing or machining), available in large quantity and at a low cost from flat

display industry. Being a replica technique, this approach is particularly convenient both for development and for the realization of modular/segmented telescopes.

In this paper we review the current status and the most recent advances in the thermal forming activities at SAO, and the perspectives for the employment of these substrates for the adjustable X-Ray optics.

10399-34, Session 8

Indirect glass slumping of grazing incidence mirror segments for lightweight x-ray telescopes

Laura Proserpio, Peter Friedrich, Emanuel Madarasz, Elias Breunig, Vadim Burwitz, Max-Planck-Institut für extraterrestrische Physik (Germany); Thorsten Döhring, Anne-Catherine Probst, Hochschule Aschaffenburg (Germany)

The paper provides a description of recent progress in the development of lightweight, precision and high-throughput grazing-incidence mirrors for x-ray astronomy made by glass. In particular, the indirect slumping technology under investigation at the Max Planck Institute for Extraterrestrial Physics (MPE) is reviewed and recent activities are presented together with the research approaches. The glass slumping technique foresees several steps: a thermal forming process using a suitable mould; a reflective layer application; the alignment and integration of mirror segments into a supporting structure; and the final verification of prototype modules by X-rays. Each step is considered at MPE, with the involvement of partner institutes and universities. The last year of activities was mainly dedicated to the procurement of new moulds and to the application of Iridium coating. The main results will be presented.

10399-35, Session 8

Recent progress on experiments and numerical analysis of air bearing slumping for x-ray telescope mirror substrates

Heng Zuo, Brandon D. Chalifoux, Massachusetts Institute of Technology (United States); Michael D. DeTienne, Izentis LLC (United States); Ralf K. Heilmann, Youwei Yao, Mark L. Schattenburg, MIT Kavli Institute for Astrophysics and Space Research (United States)

Slumping of thin glass sheets onto high precision mandrels was used by NASA Goddard Space Flight Center to fabricate the NuSTAR telescope with spectacular success. Though this process generates mirrors with good resolution, it requires long thermal cycles and produces mid-range spatial frequency errors due to the anti-stick mandrel coatings.

Over the last few years, MIT Space Nanotechnology Lab has developed a slumping process which utilizes a pair of porous air bearing mandrels through which compressed nitrogen is forced, with the round flat glass sheet floating on a thin layer of nitrogen during the thermal cycle. A series of design and tests on horizontal slumping with improved control algorithm and fiber sensing techniques have shown results in glass with reduced mid-range spatial frequency errors that could be accomplished in much shorter thermal cycles. We examined the influence of the nitrogen pressure, the thickness of air gaps and the design of thermal cycles to the final shape of the wafers with this design. To complement the experiments and to understand the underlying mechanism, we utilized ADINA to carry out finite element analysis of the viscoelastic behavior of glass during the heating processes. We proved that for the 2D axisymmetric circular wafer, experimental approaches and numerical simulations have comparable results. We also discovered the crucial impacts of bearing permeability to the resulting shape of the wafers. A novel vertical slumping set-up is under test to eliminate the undesirable influence of gravity. 3D cylindrical air bearing simulations are also in development.

10399-36, Session 8

X-ray mirror prototype based on cold shaping of thin glass foils

Stefano Basso, Marta M. Civitani, Mauro Ghigo, Joanna Ho?yszko, Giovanni Pareschi, Bianca Salmaso, Daniele Spiga, Gabriele Vecchi, INAF - Osservatorio Astronomico di Brera (Italy)

The Slumping Glass Optics technology for the fabrication of astronomical X-ray mirrors has been developed in recent years in USA and Europe. The process has been used for making the mirrors of the Nustar, mission. The process starts with very thin glass foils hot formed to copy the profile of replication moulds. At INAF - Osservatorio Astronomico di Brera a process based on cold shaping is being recently developed, together with an integration method involving the use of inter-connecting ribs for making stacks. Each glass foil in the stack is shaped onto a very precise integration mould and the correct shape is frozen by means of glued ribs, that act as spacer between one layer and the adjacent ones (the first layers being attached to a thick substrate). Therefore, the increasing availability of flexible glass foils with a thickness of few tens of micron driven by electronic market for ultra-thin displays opens new possibilities for the fabrication of X-ray mirrors. This solution appears interesting especially for making hard X-ray mirrors based on multilayer coatings, taking advantage from the intrinsic low roughness of the glass foils that should grant a low scattering level. The stress on the glass due to the cold shaping is not negligible, but it is kept into account in the error budget in the design of X-ray optics. The simulations performed after FEM analysis are compliant with angular resolutions of the order of 15 arcsec HEW. As an exercise, we have considered the requirements and specs of the FORCE hard X-ray mission concept (being studied by JAXA) and we have designed the mirror modules assuming the cold slumping as a fabrication method. In the meantime, a prototype (representative of the FORCE mirror modules) is being design

and integrated in order to demonstrate the feasibility and the capacity to reach good angular resolution.

10399-37, Session 8

Lamination of ultra-thin silicon and glass wafers for producing high-quality and low-cost x-ray telescope mirrors

Youwei Yao, Mark L. Schattenburg, MIT Kavli Institute for Astrophysics and Space Research (United States)

We present a thin wafer lamination method for producing X-ray telescope mirrors. Future X-ray telescope missions require light weight optics with high resolution (<1'') and low fabrication cost. Traditional grinding/polishing and hot slumping methods find difficulty to meet the required figure accuracy when the mirror thickness is below 1 mm. In this paper, we introduce a new fabrication procedure to satisfy those requirements: first, we laminate flat and ultra-thin silicon or glass wafers on a well polished mandrel via direct bonding until the wafer stacking achieves the designed thickness. Second, we release the stacking from the mandrel since the direct bonding is temporary. Third, we anneal the stack to create permanent bonding and concrete the deformation. In such a manner, the intrinsic waviness of each wafer can be alleviated. Our FEA simulation shows the RMS slope error of the stacking surface released from a flat mandrel is improved by a factor of 6 when the layer number is doubled, regardless of the total thickness. In case of a cylindrical mandrel, the factor could be increased to 60, which indicates the lamination mirror is very promising to satisfy the requirements for future missions.

10399-38, Session 9

Diffraction efficiency of a replicated large-format x-ray reflection grating

Drew M. Miles, Jake McCoy, Randall L. McEntaffer, The Pennsylvania State Univ. (United States); Casey T. DeRoo, Harvard-Smithsonian Ctr. for Astrophysics (United States)

Future soft X-ray spectroscopy missions have science requirements that demand higher instrument throughput and higher resolution than currently available technology. A key element in such spectrometers are dispersive elements such as diffraction gratings. Our group at Penn State University develops and fabricates off-plane reflection gratings in an effort to achieve the level of performance required by future missions. We present here efficiency measurements made in the 0.2 – 1.3 keV energy band at the Advanced Light Source (ALS) at Lawrence Berkley National Laboratory for one such grating, which was fabricated to achieve the high-throughput required for future observatories. This grating was replicated from a grating master using UV-nanoimprint techniques which are suitable for mass-production and is coated in a layer of gold. Total absolute diffraction efficiency was measured to be ~55-65% across the energy range, with relative diffraction efficiency approaching 90%. These results represent the first successful demonstration of off-plane grating replicas produced via these fabrication techniques and exceed the grating efficiency requirements for future X-ray missions.

10399-39, Session 9

Critical-angle transmission gratings for high resolving power soft x-ray spectrometers on Arcus and Lynx

Ralf K. Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States); Alexander R. Bruccoleri, Izentis LLC (United States); Mark L. Schattenburg, MIT Kavli Institute for Astrophysics and Space Research (United States)

Soft x-ray spectroscopy with high resolving power (R) and large effective area (A) addresses numerous unanswered science questions about the structure and physics of our universe. In the soft x-ray band R > 500 can only be achieved with diffraction grating-based spectroscopy. Critical-angle transmission (CAT) gratings combine the advantages of blazed reflection gratings (high efficiency, use of higher diffraction orders) with those of conventional transmission gratings (relaxed alignment tolerances and temperature requirements, transparent at higher energies, low mass), resulting in minimal mission resource requirements. Diffraction efficiency > 33% and R > 10,000 have been demonstrated for CAT gratings. Last year the technology has been certified at TRL4 for a probe class mission concept.

An Explorer-scale (A > 500 sqcm, R > 2500) grating spectroscopy mission can be built with today's CAT grating technology and has been submitted to the current Explorer round as the Arcus mission. Its figure of merit for the detection of weak absorption lines will be an order of magnitude larger than current instruments on Chandra and XMM-Newton. Further CAT grating technology development and improvements in the angular resolution of x-ray optics can provide another order of magnitude improvement in performance, as is envisioned for the X-ray Surveyor/Lynx mission concept currently under development for input into the 2020 Decadal Survey.

We recently have fabricated the largest (32 mm x 32 mm) CAT gratings to date, and plan to increase grating size further. We report on our latest fabrication and x-ray efficiency, resolving power, and environmental testing results.

10399-40, Session 9

Toward measurement of period variation in Critical-Angle Transmission (CAT) gratings

Jungki Song, Ralf K. Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States); Mark L. Schatternburg, Massachusetts Institute of Technology (United States)

With the combined advantages of blazed reflection gratings and conventional transmission gratings, CAT grating technology is expected to meet the performance requirements for future x-ray missions. While resolving power > 10,000 has been experimentally demonstrated in a CAT grating spectrometer breadboard system, period variation, one of the potentially limiting factors for very high resolving power, has not been thoroughly studied. In this work we report progress towards developing a scanning laser reflection (LR) period measurement tool for generating high-precision grating period maps across CAT gratings. The LR tool operates on the same measurement principle as a tool built in 1994 for characterizing period variations of grating facets in Chandra X-ray Observatory, but with higher spatial resolution and enhanced measurement sensitivity (dp/p < 10 ppm rms). It uses a specularly reflected beam and a first-order diffracted beam to record local period variations, grating surface tilt and tip, and grating line orientation. The capability to measure small period variations was demonstrated by measuring grating samples that show only built-in period variations of the interference lithographic process. Preliminary results for period measurement of CAT grating samples will be presented.

10399-41, Session 9

Laboratory progress in soft x-ray polarimetry

Sarah Heine, Herman L. Marshall, Norbert Schulz, Massachusetts Institute of Technology (United States); Ralf K. Heilmann, MIT Kavli Institute for Astrophysics and Space Research (United States); David Windt, Reflective X-Ray Optics LLC (United States); Kyle A. Beeks, Massachusetts Institute of Technology (United States)

We present continued development of components for measuring linear

X-ray polarization over the 0.2-0.8 keV (15-62 A) band. We employ multilayer-coated mirrors as Bragg reflectors at the Brewster angle. By matching to the dispersion of a spectrometer, we take advantage of high multilayer reflectivities at these energies and achieve polarization modulation factors over 95%. We have constructed a source of polarized X-rays that operates at a wide range of energies with a selectable polarization phase. We will present results from measurements of new laterally graded multilayer mirrors and critical angle transmission gratings essential to the approach. While the lab is designed to verify components to be used in a soft X-ray polarimeter, it is reconfigurable and has been used to verify grating efficiencies with our new CCD detector. Our development work is the basis for a sounding rocket mission (Rocket Experiment Demonstration of a Soft X-ray Polarimeter) and future orbital missions.

10399-42, Session 9

REDSoX: Monte-Carlo ray-tracing for a soft x-ray spectroscopy polarimeter

Hans Moritz Günther, Mark D. Egan, Ralf K. Heilmann, Tim Hellickson, MIT Kavli Institute for Astrophysics and Space Research (United States); Jason Frost, Stanford Univ. (United States) and MIT Kavli Institute for Astrophysics and Space Research (United States); Herman L. Marshall, Norbert Schulz, Adam Theriault-Shay, Sarah M. Trowbridge Heine, MIT Kavli Institute for Astrophysics and Space Research (United States)

X-ray polarimetry o?ers a new window into the high-energy universe, yet there has been no instrument so far that could measure the polarization of soft X-rays (about 17-80 ˚A) from astrophysical sources. The Rocket Experiment Demonstration of a Soft X-ray Polarimeter (REDSoX Polarimeter) is a proposed sounding rocket experiment that uses a focusing optic and splits the beam into three channels. Each channel has a set of critical-angle transmission (CAT) gratings that disperse the x-rays onto a laterally graded multilayer (LGML) mirror, which preferentially reflects photons with a specific polarization angle. The three channels are oriented at 120 deg to each other and thus measure the three Stokes parameters: I, Q, and U. The period of the LGML changes with position. The main design challenge is to arrange the gratings so that they disperse the spectrum in such a way that all rays are dispersed onto the position on the multi-layer mirror where they satisfy the local Bragg condition despite arriving on the mirror at di?erent angles due to the converging beam from the focusing optics. We present a polarimeteric Monte-Carlo ray-trace of this design to assess non-ideal e?ects from e.g. mirror scattering or the finite size of the grating facets. With mirror properties both simulated and measured in the lab for LGML mirrors of 80-200 layers we show that the reflectivity and the width of the Bragg-peak are su?cient to make this design work when non-ideal e?ects are included in the simulation. Our simulations give us an e?ective area curve, the modulation factor and the figure of merit for the REDSoX polarimeter. As an example, we simulate an observation of Mk 421 and show that we could easily detect a 20% linear polarization.

10399-63, Session PWed

Readout electronics testing during mass production of FlashCam cameras for the Cherenkov Telescope Array

Sebastian Diebold, Felix Eisenkolb, Christoph Kalkuhl, Gerd Puehlhofer, Andrea Santangelo, Thomas Schanz, Chris Tenzer, Eberhard Karls Univ. Tübingen (Germany); the FlashCam Team, see F. Werner et al., NIM A, 2016, for all team members (Germany); the CTA Consortium, Full author and affiliation list on http://www.cta-observatory.org (Italy)

The Cherenkov Telescope Array (CTA) will be the future observatory for ground-based TeV gamma-ray astronomy. At two sites, one in the northern and one in the southern hemisphere, CTA will feature about one hundred telescopes of different size classes in order to significantly improve the sensitivity and energy range with respect to current Cherenkov facilities. FlashCam is a camera system proposed for the medium-sized telescopes of CTA that implements a fully digital readout and trigger processing, which allows the reconfiguration of parameters and routines for the trigger algorithm and the signal shaping. Extensive tests with a full-scale prototype yielded excellent performance and stability results, which surpass CTA requirements. For the mass production of a substantial number of FlashCam cameras, efficient and reliable testing routines have been developed. In this contribution the approach, the setups, and the procedures for the mass testing of the readout electronics are presented.

10399-64, Session PWed

McXtrace simulation of x-ray optics for astronomical telescopes

Desirée Della Monica Ferreira, DTU Space (Denmark); Erik B. Knudsen, Technical Univ. of Denmark (Denmark); Niels Joergen S. Westergaard, Sonny Massahi, Finn E. Christensen, DTU Space (Denmark)

We make use of the software package McXtrace to access the performance of X-ray telescopes concept designs. We consider the Athena X-ray telescope based on Silicon Pore Optics (SPO) technology as reference design to demonstrate the performance of individual pores within SPO mirror modules. After presenting our approach for simulations and concept designs, we present the effective areas generated from our studies for both SPO and concentric mirror shell optics.

10399-65, Session PWed

Development of the thermal shield with high x-ray transmission for PRAXyS x-ray telescopes

Yuzuru Tawara, Ikuyuki Mitsuishi, Ryoki Suganuma, Taisuke Futamura, Takafumi Onishi, Kazushi Tachibana, Kenji Tachibana, Ikuya Sakurai, Nagoya Univ. (Japan)

PRAXyS was proposed as a SMEX mission that observes X-ray polarization at 2 - 10 keV, and a Phase A study was conducted. The X-ray telescope for this mission is temperature-controlled by a heater and a thermal shield to realize a temperature environment of about room temperature. We developed a thermal shield using a plastic thin film with high X-ray transmission placed in front of and behind the telescope for this purpose. In addition to the above characteristics, the performance required for a thermal shield is resistance against the launch and orbital environment (acoustic vibration, aerodynamic heating, thermal vacuum, atomic oxygen). The basic structure of thermal shield consists of metal frame, film support mesh, aluminum-coated polyimide thin film following the XRT-TS of ASCA, Suzaku, Hitomi. Especially, we aimed at transmission of mesh higher than conventional, and newly developed an evaluation test apparatus for high temperature mechanical resistance accompanying acoustic and aerodynamic heating. In this paper, thermal shield design, temperature prediction by numerical simulation, prototype thermal shield sample, an evaluation test apparatus and details of its evaluation will be described.

10399-66, Session PWed

Industrialization of the mirror plate coatings for the Athena mission

Sonny Massahi, Finn E. Christensen, Desiree D. M. Ferreira, DTU Space (Denmark); Brian Shortt, European Space Research and Technology Ctr. (Netherlands); Maximilien J.

Collon, Boris Landgraf, cosine B.V. (Netherlands)

In the frame of the development of the Advanced Telescope for High-ENergy Astrophysics (Athena) mission, currently in phase A, ESA is continuing to mature the optics technology and the associated mass production techniques. These efforts are driven by the programmatic and technical requirement of reaching TRL 6 prior to proposing the mission for formal adoption, currently planned for 2020. A critical part of the current phase A preparation activities is addressing the industrialization of the Silicon Pore Optics mirror plates coating.

An essential part of this effort is the transfer of the well-established coating processes and techniques to an industrial scale facility suitable for coating the more than 100,000 mirror plates required for Athena.

In this paper we explain the work being undertaken in this area including, requirement specification, equipment and supplier selection, preparing the coating facility for the deposition equipment, designing and fabricating the deposition equipment.

10399-67, Session PWed

Characterization of multilayer coated replicated Wolter optics for fusion experiments at the Z Pulsed Power Facility

Andrew Ames, Harvard-Smithsonian Ctr. for Astrophysics (United States); David Ampleford, Sandia National Labs. (United States); Ricardo Bruni, Harvard-Smithsonian Ctr. for Astrophysics (United States); Chris Bourdon, Sandia National Labs. (United States); Bernard Kozioziemski, Lawrence Livermore National Lab. (United States); Suzanne E. Romaine, Harvard-Smithsonian Ctr. for Astrophysics (United States); Brian D. Ramsey, National Space Sciences and Technology Ctr. (United States); Michael J. Pivovaroff, Julia Vogel, Christopher Walton, Lawrence Livermore National Lab. (United States); M. Wu, Sandia National Labs. (United States)

Multilayer coatings can be applied to Wolter X-ray optics to extend the bandpass to high energies or to create a narrow high energy bandpass. For large diameter full shell optics these coatings can be directly applied to the inside surface of the optic and several such multilayer coated prototype telescopes have been fabricated and tested. However, for small diameter full shell optics direct deposition of the multilayers is not possible. Therefore we have developed a process for indirectly coating arbitrarily small diameter electroformed nickel replicated optics with multilayers to increase their response at high energy (i.e. > 10 keV). The multilayer coating is applied to the mandrel before the NiCo optic is electroformed onto the mandrel. The multilayer coating is then released along with the optic when the optic is separated from the mandrel. The ability to fabricate small diameter multilayer coated full shell Wolter X-ray optics with narrow bandpass opens the door to several applications within astronomy and also provides a path for cross-fertilization to other fields.

We report on the characterization and evaluation of the first two prototype X-ray Wolter optics to be tested at the Z Pulsed Power Facility at Sandia National Laboratory. The intent is to develop and field several optics as part of an imaging system with targeted spectral ranges.

10399-68, Session PWed

Development of a second generation SiLC-based Laue lens

David Girou, Nicolas M. Barrière, Maximilien J. Collon, cosine B.V. (Netherlands); Eric Ford, Univ. of Washington Medical Ctr. (United States); Ramses Günther, cosine Science & Computing B.V. (Netherlands); Lorraine Hanlon, Univ. College Dublin (Ireland); John Tomsick, Space Sciences Lab. (United States); Alexey Uliyanov, Univ. College Dublin (Ireland); Giuseppe Vacanti, cosine Science & Computing B.V. (Netherlands); Colin Wade, Univ. College Dublin (Ireland); Andreas Zoglauer, Space Sciences Lab. (United States)

cosine has been developing for more than a decade silicon pore optics (SPO), lightweight modular X-ray optic made of stacks of bent and directly bonded silicon mirror plates. This technology, which has been selected by ESA to realize the optics of ATHENA, can also be used to fabricate soft gamma-ray Laue lenses if Bragg diffraction through the bulk silicon is exploited, rather than grazing incidence reflection.

Silicon Laue Components (SiLCs) are made of stacks of curved, polished, wedged silicon plates, allowing the concentration of radiation in both radial and azimuthal directions. This greatly increases the focusing properties of a Laue lens since the size of the focal spot is no longer determined by the size of the individual single crystals, but by the accuracy of the applied curvature.

After a successful proof of concept in 2013, establishing the huge potential of this technology, a new project has been launched in Spring 2017 at cosine to further develop and test this technique. Here we present the latest advances of the second generation of SiLCs made from even thinner silicon plates stacked by a robot with dedicated tools in a class-100 clean room environment.

10399-43, Session 10

Design, development, and performance of x-ray mirror coatings for the Athena mission

Desirée Della Monica Ferreira, Sonny Massahi, Finn E. Christensen, DTU Space (Denmark); Brian Shortt, European Space Research and Technology Ctr. (Netherlands); Maximilien J. Collon, cosine B.V. (Netherlands); Chantal Silvestre, DTU Space (Denmark); Michael Krumrey, Levent Cibik, Swenja Schreiber, Physikalisch-Technische Bundesanstalt (Germany)

We report the latest results on coating design optimization and optics performance for the present Ir/B4C baseline coating and alternative designs and materials including bi/tri-layers and linear graded multilayers.

We make use of X-ray reflectometry (XRR) and atomic force microscopy (AFM), among other techniques, to test both coating performance and robustness.Deposition of coatings on Silicon Pore Optics substrates, evaluation of the coatings characteristics and long term stability are presented.

10399-44, Session 10

Development of multilayer coatings for hard x-ray optics at NASA Marshall Space Flight Center

Danielle N. Gurgew, The Univ. of Alabama in Huntsville (United States); David M. Broadway, Brian D. Ramsey, NASA Marshall Space Flight Ctr. (United States); Don Gregory, The Univ. of Alabama in Huntsville (United States)

In this work, we describe the development of multilayer coating capabilities of the X-ray astronomy group at NASA Marshall Space Flight Center (MSFC). A DC magnetron sputtering system has been constructed to deposit periodic, depth-graded and aperiodic multilayer coatings on flat silicon and glass substrates of various diameters. The main goal of this new area of research at MSFC is the development of coatings for use on future hard

X-ray astronomical telescopes, extending the reflected energy range into the hard X-ray to soft gamma ray band. Descriptions of the system geometry and calibration process as well as initial results from the first few months of deposition and coating recipe optimization are presented.

10399-45, Session 10

Cross-fertilization of multilayer coated Wolter optics: developing optics for fusion experiments at the Z Pulsed Power Facility

Suzanne E. Romaine, Andrew Ames, Harvard-Smithsonian Ctr. for Astrophysics (United States); David Ampleford, Chris Bourdon, Sandia National Labs. (United States); Bernard Kozioziemski, Lawrence Livermore National Lab. (United States); Ricardo Bruni, Harvard-Smithsonian Ctr. for Astrophysics (United States); Michael J. Pivovaroff, Lawrence Livermore National Lab. (United States); Brian D. Ramsey, National Space Sciences and Technology Ctr. (United States); Julia Vogel, Christopher Walton, Lawrence Livermore National Lab. (United States); M. Wu, Sandia National Labs. (United States)

Multilayer coatings can be applied to Wolter X-ray optics to extend the bandpass to high energies or to create a narrow high energy bandpass. For large diameter full shell optics these coatings can be directly applied to the inside surface of the optic and several such multilayer coated prototype telescopes have been fabricated and tested. However, for small diameter full shell optics direct deposition of the multilayers is not possible. Therefore we have developed a process for indirectly coating arbitrarily small diameter electroformed nickel replicated optics with multilayers to increase their response at high energy (i.e. > 10 keV). The multilayer coating is applied to the mandrel before the NiCo optic is electroformed onto the mandrel. The multilayer coating is then released along with the optic when the optic is separated from the mandrel. The ability to fabricate small diameter multilayer coated full shell Wolter X-ray optics with narrow bandpass opens the door to several applications within astronomy and also provides a path for cross-fertilization to other fields.

We report on the fabrication of the first two prototype X-ray Wolter optics to be tested at the Z-Pulsed Power Facility at Sandia National Laboratory (SNL). SNL and Lawrence Livermore National Laboratory are collaborating in the development of an x-ray imaging system for use on the Z Machine to image warm X-ray emission from Z pinches. The concept is to use multilayer mirror coatings on a cylindrical glancing incidence focusing mirror in a Wolter geometry. The intent is to develop and field several optics as part of an imaging system with targeted spectral ranges.

10399-46, Session 10

Simulation and optimization of a soft gamma-ray concentrator using thin film multilayer structures

Farzane Shirazi, Peter Bloser, James Krzanowski, Jason Legere, Mark McConnell, The Univ. of New Hampshire (United States)

We are reporting the investigation result of using multilayer thin film structures for channeling and concentrating soft gamma rays with energies greater than 100 keV, beyond the reach of current grazing-incidence hard X-ray mirrors. This will enable future telescopes for higher energies with same mission parameters already proven by NuSTAR. A suitable arrangement of bent multilayer structures of alternating low and high-density materials will channel soft gamma-ray photons via total external reflection and then concentrate the incident radiation to a point. We present the latest results of producing Si/Ir multilayers with the required thicknesses and smoothness by using magnetron sputter technique. In addition of experimental works, we have been working on gamma ray tracing model of the concentrator by IDL, making use of optical properties calculated by the IMD software. This modeling allows us to calculate efficiency and focal length for different energy bands and materials and compare them with experimental result. Also we describe combine concentrator modeling result and detector simulation by MEGAlib to archive a complete package of gamma-ray telescope simulation. This technology offers the potential for soft gamma-ray telescopes with focal lengths of less than 10 m, removing the need for formation flying spacecraft and providing greatly increased sensitivity for modest cost and complexity and opening the field up to balloon-borne instruments.

10399-47, Session 11

In-situ stress measurement of single and multilayer thin-films used in x-ray astronomy optics applications

David M. Broadway, Stephen L. O'Dell, Brian D. Ramsey, NASA Marshall Space Flight Ctr. (United States); Danielle N. Gurgew, The Univ. of Alabama in Huntsville (United States)

We report on the dependence of the stress and surface roughness of chromium and iridium single layer and bi-layer films deposited by magnetron sputter deposition for various process conditions such as argon pressure and substrate temperature. The stress is measured in-situ with a novel device developed at the NASA MSFC. The elegant device's capability and sensitivity are discussed and compared to other more complex current state-of-the-art optical stress measurement instruments such as the multiple beam optical stress sensor (MOSS). We further discuss the capability of in-situ stress measurement as a technique for the direct measurement of the physical thicknesses of the layers and the material profile at the interfaces of multilayer structures.

10399-48, Session 11

Development of iridium-coated x-ray mirrors for astronomical applications

Veronika Stehlíková, Max-Planck-Institut für extraterrestrische Physik (Germany) and Czech Technical Univ. in Prague (Czech Republic); Thorsten Döhring, Anne-Catherine Probst, Florian Emmerich, Manfred Stollenwerk, Hochschule Aschaffenburg (Germany); Laura Proserpio, Peter Friedrich, Max-Planck-Institut für extraterrestrische Physik (Germany)

Due to their excellent reflection properties iridium coatings are often applied for grazing incidence mirrors in astronomical X-ray telescopes. Future space-based X-ray observatories need to be very lightweighted for launcher mass constrains. Therefore they will use a reduced mirror thickness, which results in the additional requirement of low coating stress to avoid deformation of the initial precisely shaped mirror substrates. At Aschaffenburg University of Applied Sciences the coating of thin iridium films by an RF-magnetron sputtering technique is under development. The work is embedded in collaborations with the Max-Planck-Institute for Extraterrestrial Physics in Germany, the Czech Technical University in Prague, the Osservatorio Astronomico di Brera in Italy, and the French Institute Fresnel. Sputtering with different parameters, especially by variation of the argon gas pressure, leads to iridium films with different properties. The current work is focused on the microstructure of the iridium coatings to study the influence of the substrate and of the deposition parameters on the thin film growing process. Correlations between coating density, surface micro-roughness, crystalline structure of the iridium layers and the expected reflectivity as well as stress-induced deformation of the X-ray mirror will be presented and discussed. The final goal of the project is to integrate the produced prototype mirrors into an X-ray telescope module. On a longer timescale measurements of the mirror modules optical performance are planned at the X-ray test facility PANTER.

10399-49, Session 11

Effects of ion implantation in different substrate materials: stress, relaxation, and strength

Brandon D. Chalifoux, Graham Wright, Massachusetts Institute of Technology (United States); Youwei Yao, MIT Kavli Institute for Astrophysics and Space Research (United States); Claire Burch, Harvard Univ. (United States); Ralf K. Heilmann, Mark L. Schattenburg, MIT Kavli Institute for Astrophysics and Space Research (United States)

Ion implantation is a promising method of correcting figure errors in thin mirror substrates. For future high-resolution, high-throughput x-ray observatories, such figure correction may be critical. Ion implantation into both glass and silicon results in surface stress, which bends the substrate. In this paper we investigate three effects of ion implantation in several types of glass, as well as crystalline silicon. The first effect we report on is the stress resulting from the implanted ions, and the implications for figure correction with each material. Each material studied also shows some relaxation after the ion implantation is stopped; we report on the magnitude of this relaxation and its implications. Finally, the surface stress may affect the strength of implanted materials. We report on ring-on-ring strength tests we conducted on implanted samples.

10399-50, Session 12

Advancements in ion beam figuring of very thin glass plates

Marta M. Civitani, Mauro Ghigo, Joanna Ho?yszko, Gabriele Vecchi, Stefano Basso, INAF - Osservatorio Astronomico di Brera (Italy); Vincenzo Cotroneo, Ryan Allured, Paul B. Reid, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The high-quality surface characteristics, both in terms of figure error and of micro-roughness, required on the mirrors of a high angular resolution x-ray telescope are challenging, but in principle well suited with a deterministic and non-contact process like the ion beam figuring. This process has been recently proven to be compatible even with very thin (thickness around 0.4mm) sheet of glasses (like D263 and Eagle). In the last decade, these types of glass have been investigated as substrates for hot slumping, with residual figure errors of hundreds of nanometres. In this view, the mirrors segments fabrication could be envisaged as a simple two phases process: a first replica step based on hot slumping (direct/indirect) followed by an ion beam figuring which can be considered as a post-fabrication correction method. The first ion beam figuring trials, realized on flat samples, showed that the micro-roughness is not damaged but a deeper analysis is necessary to characterize and eventually control/compensate the glass shape variations. In this paper, we present the advancements in the process definition, both on flat and slumped glass samples.

10399-51, Session 12

Improving x-ray optics via differential deposition

Kiranmayee Kilaru, Universities Space Research Association (United States)

Differential deposition is a means of figure correction in x-ray optics. In this technique physical vapor deposition is used to smooth out irregularities in an optic's figure, thereby significantly improving the imaging performance. A system has been developed to apply differential deposition to full-shell optics being developed for x-ray astronomy. Initial tests with a single stage of correction showed that a factor of three improvement in angular resolution was possible. Since that time, the coating system has been improved through increased automation so that the coating head more accurately tracks the tapering optic's surface. Here, we show new x-ray results for two stages of correction, the second stage addressing higher-frequency errors in the mirrors axial figure profile. We discuss challenges that must be addressed to achieve still higher angular resolution.

10399-52, Session 12

Additive manufactured x-ray optics for astronomy

Carolyn Atkins, UK Astronomy Technology Ctr. (United Kingdom); Charlotte H. Feldman, Univ. of Leicester (United Kingdom); David Brooks, Univ. College London (United Kingdom); Richard Willingale, Univ. of Leicester (United Kingdom); Peter Doel, Univ. College London (United Kingdom)

Additive manufacturing, more commonly known as 3D printing, has become a commercially established technology for rapid prototyping and the fabrication of bespoke intricate parts. Optical components, such as mirrors and lenses, are now being fabricated via additive manufacturing, where the printed substrate is polished in a post-processing step. One application of additively manufactured optics could be within the astronomical X-ray community, where there is a growing need to demonstrate thin, light-weight, high precision optics for a 'beyond Chandra' style mission.

This paper will follow a proof-of-concept investigation, sponsored by the UK Space Agency's National Space Technology Programme, into the feasibility of applying additive manufacturing in the production of thin, light-weight, precision X-ray optics for astronomy. One of the benefits of additive manufacturing is the ability to construct intricate light-weighting, which can be optimised to minimise weight while ensuring rigidity. This concept of optimised light-weighting will be applied to a series of polished additively manufactured test samples and experimental data from these samples, including an assessment of the optical quality and the magnitude of any print-through, will be presented. In addition, the finite element analysis optimisations of the light-weighting development will be discussed.

10399-53, Session 12

Design and modeling of an additive manufactured thin shell for x-ray astronomy

Charlotte H. Feldman, Univ. of Leicester (United Kingdom); Carolyn Atkins, UK Astronomy Technology Ctr. (United Kingdom); Richard Willingale, Univ. of Leicester (United Kingdom); David Brooks, Peter Doel, Univ. College London (United Kingdom)

Future X-ray astronomy missions require light-weight thin shells to provide large collecting areas within the weight limits of launch vehicles, whilst still delivering angular resolutions close to that of Chandra (0.5 arc seconds). Additive manufacturing, also known as 3D printing, is a well-established technology with the ability to construct or `print' intricate support structures, which can be both integral and light-weight, and is therefore a candidate technique for producing shells for space-based X-ray telescopes. The work described here is a feasibility study into this technology for precision X-ray optics for astronomy and has been sponsored by the UK Space Agency's National Space Technology Programme. The goal of the project is to use a series of test samples to trial different materials and processes with the aim of developing a viable path for the production of an X-ray reflecting prototype for astronomical applications. The initial design of an additive manufactured prototype X-ray shell is presented with ray-trace modelling and analysis of the X-ray performance. The polishing process may cause print-through from the light-weight support structure on to the reflecting surface. Investigations in to the effect of the print-through on the X-ray performance of the shell are also presented.

10399-54, Session 13

Experimental evaluation of solder bonding and actuation for thin-shell x-ray telescope mirror assembly

Michael D. DeTienne, Alexander R. Bruccoleri, Ross Tedesco, Massachusetts Institute of Technology (United States); Ralf K. Heilmann, Mark L. Schattenburg, MIT Kavli Institute for Astrophysics and Space Research (United States)

In past work, we demonstrated a new adjustable bonding technique utilizing solder to bond metal and glass, referred to as liquid metal actuation. The concept is to bond via solder, and then momentarily melt the solder surface with a laser while applying a force to compress or stretch the joint. We demonstrated sub 100 nm adjustments (0.2 arc seconds for a 200 mm mirror) via liquid metal actuation. This precision provides additional tools towards a sub-arcsecond telescope, such as the X-ray Surveyor mission concept. Further research and development of the technique is presented to evaluate the feasibility for mirror assembly.

At present, epoxy is used to bond thin-shell x-ray mirrors, which has several drawbacks including instability, time consuming application, shrinkage, creep, and sensitivity to ambient conditions such as humidity. Furthermore, epoxy bonds cannot be easily adjusted post curing and any errors in the initial bond are permanent. Preliminary structural testing was done comparing the strengths of solder to epoxy for Kovar pins and clips. Tin/silver solder joints were at least 4 times stronger than epoxy as measured via a Zwick mechanical tester.

We designed and built an in-house laser soldering and adjustment station. The apparatus is equipped with a 100 W infrared laser, and a suite of metrology tools. Preliminary experiments were focused on reproducing and understanding the results of past work. Specifically, we present more detailed experimental results for the joint adjustments, with a focus on understanding the heat transfer from the laser to the solder.

10399-55, Session 13

Adjustable optics applied to Laue lenses

Enrico Virgilli, Piero Rosati, Filippo Frontera, Univ. degli Studi di Ferrara (Italy); Ezio Caroli, John B. Stephen, Natalia Auricchio, Stefano Silvestri, Angelo Basili, INAF - IASF Bologna (Italy)

Given the unprecedented sensitivity level which is expected to be achievable in the hard X-/soft gamma-ray band using Laue lenses based on bent crystals (e.g., Frontera et al. 2013, SPIE Procs 8861; Virgilli et al. 2017, in preparation), great effort is being performed to refine the technology for assembling such a lens.

Indeed, the results so far obtained in the alignment process of a large number of crystal tiles for diffraction still require an improvement in order to achieve the limiting Point Spread Function (about 20 arcsec).

In our presentation we will discuss a modular approach for the realization of an entire Laue lens. Under this approach, the Laue lens comprises a significant number of sub-modules, each filled with accurately oriented crystals, which are mounted on the lens frame through an active alignment system. We will present the first results of this adjustment technology to demonstrate the capability of minimizing the alignment uncertainties.

10399-56, Session 13

Design and fabrication of adjustable x-ray optics using piezoelectric thin films

Julian Walker, Tianning Liu, Mohit Tendulkar, David Burrows, The Pennsylvania State Univ. (United States); Casey T. DeRoo, Ryan Allured, Edward Hertz, Vincenzo Cotroneo, Paul B. Reid, Eric D. Schwartz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Thomas N. Jackson, The Pennsylvania State Univ. (United States); Susan Trolier-McKinstry, Harvard-Smithsonian Ctr. for Astrophysics (United States)

The Lynx X-ray telescope aims to have < 0.5 arc seconds resolution, large collection area and low weight. The development of adjustable X-ray optics is a potential method for facilitating this. Here we used 1.5μm thick, radio frequency RF deposited piezoelectric PbZr0.52Ti0.48O3 (PZT) thin films on the convex side of curved glass substrates to make adjustable X-ray mirrors. The electromechanical coupling of PZT allows the application of voltage to adjust the mirror figure. Double layer lithography by spray deposition and spinning was used to patterned top electrodes as separately controllable cells. ZnO-based thin film transistors (TFT) were developed as the control circuitry to modulate the applied voltage. Electrically conductive adhesive bonds (ACF bonding) were used to connect 112 electrodes on each mirror. 5 μm solution cast thin flex cables were used to minimize the impact of the bond on the mirror figure. After measurement of the change of the mirror figure due to the processing of the piezoelectric device layers, Cr and Ir layers were deposited on the concave side of the glass substrate to correct the X-ray mirror coating. The thickness of the Ir layer and the chamber pressure during deposition were modulated to balance the figure distortion resulting from the piezoelectric device layers.

This work will discuss the challenges involved with processing piezoelectric thin film devices on curved glass substrates, and detail the approaches being employed to overcome these for eventual application in flight quality adjustable X-ray optics.

10399-57, Session 13

Characterizing the poling process for piezoelectric cells in adjustable x-ray optics

Casey T. DeRoo, Ryan Allured, Sagi Ben-Ami, Paul B. Reid, Vincenzo Cotroneo, Daniel A. Schwartz, Edward Hertz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Julian Walker, Tianning Liu, Mohit Tendulkar, David Burrows, Tom N. Jackson, Susan Trolier-McKinstry, The Pennsylvania State Univ. (United States)

The NASA large strategic mission candidate Lynx offers the opportunity to study the cosmological evolution of the large scale structure of the Universe in X-rays, performing observations of low surface brightness outflows in galaxy clusters and observing initial black hole seed masses at extreme redshift. To support Lynx, however, lightweight, high angular resolution (< 0.5") X-ray mirrors are needed. Fabricating adjustable X-ray optics is a potential method for realizing such mirrors; by constructing actuatable cells from a piezoelectric, thin-film layer of lead zirconate titanate (PZT), the figure of a thin-shelled mirror segment can be improved. In order to maximize the influence function of each actuator cell, the piezoelectric cells must first be "poled", which serves to orient polarization of the PZT domains with an applied electric field. In the present work, we report on the impact of variables in the poling process (temperature, applied field strength, etc.) on both the magnitude of the piezoelectric coefficient, and its stability over time. Using wavefront sensing metrology, we measure the stress induced by poling the discrete PZT cells on a fabricated adjustable X-ray optic. We also quantify the cell-to-cell variation of the piezoelectric coefficients produced by identical poling processes.

10399-58, Session 13

Deterministic figure correction of piezoelectrically adjustable slumped glass optics

Ryan Allured, Paul B. Reid, Casey T. DeRoo, Vincenzo Cotroneo, Alexey Vikhlinin, Edward Hertz, Vanessa Marquez, Eric D. Schwartz, Harvard-Smithsonian Ctr. for Astrophysics (United States); Susan Trolier-McKinstry, Julian Walker, Thomas N. Jackson, Tianning Liu, The Pennsylvania State Univ. (United States)

The Lynx (X-ray Surveyor) mission concept requires high resolution, lightweight X-ray optics. Our group has continued to advance cylindrical optics featuring thin film piezoelectric actuators as a viable technology to fulfill this need. For the first time, we have fabricated adjustable optics on thermally formed glass substrates and demonstrated absolute figure correction. Furthermore, we have quantified mirror correctability in terms of two dimensional orthogonal functions and extrapolated these results to larger format optics envisioned for the Lynx mission. Finally, we will discuss the limitations of our current approach and the facilities needed for fabrication of flight quality adjustable optics.

10399-59, Session 13

Controlling the shaping of Si and glass substrates via stresses in the coatings: via bias stress control and magnet fields

Melville P. Ulmer, Xiaoli Wang, Jian Cao, David B. Buchholz, Northwestern Univ. (United States); Lahsen Assoufid, Argonne National Lab. (United States)

We describe our progress in developing technologies that can be applied to making mirrors that could be used both at the Argonne National Laboratory's (ANL's) Advanced Photon Source (APS) as well as for X-ray astronomy. We have been able to apply enough controlled coating stress to a Si substrate so as to produce a radius of curvature of 17m. The Si substrates are also to be coated with Tefenol-D and then NiCo. The Terfenol-D (T-D)will be used to apply a magnetic field induced stress. The NiCo will retain the magnetic field. Progress has been made in producing nearly stress free T-D coatings. An update on how the entire process works will be presented along with results from shaping 50 mm x 50 mm coated glass substrates.

10399-60, Session 14

Characterization of x-ray lobster optics with a hybrid CMOS sensor

Tanmoy Chattopadhyay, Mitchell Wages, David Burrows, Evan Bray, The Pennsylvania State Univ. (United States); Adolf Inneman, Rene Hudec, Veronika Stehlikova, Czech Technical Univ. in Prague (Czech Republic); David Schendt, Sam Hull, Abe Falcone, Maria McQuaide, The Pennsylvania State Univ. (United States)

X-ray lobster optics provide a unique way to focus X-rays onto a small focal plane imager with wide field of view imaging. Such an instrument with angular resolution of a few arcminutes can be used to study GRB afterglows, as well as the variability and spectroscopic characteristics for other astrophysical objects. At Penn state University, we characterize these lobster optics with an H1RG CMOS sensor (100 ?m thick Silicon with 18 ?m pixel size), procured from Teledyne Imaging Sensors at its focal plane. The light-weight compact lobster optic with a 25 cm focal length provides two dimensional imaging with ~25 cm^2 effective area at 2 keV. We chose the hybrid CMOS detector (HCD) since X-ray HCDs offer several advantages (e.g. radiation hard, low power, faster and flexible readout rate) over CCDs for future X-ray missions. We utilize 47 m long X-ray beam line at Penn state University to do our experiments where we characterize the overall effective area of the instrument at 1.5 - 8 keV for both on-axis and off-axis angles.

In this presentation, we will describe the characterization test stand and methods, as well as the detailed results. We perform ray-tracing simulations to theoretically validate the results which would also be briefly discussed here. While this is simply a proof-of-concept experiment, such an instrument with significant collecting area can be explored for future rocket or CubeSat experiments.

10399-61, Session 14

Testing and modelling of the SVOM MXT narrow field lobster-eye telescope

Charlotte H. Feldman, James F. Pearson, Richard Willingale, Jonathan M. Sykes, Christopher L. Bicknell, Paul R. Houghton, Paul Drumm, Adrian Martindale, Julian P. Osborne, Paul T. O'Brien, Univ. of Leicester (United Kingdom); Ray Fairbend, Sylvain Petit, Romain Roudot, Emile Schyns, PHOTONIS France S.A.S. (France); Karine Mercier, Jean-Michel Le Duigou, Ctr. National d'Études Spatiales (France); Diego Gotz, CEA-IRFU (France)

SVOM is a French-Chinese space mission to be launched in 2021 with the goal of studying Gamma-Ray Bursts (GRBs), the most powerful stellar explosions in the Universe. The Microchannel X-ray Telescope (MXT) on-board SVOM, is an X-ray focusing telescope with a detector limited field of view of 1 degrees, working in the 0.2-10 keV energy band. The SVOM MXT is a narrow field lobster eye telescope, designed to detect and accurately locate GRBs, very soon after the initial GRB trigger. The MXT mirror comprises of an array of square pore Microchannel Plate Optics (MPOs) which are slumped to a spherical radius of 2m giving a focal length of 1m and an intrinsic field of view of 6 degrees. We present details of the baseline design and results from the on-going X-ray tests of the breadboard and STM MPOs performed at the University of Leicester (UoL) and Panter (MPE). In addition, we present details of modelling and analysis which reveals the factors that limit the angular resolution, characteristics of the point spread function (PSF) and the efficiency/collecting area of the currently available MPOs.

10399-62, Session 14

A principle for an x-ray defocusing telescope system with an angular resolution booster

Yoshitomo Maeda, Institute of Space and Astronautical Science (Japan) and The Graduate Univ. for Advanced Studies (Japan); Ryo Iizuka, Institute of Space and Astronautical Science (Japan); Takayuki Hayashi, Nagoya Univ. (Japan) and NASA Goddard Space Flight Ctr. (United States); Manabu Ishida, Institute of Space and Astronautical Science (Japan)

We present a novel concept to gives an opportunity to make a high resolution spectroscopy that is better than 0.5 arcsec of the Chandra HRMA. Since we concentrate X-rays with focusing optics, we can attain the high sensitivity such as the ASCA XRTs. Since our principle make available a small-size detector such as the X-ray CCD or the calorimeter, the telescope system gives an opportunity to make a high resolution spectroscopy with a good angular resolution and with a large effective area.

10400-1, Session 1

Science capabilities of the WFIRST coronagraph *(Invited Paper)*

Bruce A. Macintosh, Stanford Univ. (United States); Margaret Turnbull, SETI Institute (United States); N. Jeremy Kasdin, Princeton Univ. (United States); John H. Debes, Space Telescope Science Institute (United States); Tom Greene, NASA Ames Research Ctr. (United States); Nikole Lewis, Space Telescope Science Institute (United States); Mark S. Marley, NASA Ames Research Ctr. (United States); Bijan Nemati, Jet Propulsion Lab. (United States); Aki Roberge, NASA Goddard Space Flight Ctr. (United States); Tyler Robinson, Univ. of California, Santa Cruz (United States); Dmitry Savransky, Cornell Univ. (United States); Christopher C. Stark, Space Telescope Science Institute (United States)

The WFIRST mission was originally ended as a wide-field survey facility. With the change to a 2.4-m telescope, the mission is capable of carrying an effective coronagraph for exoplanet imaging. The baseline architecture allows use of a hybrid lyot or shaped pupil coronagraph, feeding a imager and integral field spectrograph. This will allow imaging and photometry of mature nearby planets and zodiacal disks in reflected light, as well as spectroscopy of the brightest targets. I will discuss the scientific motivations of the mission and show simulated science capabilities, and discuss the process towards definition of a science mission.

10400-2, Session 1

The WFIRST coronagraph instrument optical design update

Hong Tang, Richard Demers, John E. Krist, James McGuire, Mayer Rud, Feng Zhao, Jet Propulsion Lab. (United States)

The WFIRST Coronagraph Instrument will perform direct imaging of exoplanets via coronagraphy of the host star. It uses both the Hybrid Lyot and Shaped Pupil Coronagraphs to meet the mission requirements. The Phase A optical design fits within the allocated instrument enclosure and accommodates both coronagraphic techniques. It also meets the challenging wavefront error requirements. We present the optical performance includimg throughput of the imaging and IFS channels, as well as the wavefront errors at the first pupil and the imaging channel. We also present polarization effects from optical coatings and analysis of their impacts on the performance of the Hybrid Lyot coronagraph. We report the results of stray light analysis of our Occulting Mask Coronagraph testbed.

10400-4, Session 1

WFIRST coronagraph optical modeling

John E. Krist, Nikta Amiri, Gary Gutt, Luis Marchen, James McGuire, Bijan Nemati, Navtej Saini, Hong Tang, Jet Propulsion Lab. (United States)

WFIRST will include a coronagraphic instrument for high contrast imaging of extrasolar planets and circumstellar disks. It will utilize two methods, the Hybrid Lyot Coronagraph for detection in an imaging channel and the Shaped Pupil Coronagraph for characterization using an integral field spectrograph. Both have been optimized for the obscured (secondary mirror and spiders) WFIRST telescope. End-to-end numerical optical modeling incorporating wavefront sensing and control is used to determine the performance of the coronagraph with realistic errors, including pointing jitter and polarization. The coronagraphic designs are continually being optimized to improve tolerances to these errors and to improve the system throughput. We present the performance estimates of the current flight designs as predicted by modeling. We also describe the release of a new version of the PROPER optical propagation library, our primary modeling tool, which is now available for Python and Matlab in addition to IDL.

10400-5, Session 1

Wavefront control performance modeling with WFIRST shaped pupil coronagraph testbed

Hanying Zhou, Bijian Nemati, John E. Krist, Eric J. Cady, Brian D. Kern, Ilya Poberezhskiy, Jet Propulsion Lab. (United States)

NASA's WFIRST mission includes a coronagraph instrument (CGI) for direct imaging of exoplanets. To achieve and maintain high contrast for the desired science goal, CGI employs a dual wavefront sensing and control (WFSC) system: a low-order WFSC subsystem using a Zernike wavefront sensor and an electric field conjugation based high order subsystem. The system's ability to suppress star light and maintain a high contrast dark hole (<1e-8) in a simulated dynamic environment was recently demonstrated on the Occulter Mask Coronagraph (OMC) testbed at JPL. Parallel to this technology development is an effort to advance the CGI's model fidelity, as it will be crucial to inform the flight system's design, error budget, verification and validation, etc. Here we present our modeling method and some examples of predicted high-order wavefront correction performance for the shaped pupil coronagraph configuration of the OMC testbed. Significant improvement in model fidelity comes from: 1) incorporation of testbed-like operation features such as probing, deformable mirror voltage constraints, regular updates of the control model, etc., and 2) better understanding and inclusion of testbed imperfections in the model (e.g., chromatic pupil aberrations). Testbed error budget modeling and Monte Carlo modeling incorporating estimated uncertainties help to identify the most critical (or missing) testbed knowledge that impacts contrast floor and/or convergence. A better than a factor of 2 agreement between model prediction and testbed result has been consistently achieved in terms of contrast floor, chromaticity, and convergence. Testbed contrast performance enhancement from the modeling feedback further confirms the quality of model fidelity.

10400-6, Session 1

Sensitivity of WFIRST coronagraph broadband contrast performance to DM actuator errors

Erkin Sidick, Byoung-Joon Seo, Brian D. Kern, Ilya Poberezhskiy, Bijan Nemati, Jet Propulsion Lab. (United States)

The WFIRST/AFTA 2.4 m space telescope currently under study includes a stellar coronagraph for the imaging and the spectral characterization of extrasolar planets. The coronagraph employs sequential deformable mirrors to compensate for phase and amplitude errors. Using the optical model of an Occulting Mask Coronagraph (OMC) testbed at the Jet Propulsion Laboratory (JPL), we have investigated the sensitivity of a Hybrid Lyot Coronagraph (HLC) broadband contrast performance to DM actuator errors and actuator limits. Considered case include drifts in actuator heights, paired actuators, as well as the limits imposed by a neighboring-actuator rule. Actual data about the actuator drifts and the knowledge about the paired-actuators obtained in several DM characterization experiments

conducted at JPL, as well as the neighboring-actuator rule implement on the OMC testbed were used in simulations. In some cases we confirmed the theoretical predictions with the testbed measured results.

10400-7, Session 2

Sensitivity of the WFIRST coronagraph performance to key instrument parameters

Bijan Nemati, John E. Krist, Bertrand Mennesson, Jet Propulsion Lab. (United States)

Space coronagraphs offer the possibility of direct detection of light from extrasolar planets. The WFIRST space-based coronagraph, currently under development and slated for launch in the mid-2020's, will offer unprecedented starlight suppression and sensitivity, with contrast better than 1e-9 and the ability to directly detect and characterize extrasolar planets down to Jupiters and perhaps Neptunes. In addition, it will allow imaging of circumstellar disks. The main technical challenge in direct detection comes from three areas: starlight suppression, low flux detection, and speckle stabilization in the dark zone where the planet or disk light is to be detected. These three aspects in turn place requirements on key instrument parameters such as system throughput, raw contrast, detector noise, and thermal stability. The link between instrument limitations and instrument performance is captured in models, and balanced using error budgets. Instrument performance can be measured in terms of the science yield, which is itself limited by available mission time and the instrument sensitivity floor. In this paper, we present an overview of the modeling and methodology to assess the sensitivity of the coronagraph and some of the key results pertaining to the WFIRST coronagraph.

10400-8, Session 2

IMPipeline: an integrated STOP modeling pipeline for the WFIRST coronagraph

Navtej Saini, Kevin Anderson, Zensheu Chang, Gary Gutt, Bijan Nemati, Jet Propulsion Lab. (United States)

We have developed an automated software pipeline to perform Structural-Thermal-Optical Performance (STOP) analysis of the WFIRST coronagraph. The Coronagraph Instrument on the Wide Field InfraRed Survey Telescope (WFIRST) will search for exoplanets by controlling the diffraction of the host star light in order to suppress it and allow the planet light to become observable. Since the planet light is billions of times dimmer than the star light, precise control of the light is challenging and susceptible to even minute imperfections such as thermally induced deformations of the optics. The observatory STOP analysis is used to assess the impact of such perturbations. The pipeline integrates the thermal, structural, and optical analysis software to run a STOP analysis in a seamless manner, with the final output being optical wave-front errors for an input observational scenario. The pipeline is written in the Python high level language and uses the Luigi framework for dependency resolution, workload management, and visualization. The initial version uses Thermal Desktop for thermal analysis, NX NASTRAN for structural analysis, SigFit for optical surface fitting, and CODE V for optical analysis. The pipeline can be easily customized using configuration files and provides users with a web interface to monitor the submitted job. This paper will present results showing how the pipeline can be used to simulate different observational scenarios to generate optical wave-front errors. Which in turn are propagated through simulated WFIRST coronagraph optical system to generate realistic speckle patterns.

10400-9, Session 2

Current science requirements and planned implementation for the WFIRST-CGI Integral Field Spectrograph (IFS)

Avi M. Mandell, Tyler D. Groff, Qian Gong, Michael W. McElwain, Maxime J. Rizzo, Prabal Saxena, Neil T. Zimmerman, NASA Goddard Space Flight Ctr. (United States)

In this paper we describe the progress on defining the science requirements, the design implementation, and the current technology demonstration for the integral field spectrograph (IFS) camera baselined for Coronagraphic Instrument (CGI) on the NASA WFIRST flagship mission. The CGI is a technology demonstration instrument meant to demonstrate high-contrast direct imaging of exoplanets from space, with the goal of both characterizing the atmospheres of known giant exoplanets as well as discovering new planets. The WFIRST 2015 Science Definition Team (SDT) defined initial science requirements for the CGI IFS including a minimum spectral resolving power, instantaneous spectral bandwidth, and field of view, with updates by the WFIRST Science Investigation Teams (SITs) in preparation for the WFIRST Systems Requirements Review (SRR) in June 2017. In addition, GSFC was tasked with designing, integrating, and testing the Prototype Imaging Spectrograph for Coronagraphic Exoplanet Studies (PISCES) integral field spectrograph to demonstrate the technological capability to meet these science requirements. This paper will outline the current formulation and motivation for the IFS science requirements, describe how the current IFS baseline design meets these science requirements, and detail the current progress in demonstrating the required capabilities using the PISCES instrument.

10400-10, Session 2

Flight Integral Field Spectrograph (IFS) optical design for WFIRST coronagraphic exoplanet demonstration

Qian Gong, Tyler D. Groff, Avi M. Mandell, Michael W. McElwain, Maxime J. Rizzo, Prabal Saxena, NASA Goddard Space Flight Ctr. (United States)

Based on the experience from Prototype Imaging Spectrograph for Coronagraphic Exoplanet Studies (PISCES) for WFIRST, we have moved to the flight instrument design phase. The flight instrument is similar to PISCES, but there are important changes to its design as our requirements have evolved. Beginning with the science and system requirements, we discuss a number of critical trade-offs. Most significantly there are trades in the type of IFS, lenslet array shape and layout, detector sampling, and accommodating the larger Field Of View (FOV) and wider wavelength band for a potential Starshade. Finally, the traditional geometric optical design is also investigated and traded. We compare a reflective versus refractive design, and the telecentricity of the relay. The relay before the lenslet array controls the chief angle distribution on the lenslet array. Our previous paper1 has addressed how the relay design combined with lenslet array/pinhole mask can further suppress the residual star light and increase the contrast. Highlighting all of these design trades, we present the phase A IFS optical design for the WFIRST coronagraph instrument.

10400-11, Session 2

Simulating the WFIRST coronagraph Integral Field Spectrograph

Maxime J. Rizzo, Universities Space Research Association (United States) and NASA Goddard Space Flight Ctr. (United States); Ewan S. Douglas, Massachusetts Institute of Technology (United States); Timothy Brandt, Institute for Advanced Study (United States); Kerri L. Cahoy, Massachusetts Institute of Technology (United States); Qian Gong, Tyler D. Groff, NASA Goddard Space Flight Ctr. (United States); John E. Krist, Jet Propulsion Lab. (United States); Avi M. Mandell, Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States); A. J. Eldorado Riggs, Jet Propulsion Lab. (United States); Aki Roberge, Prabal Saxena, Neil T. Zimmermann, NASA Goddard Space Flight Ctr. (United States)

A primary goal of direct imaging techniques is to spectrally characterize the atmospheres of planets around other stars at extremely high contrast levels. To achieve this goal, coronagraphic instruments have favored integral field spectrographs (IFS) as the science cameras to disperse the entire search area at once and obtain spectra at each location, since the positions of planets are not known a priori. These spectrographs are useful against confusion from speckles and background objects, and can also help in the speckle subtraction and wavefront control stages of the coronagraphic observation. We present a software package to simulate the WFIRST Coronagraph Instrument (CGI), and produce an end-to-end, realistic simulation of the CGI IFS. The software takes a broadband input science cube, transforms it into IFS detector maps using a CGI Shaped Pupil Coronagraph (SPC) model, and extracts the final cube from those maps. We validate the simulator by comparing to experimental data obtained from the PISCES instrument, a prototype IFS for the CGI-IFS, at JPL's High-Contrast Imaging Testbed. Simulated IFS cubes will be used to test data extraction techniques, refine sensitivity analyses and carry out design trade studies of the flight CGI-IFS. The open-source package is written in Python and designed to being user-friendly and fast.

10400-12, Session 3

Systematic errors and defects in fabricated coronagraph masks and laboratory scale star-shade masks and their performance impact

Kunjithapatham Balasubramanian, Eric J. Cady, Richard Muller, Bijan Nemati, Ilya Poberezhskiy, A. J. Eldorado Riggs, Daniel Ryan, Victor White, Daniel Wilson, Karl Yee, Hanying Zhou, Jet Propulsion Lab. (United States)

NASA WFIRST mission has planned to include a coronagraph instrument to find and characterize exoplanets. Masks are needed to suppress the host star light to better than 10-8 level contrast over a broad bandwidth to enable the coronagraph mission objectives. Such masks for high contrast coronagraphic imaging require various fabrication technologies to meet a wide range of specifications, including precise shapes, micron scale island features, ultra-low reflectivity regions, uniformity, wave front quality, etc. We present the technologies employed at JPL to produce these pupil plane and image plane coronagraph masks, and lab-scale external occulter masks, highlighting accomplishments from the high contrast imaging testbed (HCIT) at JPL and from the high contrast imaging lab (HCIL) at Princeton University. Inherent systematic and random errors in fabrication and their impact on coronagraph performance are discussed with model predictions and measurements.

10400-13, Session 3

Testbed demonstration of low-order wavefront sensing and control for WFIRST coronagraph

Fang Shi, Xin An, Kunjithapatham Balasubramanian, Randall Bartos, Eric J. Cady, Brian D. Kern, Raymond Lam, David S. Marx, Camilo Mejia Prada, Dwight Moody, Richard Muller, Keith Patterson, Ilya Poberezhskiy, A. J. Eldorado Riggs, Daniel Ryan, Byoung-Joon Seo, Chris Shelton, Joel Shields, Erkin Sidick, Hong Tang, John Trauger, Tuan Truong, Victor White, Daniel Wilson, Hanying Zhou, Robert Zimmer, Jet Propulsion Lab. (United States)

To maintain the required performance of WFIRST Coronagraph in a realistic space environment, a Low Order Wavefront Sensing and Control (LOWFS/C) subsystem is necessary. The LOWFS/C uses a Zernike wavefront sensor (ZWFS) with the phase shifting disk combined with the stellar light rejecting occulting mask, a key concept to minimize the non-common path error. For wavefront corrections, WFIRST LOWFS/C uses a fast steering mirror (FSM) for line-of-sight correction, a focusing mirror for focus drift correction, and one of two deformable mirrors (DM) for other low order wavefront error correction. As a part of technology development and demonstration for WFIRST Coronagraph a dedicated Occulting Mask Coronagraph (OMC) testbed has been built and commissioned. With its configuration similar to the WFIRST flight coronagraph instrument the OMC testbed consists of two coronagraph modes, Shaped Pupil Coronagraph (SPC) and Hybrid Lyot Coronagraph (HLC), a Low Order Wavefront Sensor, and an Optical Telescope Assembly (OTA) Simulator which can generate the realistic LoS drift and jitter as well as low order wavefront error that would be induced by the WFIRST telescope's vibration and thermal changes. In this paper we will present the recent testbed results of LOWFS/C and dynamic coronagraph tests in which we have demonstrated that LOWFS/C is able to maintain the coronagraph contrast with the presence of WFIRST like line-of-sight and low order wavefront disturbances.

10400-14, Session 3

Shaped pupil coronagraphy for WFIRST: high-contrast broadband testbed demonstration

Eric J. Cady, Kunjithapatham Balasubramanian, Jet Propulsion Lab. (United States); Jessica Gersh-Range, N. Jeremy Kasdin, Princeton Univ. (United States); Brian D. Kern, Raymond Lam, Camilo Mejia Prada, Dwight Moody, Keith Patterson, Ilya Poberezhskiy, A. J. Eldorado Riggs, Byoung-Joon Seo, Fang Shi, Hong Tang, John Trauger, Hanying Zhou, Jet Propulsion Lab. (United States); Neil T. Zimmerman, Space Telescope Science Institute (United States)

The Shaped Pupil Coronagraph (SPC) is one of the two operating modes of the WFIRST coronagraph instrument. The SPC provides starlight suppression in a pair of wedge-shaped regions, and is well suited for spectroscopy of known exoplanets. To demonstrate this starlight suppression in the presence of expected on-orbit input wavefront disturbances, we have recently built a dynamic testbed at JPL analogous to the WFIRST flight instrument architecture, with both Hybrid Lyot Coronagraph (HLC) and SPC architectures and a Low Order Wavefront Sensing and Control (LOWFS/C) subsystem to apply, sense, and correct dynamic wavefront disturbances. We present our best up-to-date results of the static SPC mode demonstration from the testbed, along with model comparisons and SPC performance under realistic dynamical conditions. HLC results will be reported separately.

10400-15, Session 3

Hybrid Lyot coronagraph for WFIRST: high-contrast broadband testbed demonstration

Byoung-Joon Seo, Eric J. Cady, Brian Gordon, Brian D. Kern, David S. Marx, Dwight Moody, Richard Muller, Keith Patterson, Ilya Poberezhskiy, Fang Shi, Erkin Sidick, John Trauger, Daniel Wilson, Jet Propulsion Lab. (United States)

Hybrid Lyot Coronagraph (HLC) is one of the two operating modes of the WFIRST coronagraph instrument. HLC can produce starlight suppression over full 360 degrees annular region and thus is particularly suitable for discovery of unknown exoplanets. Since being selected by National Aeronautics and Space Administration (NASA) in December 2013, the coronagraph technology is being matured to Technology Readiness Level (TRL) 6 by 2017. To demonstrate starlight suppression in presence of expecting on-orbit input wavefront disturbances, we have built a

dynamic testbed in JPL in 2016. This testbed, named as Occulting Mask Coronagraph (OMC) testbed, is designed analogous to the WFIRST flight instrument architecture: It has both HLC and Shape Pupil Coronagraph (SPC) architectures, and also has the Low Order Wavefront Sensing and Control (LOWFS/C) subsystem to sense and correct the dynamic wavefront disturbances. We are not reporting the dynamic test result or the SPC mode test in this paper. We present only up-to-date progress of HLC mode demonstration from the testbed. HLC occulter masks consisting of metal and dielectric layers have been fabricated and characterized. Wavefront control using two deformable mirrors is demonstrated in a vacuum testbed with 10% broadband light centered at 550 nm. As a result, we obtain repeatable convergence below 2E-9 mean contrast in the 360 degrees dark hole with working angle between 3 ?/D and 9 ?/D. We present the key hardware and software used in the testbed, the performance results and their comparison to model expectations.

10400-16, Session 4

Two deformable mirror methods for the correction of aperture discontinuities

Johan Mazoyer, Johns Hopkins Univ. (United States); Laurent Pueyo, Space Telescope Science Institute (United States); Mamadou N'Diaye, Observatoire de la Cote d'Azur (France); Kevin Fogarty, Johns Hopkins Univ. (United States); Rémi Soummer, Space Telescope Science Institute (United States); Neil T. Zimmerman, NASA Goddard Space Flight Ctr. (United States); Colin Norman, Johns Hopkins Univ. (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States)

The increasing complexity of the aperture geometry of the future space- and ground based-telescopes will limit the performance of the next generation of coronagraphic instruments for high contrast imaging of exoplanets. We propose here a new closed-loop optimization technique to use two deformable mirrors to correct for the effects of complex apertures on coronagraph performance, alternative to the ACAD technique previously developed by our group. This technique allows the use of any coronagraphs, designed for continuous apertures, with complex, segmented, apertures, maintaining high performance in contrast and throughput.
We present a numerical study on several pupil geometries (segmented LUVOIR type aperture, WFIRST, ELTs) for which we obtained high contrast levels with several deformable mirror setups (size, number of actuators, separation between them), coronagraphs (apodized pupil lyot and vortex coronagraphs) and spectral bandwidths, which will help us present recommendations for future coronagraphic instruments.

10400-17, Session 4

Optimization of coronagraph design for segmented aperture telescopes

Jeffrey B. Jewell, Jet Propulsion Lab. (United States); Garreth Ruane, California Institute of Technology (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States); Dimitri Mawet, California Institute of Technology (United States); David Redding, Jet Propulsion Lab. (United States)

The goal of directly imaging Earth-like planets in the habitable zone of other stars has motivated the design of coronagraphs for use with large segmented aperture space telescopes. In order to achieve an optimal trade-off between planet light throughput and diffracted starlight suppression, we consider coronagraphs comprised of a stage of phase control implemented with deformable mirrors (or other optical elements), pupil plane apodization masks (gray scale or complex valued), and focal plane masks (either amplitude only or complex-valued, including phase only such as the vector vortex coronagraph). We approach the coronagraph design problem from a function space perspective - an ideal coronagraph "rotates", with a unitary linear operator, the collection of telescope on-axis modes (the star or resolved stellar disc) into the null space of a singular linear operator blocking the starlight from reaching the science focal plane. Viewed in this setting, the coronagraph design problem involves a search for the phase control and focal or pupil plane masks to best approximate the ideal unitary and singular linear operators respectively. We apply this framework to the design of pupil plane apodization masks, as well as phase only beam-shaping, enabling vortex coronagraphs to be used with segmented aperture telescopes. We also provide examples of the optimization of complex-valued focal plane masks, and end-to-end joint coronagraph optimization.

10400-18, Session 4

Apodized/shaped pupil Lyot coronagraph designs for segmented aperture space telescopes

Neil T. Zimmerman, NASA Goddard Space Flight Ctr. (United States); Mamadou N'Diaye, Observatoire de la Côte d'Azur (France); Kathryn St. Laurent, Rémi Soummer, Christopher C. Stark, Laurent Pueyo, Anand Sivaramakrishnan, Marshall D. Perrin, Space Telescope Science Institute (United States); Robert J. Vanderbei, Princeton Univ. (United States)

Advanced Lyot coronagraphs of the apodized/shaped pupil variety are a candidate technology for directly imaging habitable exoplanets with future space telescopes. Until recently, the compatibility of this design family with segmented mirror telescopes was poorly understood. In support of the NASA Exoplanet Exploration Program's Segmented Coronagraph Design & Analysis effort, we are carrying out a comprehensive investigation on the performance of apodized/shaped pupil Lyot coronagraphs (APLC) with segmented and obscured telescope apertures. We have developed a software toolkit to automate the exploration of thousands of coronagraph design parameter combinations. This has enabled us to empirically establish relationships between planet throughput and telescope aperture geometry, inner working angle, bandwidth, and contrast level. Preliminary scientific yield evaluations based on design reference mission simulations indicate the APLC is a viable tool for surveying the local exoEarth population, producing detection tallies competitive with other starlight suppression concepts.

10400-19, Session 4

Performance and sensitivity of vortex coronagraphs on segmented space telescopes

Garreth Ruane, California Institute of Technology (United States); Jeffrey B. Jewell, Jet Propulsion Lab. (United States); Dimitri Mawet, California Institute of Technology (United States) and Jet Propulsion Lab. (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States)

The detection of molecular species in the atmospheres of earth-like planets orbiting nearby stars requires an optical system that suppresses starlight and maximizes the sensitivity to the weak planet signals at small angular separations. Achieving sufficient contrast performance on a segmented aperture space telescope is particularly challenging due to unwanted diffraction within the telescope from amplitude and phase discontinuities in the pupil. Apodized vortex coronagraphs are a promising solution that theoretically meet the performance needs for high contrast imaging with future segmented space telescopes. We investigate the sensitivity of apodized vortex coronagraphs to the expected aberrations, including segment co-phasing errors in piston and tip/tilt as well as low-order aberrations on individual segments. Telescope requirements are identified for notional HabEx and LUVOIR telescope designs.

10400-20, Session 4

Phase-induced amplitude apodization complex mask coronagraphy (PIAACMC) for large segmented apertures

Olivier Guyon, The Univ. of Arizona (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States); Brian D. Kern, Jet Propulsion Lab. (United States); Alexander T. Rodack, Justin M. Knight, The Univ. of Arizona (United States); Ruslan Belikov, Dan Sirbu, Stephen T. Bryson, Christopher E. Henze, NASA Ames Research Ctr. (United States); Johanan L. Codona, The Univ. of Arizona (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States)

High contrast imaging of exoplanets around nearby stars with future large segmented apertures requires starlight suppression systems optimized for such geometries, with the ability to control diffraction created by gaps between segments.

The PIAACMC approach is well-suited for high high efficiency coronagraphic imaging of exoplanets at small angular separations, offering an inner working angle (IWA) as small as 1 lambda/D. We show that PIAACMC can be designed for segmented apertures and present a few representative designs. The design process can mitigate leaks due to stellar angular size and chromatic diffraction by segment gaps by co-optimizing a multi-zone diffractive focal plane mask and a Lyot stop. The resulting performance is ultimately limited by stellar angular size, and the IWA must be carefully traded against contrast and throughput at small angular separations.

We show that PIAACMC's small IWA enables space-based near-IR imaging and spectroscopy of exoplanets around Sun-stars, and ground-based imaging and characterization of habitable planets around nearby M-type stars. We review the current status of PIAACMC laboratory development and near-term prospects for ground-based use.

10400-21, Session 4

Incorporating deformable mirrors into shaped pupil coronagraph optimizations to increase throughput

Jessica Gersh-Range, N. Jeremy Kasdin, Princeton Univ. (United States)

Shaped pupil and shaped pupil Lyot coronagraphs use a binary pupil mask to reduce the amount of starlight entering specific regions of the image plane. The advantages of these coronagraphs are their achromaticity, relative insensitivity to low-order aberrations and jitter, and low technical risk, which makes them attractive for missions such as the Wide-Field Infrared Space Telescope. The downside is that they have lower throughput than other coronagraph types because the binary pupil mask works by blocking selected patches of starlight in order to modify the diffraction pattern. To increase the throughput, we explore offloading some of the starlight suppression effort to the pair of deformable mirrors (DMs) in the wavefront control system. We first use a linear stroke minimization algorithm to determine DM settings that generate a dark hole with a specified contrast, with the shaped pupil mask omitted but all other coronagraphic masks present in the wavefront estimation and control model. We then calculate the corresponding amplitude and phase maps in the pupil plane and incorporate these into the shaped pupil optimization. With the optimized shaped pupil mask included, we determine updated DM settings, and we iterate until the shaped pupil design converges. We discuss the throughput gains that are possible with varying amounts of the final contrast generated by the DMs. We also preliminarily discuss the potential disadvantages of this modification to a shaped pupil Lyot coronagraph, which include greater technical risk and increased chromaticity and sensitivity to aberrations.

10400-22, Session 4

Sensitivity analysis for high-contrast missions with segmented telescopes

Lucie Leboulleux, ONERA (France) and Space Telescope Science Institute (United States) and Aix Marseille Université (France); Jean-François Sauvage, Thierry Fusco, ONERA (France) and Aix Marseille Univ. (France); Rémi Soummer, Laurent Pueyo, Space Telescope Science Institute (United States)

Segmented telescopes are a possible approach to enable large-aperture space telescopes for the direct imaging and spectroscopy of habitable worlds. However, the increased complexity of their aperture geometry, due to their central obstruction, support structures and segment gaps, makes high-contrast imaging very challenging.

In this context, we present a complete and comprehensive error budget allowing to evaluate the constraints on the segments and the influence of the error terms on the final image and contrast. Indeed, the optimal contrast of 10^10 to image Earth-like planets requires drastic conditions, both in term of segment alignment and telescope stability, since space telescopes have to evolve in unfriendly environments due to the flight conditions: vibrations and resonant modes of the segments.

In this communication, we study the impact of selected error terms on the final contrast, such as local or global, low order or higher order, correlated or non-correlated aberrations, in a static or dynamic environment. These results will then be compared to a theoretical model thanks to an analytic analysis of the image formation.

10400-23, Session 5

Electric field conjugation in the presence of model uncertainty

David S. Marx, Byoung-Joon Seo, Erkin Sidick, Brian D. Kern, Bijan Nemati, Ilya Poberezhskiy, Jet Propulsion Lab. (United States)

The Wide-Field Infrared Survey Telescope (WFIRST) is a 2.4m diameter space telescope NASA program. The payload will include a coronagraph instrument (CGI). The CGI designs under development use deformable mirrors (DM) to create a point spread function (PSF) with a dark region around the obscured star object. Electric field conjugation (EFC) is an iterative nonlinear optimization procedure that uses measurements of the electric field at the image to determine the DM displacements to modify the PSF to create the region of high contrast in the image. EFC requires a numerical model of the coronagraph to calculate the Jacobian of the system, which is used, along with regularization, to solve for the DM displacements for each iteration of the nonlinear optimization. Ideally, the coronagraph is aligned and calibrated, and the calibration data are used in the numerical model for calculating the Jacobian. However, calibration and alignment measurements always contain uncertainty resulting in calibration error. Therefore, the Jacobian calculated from the numerical model is not an exact representation of the physical coronagraph, and the resulting DM solution for an EFC iteration does not have the exact impact on the electric field of the coronagraph as predicted by the EFC. The result is slow convergence, and, as will be shown, drives the use of more restrictive regularization. Using Monte Carlo trials, we investigate the effect of calibration error on EFC convergence and regulatization. Comparison to results from the High Contrast Imaging Testbed Hybrid Lyot Coronagraph are also presented.

10400-24, Session 5

Wavefront control methods for high-contrast integral field spectroscopy

Tyler D. Groff, NASA Goddard Space Flight Ctr. (United

States); Olivier Guyon, Subaru Telescope, National Astronomical Observatory of Japan (United States); Camilo Mejia Prada, Eric J. Cady, Jet Propulsion Lab. (United States); Maxime J. Rizzo, Prabal Saxena, Avi M. Mandell, Qian Gong, Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States); N. Jeremy Kasdin, Princeton Univ. (United States)

Direct imaging of exoplanets using a coronagraph has required the development of new technologies for both ground- and space-based observations. Key to the science of direct imaging is the spectroscopic capabilities of the instrument, our ability to obtain a spectrum of the exoplanet, which provides insights to the chemical composition, temperatures, atmospheric structure. Direct imaging instruments generally use an integral field spectrograph (IFS), which disperses each field point in an image plane onto the detector. The spatial and spectral content enhances detection and characterization capability, and the spectral information is critical to achieving detection limits below the speckle floor. The most mature application of these high contrast IFS techniques is at more modest contrast ratios on ground-based telescopes, achieving 5-6 orders of magnitude suppression. In space, where we are attempting to detect Earth-analogs, the contrast requirements are more severe and the IFS must be incorporated into the wavefront control loop to reach 1e-10 detection limits required for Earth-like planet detection. A new mathematical framework is presented that closes a control loop around the on the unprocessed IFS image for better computational efficiency, which considers sensitivity to the data pipeline accuracy. Experimental results and tested methodologies are presented using on-sky data from the Coronagraphic High Angular Resolution Imaging Spectrograph (CHARIS) and testbed data from the Prototype Imaging Spectrograph for Coronagraphic Exoplanet Studies (PISCES) at the JPL High Contrast Imaging Testbed. Efficient IFS wavefront control algorithms will be critical to the WFIRST IFS, which is currently in Phase A of its design.

10400-25, Session 5

Improved high-contrast wavefront controllers for exoplanet coronagraphic imaging systems

He Sun, N. Jeremy Kasdin, Princeton Univ. (United States); A. J. Eldorado Riggs, Jet Propulsion Lab. (United States); Tyler D. Groff, NASA Goddard Space Flight Ctr. (United States) and Princeton Univ. (United States); Robert J. Vanderbei, Princeton Univ. (United States)

All coronagraphs for exoplanet high-contrast imaging employ a wavefront estimation and control system to reject system aberrations and create sufficiently dark holes. Currently, two control schemes are being employed: electric field conjugation (EFC) and stoke minimization. Both of them are based on a linearized state transition model and both have achieved great success over the past decade. Mathematically, both controllers find the deformable mirror commands by balancing the final intensity in the dark holes and the mirror surface deformation in a quadratic minimization. In this paper, we introduce two new ideas to improve model-based wavefront controllers. Firstly, linear programming is applied to enable the use of inequality constraints. Then, without linearizing the system state transition model, we directly formulate the controller as a nonlinear optimization problem. Simulation and experimental results from Princeton High Contrast Imaging Lab (HCIL) are reported in this paper and the advantages and disadvantages of these new controllers are carefully investigated compared to the existing quadratic controllers. Both controllers reveal great potential for creating more uniform dark holes and increasing the correction speed.

10400-26, Session 5

Low-order wavefront sensing for coronagraphic telescopes

Hari Subedi, N. Jeremy Kasdin, Princeton Univ. (United States)

Space telescopes equipped with a coronagraph to detect and characterize exoplanets must have the ability to sense and control low-order wavefront aberrations. Most concepts for low-order wavefront sensing use the starlight rejected by the coronagraph to sense these aberrations. The sensor must be able to make precise estimates and be robust to photon and read noise. A thorough study of various differential low-order wavefront sensors (LOWFSs) would be beneficial for future space-based observatories designed for exoplanet detection and characterization. In this paper, we will expand on the comparison of different LOWFSs that use the rejected starlight from the coronagraphic focal plane to estimate these aberrations. We will also present the experimental results of the sparse aperture mask (SAM) LOWFS that we have designed at the Princeton High Contrast Imaging Lab (PHCIL). In addition, we will present simulation results of combined low-order and higher-order wavefront control loops.

10400-27, Session 5

Polynomial apodized vortex coronagraphs for obscured telescope pupils

Kevin Fogarty, Johns Hopkins Univ. (United States); Laurent Pueyo, Space Telescope Science Institute (United States); Johan Mazoyer, Johns Hopkins Univ. (United States) and Space Telescope Science Institute (United States); Mamadou N'Diaye, Lab. J.L. Lagrange (France) and Space Telescope Science Institute (United States)

Coronagraphs using vector vortex phase masks offer theoretically ideal starlight suppression when paired with telescopes with unobstructed, circular pupils, making them an attractive option for missions to directly image exoplanets. However, pupil obstructions in the form of secondary mirror central obscurations, primary mirror segmentation, and secondary mirror support struts all introduce diffraction artifacts that limit the performance offered by these instruments. We use an analytical prescription describing the propagation of starlight through a vortex coronagraph paired with a centrally obscured telescope pupil to derive polynomial pupil plane apodizations that compensate for the diffraction artifact introduced by central obscurations. The Polynomial Apodized Vortex Coronagraph (PAVC) provides theoretically ideal cancellation of on-axis starlight, with off-axis throughput that improves as the topological charge of the vortex increases. For a charge 6 vector vortex, PAVC provides 50% encircled energy throughput (nearly 70% total energy throughput) in the presence of a central obscuration that is 30% the radius of the pupil. These designs provide a large number of degrees of freedom, and we optimized these designs in combination with active methods to correct for pupil struts and segmentation. We also examine the sensitivity of PAVC designs to low order aberrations and finite stellar angular size, and discuss methods for mitigating these effects.

10400-28, Session 5

Patterned liquid-crystal optics for broadband coronagraphy and wavefront sensing

David Doelman, Frans Snik, Leiden Observatory (Netherlands); Zane Warriner, Michael Escuti, North Carolina State Univ. (United States)

The direct-write technology for liquid-crystal patterns allows for manufacturing of extreme geometric phase patterned coronagraphs that

are inherently broadband, e.g. the vector Apodizing Phase Plate (vAPP). The vAPP generates two coronagraphic PSFs with an efficiency, i.e. the amount of light in these PSFs, that depends on the retardance offset to half-wave. Three operational vAPPs have been installed with more than 96% efficiency from 2-5 micron on MagAO and LMIRCAM on LBT. We report a new liquid-crystal design for a broadband vAPP coronagraph with 10-5 raw contrast and more than 98% efficiency for a wavelength range of 1-2.5 micron. To decrease the leakage terms and increase efficiency for vAPPs with 360-deg dark holes, we introduce the double-grating vAPP, which consists of a standard "grating-vAPP", followed by another polarization grating. This combination has been tested on-sky with the LBT and decreases the relative leakage term of the vAPP to 10-4 and folds the two PFSs back on top of each other. Furthermore, we show new liquid-crystal designs for wavelength-selective devices that change between high coronagraphic efficiency and low efficiency for different wavelength ranges. The vAPP works as a coronagraph for selected wavelengths and transmits light unapodized for others. Therefore, a wavelength-selective vAPP can be used in a pupil plane before a WFS or used to feed multiple instrument arms. Any coronagraphic leakage can be used for focal plane wavefront sensing. Lastly, we present geometric phase patterns for advanced implementations of WFS (e.g. Zernike-type) that are enabled only by this liquid-crystal technology.

10400-29, Session 6

Optimal design of apodizing phase plate coronagraphs

Emiel Por, Leiden Observatory (Netherlands)

Direct observations of exoplanets require a stellar coronagraph to suppress the diffracted starlight. An Apodizing Phase Plate (APP) coronagraph consists of a carefully designed phase-only mask in the pupil plane of the telescope. This mask alters the point spread function in such a way that it contains a dark zone at some off-axis region of interest, while still retaining a high Strehl ratio (and therefore high planet throughput).

Although many methods for designing such a phase mask exist, none of them provide a guarantee of global optimality. Here we present a method based on generalization of the phase-only mask to a complex amplitude mask. Maximizing the Strehl ratio while simultaneously constraining the stellar intensity in the dark zone turns out to be a quadratically constrained linear algorithm, for which a global optimum can be found using large-scale numerical optimizers. This generalized problem yields phase-only solutions. These solutions are therefore also solutions of the original problem.

Using this optimizer we perform parameter studies on the inner and outer working angle, the contrast and the size of the secondary obscuration of the telescope aperture for both one-sided and annular dark zones. We reach Strehl ratios of >65% for a 10^{-5} contrast from 1.8 to 10 $lambda/D$ with a one-sided dark zone for a VLT-like secondary obscuration. This study provides guidelines for designing APPs for more realistic apertures.

10400-30, Session 6

High-contrast imaging in multi-star systems: progress in technology development and lab results

Ruslan Belikov, Eugene A. Pluzhnik, Eduardo A. Bendek, Dan Sirbu, NASA Ames Research Ctr. (United States)

We present the continued progress and laboratory results advancing the technology readiness of Multi-Star Wavefront Control (MSWC), a method to directly image planets and disks in multi-star systems such as Alpha Centauri. This method works with almost any coronagraph (or external occulter with a DM) and requires little or no change to existing and mature hardware. In particular, it works with single-star coronagraphs and does not require the off-axis star(s) to be coronagraphically suppressed. Because of the ubiquity of multistar systems, this method potentially multiplies the science yield of many missions and concepts such as WFIRST, Exo-C/S, HabEx, LUVOIR, and potentially enables the detection of Earth-like planets (if they exist) around our nearest neighbor star, Alpha Centauri, with a small and low-cost space telescope such as ACESat.

Our lab demonstrations were conducted at the Ames Coronagraph Experiment (ACE) laboratory and show both the feasibility as well as the trade-offs involved in using MSWC. We used a 32x32 Boston Micromachines deformable mirror both with and without a (PIAA) coronagraph, in monochromatic as well as broadband light. We show several tests corresponding to real targets and missions, including Alpha Centauri with ACESat and WFIRST, and others spanning a range of stellar separations, magnitude differences, and mission concepts. In addition, we demonstrate MSWC in Super-Nyquist mode, where the distance between the desired dark zone and the off-axis star is larger than the conventional (sub-Nyquist) control range of the DM.

10400-31, Session 6

High-contrast spectroscopy testbed for segmented telescopes (HCST)

Dimitri Mawet, Jason Fucik, California Institute of Technology (United States); James K. Wallace, Jet Propulsion Lab. (United States); Jacques-Robert Delorme, Nikita S. Klimovich, Garreth Ruane, California Institute of Technology (United States); Wenhao J. Xuan, Pomona College (United States); Daniel Echeverri, Princeton Univ. (United States); Reed Riddle, Richard G. Dekany, California Institute of Technology (United States); Michael Randolph, California Polytechnic State Univ., San Luis Obispo (United States); Gautam Vasisht, Bertrand Mennesson, Élodie Choquet, Jet Propulsion Lab. (United States); Ji Wang, California Institute of Technology (United States)

The High Contrast Spectroscopy Testbed for Segmented Telescopes (HCST) at Caltech is aimed at filling gaps in technology for future exoplanet imagers and providing the US community with an academic facility to test high contrast components and techniques for future segmented ground-based telescope (TMT, E-ELT) and space-based telescopes (LUVOIR, HDST, HabEx).

The HCST is capable of simulating any segmented telescope geometry up to 1000 segments and time-varying external wavefront disturbances. It also contains a wavefront corrector module based on two deformable mirrors and a Zernike wavefront sensor followed by a classical 3-plane single-stage coronagraph (entrance apodizer, focal-plane mask, Lyot stop), and a science instrument.

The back-end instrument will consist of an imaging detector and a high-resolution spectrograph, which is a unique feature of the HCST. The spectrograph instrument will utilize spectral information in exoplanet detection as a way to improve contrast down to the photon-noise limit as well as measure the chromaticity of new optimized coronagraph and wavefront control concepts, and test the overall scientific functions of high-resolution spectrographs on future segmented telescopes.

10400-32, Session 6

Utilizing active single-mode fiber injection for speckle nulling in exoplanet characterization

Nikita S. Klimovich, Dimitri Mawet, Garreth Ruane, Wenhao J. Xuan, Daniel Echeverri, Michael Randolph, Jason Fucik, Ji Wang, Richard G. Dekany, Jacques-Robert Delorme, California Institute of Technology (United States); James K. Wallace, Gautam Vasisht, Bertrand Mennesson, Élodie Choquet, Eugene Serabyn, Jet Propulsion Lab. (United States)

High dispersion coronagraphy is on the critical path to the full characterization of Earth-like exoplanet atmospheres, but such

measurements are still limited by the raw contrast between the remaining star speckle field and exoplanet. Using an adaptive optics system, the wave front of the starlight can be modified to create destructive interference at the planet location, further reducing the background from the star. We have demonstrated a new concept for speckle nulling via injecting the directly-imaged planet light into a single-mode fiber, linking a high-contrast adaptively-corrected coronagraph to a high-resolution spectrograph (diffraction-limited or not). The restrictions on the E-field that will couple into the single-mode fiber give the adaptive optics system additional degrees of freedom to suppress the speckle noise on top of destructive interference. Using this technique, we are able to show a significant improvement in starlight suppression at a given location.

10400-33, Session 6

Simulating instruments using the high-dispersion coronagraphy technique

Ji Wang, Dimitri Mawet, Garreth Ruane, Bjorn Benneke, California Institute of Technology (United States); Renyu Hu, Jet Propulsion Lab. (United States)

Direct imaging of exoplanets presents a formidable technical challenge owing to the small angular separation and high contrast between exoplanets and their host stars. High Dispersion Coronagraphy (HDC) is a pathway to achieve unprecedented sensitivity to Earth-like planets in the habitable zone. Here, we present a framework to simulate HDC observations and the corresponding data analyses. The goal of these simulations is to perform a detailed analysis of the trade-off between raw star light suppression and spectral resolution for various instrument configurations, target types, and science cases. We predict the performance of an HDC instrument at Keck observatory for characterizing two known, directly imaged planets (HR 8799 e and 51 Eri b) and investigate the potential for using HDC for new planet discoveries and molecular species detection in near infrared bands, in- cluding J, H, KS and L?. We also simulate HDC observations of an Earth-like planet using next-generation ground-based (TMT) and spaced-base telescopes (HabEx and LUVOIR). Potential targets for ground-based extremely large telescopes (ELTs) include Proxima Centauri b and habitable terrestrial planets around M dwarfs whereas space missions will target habitable planets orbiting solar-type stars. We conclude that ground-based ELTs are more suitable for HDC observations of an Earth-like planet than future space-based missions owing to the considerable difference in collecting area. For ground-based telescopes, HDC observations can detect an Earth-like planet in the habitable zone around an M dwarf star at 10?4 starlight suppression level. Compared to the 10?7 planet/star contrast, HDC relaxes the starlight suppression requirement by a factor of 103. For space-based telescopes, detector noise will be a major limitation at spec- tral resolutions higher than 104. Considering detector noise and speckle chromatic noise, R=400 and R=1600 are the optimal spectral resolutions for HabEx and LUVOIR. The corresponding starlight suppression requirement to detect a planet with planet/star contrast of 6.1 ? 10?11 is relaxed by a factor of 10 and 100 for HabEx and LUVOIR, respectively.

10400-34, Session 6

Optical tolerances for the PICTURE-C mission: Error budget for electric field conjugation, beam walk, surface scatter, and polarization aberration

Christopher B. Mendillo, Glenn A. Howe, Kuravi Hewawasam, Jason Martel, Susanna C. Finn, Timothy A. Cook, Supriya Chakrabarti, Univ. of Massachusetts Lowell (United States)

The Planetary Imaging Concept Testbed Using a Recoverable Experiment - Coronagraph (PICTURE-C) mission will directly image debris disks and exozodiacal dust around nearby stars from a high-altitude balloon using a vector vortex coronagraph. The mission contrast requirement is 10^-7 averaged over the inner 1.7-2.7 ?/D and covering a 20% bandpass centered at 600 nm. A comprehensive error budget has been developed to account for and set requirements on all sources of coronagraph leakage. Four leakage sources owing to the optical fabrication tolerances and metallic coatings are: electric field conjugation (EFC) residuals, beam walk on the secondary and tertiary mirrors, optical surface scattering, and polarization aberration. Simulations and analysis of these four leakage sources for the PICTURE-C optical design are presented here. These simulations utilize the PROPER optical propagation library for IDL, a dynamics simulation of the WASP balloon pointing system, an efficient surface scattering code, and a polarization raytrace of the complete optical system.

10400-35, Session 7

Characterization of low-mass deformable mirrors and ASIC drivers for high-contrast imaging

Camilo Mejia Prada, Jet Propulsion Lab. (United States); Li Yao, Yuqian Wu, Microscale, Inc. (United States); Lewis C. Roberts Jr., Chris Shelton, Jet Propulsion Lab. (United States)

The development of compact, high performance Deformable Mirrors (DMs) is one of the most important technological challenge for high-contrast imaging on space missions. With this technological need in mind, Microscale Inc. has fabricated and characterized piezoelectric stack actuator deformable mirrors (PZT-DM) and Application Specific Integrated Circuit (ASIC) drivers for direct integration. The DM-ASIC system is designed to eliminate almost all cables, enabling a very compact optical system with low mass and low power consumption. We report on the optical and electrical tests used to evaluate the performance of the DM and ASIC units. We also compare the results to the requirements for space-based high-contrast imaging of exoplanets.

10400-36, Session 7

Ferrofluid deformable mirror for high-contrast imaging: performance evaluation and design improvements

Aaron J. Lemmer, Princeton Univ. (United States); Tyler D. Groff, NASA Goddard Space Flight Ctr. (United States) and Princeton Univ. (United States); N. Jeremy Kasdin, Princeton Univ. (United States)

We report the current developmental status of a ferrofluid deformable mirror (DM) tailored for high-contrast imaging applications which demand high nominal optical surface quality, extreme-precision actuation at low strokes, and excellent low-spatial-frequency performance. Its optical surface is a flexible solid facesheet which is fixed along the perimeter and continuously supported across the aperture by a ferrofluid medium. There are two actuation modes for controlling the facesheet deflection. The nominal surface curvature may be tuned with hydraulic adjustments of the hydrostatic ferrofluid pressure. An array of current-controlled electromagnets beneath the ferrofluid reservoir create magnetic field gradients within the fluid medium which, in turn, determine the stress distribution on the facesheet and permit localized actuation. In this article we describe our experimental metrology method and present the performance of our 7-actuator ferrofluid DM prototype. The tunable focus capability is measured and compared with theoretical measurements, and the stroke precision for both the hydraulic and magnetic actuation modes are evaluated. Creating facesheet deflections with a useful degree of localization is a significant engingeering challenge for this DM concept. We outline our efforts, supported by theoretical predictions and computational multiphysics simulations, to modify the facesheet design and the magnetic actuation scheme to improve this aspect of the mirror's performance.

10400-37, Session 7

Design of the deformable mirror demonstration CubeSat (DeMi)

Ewan S. Douglas, Gregory Allan, Derek Barnes, Massachusetts Institute of Technology (United States); Ruslan Belikov, Eduardo A. Bendek, NASA Ames Research Ctr. (United States); Anne Marinan, Jet Propulsion Lab. (United States); John Merck, Aurora Flight Sciences Corp. (United States); Tenzin Ukyab, Kerri L. Cahoy, Massachusetts Institute of Technology (United States)

The Deformable Mirror Demonstration Mission (DeMi) was recently selected by DARPA to fly a 6U CubeSat with a wavefront sensor and Microelectromechanical system (MEMS) deformable mirror (DM) payload.

Space telescopes designed to make high-contrast observations using internal coronagraphs for direct characterization of exoplanets require the use of high-actuator density deformable mirrors. These DMs can correct image plane aberrations and speckles caused by imperfections, thermal distortions, and diffraction in the telescope and optics that would otherwise corrupt the wavefront and leaking allow starlight to contaminate coronagraphic images. There has not yet been long-term on-orbit performance qualification of MEMS deformable mirrors or closed loop wavefront sensing.

The DeMi mission has two operational modes, one mode that images an internal light source and another mode that uses external aperture that images stars to achieve its initial objectives, which are still being refined as the design matures. The objective of the internal source is measurement of the 140-actuator MEMS DM actuator displacement and to demonstrate close-loop correction of aberrations in the optical path. Using the external aperture to observe stars of magnitude 2 or brighter, and assuming 3-axis stability with > 0.1 degree of attitude knowledge and jitter < 10 arcsec DeMi will also demonstrate closed loop wavefront control on an astrophysical target. We will present an new payload design, and results from simulations and laboratory optical prototyping, as well as findings on accommodating high-voltage multichannel drive electronics for the DM on a CubeSat.

10400-38, Session 8

Combining angular differential imaging and accurate polarimetry with SPHERE/IRDIS to characterize young giant exoplanets

Rob van Holstein, Frans Snik, Leiden Observatory (Netherlands); Julien Girard, European Southern Observatory (Chile); Jozua de Boer, Christoph Keller, Leiden Observatory (Netherlands); Daphne Stam, Technische Univ. Delft (Netherlands); Jean-Luc Beuzit, David Mouillet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Markus Kasper, European Southern Observatory (Germany); Maud Langlois, Ctr. de Recherche Astronomique de Lyon (France); Arthur Vigan, Lab. d'Astrophysique de Marseille (France); Alice Zurlo, Univ. Diego Portales (Chile) and Univ. de Chile (Chile); Remco de Kok, Leiden Observatory (Netherlands)

Young gas giants emit infrared radiation that can be linearly polarized up to several percent. This linear polarization reveals: 1) the presence of haze layers, 2) spatial structure, e.g. rotational flattening and bands, 3) the spin axis orientation and 4) the particle size and cloud top pressure. We introduce a novel high-contrast imaging scheme that combines angular differential imaging (ADI) and accurate near-infrared polarimetry to characterize self-luminous giant exoplanets. We implemented this technique at VLT/SPHERE-IRDIS and developed the corresponding observing strategies, the polarization calibration and the data-reduction approaches.

By combining ADI and polarimetry we can characterize planets that have already been directly imaged in intensity with high signal-to-noise ratio. We use the IRDIS pupil-tracking mode and apply Principal Component Analysis to reduce speckle noise. We take advantage of IRDIS' dual-beam polarimetric mode to eliminate differential effects that severely limit the polarimetric sensitivity (flat-fielding errors, differential aberrations and seeing), and thus further suppress speckle noise. We developed a detailed Mueller matrix model that describes the telescope and instrument and applied this model to correct for instrumental polarization effects. Our model has been validated with measurements using the internal source and observations of unpolarized standard stars, thereby reaching an absolute polarimetric accuracy ≤0.1%. The modular data-reduction software integrates ADI and polarimetry and incorporates the optimal order of data-reduction steps. We present first results of applying our methods to observations of the planets around HR 8799.

10400-39, Session 8

First light of the CHARIS high-contrast integral-field spectrograph

Tyler D. Groff, NASA Goddard Space Flight Ctr. (United States); Jeffrey K. Chilcote, Univ. of Toronto (Canada); Timothy Brandt, Institute for Advanced Study (United States); N. Jeremy Kasdin, Michael B. Galvin, Craig Loomis, Gillian Knapp, Princeton Univ. (United States); Olivier Guyon, Nemanja Jovanovic, Julien Lozi, Naruhisa Takato, Subaru Telescope, National Astronomical Observatory of Japan (United States); Masahiko Hayashi, Subaru Telescope, National Astronomical Observatory of Japan (Japan)

One of the leading direct Imaging techniques, particularly in ground-based imaging, uses a coronagraphic system and integral field spectrograph (IFS). The Coronagraphic High Angular Resolution Imaging Spectrograph (CHARIS) is an IFS that has been built for the Subaru telescope. CHARIS has been delivered to the observatory and now sits behind the Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) system. CHARIS has 'high' and 'low' resolution operating modes. The 'high-resolution' mode is used to characterize targets in J, H, and K bands at ~R70. The 'low-resolution' prism is meant for discovery and spans J+H+K bands (1.15-2.37 microns) with a spectral resolution of ~R18. This discovery mode has already proven better than 15-sigma detections of HR8799c,d,e when combining ADI+SDI. Using SDI alone, planets c and d have been detected in a single 24 second image. The CHARIS team is optimizing instrument performance and refining ADI+SDI recombination to maximize our contrast detection limit. In addition to the new observing modes, CHARIS has demonstrated a design with high robustness to spectral crosstalk. CHARIS is in the final stages of commissioning, with the instrument open for science observations beginning February 2017. Here we review the science case, design, on-sky performance, engineering observations of exoplanet and disk targets, and specific lessons learned for extremely high contrast imagers. Key design aspects that will be demonstrated are crosstalk optimization, wavefront correction using the IFS image, lenslet tolerancing, the required spectral resolution to fit exoplanet atmospheres, and the utility of the spectrum in achieving higher contrast detection limits.

10400-40, Session 8

Subaru coronagraphic extreme adaptive optics (SCExAO): wavefront control optimized for high-contrast imaging

Olivier Guyon, The Univ. of Arizona (United States) and Subaru Telescope, National Astronomical Observatory of Japan (United States); Nemanja Jovanovic, Julien Lozi, Subaru Telescope, National Astronomical Observatory of Japan (United States); Jared Males, The Univ. of Arizona

(United States); Frantz Martinache, Observatoire de la Côte d'Azur (France); Ben Mazin, Univ. of California, Santa Barbara (United States); Barnaby Norris, The Univ. of Sydney (Australia); Prashant Pathak, Subaru Telescope, National Astronomical Observatory of Japan (United States)

The SCExAO system is a flexible high contrast imaging platform for exoplanet imaging on the 8-m Subaru Telescope. SCExAO's wavefront control architecture relies on both visible and infrared wavefront sensors to measure, correct and calibrate wavefront errors. The wavefront control loop, optimized for high contrast imaging, includes predictive control, sensor fusion and focal plane speckle control to address the performance limits of current extreme-AO systems: non-common path errors, time-lag and chromaticity. The control software is also designed to enable rapid prototyping of new wavefront algorithm, as one goal of the SCExAO project is to explore and validate new high contrast imaging approaches to guide the design of future ELT high contrast imaging systems.

We describe the SCExAO wavefront control architecture and its software implementation. Recent on-sky results are presented, and future steps are describbted. Current and future high contrast imaging performance are provided. We discuss findings (lessons learned) in the context of future exoplanet imaging instrument developments.

10400-41, Session 8

NIRPS: an adaptive-optics assisted radial velocity spectrograph to chase exoplanets around M-stars

François Wildi, Observatoire de Genève (Switzerland); François Bouchy, Lab. d'Astrophysique de Marseille (Switzerland); Rene Doyon, Étienne Artigau, Univ. de Montréal (Canada); Nicolas Blind, Observatoire de Genève (Switzerland); Vladimir Reshetov, NRC - Herzberg Astronomy & Astrophysics (Canada); Olivier Hernandez, Univ. de Montréal (Canada)

Since 1st light in 2002, HARPS has been setting the standard in the exo-planet detection by radial velocity measurements. Based on this experience, our consortium is developing is an high accuracy near-infrared radial velocity (RV) spectrograph covering YJH bands to detect and characterize low-mass planets in the habitable zone of M dwarfs. It will allow precise RV measurements at the 1?m/s level.

It will open up the path to look for habitable planets around M- type stars by following up the candidates found by the upcoming space missions TESS, CHEOPS and later PLATO.

NIRPS and HARPS, working simultaneously on the ESO 3.6m are bound to become a single powerful high?resolution, high?fidelity spectrograph covering from 0.4 to 1.8 micron,. NIRPS will complement HARPS in validating earth-like planets found around G and K-type stars whose signal is at the same order of magnitude than the stellar noise.

Because at equal resolving power the overall dimensions of a spectrograph vary linearly with the input beam etendue, spectrograph designed for seeing-limited observations are large and expensive. NIRPS will use a high order adaptive optics system to couple the starlight into a fiber corresponding to 0.4" on the sky as efficiently or better than HARPS or ESPRESSO couple the light 0.9" fiber.

This allows the spectrograph to be very compact, more thermally stable and less costly. Using a custom tan(?)=4 dispersion grating in combination with a start-of-the-art Hawaii4RG detector makes NIRPS very efficient with complete coverage of the YJH bands at 110'000 resolution.

NIRPS works in a regime that is in-between the usual multi-mode (MM) where 1000's of modes propagates in the fiber and the single mode well suited for perfect optical systems. This regime called few-modes regime is prone to modal noise- A significant R&D effort is made to characterize and circumvent the modal noise seen in the spectrum.

This paper will be the first presentation of NIRPS to the exo-planet instrumentation community.

10400-58, Session PWed

Commissioning and performance results of the PISCES instrument

Prabal Saxena, Maxime J. Rizzo, NASA Goddard Space Flight Ctr. (United States); Camilo Mejia Prada, Jet Propulsion Lab. (United States); Jorge D. Llop Sayson, California Institute of Technology (United States); Qian Gong, NASA Goddard Space Flight Ctr. (United States); Eric J. Cady, Jet Propulsion Lab. (United States); Avi M. Mandell, Tyler D. Groff, Michael W. McElwain, NASA Goddard Space Flight Ctr. (United States)

The Prototype Imaging Spectrograph for Coronagraphic Exoplanet Studies (PISCES) is a high contrast integral field spectrograph designed to demonstrate readiness of high contrast integral field spectroscopy for the WFIRST coronagraph instrument (CGI). PISCES was designed and built in the Goddard Integral Field Spectroscopy Laboratory as a prototype instrument for the WFIRST CGI and was integrated with a High Contrast Imaging Testbed at the Jet Propulsion Laboratory. We present results demonstrating the ability of PISCES to carry out flight-like data reduction and analysis that has enabled spectral retrieval at high contrast. Calibration and testing datasets were taken and analyzed using a modified version of the Gemini Planet Imager data reduction pipeline. The pipeline was used to generate IFS datacubes where wavefront control has been set to deconstructively interfere speckles in the image plane, producing a high contrast scene. Comparison with an imaging camera reveals change in contrast induced by non-common path optics in PISCES. Preliminary results using conventional wavefront control algorithms with the imaging camera have produced dark hole contrasts of ~1e-8 and indicate contrast achieved by PISCES is similar to that seen in the imaging camera (differing by ~3e-9). In the future, we will incorporate PISCES measurements into an automated wavefront control algorithm and demonstrate improvements in the achievable contrast in preparation for WFIRST flight IFS design. In spring of 2017, PISCES will be integrated with the Occulting Mask Coronagraph (OMC) testbed, enabling a dynamic stellar input to assess end to end high contrast wavefront control with representative pointing jitter.

10400-60, Session PWed

Development status and performance of the evanescent wave coronagraph testbed

Mary Angelie M. Alagao, Christophe Buisset, National Astronomical Research Institute of Thailand (Thailand); Yves Rabbia, Observatoire de la Côte d'Azur (France); Thierry Lépine, Lab. Hubert Curien (France); Saran Poshyachinda, Boonrucksar Soonthornthum, National Astronomical Research Institute of Thailand (Thailand)

The Evanescent Wave Coronagraph (EvWaCo) is a new specific kind of "Band-limited coronagraph" which mask involves the tunneling effect to separate the star and the planet beams thus producing the coronagraphic effect. The first advantage is that this mask adapts itself to wavelength due to the evanescent wave properties thus yielding a potential achromatization of the star extinction. The second advantage is that the star light can be collected for astrometry and/or wavefront analysis.

NARIT has developed a specific optical setup operating over the spectral band [800 nm, 1?m] to demonstrate high-level contrasts and inner working angles in line with the exoplanet direct detection requirements. Our aims are: to test and characterize EvWaCo performance in diffraction-limited regime, to install a simulator of turbulence and an adaptive optics setup to simulate on-ground observations and to define the best scheme for the wavefront correction. The preliminary results obtained in diffraction-limited regime demonstrated contrasts equal to few 10^-6 at a distance comprised between 10 and 20 ?/D from the PSF center with an unpolarized source emitting at ?≈880 nm with a relative spectral bandwidth ??/?≈6%.

In this paper, we first describe the setup and we present the results of the performance characterization that comprises: stability of the setup, variation of the contrast with the wavelength and with the polarization. Then, we describe the end-to-end numerical model of EvWaCo, we confront the experimental and the simulation results to identify the origin of the performance limitation. Finally, we discuss the future improvements to optimize the performance.

10400-61, Session PWed

Further exoplanet suppression using microlens/pinole mask for Luvoir coronagraph

Qian Gong, Lee Feinberg, Michael W. McElwain, Neil T. Zimmerman, Tyler D. Groff, Avi M. Mandell, Matthew R. Bolcar, Brian A. Hicks, NASA Goddard Space Flight Ctr. (United States); Rémi Soummer, Laurent Pueyo, Space Telescope Science Institute (United States)

Direct detection of habitable Earth-like exoplanets is a challenging problem that requires several components that exceed the current technical capabilities. Several approaches to starlight suppression are being developed and demonstrated in the laboratory, including external occulters, a shaped pupil coronagraph, hybrid-Lyot coronagraph, apodized pupil Lyot coronagraph, vector vortex coronagraph, phase induced amplitude apodization coronagraph, and the visible nulling coronagraph. We present an innovative method of starlight suppression using a microlens and pinhole mask, which can be incorporated as part of the integral field spectrograph to further suppress residual starlight by an additional 2-4 orders of magnitude. Most high contrast imaging architectures uses an integral field spectrograph (IFS) after the external or internal coronagraph to characterize the exoplanet atmosphere, with the ultimate goal of determining whether an exoplanet is inhabited. The microlens array is traditionally used in the focal plane input to the spectrometer. With a non-telecentric reimaging system onto the lenslet array, this optic can be used to introduce spatial diversity between the on-axis star and the off-axis planet. In this proceeding, we present an optimization of the design based on the desired starlight suppression and use this design do simulate a hybrid coronagraph and IFS that could be used as a future space instrument on the LUVOIR mission concept. The IFS is designed to be compatible with STScI's APLC design (Zimmerman, et al., 2016), creating an additional 2 – 4 orders of magnitude starlight suppression. This additional suppression can be used to offset existing technological challenges such as fabrication, assembly, alignment, and pointing stability. This method does add any additional complexity to the coronagraph itself and is compatible with all coronagraph suppression architectures proposed to date.

10400-62, Session PWed

Detection and characterization of exoplanets and disks in starshade mission

Mengya Hu, Anthony D. Harness, N. Jeremy Kasdin, Robert J. Vanderbei, Princeton Univ. (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States)

Direct imaging using a starshade is a powerful technique for exoplanet detection and characterization. While much work has been performed on the mechanical and optical designs of starshade, little attention has been paid to date on post-processing methods. In this paper we report on our recent efforts to develop a model of Starshade imaging considering the effects of various defects on the starshade and the dynamics of the system/telescope system. We adapt the image processing methods such as Locally Optimized Combination of Images (LOCI), KLIP, and inversion methods in a Bayesian framework and report on our preliminary results.

10400-63, Session PWed

Shape accuracy requirements on starshades for large and small apertures

Stuart B. Shaklan, Luis Marchen, Eric J. Cady, Jet Propulsion Lab. (United States)

Starshades can be designed to work with large and small telescopes alike. With smaller telescopes, the targets tend to be brighter and closer to the Solar System, and their putative planetary systems span angles that require starshades with radii of 10-30 m at distances of 10s of Mm. With larger apertures, the light-collecting power enables studies of more numerous, fainter systems, requiring larger, more distant starshades with radii >50 m at distances of 100s of Mm. Characterization using infrared wavelengths requires ever larger starshade radius, as does increasing the instantaneous bandwidth both on the blue and red ends of the bandpass. A mitigating approach is to observe planets between the petals. We compare the starshade shape requirements, including petal shape, petal positioning, and other key terms, for a range of starshade and telescope sizes, bandwidths, and working angles.

10400-64, Session PWed

Design, fabrication, and testing of stellar coronagraphs for exoplanet imaging

Justin M. Knight, John Brewer, Ryan Hamilton, Karen Ward, Thomas D. Milster, The Univ. of Arizona (United States); Olivier Guyon, The Univ. of Arizona (United States) and Subaru Telescope, National Astronomical Observatory of Japan (Japan)

Complex-mask coronagraphs destructively interfere unwanted starlight with itself to achieve the required contrast for direct imaging of exoplanets. This is accomplished using a device called a focal plane mask (FPM). A FPM can be a simple occulter mask, or it can be a multi-featured device designed to phase-shift starlight in a specific manner to have a desired interference effect in the science plane. Creating these masks requires nanofabrication techniques, yet many such methods remain largely unexplored in this context. In this paper we explore several nanofabrication methods for creating FPMs designed for Phase Induced Amplitude Apodization Complex-Mask Coronagraphs (PIAACMC). Previous FPM manufacturing efforts in the context of PIAACMC have concentrated on manufacturability of the devices as well as assessing broadband wavelength operation. Moreover, current fabrication efforts are concentrated on assessing achievable contrast given a single approach. We present FPMs fabricated from the lithographic and etching processes such as e-beam lithography, deep reactive ion etching, and focused ion beam etching using a Silicon substrate. The characteristic size of the mask features is five microns with depths ranging over a micron. The masks are characterized for manufacturing quality using equipment such as an optical interferometer and a scanning electron microscope. Ideal coronagraph performance is compared to experimental performance using the devices in the lab and with a PIAACMC coronagraph at SCExAO. Recommendations for improving the design and fabrication of these FPMs is outlined and discussed along with future experiments and potential applications.

A coronagraph focal plane mask (FPM) for exoplanet imaging typically requires a multi-featured device designed to phase-shift starlight in a specific manner to generate destructive interference in the science plane. We explore several nanofabrication methods for creating FPMs designed for Phase Induced Amplitude Apodization Complex-Mask Coronagraphs. We present PIAACMC FPMs fabricated from several lithographic and etching processes using Silicon. The characteristic size of the mask features is five microns with depths ranging over a micron. Ideal coronagraph performance is compared to simulated performance with the measured FPM errors as well as experiments using the devices in the lab.

10400-65, Session PWed

Starshade orbital maneuver study for WFIRST

Gabriel Soto, Dmitry Savransky, Christian Delacroix, Daniel Garrett, Amlan Sinha, Cornell Univ. (United States)

The Wide Field Infrared Survey Telescope (WFIRST) mission, scheduled for launch in the mid-2020s will perform exoplanet science via both a microlensing survey and direct imaging. An internal coronagraph is planned to perform starlight suppression for exoplanet imaging, but an external starshade could be used to achieve the required high contrasts with potentially higher throughput. This approach would require a separately-launched occulter spacecraft to be positioned at exact distances from the telescope along the line of sight to a target star system. We present a detailed study to quantify the ?v requirements and feasibility of deploying this additional spacecraft as a means of exoplanet imaging. The primary focus of this study is the fuel use of the occulter while repositioning between targets. Based on its designed IWA, the occulter is given an offset distance from the nominal WFIRST halo orbit. Target star systems and look vectors are generated using Exoplanet Open-Source Imaging Simulator (EXOSIMS); a boundary value problem is then solved between successive targets. On average, 50 observations are achievable with randomly selected targets with a 20-day transfer time. Minimizing ?v allows for more than 300 observations while exceeding the 6-year lifetime of the WFIRST mission; minimizing transfer time allows for 240 observations in a 1 year span while exceeding the expected fuel capacity of the occulter spacecraft. A comprehensive cost function conciliates these two constraints given two target stars from a target list. A method for determining the next best target given is also proposed.

Line profile analysis of the laser frequency comb in FOCES

Liang Wang, Hanna Kellermann, Max-Planck-Institut für extraterrestrische Physik (Germany); Anna Brucalassi, European Southern Observatory (Germany); Frank U. Grupp, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany); Ralf Bender, Univ.-Sternwarte München (Germany) and Max-Planck-Institut für extraterrestrische Physik (Germany)

The broad-band, optical laser frequency comb covers a wavelength range of 510 nm to 700 nm, spanning 30 dispersion echelle orders in the 2k x 2k CCD. Each comb mode is narrow compared to the pixel size. Therefore, the line shape represents the local instrumental profile (or line spread function). We isolate each comb line, and use Gaussian function plus a constant background to fit the profile. The full width at half maximums (FWHMs) of the Gaussian functions are ~2.2 pixels at the center of echelle orders, and show a steep increase towards one side of the CCD. Moreover, the residuals of Gaussian fittings shows a consistent pattern after normalizing by the amplitudes in their intensities and sigma in x direction. And their shapes slowly vary along the dispersion direction. Such deviations from the Gaussian profiles are reconstructed and all of the astro-comb lines are re-modelled with Gaussian functions plus the interpolation of these empirical shapes. The same model is also used to derive the radial velocities from a series of the overlapped spectra of the Sun and astro-comb. In the latter case, a high signal-to-noise ratio (S/N) template is obtained by stacking a series of solar spectra after removing the relative velocity drifts. This technique is of particular interest to the existing spectrographs of which the order spacing along the cross-dispersion direction are not large enough to accommodate an additional optical fiber carrying lights from a wavelength calibration source

10400-67, Session PWed

Performance evaluation of the frequency comb calibrated Echelle spectrograph FOCES

Hanna Kellermann, Liang Wang, Max-Planck-Institut für extraterrestrische Physik (Germany); Frank U. Grupp, Max-Planck-Institut für extraterrestrische Physik (Germany) and Univ.-Sternwarte München (Germany); Anna Brucalassi, European Southern Observatory (Germany); Florian Lang-Bardl, Ulrich Hopp, Univ.-Sternwarte München (Germany); Ralf Bender, Univ.-Sternwarte München (Germany) and Max-Planck-Institut für extraterrestrische Physik (Germany)

We present the first performance evaluation of the upgraded high-resolution spectrograph FOCES (Fiber Optics Cassegrain Échelle Spectrograph), which has been installed at the 2m Fraunhofer telescope at the Wendelstein Observatory in late 2016. FOCES has been successfully operated at the Calar Alto Observatory in southern Spain from 1995 to 2009 and brought back to Munich in 2010 for refurbishment and major upgrades. Among other improvements the spectrograph has been equipped with a laser frequency comb based system for simultaneous wavelength calibration and is now housed inside a pressure- and temperature- stabilized tank. The new system is designed to provide high-accuracy and long-term stability for precise radial velocity measurements as they are needed for discovering/characterizing earth-like extra-solar planets and for stellar atmosphere analyses.

Optimization of high-inclination orbits using planetary flybys for a zodiacal light-imaging mission

Gabriel Soto, James Lloyd, Dmitry Savransky, Cornell Univ. (United States); Keith Grogan, Jet Propulsion Lab. (United States) and California Institute of Technology (United States); Amlan Sinha, Cornell Univ. (United States)

The zodiacal light caused by interplanetary dust grains is the second-most luminous source in the solar system. The dust grains coalesce into structures reminiscent of early solar system formation; their composition has been predicted through simulations and some edge-on observations but better data is required to validate them. Scattered light from these dust grains presents challenges to exoplanet imaging missions—resolution of their stellar environment is hindered by exozodiacal emissions and therefore sets the size and scope of these imaging missions. Understanding the composition of this interplanetary dust in our solar system requires an imaging mission from a vantage point above the ecliptic plane. The high surface brightness of the zodiacal light requires only a small aperture with moderate sensitivity; therefore, a 3cm camera is enough to meet the science goals of the mission at an orbital height of 0.1AU above the ecliptic. A 3U CubeSat is the target mass for this mission which will be a secondary payload detaching from an existing interplanetary mission. Planetary flybys are utilized to produce most of the plane change ?v; deep space corrective maneuvers are implemented to optimize each planetary flyby. We develop an algorithm that determines the minimum ?v required to place the CubeSat on a transfer orbit to a planet's sphere of influence, which maximizes the resultant inclination angle with respect to the ecliptic plane. Successive planetary flybys are computed to achieve the desired orbital height for imaging zodiacal light.

Detected exoplanet population distributions found analytically

Daniel Garrett, Dmitry Savransky, Cornell Univ. (United States)

Predicting the distributions of planetary population parameters detected by direct imaging planet-finding missions may be accomplished by Monte Carlo simulation. When the assumed planetary parameters vary over a wide range, the number of simulated planets and computational cost to determine the detected distributions must increase. We present an analytical method of predicting the distribution of detected planetary parameters which is more accurate and less computationally expensive than Monte Carlo simulation.

A planet will be detected if its separation from its star is inside the annulus defined by the observing instrument's inner and outer working angles and if it is bright enough to be above the minimum contrast of the observing instrument. The relevant planetary parameters for detection by direct imaging are semi-major axis, eccentricity, geometric albedo, planetary radius, and phase angle (with associated phase function). An assumed planet population is formed by choosing probability density functions for each of these parameters.

We derive the detected planetary parameter distributions by first forming a joint probability density function from the assumed planet population probability density functions. To find the detected distribution of one of the planetary parameters, we marginalize the joint probability density function by all of the other parameters subject to the constraints imposed by the detection conditions of a given instrument. The resulting distributions are computed quicker and show good agreement with distributions determined by Monte Carlo simulations.

The low-order wavefront control system for the PICTURE-C mission: preliminary testbed results from the Shack-Hartmann sensor

Glenn A. Howe, Christopher B. Mendillo, Kuravi Hewawasam, Jason Martel, Susanna C. Finn, Supriya Chakrabarti, Timothy A. Cook, Univ. of Massachusetts Lowell (United States)

The Planetary Imaging Concept Testbed Using a Recoverable Experiment - Coronagraph (PICTURE-C) mission will directly image debris disks and exozodiacal dust around nearby stars from a high-altitude balloon using a vector vortex coronagraph. We present experimental results of the PICTURE-C low-order wavefront control (LOWC) system utilizing a Shack-Hartmann (SH) sensor in an instrument testbed. The SH sensor drives both the alignment of the telescope secondary mirror using a 6-axis hexapod and a surface parallel array deformable mirror to remove residual low-order aberrations. The sensor design and actuator calibration methods are discussed and the preliminary closed-loop performance is presented.

10400-71, Session PWed

The low-order wavefront control system for the PICTURE-C mission: high-speed image acquisition and processing

Kuravi Hewawasam, Christopher B. Mendillo, Glenn A. Howe, Jason Martel, Susanna C. Finn, Supriya Chakrabarti, Timothy A. Cook, Univ. of Massachusetts Lowell (United States)

The Planetary Imaging Concept Testbed Using a Recoverable Experiment - Coronagraph (PICTURE-C) mission will directly image debris disks and exozodiacal dust around nearby stars from a high-altitude balloon using a vector vortex coronagraph. The PICTURE-C low-order wavefront control (LOWC) system will be used to correct time varying low-order aberrations due to pointing jitter, gravity sag, thermal deformation, and the gondola pendulum motion. We present the hardware and software implementation of the low-order Shack-Hartmann and reflective Lyot stop sensors. Development of the high-speed image acquisition and processing system is discussed with the emphasis on the reduction of hardware and computational latencies through the use of a real-time operating system and optimized data handling.

10400-72, Session PWed

Post-processing of the HST STIS coronagraphic observations

Bin Ren, Johns Hopkins Univ. (United States); John H. Debes, Laurent Pueyo, Marshall D. Perrin, Space Telescope Science Institute (United States); Élodie Choquet, Jet Propulsion Lab. (United States)

In the past 20 years, the STIS coronagraphic instrument has observed more than 80 stars with more than 4,000 exposures since its installment on the Hubble Space Telescope in 1997, and the numbers are still increasing. We focus on two occulting positions (WEDGEA0.6 and WEDGEA1.0), reduce the whole HST STIS coronagraphic archive at these positions with new post-processing methods, and present our method and results here.

We also explain our efforts in the calibration of STIS's new BAR5 occulting position for high contrast imaging, enabling STIS to explore inner regions as close as 0.2'' at a contrast of 10^4, and at 0.7'' at a contrast of 10^6 for point sources, indicating the 20-year-old STIS is able to compete with the best ground-based telescopes with extreme adaptive optics implemented. The detection limits of circumstellar disks with the BAR5 position is also investigated and reported.

The combination of the STIS results, with the HST/NICMOS results from the ALICE program, as well as other ground based high contrast imaging telescopes (e.g., GPI, P1640, and SPHERE) and future telescopes (e.g., JWST, and WFIRST), will provide us direct evidences in the understanding of planetary system formation and evolution.

10400-73, Session PWed

Shaped pupil coronagraph design developments for the WFIRST coronagraph instrument

A. J. Eldorado Riggs, Jet Propulsion Lab. (United States) and California Institute of Technology (United States); Neil T. Zimmerman, NASA Goddard Space Flight Ctr. (United States); Stuart B. Shaklan, Jeffrey B. Jewell, Jet Propulsion Lab. (United States) and California Institute of Technology (United States); Jessica Gersh-Range, Princeton Univ. (United States)

NASA's WFIRST Coronagraph Instrument (CGI) is planned to image and characterize exoplanets at high contrast. The CGI operating modes are the hybrid Lyot coronagraph for planet detection, a shaped pupil coronagraph for planet characterization, and another shaped pupil for disk imaging. Early CGI designs focused on overcoming the diffraction of the large pupil obscurations. Now that those designs have been proven to work in the lab, the design emphasis has been on achieving higher throughput and lower sensitivities to jitter and polarization-induced astigmatism. Here we present various coronagraph design and tolerancing studies to improve the performance of the CGI.

10400-74, Session PWed

Optimizing the regularization in broadband wavefront control algorithm for WFIRST coronagraph

Erkin Sidick, Byoung-Joon Seo, Brian D. Kern, David S. Marx, Ilya Poberezhskiy, Bijan Nemati, Jet Propulsion Lab. (United States)

The WFIRST/AFTA 2.4 m space telescope currently under study includes a stellar coronagraph for the imaging and the spectral characterization of extrasolar planets. The coronagraph employs sequential deformable mirrors to compensate for phase and amplitude errors. Using the optical model of an Occulting Mask Coronagraph (OMC) testbed at the Jet Propulsion Laboratory, we have investigated and compared through modeling and simulations the performance of several regularization-schemes in broadband wavefront control algorithm used to generate dark holes in an OMC, such as a Hybrid Lyot Coronagraph (HLC). Using the concept of Tikhonov filter constituting the G-matrix, we have explained what the different regularization schemes do to singular components during a wavefront control process called Electric Field Conjugation (EFC). In some cases we confirmed the numerical predictions with the testbed measured results.

10400-75, Session PWed

Mission design concept for detection of biosignatures of transiting planets

Jonathan W. Arenberg, Northrop Grumman Aerospace Systems (United States); Daniel Apai, The Univ. of Arizona (United States); Thomas D. Milster, College of Optical Sciences, The Univ. of Arizona (United States)

This paper discusses a feasibility argument for a mission concept to detect biosignatures in the spectra of transiting planets. Our design is based on the use of a large Fresnel optic based system operating from approximately 400-800 nm to collect the light from known transiting planet systems. The collected light is then analyzed for the presence of such gasses ozone and water. Use of a Fresnel lens system allows the construction of very large apertures for more modest cost than traditionally employed mirrors. We will discuss the science requirements and the basic design and options for our proposed mission.

10400-76, Session PWed

Focal-plane-based wavefront sensing with random DM probes

Eugene A. Pluzhnik, Dan Sibru, Ruslan Belikov, Eduardo A. Bendek, NASA Ames Research Ctr. (United States); Vladimir N. Dudinov, Kharkiv National Univ. of Radio Electronics (Ukraine)

An internal coronagraph with an adaptive optical system for wavefront control is being considered for direct imaging of exoplanets with upcoming space missions and concepts, including WFIRST, HabEx, LUVOIR, EXCEDE, and ACESAT.

The main technical challenge associated with direct imaging of exoplanets is to control of both diffracted and scattered light from the star so that even a dim planetary companion can be imaged. For a deformable mirror (DM) to create a dark hole with 10^-10 contrast in the image plane, wavefront errors must be accurately measured on the science focal-plane detector to ensure a common optical path.

We present here a method that uses a set of random phase probes applied to the DM to obtain a high accuracy wavefront estimate even in the case when the optical parameters/pupil plane phases of the system are dynamically changing.

The presented numerical simulations and experimental results show low noise sensitivity, high reliability, and robustness of the proposed approach. The method does not use any additional optics or complex calibration procedures and can be used during the calibration stage for any direct imaging mission. It can also be used in any optical experiment that uses the DM as the active optical element of the layout.

Modeling of planetary signal detection through ray-tracing-based beam propagation

Dongok Ryu, Sug-Whan Kim, Yonsei Univ. (Korea, Republic of)

High contrast images of exoplanet are limited by diffraction from optical and optomechanical components of instrumentation. Therefore it needs optimized solution of these components design with accurate estimation of its optical performance. We are developing model of planetary signal detection through ray-tracing related beam propagation. Sun-like G-star with 695,500km in radius is a light source that emitting rays towards a planet and an instrument model. Earth-like planet with 6,400km in radius is composed with atmosphere, land, and ocean optical scattering model. The star and Earthlike planet are located 10-parsec away from hypothetic instrument model that has 6.5-meter diameter and F/20 telescope with spiders and Lyot coronagraph. Total 100,000,000 rays per spectral unit are emitted inside of the star surface and traced to directly instrument aperture or reflected and scattered through earth-like planetary model. The rays from emission to instrument aperture through star and planet model are traced by geometric optics condition. Then the rays passing through aperture in telescope model are traced with 8 additional para-basal rays that calculate beam propagation in order to wave optics properties. The model allows for simultaneous evaluations of the beam propagated imaging and radiometric performances for planetary signal detection with some cases of simulation. This simulation results would evaluate valuable information improving estimates space optical instrument in all phases of a space mission.

The automated data processing architecture for the GPI Exoplanet Survey

Jason J. Wang, Univ. of California, Berkeley (United States); Marshall D. Perrin, Space Telescope Science Institute (United States); Dmitry Savransky, Cornell Univ. (United States); Pauline Arriaga, Univ. of California, Los Angeles (United States); Jeffrey K. Chilcote, Univ. of Toronto (Canada); Robert J. De Rosa, Univ. of California, Berkeley (United States); Maxwell A. Millar-Blanchaer, Jet Propulsion Lab. (United States); Jacob Shapiro, Cornell Univ. (United States); Julien Rameau, Univ. de Montréal (Canada); Schuyler G. Wolff, Johns Hopkins Univ. (United States) and Space Telescope Science Institute (United States); James R. Graham, Univ. of California, Berkeley (United States); Bruce A. Macintosh, Stanford Univ. (United States)

The Gemini Planet Imager Exoplanet Survey (GPIES) is a multi-year survey of 600 stars to discover and characterize young Jovian exoplanets and their planet-forming environments. We have developed an automated data architecture to uniformly process and index all data related to the survey. A back-end MySQL database indexes all files, which are synced to the cloud, and a front-end web server allows for easy browsing of all files associated with GPIES. An automated and flexible data processing framework which we term the GPIES Data Cruncher combines multiple data reduction pipelines together to intelligently process all spectroscopic, polarimetric, and calibration data taken with GPIES. With no human intervention, fully

reduced and calibrated data products are available in real-time less than an hour after the data is taken to expedite follow-up on potential objects of interest. All data of interest can be queried and reprocessed on a supercomputer as new algorithmic improvements are made to our data reduction pipelines. By uniformly processing all data with the most-updated data reduction techniques, we reduce our own workload, optimize our sensitivity to exoplanets, and also maintain a homogenously reduced dataset to study planet occurrence and instrument performance.

10400-79, Session PWed

Improving exoplanet sensitivity of the GPI Exoplanet Survey with a forward model matched filter

Jean-Baptiste Ruffio, Bruce A. Macintosh, Stanford Univ. (United States); Jason J. Wang, Univ. of California, Berkeley (United States); Laurent Pueyo, Space Telescope Science Institute (United States); Eric L. Nielsen, Stanford Univ. (United States); Robert J. De Rosa, Univ. of California, Berkeley (United States); Mark S. Marley, NASA Ames Research Ctr. (United States)

We developed a new matched filter based algorithm to detect point sources candidates for direct imaging of exoplanets. A forward model of the planet point spread function (PSF) is used as the matched filter template to account for distortions of the PSF of the planet due to the Karhunen-Loève Image Processing (KLIP) algorithm for stellar PSF subtraction. The new algorithm is optimized with respect to aggressiveness of KLIP and for exoplanet spectra by maximizing the Signal to Noise Ratio (SNR) of injected fake planet. We show that only two spectral templates are necessary to recover any young Jovian exoplanets with limited signal loss. We developed a complete pipeline for fully automated detection of point source candidates and the calculation of Receiver Operating Characteristic (ROC) curves, contrast curves and completeness contours. We uniformly processed more than 300 datasets from the Gemini Planet Imager Exoplanet Survey (GPIES) allowing for an unprecedented comparison of different detection algorithms with respect to both planet completeness and false positive rates.

To conclude, we show that the forward model matched filter allows the detection of 50% fainter objects in median compared to a conventional cross-correlation with a Gaussian PSF template at constant false positive rate.

10400-80, Session PWed

Fundamental limits to high-contrast wavefront control

Laurent Pueyo, Space Telescope Science Institute (United States)

In this paper we discuss fundamental limits associated with wavefront control with deformable mirrors in high contrast coronagraph. We start with an analytical prescription of wavefront errors, along with their wavelength dependence, and propagate them through coronagraph models. We then consider a few wavefront control architectures, number of deformable mirrors and their placement in the optical train of the instrument, and algorithms that can be used to cancel the starlight scattered by these wavefront errors over a finite bandpass. For each configuration we derive the residual contrast as a function of bandwidth and of the properties of the incoming wavefront. All errors, up to a finite spatial frequency set by the number of actuator on the deformable mirror, can be in principle perfectly cancelled under monochromatic light. However we show here that there exists modes of the wavefront that are uncorrectable under broadband light. We then carry out numerical simulations that illustrate these properties. This result has consequences when setting the wavefront requirements, along with the wavefront control architecture of future high contrast instrument both from the ground and from space. In particular we show that these limits can severely affect the effective Outer Working Angle that can be achieved by a given coronagraph instrument.

10400-81, Session PWed

Identification of the focal plane wavefront control system using E-M algorithm

He Sun, N. Jeremy Kasdin, Robert Vanderbei, Princeton Univ. (United States)

In a typical focal plane wavefront control (FPWC) system, such as the adaptive optics system of NASA WFIRST mission, all the efficient controllers and estimators in use are model-based. As a result, the modeling accuracy of the system influences the performance of the control and estimation. Currently, a linear state space model is used and calculated based on lab measurements using Fourier optics. Although the physical model is clearly defined, the calculated model is usually biased due to the incorrect distance measurements, imperfect diagnoses of the optical aberrations, and our lack of knowledge of the deformable mirrors (actuator gains and influence functions). In this paper, we present a new approach for measuring/estimating the linear state space model of a FPWC system using the expectation-maximization (E-M) algorithm. Simulation and lab results in the Princeton High Contrast Imaging Lab (HCIL) show that the E-M algorithm can well handle both the amplitude and phase errors and accurately recover the system. Using the recovered state space model, the controller creates dark holes with better contrast in the image plane and only needs around one-third the number of iterations compared to the experimental results using a physical model.

10400-82, Session PWed

A fiber injection unit for the Keck Planet Imager and Characterizer (KPIC)

Jacques-Robert Delorme, California Institute of Technology (United States); Dimitri Mawet, California Institute of Technology (United States) and Jet Propulsion Lab. (United States); James K. Wallace, Jet Propulsion Lab. (United States); Peter L. Wizinowich, W. M. Keck Observatory (United States); Garreth Ruane, Nikita S. Klimovich, Ji Wang, California Institute of Technology (United States)

Coupling a high-resolution spectrograph to a high-contrast imaging instrument is the next big step in the direct characterization of exoplanet atmospheres. In this scheme, the high-contrast imaging system serves as a spatial filter to separate the light from the star and the planet and the high-resolution spectrograph serves as spectral filter, which differentiates between features in the stellar and planetary spectra.

The Keck Planet Imager and Characterizer (KPIC) located downstream of the current Keck AO system will contain a fiber injection unit (FIU) capable of combing the high-contrast imaging system of KPIC with the current Keck high resolution infrared spectrograph (NIRSPEC). Thermal emission from young giant planets will be injected into a single mode fiber linked to NIRSPEC thereby allowing spectral characterization of exoplanet atmospheres. Moreover, the spectral resolution of NIRSPEC is high enough to enable spin measurements and Doppler imaging of atmospheric weather phenomenon.

Currently under development, the FIU design will be completed by the end Spring 2017. The module will then be integrated and tested at Caltech before being transferred to Keck in September 2017. During this presentation, I will present the design of the fiber injection unit, its science applications, and the expected results.

10400-83, Session PWed

Keck Institute for Space Studies. Report on exoplanet imaging and characterization: coherent differential imaging and signal detection statistics

Dimitri Mawet, California Institute of Technology (United States); Gautam Vasisht, Jet Propulsion Lab. (United States); Michael P. Fitzgerald, Univ. of California, Los Angeles (United States)

Here we report on the study recently held at the Keck Institute of Space Studies on the subject of Exoplanet Imaging and Characterization: Coherent Differential Imaging and Signal Detection Statistics. Direct imaging of a planet around another star is exceedingly challenging. For even the closest stars observed with the largest ground-based telescopes, the angular separation between star and planet will be near the classical diffraction limit. Moreover, a typical star will be about a billion times brighter than the planet to be imaged, a challenge even for the most stable telescope in space. The planetary image is also buried in "speckle noise," which is the result of uncorrected wavefront errors that propagate through the atmosphere and even the most accurately polished optical system. This speckle noise has complex properties which are different from planetary signals. While algorithms now exist that exploit some differences between the signal and noise characteristics, there has been little effort to address the full problem in a rigorous and comprehensive way. Our focus on speckle discrimination and control is motivated by key scientific measurements of exoplanetary systems:

Pure detection: Is there a planet present in the image(s)?

Astrometry: Where precisely is the planet located?

Photometry: How bright is the planet, and does its brightness vary with time?

Estimation of orbital parameters: How does it move relative to other bodies in the system?

Spectrometry: What are the spectral characteristics of the light from the planet?

Detection of life: Does the spectrum contain components consistent with living organisms?

Given the advent of high-precision focal plane wavefront control and low-noise fast-frame-rate detectors as well as the ongoing development of new facilities for exoplanet study, our KISS workshop sought to address several questions related to the development of statistically grounded strategies for detecting faint signals in the presence of both coherent and incoherent backgrounds:

What are the fundamental limits to focal-plane wavefront sensing and coherent differential imaging?

How is modulation best used in source-speckle discrimination and in speckle control?

How do ground-based focal-plane wavefront sensing and control differ from the space-based case?

What is the potential impact of new post-processing techniques, and rigorous statistical analyses on the next-generation instruments for extremely large ground- and space-based telescopes?

10400-42, Session 9

Modeling and performance predictions for the Princeton Starshade Testbed

Anthony D. Harness, N. Jeremy Kasdin, Robert J. Vanderbei, Yunjong Kim, Princeton Univ. (United States); Philip Dumont, Stuart B. Shaklan, Jet Propulsion Lab. (United States)

Starshades are a leading technology to enable the direct detection and spectroscopic characterization of Earth-like exoplanets. Two key aspects to advancing starshade technology are the demonstration of starlight suppression to the level required for flight and validation of optical models at this high level of suppression. These technologies are addressed in current efforts underway at the Princeton Starshade Testbed. We report on results from modeling the performance of the Princeton Starshade Testbed to help achieve the milestone 10-9 suppression. We use our optical model to examine the effects that errors in the occulting mask shape and external environmental factors have on the limiting suppression. We look at deviations from the ideal occulter shape such as over-etching during the lithography process, edge roughness of the mask, and random defects introduced during manufacturing. We also look at the effects of dust and wavefront errors in the open-to-atmosphere testbed. These results are used to set fabrication requirements on the starshade and constraints on the testbed environment. We use detailed measurements of the manufactured occulting mask to converge towards agreement between our modeled performance predictions and the suppression measured in the testbed, thereby building confidence in the validity of our optical models. We conclude with a discussion of the advantages and practicalities of scaling to a larger testbed to further advance the optical aspect of starshade technology.

10400-43, Session 9

Optical demonstration of a starshade at flight Fresnel numbers in the laboratory

Yunjong Kim, Anthony D. Harness, Princeton Univ. (United States); Dan Sirbu, NASA Ames Research Ctr. (United States); Mia Hu, Michael B. Galvin, N. Jeremy Kasdin, Robert J. Vanderbei, Princeton Univ. (United States); Stuart B. Shaklan, Jet Propulsion Lab. (United States)

A major science goal of exoplanet exploration is the direct detection and spectral characterization of Earth-like planets. The main challenge with the direct observation of Earth-like extra planets is that these planets are ten billion times fainter than the parent stars and the angular separation between the parent stars and the planets are less than a hundred milliarcseconds.

One of the main candidates for creating high-contrast for future Earth-like planet detection is a sharshade. The starshade is a spacecraft flown along the line-of-sight of a space telescope to suppress starlight and enable high-contrast direct imaging of exoplanets. However, optical testing of a full-scale starshade on the ground is impossible because of the long separations. Therefore, laboratory verification of starshade designs is necessary to validate the optical models used to design and predict starshade performance.

At Princeton, we have designed and built a testbed that allows verification of a scaled starshade at a flight-like Fresnel number whose suppressed shadow is mathematically identical to that of a space starshade. The goal of this experiment is to demonstrate a pupil plane suppression of better than 1e-9 with a corresponding image plane contrast of better than 1e-11. The starshade testbed uses a 77.2 m optical propagation distance to realize the flight Fresnel number of 14.5. Based on the first-light result we have added a gap at the inner tip region of the scaled starshade to minimize the effect of diffraction.

Here, we present lab result of the revised sample design operating at a flight Fresnel number. We compare the experimental results with simulations that predict the ultimate contrast performance.

10400-44, Session 9

Precise starshade stationkeeping and pointing with a Zernike wavefront sensor

Michael Bottom, Carl Seubert, Shannon K. G. Zareh, Stefan R. Martin, Eric J. Cady, Stuart B. Shaklan, Jet Propulsion Lab. (United States)

Starshades, large occulters positioned tens of thousands of kilometers in front of space telescopes, offer one of the few paths to imaging and characterization of Earth-like extrasolar planets. However, for the starshade to generate a sufficiently dark shadow on the telescope, the two must be coaligned to just 1 meter laterally at these large separations. The principal challenge to achieving this level of control is in determining the position of the starshade with respect to the space telescope. In this paper, we present numerical simulations and laboratory results demonstrating that a Zernike wavefront sensor coupled to a WFIRST-type telescope is able to deliver the stationkeeping precision required. The sensor can determine the starshade lateral position to centimeter level in seconds of open shutter time for stars brighter than eighth magnitude, with a capture range of ~10 meters. We discuss the potential for fast (ms) tip/tilt pointing control at the milli-arcsecond level by illuminating the sensor with a laser mounted on the starshade. Finally, we present early laboratory results validating the main components of the numerical simulations.

10400-45, Session 9

Starshade mechanical design for the Habitable Exoplanet Imaging Mission (HabEx)

Manan Arya, Jet Propulsion Lab. (United States); Steve Warwick, Northrop Grumman Aerospace Systems (United States); David Webb, P. D. Lisman, Stuart B. Shaklan, S. C. Bradford, John Steeves, Evan Hilgemann, Jet Propulsion Lab. (United States); Brian Trease, The Univ. of Toledo (United States); Mark Thomson, Northrop Grumman Aerospace Systems (United States); Neal Beidleman, Gregg Freebury, TENDEG, LLC (United States)

An external occulter for starlight suppression -- a starshade -- flying in formation with the Habitable Exoplanet Imaging Mission (HabEx) space telescope could enable the direct imaging and spectrographic characterization of Earth-like exoplanets in the habitable zone. This starshade is flown between the telescope and the star, and blocks stellar light while allowing the reflected planetary light through. This paper presents two mechanical architectures for this occulter, which must stow in a ~5 m diameter launch fairing and then deploy to a ~60-80 m diameter structure. The optical performance of the starshade requires that the edge profile is accurate and stable. The stowage and deployment of the starshade to meet these requirements present unique challenges that are addressed in these proposed architectures. The first mechanical architecture consists of a number of petals attached to a deployable perimeter truss, which is connected to central hub using tensioned spokes. The petals are furled around the stowed perimeter truss for launch. The second design uses telescoping booms to drive out each of the petals. The petal edges are stiff machined shapes with hinges between segments. These architectures demonstrate that there are identified mechanical design solutions that support an 80 m-class starshade for flight as part of the HabEx mission.

10400-46, Session 9

Prospects for exoplanet imaging in multi-star systems with starshades

Dan Sirbu, Ruslan Belikov, NASA Ames Research Ctr. (United States)

The main technical challenge associated with direct imaging of exoplanets is the control of diffracted and scattered light from the host star so that a dim planetary companion can be imaged at small angular separations and at high contrast ratios. Upcoming space missions including WFIRST, HabEx, and LUVOIR are currently exploring the usage of both internal coronagraphs and starshades to enable direct imaging of exoplanets. Multi-star systems pose additional challenges for both types of starlight suppression systems due to the combined off-axis star's diffraction and aberration leakage into the region of interest. As a result, many multi-star systems are considered unsuitable for direct imaging and not included in direct imaging survey target lists, even though the majority of (non-Mdwarf) stars belong to multi-star systems.

Here, we explore the capabilities of a starshade mission to directly image multi-star systems. A basic option is for additional starshades to block the off-axis stars. A more interesting option takes the form of operating a starshade in conjunction with internal starlight suppression. Two scenarios are considered. First, even without a coronagraph, a recent multi-star wavefront control (MSWC) technique can remove the off-axis star's leakage to enable a region of high-contrast around the on-axis star blocked by the starshade. Second, the coronagraph instrument blocking the on-axis star, with the starshade blocking off-axis starlight. We present simulation results of such starshade case studies to enable multi-star system imaging.

10400-47, Session 10

Gaia and exoplanets: a revolution in the making *(Invited Paper)*

Alessandro Sozzetti, INAF - Osservatorio Astrofisico di Torino (Italy)

The Gaia global astrometry mission is now headed towards the end of the third year of routine science operations. With the publication of the first data release in September 2016, it has begun to fulfil its promise for revolutionary science in countless aspects of Galactic astronomy and astrophysics. I will briefly review the Gaia mission status of operations and the scenario for the upcoming intermediate data releases, focusing on important lessons learned. I will then illustrate the Gaia exoplanet science case, and discuss how the field will be revolutionized by the power of micro-arcsecond (?as) astrometry that is about to be unleashed. I will conclude by touching upon future developments in the field of ultra-high precision astrometry that hold promise for much improved understanding of exoplanetary systems, particularly when seen in combination with other indirect and direct detection and characterization techniques.

10400-48, Session 10

The exoplanet program of the microarcsecond astrometric observatory Theia

Lucas Labadie, Univ. zu Köln (Germany); Fabien Malbet, Institut de Planétologie et d'Astrophysique de Grenoble (France); Alain Léger, Institut d'Astrophysique Spatiale (France); Céline Boehm, Durham Univ. (United Kingdom); Antoine Crouzier, Institut de Planétologie et d'Astrophysique de Grenoble (France); Alberto Krone-Martins, Univ. de Lisboa (Portugal)

The Theia mission, as a natural successor to Gaia, will be the first extremely-high-precision astrometric surveyor that may emerge from the last ESA M5 call in October 2016. A major objective of Theia in the context of this conference is the detection by astrometry of Earths and Super-Earths exoplanets in the habitable zone of nearby A to M stars. This can be done by astrometry from space if a motion of <1-microarcesec can be recorded (0.3 microarcsec for an Earth/Sun system at 10 pc). Such an accuracy can be reached by Theia in the form of an 0.8-m telescope with 0.5° FOV in orbit at L2 for 3,5 years and providing repeated differential astrometric measurements between the science target and background reference stars. The exoplanet program will use circa 10% of the mission lifetime and will be able to survey 63 nearby stars with a ~0.6 microarssec astrometric floor to eventually detect planets down to 0.2 M_earth over circa 50 visits. In order to measure a centroid position on the CCD with an accuracy of 1e-5 pixels, Theia's high-precision measurement relies on an on-board interferometric laser metrology unit to calibrate out the pixel's offset to the nominal position, as well as the inter- and intra-pixel quantum efficiency.

The preliminary Theia mission assessment allowed us to identify a safe and robust mission architecture that demonstrates the mission feasibility within the Soyuz ST launch envelope and a small M-class mission cost cap. We present here these features and the corresponding exoplanet program.

10400-49, Session 10

Results of the astrometry and direct imaging testbed for exoplanet detection

Eduardo A. Bendek, Ruslan Belikov, Eugene A. Pluzhnik, NASA Ames Research Ctr. (United States); Emily Finan, The Univ. of Arizona (United States)

Measuring masses of long-period planets around F, G, K or brighter stars is necessary to characterize exoplanets and assess their habitability. Imaging stellar astrometry offers a unique opportunity to solve radial velocity system inclination ambiguity and determine exoplanet masses.

The main limiting factor in sparse-field astrometry, besides photon noise, is the non-systematic dynamic distortions that arise from perturbations in the optical train. Even space optics suffers from dynamic distortions in the optical system at the sub-µas level. To overcome this limitation we propose to develop to use a diffractive pupil that uses an array of dots on the primary mirror creating polychromatic diffraction spikes in the focal plane, which are used to calibrate the distortions in the optical system. Combining this technology with a high-performance coronagraph allows measuring orbit and mass of planetary systems, faster and more accurately than using each technique separately.

In this paper, we will review the system architecture, milestones, and performance of the simultaneous astrometry and high-contrast imaging laboratory built at NASA Ames Research Center as part of a TDEM program. We will also discuss prospective technologies to enable an active diffractive pupil that would work on demand avoiding contaminating active the telescope field of view with diffracted light when precision astrometry is not required.

10400-50, Session 11

New technologies for nulling interferometry: laboratory demonstration of integrated optics beam combiners in the L and M bands

Lucas Labadie, Univ. zu Köln (Germany); Stefano Minardi, Friedrich-Schiller-Univ. Jena (Germany); Jan Tepper, Univ. zu Köln (Germany); Romina Diener, Friedrich-Schiller-Univ. Jena (Germany); Robert R. Thomson, Heriot-Watt Univ. (United Kingdom); Jörg-Uwe Pott, Max-Planck-Institut für Astronomie (Germany); Stefan Nolte, Friedrich-Schiller-Univ. Jena (Germany)

In the era of large telescopes and RV/Transit planetary missions, nulling interferometry remains a competitive technique for the characterization of Earths and Super-earths around Sun analogs in the mid-IR (Léger 2015, ApJ 808, 194). This is a spectral range where a number of bio-signatures can be accessed from space. One challenge of nulling is to benefit from well-established and qualified infrared fibers and integrated optics capable of mitigating the instrumental constraints on the beam combination and wavefront filtering to reach high extinction ratios. Such photonics devices have reached high maturity in the near-IR range as in the case of the integrated optics (IO) beam combiner of GRAVITY at the VLTI, leading to unprecedented interferometric accuracy.

Driven by the need of next-generation interferometers, we expand the photonic approach towards longer wavelengths and develop IO combiners based on the ultrafast laser writing technique. We developed single-mode, low-loss evanescent couplers in gallium lanthanum sulfide with a 50/50 splitting behavior around 3.4 µm and characterized the intrinsic chromaticity by FTS. High monochromatic and broadband contrasts are measured with unpolarized light at 3.39µm (>98%), over the L band (>95%), and over the M Band (4.5-4.8µm) (>95%). Our analysis of the interferometric visibilities and phase shows a small differential birefringence in the component and negligible differential dispersion. This results points out the promising properties of mid-infrared laser writing integrated optics devices to serve as high quality beam combiners. The extension to a four-aperture architecture appears plausible, with care to be taken about the impact of the design on the total throughput.

10400-51, Session 11

Segmented Aperture Interferometric Nulling Testbed (SAINT) II: component systems update

Brian A. Hicks, Univ. of Maryland (United States) and NASA Goddard Space Flight Ctr. (United States); Matthew R. Bolcar, NASA Goddard Space Flight Ctr. (United States); Michael A. Helmbrecht, Iris AO, Inc. (United States); Peter Petrone III, Sigma Space Corp. (United States) and NASA Goddard Space Flight Ctr. (United States); Jeffrey A. Bolognese, Mark Clampin, NASA Goddard Space Flight Ctr. (United States); James A. Corsetti, Univ. of Rochester (United States) and NASA Goddard Space Flight Ctr. (United States); Andrew Eberhardt, Univ. of Washington (United States); Corina Koca, NASA Goddard Space Flight Ctr. (United States); Andrew M. Lea, Stinger Ghaffarian Technologies (United States) and NASA Goddard Space Flight Ctr. (United States); Ron Shiri, Neil T. Zimmerman, NASA Goddard Space Flight Ctr. (United States)

This work presents updates to the coronagraph and telescope components of the Segmented Aperture Interferometric Nulling Testbed (SAINT). The project pairs an actively-controlled macro-scale segmented mirror with the Visible Nulling Coronagraph (VNC) towards demonstrating capabilities for the future space observatories needed to directly detect and characterize a significant sample of Earth-sized worlds around nearby stars in the quest for identifying those which may be habitable and possibly harbor life. Efforts to improve the VNC wavefront control optics and mechanisms towards repeating narrowband results are described. A narrative is provided for the design of new optical components aimed at enabling broadband performance. Initial work with the hardware and software interface for controlling the segmented telescope mirror is also presented.

10400-59, Session PWed

Phase-shifting coronagraph

François B. Hénault, Alexis Carlotti, Christophe Verinaud, Institut de Planétologie et d'Astrophysique de Grenoble (France)

With the recent commissioning of ground instruments and future space observatories, coronagraphy should become the most efficient the most efficient tool for identifying and characterizing extra-solar planets in the forthcoming years. Coronagraphic instruments are divided into sub-families such as Phase-mask coronagraphs spreading starlight outside the diameter of a Lyot stop. In this communication is investigated the capability of a PMC acting as a phase-shifting wavefront sensor. We propose an original design where phase-shifts are introduced in an image plane, and pupil images are acquired for wavefront sensing in presence of the coronagraphic mask. Numerical simulations allow for better understanding of the performance of the system. They demonstrate that the phase-shifting process is compatible with the most popular phase masks currently employed

10400-53, Session 12

ExEP yield modeling tool and validation test results

Rhonda M. Morgan, Michael Turmon, Jet Propulsion Lab. (United States); Dmitry Savransky, Christian Delacroix, Daniel Garrett, Cornell Univ. (United States); Patrick Lowrance, Xiang Cate Liu, California Institute of Technology (United States); Paul Nunez, Jet Propulsion Lab. (United States)

EXOSIMS is a modular, open-source simulation tool for parametric modeling of the detection yield and characterization of exoplanets. EXOSIMS has been adopted by the Exoplanet Exploration Program's Standard Definition and Evaluation Team (ExSDET) as a common yardstick for comparison of various exoplanet mission concept studies. To ensure trustworthiness of the tool, we developed a validation test plan that leverages the python unit-test framework, utilizes integration tests, and performs end-to-end cross-validation with other yield tools. Here we present the test results, with the physics-based tests such as photon counts and integration times treated in detail and the functional tests treated summarily.

The test case utilized a 4m unobscured telescope with an idealized coronagraph and exoplanets from the IPAC RV exoplanet catalog. The known RV planets were set at quadrature to allowed for deterministic validation of the calculation of physical parameters, such as photon counts and integration time. The observing keepout region was tested by generating a video of the targets in the keepout zone over a year; though the keepout integration test required the interpretation of a user, the test revealed several important errors in the L2 HALO orbit and the definition of keepout applied to other system bodies. The validation testing of EXOSIMS was performed iteratively with the Cornell developers of EXOSIMS and resulted in a more robust, stable, and trustworthy tool that the exoplanet community can use for simulating exoplanet direct detection missions from probe class to WFIRST to large mission concept such as HabEx and LUVOIR.

10400-54, Session 12

Multi-mission modeling for space-based exoplanet imagers

Dmitry Savransky, Christian Delacroix, Daniel Garrett, Cornell Univ. (United States)

In addition to the Wide-Field Infrared Survey Telescope Coronagraphic Imager (WFIRST CGI), which is currently scheduled for launch in the mid 2020s, there is currently an extensive, ongoing design effort for next-generation, space-based, exoplanet imaging instrumentation. This work involves mission concepts such as the Large UV/Optical/Infrared Surveyor (LUVOIR), the Habitable Exoplanet Imaging Misson (HabEx), and a starshade rendezvous mission for WFIRST, among others. While each of these efforts includes detailed mission analysis targeted at the specifics of each design, there is also interest in being able to analyze all such concepts in a unified way (to the extent that this is possible) and to draw specific comparisons between projected concept capabilities. Here, we discuss and compare two fundamental approaches to mission analysis---full mission simulation and depth of search analysis---in the specific context of simulating and comparing multiple different mission concept. We present results of mission analysis for various concepts at varying stages of definition and discuss useful metrics for cross-mission comparison, as well as strategies for evaluating these metrics.

10400-55, Session 12

Report on EXOPAG study analysis group 19: exoplanet imaging signal detection theory and rigorous contrast metrics

Dimitri Mawet, Rebecca Jensen-Clem, California Institute of Technology (United States)

As planning for the next generation of high contrast imaging instruments (e.g. WFIRST, HabEx, and LUVOIR, TMT-PFI, EELT-EPICS) matures, and second-generation ground-based extreme adaptive optics facilities (e.g. VLT-SPHERE, Gemini-GPI) are halfway through their large main surveys, it is imperative that the performance of different designs, post-processing routines, observing strategies, and survey results be compared in a consistent, statistically robust framework. SAG19, exoplanet imaging signal detection theory and rigorous contrast metrics, is overarching to all direct imaging instrument, strategies, and methods. The scope of SAG19 is:

1- To go back to the basics of Bayesian Signal Detection Theory (SDT).

2- To rebuild a solid set of usual definitions used for or in lieu of "contrast" in different contexts, such as astrophysical contrast or ground truth, instrumental contrast used for coronagraph/instrument designs, and the measured on-sky data-driven contrast.

3- To identify what we can learn and apply from communities outside our field (e.g. medical imaging). A good example is the widespread use of receiver operating characteristic curve (ROC) and area under the curve (AUC).

4- To define precise contrast computation and ROC curve computation recipes, a new "industry standard". The goal is to be able to compare results from surveys, instrument and/or telescope designs on a level-playing field.

5- To identify how the new metrics and recipes can be used to define confidence levels for detection (H1) and subsequently error bars for photometric, spectroscopic, astrometric characterization.

6- To perform a community data challenge before and after applying our proposed set of standardized SDT rules and recipes, and apply lessons learned.

10400-56, Session 12

Quantifying the impact of small statistics at small inner working angles

Stephen T. Bryson, Ruslan Belikov, NASA Ames Research Ctr. (United States)

The coronagraphic detection of exoplanets in the habitable zone requires the ability to detect exoplanets with small angular separation from their host star. Mawet et al. (ApJ 792, 2, 2014) pointed out that at such small inner working angles, small number statistics can have a significant impact on the delectability of exoplanets. We quantify the impact of small statistics by simulating the delectability of a standard set of exoplanets at small working angles. We describe a general method to estimate the impact on contrast curves as a function of inner working angle compared with the standard assumption of Gaussian noise after post-processing. To provide a specific example, we focus on the PIAACMC coronagraph designed for WFIRST, which features high throughput at small inner working angle. We find that for inner working angles as small as 1 lambda/D and a detection threshold of 5 sigma, 43% of the standard exoplanet test population is still detected after accounting for the small statistics effect of Mawet et al. We discuss mitigation strategies to recover lost planets, emphasizing observation strategies. We find that when multiple observations are possible over time, lowering the detection threshold to 3 sigma allows the detection of 89% of the test planets at small inner working angle.

10400-57, Session 12

Planet signal extraction from direct imaging using common spatial pattern filtering

Jacob Shapiro, Nikhil Ranganathan, Dmitry Savransky, Cornell Univ. (United States); Jean-Baptiste Ruffio, Bruce A. Macintosh, Stanford Univ. (United States)

The principal difficulty with detecting planets via direct imaging is that the target signal is similar in magnitude, or fainter, than the and structure compared to noise sources in the image . To compensate for this, several methods exist to subtract the PSF of the host star and other confounding noise sources. One of the most effective methods is Karhunen-Loève Image Processing (KLIP). The core algorithm within KLIP is Principal Component Analysis, which is a member of a class of algorithms called Blind Source Separation (BSS).

We examine another BSS algorithm that may potentially also be used for PSF subtraction: Common Spatial Pattern Filtering. The underlying principles of this algorithm are discussed, as well as the processing steps needed to achieve PSF subtraction. CSP is examined both as a primary PSF subtraction technique, as well as in comparison with KLIP.

These algorithms have been used onare applied to data from the Gemini Planet Imager, analyzing images of ? Pic b. To build a reference library, both Angular Differential Imaging and Spectral Differential Imaging arewere used. To compare to KLIP, three major metrics are examined: computation time, resulting signal-to-noise ratio, and astrometric biases in different image regimes (ie.eg., speckle-dominated compared to Poisson-noise dominated). Preliminary results indicate that CSP can achieve similar results to KLIP when used as the primary method of PSF subtraction.

10401-2, Session 1

NEO deflection by laser ablation: experimental results

Jessie Su, Jonathan A. Madajian, Philip M. Lubin, Travis R. Brashears, Nicholas Rupert, Univ. of California, Santa Barbara (United States); Gary B. Hughes, California Polytechnic State Univ., San Luis Obispo (United States)

Asteroids impact Earth daily. Some, like the Chelyabinsk Meteor that exploded over Siberia in 2013, can cause massive disruption to human enterprise (~$33M in damages) and thousands of injuries. To mitigate this potentially disastrous threat, our group has posited a phased laser array which would be used to direct energy towards approaching asteroids or other dangerous near Earth objects (NEOs). The laser array would ablate the NEO's surface, inducing mass ejection, that would then cause a reactant thrust on the NEO in the opposite direction of the laser. To verify this concept in a laboratory environment, this work quantitatively measured the thrust induced on basalt and other asteroid regolith simulant by a 350W laser array. By placing the sample target on a torsion balance and measuring its angle of deflection under ablation, it is possible to calculate the induced thrust per unit watt. This angular change is measured with a secondary laser that reflects off of the torsion balance into an optical position sensor. By comparing this paper's experimental results with prior theoretical and computational work, we can surmise a theoretical relationship between NEO size and required laser power for future NEO deflection missions.

10401-3, Session 1

Deflection of inert objects in comet-like orbits by laser ablation

Qicheng Zhang, Philip M. Lubin, Univ. of California, Santa Barbara (United States); Gary B. Hughes, California Polytechnic State Univ., San Luis Obispo (United States)

Planetary defense strategies have traditionally focused on the impact threat posed by near-Earth asteroids (NEAs). Typical NEAs follow prograde orbits with low inclination, low eccentricity, and short orbital periods—properties conducive to early detection and subsequent interception by spacecraft years or even decades in advance of any potential impact. Interception strategies, however, are ineffective against most comets which follow highly eccentric and highly inclined orbits, and are, moreover, often discovered only a few months before their encounters with Earth. Volatiles such as water ice on or near the surface of comets sublimate and perturb the comet's trajectory when heated, even naturally by solar heating, making comets particularly well-suited for deflection by directed energy laser heating. This method involves one or more laser arrays on or near the Earth which target and heat the threatening comet, shifting its trajectory to prevent an impact. Many comets, however, have depleted their surface volatiles after repeated perihelion passages and consequently become dormant or even extinct—effectively asteroids in comet-like orbits. These "inert comets" experience little if any measurable orbital perturbation from solar heating and will be similarly unresponsive to comparable levels laser illumination. Deflecting such an object demands a much greater laser flux than needed for active comets—one sufficiently high to vaporize the silicate materials that presumably comprise its surface. Strategies to divert inert comets are analyzed for a range of hypothetical scenarios.

10401-4, Session 1

High-beam quality all-solid-state nanosecond Nd:YAG laser system of high-repetition frequency for space-debris detection

Zhongwei Fan, Academy of Opto-Electronics, CAS (China)

Space debris endangers many space activities, therefore target detection has become an essential aspect of defensive and offensive strategies toward space debris management. Laser detection has good directivity, strong anti-jamming active-detection, and the advantage of around-the-clock operation. The main difficulty with laser-based space debris detection lies in that there are relatively few echo photons to measure due to small cross section of debris and long distance. The most direct and effective means to improve the accuracy of space debris detection is by improving the laser performance via higher pulse frequency and energy.

In order to develop our nanosecond Nd:YAG laser of high-repetition frequency and high-beam quality for space debris detection, we have achieved many key technologies and manufacturing processes like: stabilized frequency of single-frequency pulse, large-diameter high-uniform side-pump amplification, stimulated Brillouin scattering (SBS) phase conjugation, high-power LD driving source, etc. The single longitudinal-mode, nanosecond-pulse of our single-frequency oscillator achieves stable output up to 8 hours without mode hopping (RMS<2%). Ninety percent of the large diameter (?15mm) side-pump amplifier realizes high-uniform pump amplification with the relevant PV less than 5%. The stimulated Brillouin scattering phase-conjugate mirror (SBS-PCM) achieves near-diffraction-limit beam quality control and high-fidelity pulse-width compression. And, our high-power power supply achieves a maximum peak power output up to 100 kW, with the current stability less than 1% and the output efficiency up to 88%.

Our high-repetition frequency and high-beam quality Nd:YAG all-solid-state nanosecond laser adopts master oscillation power amplification (MOPA) technical solution including mainly four parts: a single longitudinal-mode oscillator, a pre-amplifier unit, a phase-conjugate beam-control unit and a power-amplification unit. The single longitudinal-mode oscillator adopts a high-stability, single-longitudinal-mode Q-switched laser as the seed laser with output pulse of?J level. The pre-amplifier unit amplifies the laser pulse up to mJ level. The phase-conjugate beam-control unit carries out real-time correction of the optical distortion caused by heating effects during the energy pre-amplification process. In the power amplifier unit, a split-amplify-combine solution is adopted to reduce the working current of the amplifier and achieve higher gain-saturated amplification. The total optical-to-optical conversion efficiency is up to 53%. The single longitudinal-mode oscillator—operating at a 100 Hz repetition frequency and a single pulse injection energy of 9.25?J—produces an output energy of 3.36J. The output laser-beam diameter is 25mm, the pulse width is 7.096ns, the far field intensity is 1.71 times the diffraction limit, and the energy stability (RMS) is 1.3%.

10401-5, Session 1

Deep-space laser communication hardware driver

Jonathan A. Madajian, Nicholas Rupert, Victoria Rosborough, Univ. of California, Santa Barbara (United States); Steven Estrella, Freedom Photonics, LLC (United States); Philip M. Lubin, Jonathan Klamkin, Univ. of California, Santa Barbara (United States)

Deep space exploration will require laser communication systems optimized

for cost, size, weight, and power. To improve these parameters, our group is developing a photonic integrated circuit (PIC) based on indium phosphide for optical pulse position modulation (PPM). A field-programmable gate array (FPGA) was programmed to serve as a dedicated driver for the PIC. The FPGA is capable of generating 2-ary to 4096-ary PPM with a slot clock rate up to 700 MHz.

10401-6, Session 1

Near-field optical model for directed energy-propelled spacecrafts

Gary B. Hughes, California Polytechnic State Univ., San Luis Obispo (United States); Lauren R. F. Busby, Univ. of California, Santa Barbara (United States)

Wafer-scale spacecraft are envisioned as interstellar probes. The spacecraft includes a reflective sail, and propulsion is achieved by focusing a directed energy beam onto the sail. The beam is created by a large array of phase-locked lasers, e.g. on the ground or in Earth orbit. In order to simulate spacecraft acceleration with directed energy, a near field intensity model of the laser array is required. This paper describes a near-field light propagation model that can be used to calculate intensity patterns for the near-field diffraction of a phased array. The model consists of an analysis of both the radiative and non-radiative near field intensities. The Rayleigh-Sommerfeld approach is used to approximate intensity distributions for lengths close to and including the aperture. Scalar diffraction theory is also employed to estimate intensity distributions in the Fresnel Regime. Ideally, the optical model will be combined with a physical model of the spacecraft, to investigate sail designs and beam patterns that optimize stability of the spacecraft during the acceleration phase.

10401-7, Session 2

Switchable optical materials for space propulsion and attitude control *(Invited Paper)*

Jeremy N. Munday, Univ. of Maryland, College Park (United States)

Radiation pressure from the sun can exert a force on spacecrafts that can either be beneficial, in the case of solar sails, or harmful, in the case of satellites in predefined orbits. As photons are reflected off a surface, they impart a momentum that pushes the object. For a solar sail, this momentum provides the necessary thrust for propulsion without the need for propellant. However, attitude control is still performed by traditional means, for example reaction wheels or propellant ejection, which limits mission lifetime. Similarly, this radiation pressure can affect satellite orbits, and a mechanism is needed to adjust them as a result. Here we present our latest work on switchable reflectivity materials to actively control the radiation pressure exerted on a spacecraft to enable real-time attitude control and steering. The devices are constructed from a polymer dispersed liquid crystal (PDLC), which can be switched between a high transparency state and a high reflectivity state with the application of an applied bias. Measurements of the reflectivity over the solar spectrum show a significant change in the momentum transferred to the spacecraft (more than a factor of two), enabling propellant-less attitude control [1]. We will discuss our first generation proof-of-concept devices, preliminary space environment testing, and provide a future outlook for this technology.

[1] Dakang Ma, Joseph Murray and Jeremy N. Munday, "Controllable Propulsion by Light: Steering a Solar Sail via Tunable Radiation Pressure" Advanced Optical Materials (in press and on the cover) DOI: 10.1002/adom.201600668

10401-9, Session 2

Evolution of wafer-scale space systems for terrestrial and deep-space missions

Nicholas Rupert, Philip M. Lubin, Univ. of California, Santa Barbara (United States); Gary B. Hughes, California Polytechnic State Univ., San Luis Obispo (United States); Russell Woods, Univ. of California, Santa Barbara (United States); Peter Ateshian, Naval Postgraduate School (United States); Prashant Srinivasan, California Polytechnic State Univ., San Luis Obispo (United States); Jonathan A. Madajian, Travis R. Brashears, Alexander Cohen, Qicheng Zhang, Jessie Su, Lauren R. F. Busby, Univ. of California, Santa Barbara (United States)

Innovation and technological advance within various fields, including microelectronics, integrated photonics and wafer based nanofabrication, has paved the way for a new class of space systems. In order to take full advantage of novel propulsion systems currently under development, a complete re-evaluation of space systems of today is required. The objective is to design, develop, assemble and characterize the initial prototypes of these robotic platforms, with focus on leveraging continued advances in semiconductor and photonics based technologies to recognize and efficiently address complexities associated with long duration autonomous robotic space flight. As with any complex system, wafer scale spacecraft technology can be projected to follow a steady evolutionary path. Initial prototypes have been based off of commercially available components and conventional printed circuit board (PCB) technologies. These systems are now roughly the size of a US quarter (24.26 mm), and despite their small size, contain a 9-axis inertial measurement unit, CMOS imaging chip, advanced photonic elements, and multiple other sensor systems. As these technologies are pushed to their extreme limits a transition to partial and eventually full wafer scale integration will be necessary. At this stage inorganic nanostructures and other various nanotechnologies will be employed to further miniaturize the spacecraft. Eventually these craft will have the ability to be mass manufactured using pre-existing techniques developed by the semiconductor industry. This evolutionary structure will produce a low cost, feature rich spacecraft which can be mass manufactured and utilized for both terrestrial and deep space applications.

10401-10, Session 2

Ions irradiation on bi-layer coatings

Enrico Tessarolo, Alain Jody Corso, CNR-IFN Padova (Italy); Alessandro Martucci, Univ. degli Studi di Padova (Italy); Marco Angiola, Maria Guglielmina Pelizzo, CNR-IFN Padova (Italy)

Optical components performances can be affected by the space environment agents and in particular by ions irradiation. The effect on bi-layers coatings of different materials induced by alpha particles implantation is under investigation. The dependence of the profiles implantation by ion energy is studied by TRIM software simulations. The experiment conceived foresees that the ions energy during experimental irradiation is selected in order to superimpose the maximum of the peak profile with the interface plane. Different optical, structural and morphological analysis are used to study the damage induced, and in particular to investigate the inter-diffusion at the bi-layer interface.

10401-11, Session 2

Systematic investigation of the optical coatings damages induced in harsh space environment *(Invited Paper)*

Alain Jody Corso, Enrico Tessarolo, CNR-IFN Padova

(Italy); Alessandro Martucci, Univ. degli Studi di Padova (Italy); Marco Angiola, Maria Guglielmina Pelizzo, CNR-IFN Padova (Italy)

Optical coatings are among the instrumental sub-systems which can highly suffer the agents in space environments. In particular, as recently demonstrated, the accelerated ions and particles can potentially jeopardize the coatings optical performances, with a consequent degradation of the overall functionality of an instrument. Despite its importance, this issue is still poorly investigated. In fact, the fragmentary knowledge of the space environments and the low number of systematic ground testing experiments complicates the definition of clear procedures to investigate the behavior of the optical coatings in space.

A systematic approach devoted to identify a methodology for the validation of optical coatings under ions irradiation is presented. Monte Carlo simulations are used to evaluate the effects induced by different ion species and energies on both layers and multilayers of different materials, getting an accurate overview of the main criticalities. Such results are then used to plan representative irradiation experiments and the subsequent analysis procedures needed for a proper characterization of the exposed samples.

10401-12, Session 3

Restoration of image distorted by atmospheric turbulence achieved by optical phase conjugation *(Invited Paper)*

Pengda Hong, Yujie J. Ding, Lehigh Univ. (United States)

In this proceeding, we systematically review our recent research results on reconstructing image quality by second order nonlinear crystal composites. The broadband and polarization-insensitive optical phase conjugated beams are generated with pretty low power, and they are demonstrated to successfully real time remove distortion caused by dynamic atmospheric turbulence. The unique features are realized by idler pair or signal pair simultaneously generated from periodically-inverted KTiOPO4 (KTP) plates and they overcomes disadvantages reported in previous literature, such as polarization sensitivity to pump, high pump power and low response speed. In this article, we demonstrated some of our preliminary results of novel configuration for removing distortion. Furthermore, we summarize our research on reflection and transmission configurations of image recovery. Compared with transmission configuration, reflection configuration can be more practically utilized in field deployment. With necessary modifications and miniaturization of setup, it can be potentially incorporated in satellite for space exploration.

10401-13, Session 3

Characterizing phase noise in long optical fibers *(Invited Paper)*

Prashant Srinivasan, California Polytechnic State Univ., San Luis Obispo (United States); Peter Krogen, Massachusetts Institute of Technology (United States); Gary B. Hughes, California Polytechnic State Univ., San Luis Obispo (United States); Philip M. Lubin, Peter Meinhold, Jonathan A. Madajian, Qicheng Zhang, Alexander Cohen, Benton Miller, Daniel Brouwer, Travis R. Brashears, Lauren R. F. Busby, Nicholas Rupert, Univ. of California, Santa Barbara (United States)

Effective transfer of energy to a spacecraft via optical requires that the source be accurately directed at the satellite with sufficient resolution to contain the beam within the absorbing area of the satellite. This can be achieved by coherently combining laser sources which are distributed throughout a kilometer-scale array. However, coherent beam combination requires that each source be synchronized with sub-wavelength accuracy over the entire array. In this work we investigate the phase and polarization noise in fiber optic links ranging from 1-25 km as could be used to synchronize such an array.

This scheme uses a 1060 nm laser source in a Mach-Zehnder interferometer where two orthogonal polarization modes are used to perform I/Q quadrature detection of the phase variations in the interferometer arms. The detectors are sampled at 250 kHz and, for spooled fibers, phase excursions on the order of 20 krad over 100 s were observed.

10401-14, Session 3

Anti-resonant hollow core fiber for precision timing applications *(Invited Paper)*

Amy Van Newkirk, The Pennsylvania State Univ. (United States); J. Enrique Antonio Lopez, Rodrigo Amezcua Correa, Axel Schülzgen, CREOL, The College of Optics and Photonics, Univ. of Central Florida (United States); John Mazurowski, The Pennsylvania State Univ. (United States)

Many applications rely on the ultra-precise timing of optical signals through fiber, such as fiber interferometers, large telescope arrays, in phase arrayed antennae, optical metrology, and precision navigation and tracking. Environmental changes, specifically those caused by temperature fluctuations, lead to variations in the propagation delay of optical signals and thereby decrease the accuracy of the system's timing.

The cause of these variations in delay is the change in the glass properties of the optical fiber with temperature. Both the refractive index of the glass and the length of the fiber are dependent on the ambient temperature. Traditional optical fiber suffers from a delay sensitivity of 39 ps/km/K. We are reducing the temperature sensitivity of the fiber delay through the application of a novel design of optical fiber, Anti-Resonant Hollow Core Fiber. The major improvement in the thermal sensitivity of this fiber comes from the fact that the light is guided in an air core, with very little overlap into the glass structure. This drastically reduces the impact that the thermally sensitive glass properties have on the propagation time of the optical signal. Additionally, hollow core fiber is inherently radiation insensitive, due to the light guidance in air, making it suitable for space applications.

10401-15, Session 3

Thermal assessment of sunlight impinging on OSIRIS-REx OCAMS PolyCam, OTES, and IMU-sunshade MLI blankets in flight *(Invited Paper)*

Michael K. Choi, NASA Goddard Space Flight Ctr. (United States)

The NASA Origins, Spectral Interpretation, Resource Identification, Security, Regolith Explorer (OSIRIS-REx) spacecraft was successfully launched into orbit on September 8, 2016. It is traveling to a near-Earth asteroid (101955) Bennu, study it in detail, and bring back a pristine sample to Earth for scientific analyses. At the Outbound Cruise nominal spacecraft (S/C) attitude, with Sun on +X, sunlight is incident on the following components on the payload deck: a) the OCAMS PolyCam sunshade multilayer insulation (MLI) with black polytetrafluoroethylene (PTFE), b) a portion of the PolyCam optics support tube (MLI with germanium black Kapton (GBK)), c) a portion of the OTES sunshade (MLI with GBK), and d) the canted panel of S/C IMU-sunshade (MLI with GBK). The black PTFE is diffuse. The specularity of GBK is 69%. Solar irradiance varies with the solar distance, which is in the 0.773 AU to 1.387 AU range in the Outbound Cruise mission phase. Sunlight is reflected by the MLIs above to the other components on the payload deck. It illuminates the payload deck. All three OCAMS cameras experienced scattered light when they were powered on for checkout. It was successfully removed from images by median filter. The amount of solar reflection varies with the solar distance. If the OCAMS PolyCam sunshade

MLI coating is GBK, instead of black PTFE, the solar flux reflected by this MLI will be much larger. In addition, the temperatures of the MLIs above vary with the solar distance. As a result, the thermal radiation from the MLIs above to the other components within their views also varies with the solar distance. This paper presents a detailed thermal assessment on the solar impingement and thermal implications for Proximity Ops at the asteroid and Touch-and Go sample acquisition.

10401-16, Session 4

SCHOTT optical glass in space

Ralf Jedamzik, Uwe Petzold, SCHOTT AG (Germany)

Optical systems in space environment have to withstand harsh radiation. Radiation in space usually comes from three main sources: the Van Allen radiation belts (mainly electrons and protons); solar proton events and solar energetic particles (heavier ions); and galactic cosmic rays (gamma- or x-rays). Other heavy environmental effects include short wavelength radiation (UV) and extreme temperatures (cold and hot). Radiation can damage optical glasses and effect their optical properties. The most common effect is solarization, the decrease in transmittance caused by high-energy radiation. This effect can be observed for UV radiation and also for gamma or electron radiation. Optical glasses can be stabilized against many radiation effects. SCHOTT offers radiation resistant glasses that do not show solarization effects for gamma or electron radiation. But a review SCHOTT optical glasses used in space missions shows that not only radiation resistant glasses are used in the optical designs, but also standard optical glasses, due to their good stability against UV radiation. This presentation gives an overview of space missions using SCHOTT optical glass over the last decades.

10401-17, Session 4

Homogeneity of the coefficient of linear thermal expansion of ZERODUR(R): a review of a decade of evaluations

Ralf Jedamzik, Thomas Westerhoff, SCHOTT AG (Germany)

The coefficient of thermal expansion (CTE) and its spatial homogeneity from small to large formats is the most important property of ZERODUR®. Since more than a decade SCHOTT has documented the excellent CTE homogeneity. It started with reviews of past astronomical telescope projects like the VLT, Keck and GTC mirror blanks and continued with dedicated evaluations of the production.

In recent years, extensive CTE measurements on samples cut from randomly selected single ZERODUR® parts in meter size and formats of arbitrary shape, large production boules and even 4 m sized blanks have demonstrated the excellent CTE homogeneity in production.

The published homogeneity data shows single ppb/K peak to valley CTE variations on medium spatial scale of several cm down to small spatial scale of only a few mm mostly at the limit of the measurement reproducibility. This review paper summarizes the results also in respect to the increased CTE measurement accuracy over the last decade of ZERODUR® production.

10401-18, Session 4

ZERODUR 4-m blank surviving up to 20 g acceleration

Thomas Westerhoff, Thomas Werner, Thorsten Gehindy, SCHOTT AG (Germany)

The glass ceramic ZERODUR® developed as astronomical telescope mirror substrate material has been widely used in many telescopes due to its excellent small coefficient of thermal expansion. Many large and medium sized mirror substrate blanks have been delivered in the almost 50 years of ZERODUR® business so far. Packaging and transportation of mirror substrates of 4 to 8 m in diameter with a weight between 3 and 20 tons requires special attention and sophisticated skills to successful deliver the blanks to their destination at polishing shops all over the world. Typically, a combination of road and sea transport needs to be organized. The requirements on the transport container are depending on the transport route and may vary from destination to destination. In any case the container needs to be able to sufficiently support the multi ton ZERODUR® blank to avoid breaking under gravity. Additionally, the configuration needs to be able to absorb shocks happening during transport and loading between truck trailer and ship. For insurance reasons the transport container is always equipped with a GPS trackable shock recorder allowing to download the recorded accelerations on the container and the blank throughout the entire journey. This paper reports on the event of a 4 m class ZERODUR® blank exposed to shocks up to 20 g during transport. The event will be discussed in detail together with lessons learned to avoid such events for future transports. Additionally, the 20 g acceleration will be discussed in respect to the data on bending strength for ZERODUR ground surfaces reported in numerous papers by Peter Hartmann et.al. in the last couple of years.

10401-19, Session 4

Parametric criteria for optimal selection of materials for spaceborne mirrors

Tony B. Hull, The Univ. of New Mexico (United States); Stephanie Behar-Lafenetre, Thales Alenia Space (France); Dominic Doyle, European Space Research and Technology Ctr. (Netherlands); Ralf Jedamzik, Thomas Westerhoff, SCHOTT AG (Germany)

Four primary criteria for spaceborne mirrors are 1) optical surface finish, 2) formable to mass-efficient structures 3) stable under mission thermal and other stimuli., and 4) thermally compatible with metering structure materials. We parametrically look at heritage and evolving mirror materials, all meeting the first criteria, that may be considered for telescope mirrors in the architecture of space missions. Materials will be graphed as specific stiffness (E/?) as a function of transient resilience (Thermal Diffusivity/ Coefficient of Thermal Expansion). We will discuss figures of merit contours as expressed on this plot, and how these can be used to optimize the passive performance of an optical telescope assembly or reflective instrument.

10401-20, Session 4

Review of space radiation interaction with ZERODUR

Antoine Carré, Thomas Westerhoff, SCHOTT AG (Germany); Tony B. Hull, The Univ. of New Mexico (United States)

Materials for space missions need to be evaluated according their behavior when exposed to radiation in their intended orbit. The extremely low thermal expansion glass ceramic ZERODUR® has been and is still being successfully used as mirror substrates for a large number of space missions. Two of those are the outstanding missions Hubble Space Telescope (HST) and the X-Ray Telescope CHANDRA. ZERODUR® was used for the secondary mirror in HST and for the Wolter mirrors in CHANDRA without any reported degradation of the optical image quality during the lifetime of the missions. Improvements in CNC machining at SCHOTT allow to achieve extremely light weighted substrates incorporating very thin ribs and face sheets. This paper is reviewing data published on the interaction of space radiation with ZERODUR®. Additionally, the paper will propose experiments in order to improve and extend the existing database and the model predicting the long lifetime behavior of ZERODUR® under space radiation. Special focus will be given on the question how to design radiation experiments to be performed in a reasonable and economic accessible time frame providing data for a long lifetime prediction. The model to be derived out of the new

experiments needs to be able to predict ZERODUR behavior under space radiation with a better accuracy as well as being applicable to the extremely light weighted ZERODUR structures described in numerous papers by Tony Hull et al. in the last recent years.

10401-21, Session 5

Design and component test results of the LSST Camera L1-L2 lens assembly

Allison A. Barto, Ball Aerospace & Technologies Corp. (United States); Scott E. Winters, Lawrence Livermore National Lab. (United States); James H. Burge, College of Optical Sciences, The Univ. of Arizona (United States); Deborah Davies, Heather A. Doty, Ball Aerospace & Technologies Corp. (United States); John Richer, Peter Seyforth, Alliance Spacesystems, LLC (United States)

The Large Synoptic Survey Telescope (LSST) camera will be the largest camera ever constructed for astronomy. When light enters the camera it will first pass through the two large lenses of the L1-L2 Lens Assembly. This assembly consists of a 1.6 m spherical lens and a 1.2 m aspheric lens held in critical alignment by a carbon fiber composite assembly which is mounted to the camera structure by six adjustable struts which provide the mechanism to align the L1-L2 Assembly to the rest of the camera optical system. Final optical performance of this assembly is based upon lens figure, lens alignment, and alignment stability. With manufacture of the individual components of the L1-L2 Lens assembly and testing of the integrated composite structure complete, design, design drivers, and test results from lens testing and deflection testing of the structure over the range of on-mountain operational camera orientations will be presented.

The L1-L2 Assembly is being designed and built by Ball Aerospace, under contract to LLNS, with major contributions from Arizona Optical Systems (lenses) and Alliance Spacesystems (composite structure to support each lens), with the lens mount design based on heritage from the Kepler program. Design drivers for this system include mass, seismic loading, and extremely tight volume constraints that greatly influenced the lens mounting and structure design. The test results presented will include final pre-coating Transmitted Wavefront Error (TWE) testing of the individual lenses and deflection testing of the structure assembly integrated with mass simulators to test the alignment shifts of each lens to each other and to the camera as the telescope slews through operational orientations.

10401-22, Session 5

Advanced mirror technology development (AMTD): year five status

H. Philip Stahl, NASA Marshall Space Flight Ctr. (United States)

The Advanced Mirror Technology Development (AMTD) project is a multiyear effort initiated in Fiscal Year (FY) 2012, to mature toward the next Technology Readiness Level (TRL) critical technologies required to enable 4-m-or-larger monolithic or segmented ultraviolet, optical, and infrared (UVOIR) space telescope primary-mirror assemblies for general astrophysics and ultra-high-contrast observations of exoplanets. AMTD Phase 2 concluded in 2017 with the thermal characterization testing of a low-temperature fusion 1.5-meter diameter ULE mirror that is a 1/3rd scale model of a 4-meter mirror.

10401-23, Session 5

Lightweight ZERODUR: Validation of mirror performance and mirror modeling predictions

Tony B. Hull, The Univ. of New Mexico (United States); H. Phillip Stahl, NASA Marshall Space Flight Ctr. (United States); Thomas Westerhoff, SCHOTT AG (Germany); Martin J. Valente, Arizona Optical Systems, LLC (United States); Thomas Brooks, Ron Eng, NASA Marshall Space Flight Ctr. (United States); Ralf Jedamzik, SCHOTT AG (Germany)

Upcoming spaceborne missions, both moderate and large in scale, require extreme dimensional stability while relying both upon established lightweight mirror materials, and also upon accurate modeling methods to predict performance under varying boundary conditions. We describe tests, recently performed at NASA's XRCF chambers and laboratories in Huntsville Alabama, during which a 1.2m diameter, f/1.29 88% lightweighted SCHOTT lightweighted ZERODUR® mirror was tested for thermal stability under static loads in steps down to 230K. Test results are compared to model predictions, based upon recently published data on ZERODUR®. In addition to monitoring the mirror surface for thermal perturbations in XRCF Thermal Vacuum tests, static load gravity deformations have been measured and compared to model predictions. Also the Modal Response (dynamic disturbance) was measured and compared to model. We will discuss the fabrication approach and optomechanical design of the ZERODUR® mirror substrate by SCHOTT, its optical preparation for test by Arizona Optical Systems (AOS), and summarize the outcome of NASA's XRCF tests and model validations.

10401-24, Session 5

Development of the camera lens system for total solar eclipse observation

Jihun Kim, Seonghwan Choi, Ji-Hye Beck, Jongyeob Park, Su-Chan Bong, Bi-Ho Jang, Korea Astronomy and Space Science Institute (Korea, Republic of); Heesu Yang, Seoul National Univ. (Korea, Republic of); Jinho Kim, Green Optics Co., Ltd. (Korea, Republic of); Geon-Hee Kim, Korea Basic Science Institute (Korea, Republic of); Kyungsuk Cho, Sung-Joon Park, Korea Astronomy and Space Science Institute (Korea, Republic of)

Korea Astronomy and Space Science Institute (KASI) has been developing the Camera Lens System (CLS) for the Total Solar Eclipse (TSE) observation. In 2016 we have assembled a simple camera system including a camera lens, a polarizer, bandpass filters, and CCD to observe the solar corona during the Total Solar Eclipse in Indonesia. Even we could not obtain the satisfactory result in the observation due to poor environment, we obtained some lessons such as poor image quality due to ghost effect from the lens system. For 2017 TSE observation, we have studied and adapted the compact coronagraph design proposed by NASA. The compact coronagraph design dramatically reduces the volume and weight and can be used for TSE observation without an external occulter which blocks the solar disk. We are in developing another camera system using the compact coronagraph design to test and verify key components including bandpass filter, polarizer, and CCD, and it will be used for the Total Solar Eclipse (TSE) in 2017. We plan to adapt this design for a coronagraph mission in the future. In this report we introduce the progress and current status of the project and focus on optical engineering works including designing, analyzing, testing, and building for the TSE observation.

10401-25, Session 5

ZERODUR expanding capabilities and capacity for future spaceborne and ground-based telescopes

Thomas Westerhoff, Thomas Werner, SCHOTT AG (Germany)

The glass ceramic ZERODUR® is well known for its extremely low coefficient of thermal expansion making it one of the key materials for ultra-precision application such as IC and LCD Lithography, High-end Metrology, Aviation and space born or ground based Astronomy. The steady growth of demand for more precision in those application together with a growing number of precision systems and components is requesting the ability to on first hand increase precision in manufacturing while on second hand in parallel increase volume in production of ZERODUR® CNC machined products. This paper reports on the measures SCHOTT is realizing to feed the continuously increasing demand on high precision material and components. Next to a second melting tank additional capacity is going to be installed along the entire value stream of ZERODUR® production. Features of new CNC machining capabilities in the two and four meter class will be reported allowing to provide tighter tolerance on mirror surface figure together with reduced sub surface damage in order to accelerate the polishing time. Examples will be discussed as the 4 m class secondary and tertiary mirrors for the ESO E-ELT. The new equipment will enable SCHOTT to light weight 4 m class mirror substrates for future space optics demand.

10401-26, Session 6

Instantaneous phase measuring deflectometry for dynamic deformable mirror characterization

Isaac Trumper, Heejoo Choi, Dae Wook Kim, College of Optical Sciences, The Univ. of Arizona (United States)

We present an instantaneous phase measuring deflectometry (PMD) system in the context of measuring a continuous surface deformable mirror (DM). Deflectometry has a high dynamic range, enabling the full range of surfaces generated by the DM to be measured. The recent development of an instantaneous PMD system leverages the simple setup of the PMD system to measure dynamic objects with accuracy similar to an interferometer. The previous instantaneous PMD system was developed on an iPhone platform. As a natural extension of this work to precision metrology, we are now using specialized hardware to increase spatial resolution and improve measurement quality. To demonstrate the capabilities of this improved technology, we perform a linearity measurement of the actuator motion in a continuous surface DM, which is critical for closed loop control in adaptive optics applications. We measure the entire set of actuators across the DM as they traverse their full range of motion, thereby obtaining the influence function. Given the influence function of each actuator, the DM can produce specific Zernike terms on its surface. We then measure the linearity of the Zernike modes available in the DM software. By obtaining this relationship, we can more accurately generate surface profiles composed of Zernike terms. This ability is useful for other dynamic freeform metrology applications that utilize the DM as a null component.

10401-27, Session 6

JWST center of curvature test method and results

David M. Chaney, Ball Aerospace & Technologies Corp. (United States); Babak N. Saif, NASA Goddard Space Flight Ctr. (United States); Perry E. Greenfield, Kyle Van Gorkom, Keira J. Brooks, Warren Hack, Space Telescope Science Institute (United States); Marcel Bluth, Josh Bluth, SGT, Inc. (United States); James Sanders, NASA Goddard Space Flight Ctr. (United States); Koby Z. Smith, Larkin B. Carey, Ball Aerospace & Technologies Corp. (United States); Sze M. Chaung, Orbital ATK (United States); Severine C. Tournois, Ritva Keski-Kuha, Lee D. Feinberg, NASA Goddard Space Flight Ctr. (United States); W. Scott Smith, NASA Marshall Space Flight Ctr. (United States)

The James Webb Space Telescope (JWST) recently saw the completion of the assembly of the Optical Telescope Element and Integrated Science Instrument Module (OTIS). This integration effort was performed at Goddard Space Flight Center (GSFC) in Greenbelt, Maryland. In conjunction with this assembly process a series of vibration and acoustic tests were performed. To help assure the telescope's primary mirror was not adversely impacted by this environmental testing an optical center of curvature (CoC) test was performed before and after to measure changes in the telescope performance. The primary is a 6.5 meter diameter mirror consisting of 18 individual hexagonal segments. Each segment is an off-axis asphere with a total of three prescriptions repeated six times each. As part of the CoC test each segment was individually measured using a high speed interferometer (HSI) designed and built specifically for this test. This interferometer is capable of characterizing both static and dynamic characteristics of the mirrors. Additionally, with the aid of a vibration stinger applying a very low level input force the dynamic characteristic changes to the PM backplane structure can also be ascertained. This paper describes the CoC test setup, an innovative alignment method, and both static and dynamic results for the test.

10401-28, Session 6

Slanted-edge MTF testing for establishing focus alignment at infinite conjugate of space optical systems with gravity sag effects

Trent Newswander, David W. Riesland, Duane Miles, Lennon Reinhart, Space Dynamics Lab. (United States)

For space optical systems that image extended scenes such as earth viewing systems, modulation transfer function (MTF) test data is directly applicable to system optical resolution. For many missions it is the most direct metric for establishing the best focus of the instrument. Additionally MTF test products can be combined to predict overall imaging performance. For fixed focus instruments, finding the best focus during ground testing is critical to achieving good imaging performance. The ground testing should account for the full imaging system, operational parameters and operational environment. Testing the full imaging system removes uncertainty caused by breaking configurations and the combination of multiple subassembly test results. For earth viewing, the imaging system needs to be tested at infinite conjugate. Operational environment test conditions should include temperature and vacuum. Optical MTF testing in the presence of operational vibration and gravity release is less straightforward and may not be possible on the ground. Gravity effects are measured by testing in multiple orientations. Many space telescope systems are designed and built to have optimum performance in a gravity free environment. These systems can have imaging performance that is dominated by aberration including astigmatism. This paper discusses how the slanted edge MTF test is applied to determine the best focus of a space optical telescope in ground testing accounting for gravity sag effects. Actual optical system test results and conclusions are presented.

10401-29, Session 6

Diffractive optics for precision alignment of Euclid space telescope optics

Jean-Michel Asfour, Frank Weidner, Dioptic GmbH (Germany)

We present a method for precise alignment of lens elements using specific

Computer Generated Hologram (CGH) with an integrated Fizeau reference flat surface and a Fizeau interferometer. The method is used for aligning the so called Camera Lens Assembly for ESAs Euclid telescope. Each lens has a corresponding annular area on the diffractive optics, which is used to control the position of each lens. The lenses are subsequently positioned using individual annular rings of the CGH. The overall alignment accuracy is below 1 μm, the alignment sensitivity is in the range of 0.1 μm. The achieved alignment accuracy of the lenses relative to each other is mainly depending on the stability in time of the alignment tower. Error budgets when using computer generated holograms and physical limitations are explained. Calibration measurements of the alignment system and the typically reached alignment accuracies will be shown and discussed.

10401-43, Session PWed

Customized broadband sloan-filters filters for the JST/T250 and JAST/T80 telescopes: summary of results

Ulf Brauneck, SCHOTT Suisse SA (Switzerland); Ruediger Sprengard, SCHOTT AG (Germany); Sébastien Bourquin, SCHOTT Suisse SA (Switzerland); Antonio Marín-Franch, Ctr. de Estudios de Física del Cosmos de Aragón (Spain)

The Centro de Estudios de Fisica del Cosmos de Aragon (CEFCA) will conduct a photometric sky survey with 2 recently setup new telescopes on the Javalambre mountain: the JST/T250 is a 2.55m telescope with a plate scale of 22.67" /mm and a 3° diameter field of view (FoV) and the auxiliary telescope JAST/T80 with a 82cm primary mirror and a FoV of 2deg diameter.

A multiple CCD (9k-by-9k 10μm pixel) mosaic camera is used together with filter trays or filter wheels each containing a multitude of filters in dimensions 101.7x96.5mm or 106.8x106.8mm.

For this project SCHOTT manufactured 56 specially designed narrow band steep edged bandpass interference filters and 5 broadband sloan-filters which were recently completed. We report here on the results of the broadband sloan-filters with transmission bands of 324-400nm (sloan-u), 400-550nm (sloan-g), 550-700nm (sloan-r), 695-850nm (sloan-i) and 830-1200nm (sloan-z). The filters are composed of SCHOTT colorglasses and clearglass substrates coated with interference filters and represent an improvement of broadband sloan filters commonly used in astronomy.

Inspite of the absorptive elements, the filters show maximum possible transmissions achieved by magnetron sputtered filter coatings. In addition the blocking of the filters is better than OD5 in the range 250–1050nm. A high image quality required a low transmitted wavefront error (<?/8 locally respectively <?/2 globally) which was achieved even by combining up to 2 substrates. We report on the spectral and interferometrical results measured on the filters.

10401-44, Session PWed

An empirical comparison of primary baffle and vanes for optical astronomical telescope

Taoran Li, Yingwei Chen, National Astronomical Observatories (China)

In optical astronomical telescopes, the primary baffle is a tube-like structure centering in the hole of the primary mirror and the vanes usually locate inside the baffle, improving the suppression of stray light. They are the most common methods of stray light control. In order to characterize the performance of primary baffle and vanes, an empirical comparison based on astronomical observations has been made with Xinglong 50cm telescope. Considering the convenience of switching, an independent vanes system is designed, which can also improve the process of the primary mirror cooling and the air circulation. The comparison of two cases: (1) primary baffle plus vanes and (2) vanes alone involves in-dome and on-sky observations. Both the single star and the various off-axis angles of the stray light source observations are presented. The photometrical images are recorded by CCD to analyze the magnitude and the photometric error. The stray light uniformity of the image background derives from the reduction image which utilizes the MATLAB software to remove the stars. The in-dome experiments results reveal the effectiveness of primary baffle and the independent vanes system. Meanwhile, the on-sky photometric data indicate there are little differences between them. The stray light uniformity has no difference when the angle between the star and the moon is greater than 20 degrees.

10401-46, Session PWed

A friction compensating method based on data fusion in telescope controller design

YongMei Huang, Qiang Wang, Dong He, ZhiJun Song, Institute of Optics and Electronics, Chinese Academy of Sciences (China)

In this paper, a friction identifier and compensator is proposed. Friction is a major disturbance of median or large volume telescope. But the dynamic friction can hardly be measured directly. This paper propose a method to observe the dynamic friction based on data fusion. And used the observed result to identify friction's parameters of LuGre model. A compensator based on these parameters is then designed to compensate the friction. Finally the experiment result is proposed.

10401-47, Session PWed

Advanced slicer design for integral field spectrograph

Shaojie Chen, Suresh Sivanandam, Univ. of Toronto (Canada)

Integral field spectroscopy, a form of spectral multiplexing, is one of the current innovations in astronomical instrumentation, which can improve the observation efficiency significantly by capturing imaging and spectral information over a large field with a single exposure. This concept is also broadly applicable and has commercial value. Image slicer-based integral field spectrographs (IFS) are one implementation of this type technology, and the key component, an image slicer, is used to rearrange the two-dimensional field of view along one dimension to form a long pseudo slit at the input of a spectrograph.

In this paper, we discuss the design of an advanced compact slicer for the IFS, which consists of slicer mirrors, pupil mirrors and field mirrors. The overall requirements and process are described, from the top level optical parameters to the detailed specifications. The geometric layout of slicer is designed first to fit a spectrograph, and then slicer-pupil-field mirrors are optimized to achieve a good quality pseudo slit at the input of a spectrograph. Besides, the performance of micro pupils and common pupil after the image slicer is considered. The slicer for the conceptual design of a high-throughput infrared IFS for the Gemini South telescope is presented, and the simulation of slicer performance is discussed.

10401-48, Session PWed

Optical design of pyramid wavefront sensor for multiple mirror telescope

Shaojie Chen, Suresh Sivanandam, Siqi Liu, Univ. of Toronto (Canada); Jean-Pierre Veran, NRC - Herzberg Astronomy & Astrophysics (Canada); Philip M. Hinz, The Univ. of Arizona (United States); Etsuko Mieda, Tim Hardy, Olivier Lardière, NRC - Herzberg Astronomy & Astrophysics (Canada)

We discuss the optical design of an infrared (1.0-1.8 μm) pyramid wavefront sensor (PWFS) that is designed for the Multiple Mirror Telescope (MMT)

to improve its existing adaptive optics system. Simulations have shown the sensitivity of PWFSs to faint stars are better than traditional Shack-Hartmann WFSs. As a result, the use of PFWSs can provide higher Strehl ratios, larger sky coverage and higher contrast imaging capability. Considering the challenge to manufacture the four-sided pyramid with a precisely sharp tip, this design employs the double-roof prism structure as the substitute of real pyramid to split light into four quadrants to form four micropupils on the detector. The wavefront error is calculated by comparing the intensities inside four pupil images, so the micropupil quality determines the accuracy of wavefront measurement for the adaptive optics system directly.

In this paper, we discuss the evaluation process of micropupils quality, and report the performance comparison between the different designs, including single pyramid, double-roof, double pyramid and two double-roof prisms. In order to decrease the chromatic aberrations, the achromatic pair is adopted for the double pyramid and two double-roof prisms. The two double-roof prism design has been adopted for the PWFS after considering the competitive performance and the challenges in manufacturing the pyramid. Finally, four high quality micropupils are imaged with sufficient fidelity on a low-noise, high frame-rate infrared avalanche photodiode image sensor.

10401-50, Session PWed

Design of large aspherical SiC mirror for spaceborne application

Il K. Moon, Young Ha Kim, Ho-Soon Yang, Yun Woo Lee, Korea Research Institute of Standards and Science (Korea, Republic of)

Optimal design study of large aspherical mirror made of SiC for a space-borne application has been conducted. By using the finite element analysis program NX NASTRAN we calculated the opto-mechanical performance of mirror and its support system under various design loads including gravity, temperature and dynamic loads. We also optimized a bi-pod type flexure bonded at the backside of the mirror with proper strength under environment of space-borne application. Optimized shape of 1.1 m lightweight SiC mirror shows good areal density and optical performance of RMS surface error. We also proposed the hybrid type bonding method between mirror and bi-pod flexure shown better bonding strength with proper flexibility to isolate the effect of environmental loads.

10401-51, Session PWed

Optical design of the long slit spectrograph for 1m telescope

Dmitry E. Sazonenko, Dmitriy E. Kukushkin, Alexey V. Bakholdin, ITMO Univ. (Russian Federation); Gennady G. Valyvin, Special Astrophysical Observatory (Russian Federation)

In this article we describe optical design of the long-slit spectrograph for the 1-m telescope in the Special Astrophysical Observatory Russian Academy of Science.

The spectral range is 350-750 nm. The spectrograph must provide few modes with a spectral resolution: R100; R1000; R4000. Moreover, removing of the spectral element from the devise must provide an observing mode. We used a CCD detector with a pixel size 13.5 μm. Size of detector 2000x4000 pix. As a dispersion element, we used a grysm for every mode. During design, we decided to divide R4000 mode to 3 spectral ranges: 350-450 nm; 450-580 nm; 580-750 nm. We did this for ability to design of projection camera. Light loses in the spectrograph must be less than 50% in all spectral range. We decided to use the Ohara glass catalog for achieving this condition. Features of this devise are ability to provide all modes in wide spectral range and using the projection camera without glued lenses. As a result, we designed multi-mode devise. Spot diagram size does not exceed 2 pixels size in all modes.

10401-52, Session PWed

Control code for laboratory adaptive optics teaching system

Moon-Seob Jin, Ryan J. Luder, Lucas R. W. Sanchez, Michael Hart, College of Optical Sciences, The Univ. of Arizona (United States)

By sensing and compensating wavefront aberration, adaptive optics (AO) systems have proven themselves crucial in large astronomical telescopes, retinal imaging, and holographic coherent imaging. Commercial AO systems for laboratory use are now available in the market. One such is the ThorLabs AO kit built around a Boston Micromachines deformable mirror. However, there are limitations in applying these systems to research and pedagogical projects since the software is written with limited flexibility. In this paper, we describe a MATLAB-based software suite to interface with the ThorLabs AO kit by using the MATLAB Engine API and Visual Studio. The software is designed to offer complete access to the wavefront sensor data, through the various levels of processing, to the command signals to the deformable mirror and fast steering mirror. In this way, through a MATLAB GUI, an operator can experiment with every aspect of the AO system's functioning. This is particularly valuable for tests of new control algorithms as well as to support student engagement in an academic environment. We plan to make the code freely available to the community.

10401-53, Session PWed

Design and simulation of image-based 2D BRDF measurement system using semicircular ring reflector

Seul Ki Yang, Yonsei Univ. (Korea, Republic of); Eunsong Oh, Yonsei Univ. (Korea, Republic of) and Korea Institute of Ocean Science & Technology (Korea, Republic of); Sug-Whan Kim, Yonsei Univ. (Korea, Republic of)

We've designed new measurement system for the 2-dimentional bidirectional reflectance distribution functions (2D BRDF) which is able to acquire images from all reflected angles with a semicircular ring type reflector simultaneously. The system simply consists of reference light source module, target material module, reflector, and imaging detector module. The light source with specific incidence angle scattered from the target material comes to the semicircular type reflector. Then, the reached rays on the reflector can be captured as images with detecting part. Theoretically, since the reflected angle by the semicircular ring is constant, it is possible to calculate the BRDF characteristic of the target material. The experiment condition consists of a 635nm laser, the semicircular ring reflector structure with diameter of 300 mm, and an imaging camera. In this study, we predicted performance of the proposed system through the dedicated ray tracing simulation. The incident angle of light source is generated as a parallel beam covering from 10 to 90°. The imaging detector module includes 8bit CMOS sensor with 768?576 pixels and a focusing lens. The target material with the BRDF of Lambertian and Harvey models were used to verify the performance of designed measurement system. The simulation results show that the BRDF of the Lambetian model tends to remain unchanged about all of beam incident angle. The BRDF of the Harvey model tends to have the highest value at the specular angle, and exponentially decrease at different angles. The technical detail of the new measurement system design and ray tracing simulations will be presented with the results and implication.

10401-54, Session PWed

Fused silica polishing and figuring using CO2 laser radiation

Ting He, Shanghai Institute of Optics and Fine Mechanics (China) and Univ. of Chinese Academy of Sciences (China);

Chaoyang Wei, Zhigang Jiang, Xiaoli Teng, Jianda Shao, Shanghai Institute of Optics and Fine Mechanics (China)

Laser polishing of glass by CO2 laser can achieve sub-nanometer scales surface roughness in a short processing time with no extra damage caused. With the assistance of laser figuring, the surface residual waviness and shape errors can be reduced. To understand the physics of melt layer temporal evolution of laser polishing, a 2D axisymmetric transient model that couples heat transfer and fluid flow was constructed. The results indicate that the fluid flows are dominated by thermo-capillary convection in the velocity of ?m/s magnitude. It is suggest that melt flows are capable of smoothing micro roughness in appropriate interaction time. To study CO2 laser local precision homogeneous ablation, we have experimentally tested depths of no-overlapped and overlapped local ablation. Simulation of fused silica heating through multiple pulses CO2 laser beam irradiate was applied to optimize processing parameters of repetition rate, scan speed.

10401-55, Session PWed

A fast measuring method of the small aperture convex hyperboloid surface reflector

Zhe Wang, Xueke Xu, Lingqi Wu, Chaoyang Wei, Jianda Shao, Shanghai Institute of Optics and Fine Mechanics (China)

In the reflective optical system, a convex aspherical mirror is often used for the secondary mirror. Hindle test is difficult to operate in actual measurement for convex hyperboloid usually?because during measuring, the star is extremely difficult to find, and the tilt and decenter of the compensating spherical mirror have great influence on the position of the star. It causes a long measurement time, the measured results will include coma, and low efficiency. This paper presents a method that can fast finding the star with specific gauge, by analyzing the aberration of the tilt and decenter according to the measurement results using self-compiled software ,we only need fine tuning to the compensating spherical mirror. Therefore, the measuring time is greatly shortened and the efficiency is improved.

10401-30, Session 7

Operation and performance of the New Horizons Long-Range Reconnaissance Imager during the Pluto encounter

Steven J. Conard, Harold A. Weaver, Jorge I. Núñez, Howard W. Taylor, John R. Hayes, Andrew F. Cheng, Johns Hopkins Univ. Applied Physics Lab., LLC (United States)

The LOng-Range Reconnaissance Imager (LORRI) is a high resolution imaging instrument on the New Horizons spacecraft. LORRI collected over 5000 images during the approach and fly-by of the Pluto system in 2015, including the highest resolution images of Pluto and Charon and the four much smaller satellites (Styx, Nix, Kerberos, and Hydra) near the time of closest approach on 14 July 2015. LORRI is a narrow field of view (0.29°), Ritchey-Chrétien telescope with a 20.8 cm diameter primary mirror and a three lens field flattener. The telescope has an effective focal length of 262 cm. The focal plane unit consists of a 1024 ? 1024 pixel charge-coupled device detector operating in frame transfer mode. LORRI provides panchromatic imaging over a bandpass that extends approximately from 350 nm to 850 nm. The instrument operates in an extreme thermal environment, viewing space from within the warm spacecraft. For this reason, LORRI has a silicon carbide optical system with passive thermal control, designed to maintain focus without adjustment over a wide temperature range from -100 C to +50 C.

LORRI operated flawlessly throughout the encounter period, providing both science and navigation imaging of the Pluto system. We describe the preparations for the Pluto system encounter, including pre-encounter rehearsals, calibrations, and navigation imaging. In addition, we describe LORRI operations during the encounter, and the resulting imaging performance. Finally, we also briefly describe the post-Pluto encounter imaging of other Kuiper belt objects and the plans for the upcoming encounter with KBO 2014 MU69.

10401-31, Session 7

High-performance integrated photonic spectrometers: arrayed waveguide gratings or echelle gratings

Andreas Stoll, Ziyang Zhang, Martin M. Roth, Leibniz-Institut für Astrophysik Potsdam (Germany)

Compact, efficient and high-performance optical components are desired in astrophotonics to reduce system cost and complexity. In particular, integrated photonic spectrometers (IPS) based on planar lightwave circuits are attractive since the compact and light-weight components also provide great robustness and flexibility in the design of spectrograph systems for airborne and space astronomy. Arrayed waveguide gratings (AWG) and integrated Echelle gratings (IEG) are the two most recognized candidates and both have been long developed for the wavelength division multiplexing (WDM) optical networks. The requirements for their practical application in astrophotonics, however, bring the design difficulty to a new level: high performances including extremely fine spectral resolution, broad free spectral range and ultra-low insertion loss often need to be achieved simultaneously. Depending on the operation principles, for AWG the difficulties lie in the arrangement of a large number of fan-out waveguides and the mode-overlapping with the free propagation region, while for IEG niche design is needed in the grating curvature (Roland circle or two stigmatic point trace) and the local facet arrangement (blazing angle, curvature and chirping) for the best performance within a reasonable footprint. This paper compares these two IPSs in detail, e.g. their sizes and performance limitations under a series of settings. The challenges for the respective device fabrication are also analyzed in terms of critical dimensions, structural conformity and material homogeneity. This paper may serve as a guideline in the design of high-performance IPS devices and provide insights in choosing AWG or IEG for astronomical application.

10401-32, Session 7

Adaptation of Dunn Solar Telescope for Jovian Doppler spectro imaging

Thomas A. Underwood, David G. Voelz, New Mexico State Univ. (United States); François-Xavier Schmider, Lab. J.L. Lagrange, Observatoire de la Côte d'Azur (France); Jason Jackiewicz, New Mexico State Univ. (United States); Julien Dejonghe, Yves Bresson, Lab. J.L. Lagrange, Observatoire de la Côte d'Azur (France); Robert Hull, New Mexico State Univ. (United States); Ivan Gonçalves, Lab. J.L. Lagrange, Observatoire de la Côte d'Azur (France); Patrick Gualme, New Mexico State Univ. (United States); Frédéric Morand, Olivier Preis, Lab. J.L. Lagrange, Observatoire de la Côte d'Azur (France)

This paper describes instrumentation used to adapt the Dunn Solar Telescope (DST) located in Sunspot, NM for observations using the Doppler Spectro Imager (DSI). The DSI is based on a Mach-Zehnder interferometer and measures the Doppler shift of solar lines to allow the study of atmospheric dynamics of giant planets and the detection of their acoustic oscillations. The instrumentation is being designed and built through a collaborative effort between a French team from the Observatoire de la Cote d'Azur (OCA) that designed the DSI and a US team at New Mexico State University. There are four major components that couple the DSI to the DST: a guider/tracker, fast steering mirror (FSM), pupil stabilizer and transfer optics. The guider/tracker processes digital video to centroid-track

the planet and outputs voltages to the DST's heliostat controls. The FSM removes wavefront tip/tilt components primarily due to turbulence and the pupil stabilizer removes any slow pupil "wander" introduced by the telescope's heliostat/turret arrangement. The light received at a science port of the DST is sent through the correction and stabilization components and into the DSI. The FSM and transfer optics designs are being provided by the OCA team and serve much the same functions as they do for other telescopes at which DSI observations have been conducted. The pupil stabilization and guider are new and are required to address characteristics of the DST.

10401-33, Session 7

An acquisition technology of optical ground station in satellite-ground QKD

Dong He, YongMei Huang, Qiang Wang, Bo Qi, WanSheng Liu, Institute of Optics and Electronics, Chinese Academy of Sciences (China)

In this paper, a method of acquisition between optical ground station and Mozi quantum communication satellite for establish optical links is proposed. The acquisition technological specification of the optical ground station system is analyzed. The acquisition strategy of optical ground station is designed. In order to point accurately to quantum satellite for optical ground station, system error modifying method is designed, using the telescope mount model to improve the absolute pointing precision. Finally the experiment result is proposed. Results show that the correction accuracy is better than 5urad. The capture time is less than 5 seconds.

10401-34, Session 7

Imaging and spectral performance of the New Horizons Ralph instrument during the 2015 Pluto encounter

Allen W. Lunsford, Dennis Reuter, Donald E. Jennings, NASA Goddard Space Flight Ctr. (United States); Catherine B. Olkin, S. Alan Stern, Southwest Research Institute (United States); Gerald E. Weigle, Big Head Endian, LLC (United States)

The Ralph instrument on New Horizons mission consists of a telescope that feeds two focal planes: the Multi-spectral Visible Imaging Camera (MVIC), and the Linear Etalon Imaging Spectral Array (LEISA). During the encounter with the Pluto system in 2015, Ralph collected numerous high spatial resolution images of the main components of the system, Pluto and Charon, as well as the four smaller objects Hydra, Kerberos, Nix and Styx.

The 75-mm aperture Ralph telescope uses an off-axis, three-mirror anastigmat design with an effective focal length of 657.5 mm. A dichroic beamsplitter transmits wavelengths longer than 1.1 micron to LEISA and reflects shorter wavelengths to MVIC. MVIC provides panchromatic (400 to 975 nm), blue (400-550 nm), red (540-700 nm), near IR (780-975 nm) and methane absorption (860-910 nm) spectral bands. The IFOV of MVIC is about 20x20 microradian^2. The cross-track FOV of is 5.7°.

LEISA images a scene through a linear variable filter, LVF that operates from 1.25-2.5 micron. The two segments of the LVF cover from 1.25 to 2.5 micron with a spectral resolving power of about 240 and 2.1 to 2.25 micron with a spectral resolving power of about 560. The LEISA IFOV is about 62x62 microradian^2 and the FOV is 0.91° x 0.91°.

Ralph operated as expected, returning a wealth of spectral imaging data. The data acquisition process, calibration procedures and data processing steps are presented here. We will also present the planned observations of the KBO 2014 MU69 that will occur during the Kuiper Extended Mission (KEM).

10401-35, Session 8

Reducing SOFIA's image jitter: an ongoing challenge

Friederike M. Graf, NASA Ames Research Ctr. (United States); Andreas Reinacher, Daniel Spohr, Holger Jakob, Deutsches SOFIA Institut (Germany); Stefanos Fasoulas, Univ. of Stuttgart (Germany)

The Stratospheric Observatory for Infrared Astronomy (SOFIA) has already successfully conducted over 350 flights. In its early science phase, SOFIA's pointing requirements and especially the image jitter requirements of less than 1 arcsec rms have driven the design of the control system. However, the increasing demands on the image size now require an image jitter of less than 0.4 arcsec rms to reach SOFIA's scientific goals.

The major portion of the remaining image motion is caused by deformation and excitation of the telescope structure in a wide range of frequencies due to aircraft motion and aero-acoustic effects. These disturbances are counteracted by the so-called Flexible Body Compensation system which uses a set of accelerometers to estimate the resulting image motion.

A new scheme of tests has been conducted by developing controlled and manually induced turbulent flight conditions. These tests clearly show the influence of several telescope Eigenmodes on the image motion and how the current control system performs. With these measurements a variety of opportunities for dramatic improvements on the image jitter have been revealed.

To better study these possibilities, a simulation tool has been developed which not only implements system identification data and FEM derived models, but also allows the inclusion of sensor data from inflight measurements.

Results of the simulation as well as inflight measurements will be presented and improvement strategies will be discussed.

10401-36, Session 8

A second-order spherical optoelectronic detector

Francesco Romano, Consultant (Italy)

Present Paper concerns a feasibility study about the 2nd order spherical or three dimensional Detector, for photonic radiation applications.

It has been developed in order to obtain a PARAXIAL approximation of the physical event observed under Coulomb gauge condition, which is essential to compute both the longitudinal and transverse rotational components of the observed 3-D Vortex field.

Generally those components are neglected by the conventional detection systems so far used.

Light and Laser are not fully Transverse and/or not-rotational phenomena. The 2nd order spherical (3-D) Detector purpose is to directly measure also the potential solenoidal energy (vortex) related to the Angular Momentum, in addition to the energy, mainly not-rotational, related to the Linear Momentum.

Direct 2nd order measure, enables a study development of a TEM + DEM monochromatic complex wave with a paraxial accuracy in the relativistic time-space domain.

This paper compares the performances of the innovative 2nd order detector technique proposed with the ones reached by a 1st order system.

The paper illustrates an innovative Matlab Model Detector which is quadratic spherical 3-D, here submitted in order to directly measure a light source power spectrum.

The paper summarizes the results of several test experiments lead by the authors, in cooperation with INAF astronomer of Arcetri (Firenze, Italy), focused on the telescopic observations of the inter-stellar electromagnetic radiations.

The innovative Quadratic Spheric 3-D Detector turns out to be optimal

for Optical and/or Radio Telescopes, Optical and Optoelectronic Sensors, Gravitational Wave 2nd order detectors.

10401-37, Session 8

4MOST optical system: presentation and design details

Nicolas Azais, Samuel C. Barden, Gregory A. Smith, Steffen Frey, Leibniz-Institut für Astrophysik Potsdam (Germany); Damien J. Jones, Prime Optics (Australia); Bernard-Alexis Delabre, European Southern Observatory (Germany)

The 4-meter Multi-Object Spectroscopic Telescope (4MOST) is a wide-field, high-multiplex spectroscopic survey facility under development for the Visible and Infrared Survey Telescope for Astronomy (VISTA) 4 meter telescope of the European Southern Observatory (ESO) at Cerro Paranal. The objective of 4MOST is to enable the simultaneous spectroscopy of a significant number of targets (>1600) within a field of view with of 2.5 degree diameter allowing high-efficiency all-sky spectroscopic surveys. A wide field corrector (WFC) is needed to couple targets across a field diameter of 2.5 degrees with the exit pupil concentric with the spherical focal surface where ~2400 fibres are configured by a fibre positioner (AESOP). It will correct optical aberrations of the primary (M1) and secondary (M2) VISTA optics across the field of view for optimal fibre optic coupling and active optics wavefront sensing, provide a well-defined and stable focal surface to which the acquisition/guiding sensors, wavefront sensors, and fibre positioner are interfaced, and compensate for the effects of atmospheric dispersion allowing good chromatic coupling of stellar images with the fibre optics over a wide range of telescope zenith angles. The fibres feed three spectrographs; two thirds of the fibres will go to two spectrographs with resolution R~4000-7500 and the remaining 812 fibres to a spectrograph with resolution R~18000-21000. The three spectrographs are fixed-configuration with three channels each. We will present the 4MOST optical system along with optical simulation of subsystems.

10401-38, Session 8

Voltage linear transformation circuit design

Lucas R. W. Sanchez, Randy P. Scott, Ryan J. Luder, Moon-Seob Jin, The Univ. of Arizona (United States); Michael Hart, The Univ. of Arizona (United States)

Many engineering projects require automated control of analog voltages over a specified range. We have developed a computer interface comprising of custom hardware and MATLAB code to provide real-time control at kilohertz rates. The hardware uses an op amp cascade to linearly shift and scale a voltage range, with the back end of the circuit allowing easy modification to accommodate any required linear transformation. In adaptive optics applications, the design is suitable to drive a range of different types deformable mirrors. Our original motivation and application was to control an Optics in Motion fast steering mirror (FSM) which requires the customer to devise a unique interface to supply voltages to the mirror controller in order to set the mirror's angular deflection.

The FSM is in an optical servo loop with a wavefront sensor, which controls the dynamic behavior of the mirror's deflection. The code reads in data from the wavefront sensor and fits a plane. The slope of the plane is then converted into its corresponding angular deflection. The OIM mirror provides +- 3 degree optical angular deflection for a +- 10 V voltage swing. Voltages are applied to the mirror via a National Instruments digital-to-analog converter followed by the op amp cascade circuit. This system will eventually be integrated into our Wide-Field Imaging Adaptive Optics Testbed. The plans and the code for our interface solution are freely available to the community, as well as our method to design virtually any level shifting circuit.

10401-45, Session 8

Design of the telescope controller rejecting ground-based disturbance based on data fusion

Qiang Wang, YongMei Huang, Dong He, Xiang Liu, Jin-ying Li, ShengPing Du, Yu Jiang, Institute of Optics and Electronics, Chinese Academy of Sciences (China)

In this paper, a telescope controller design method rejecting ground base disturbance based on data fusion is proposed. Telescope systems usually suffer some uncertain disturbances. One of these is the disturbance come from ground base. Unlike the other disturbances, such as wind load, friction etc. The ground base disturbance can hardly be rejected by improve the stiffness of control system. This paper gives the measurement of the influence to the telescope coming from ground base disturbance. The property of ground base disturbance to the control system is concluded. Then, a control method is proposed. Finally the experiment result is proposed.

10401-39, Session 9

Active optics as enabling technology for future large missions: current developments for astronomy and Earth observation at ESA

Pascal Hallibert, European Space Research and Technology Ctr. (Netherlands)

In recent years, a trend for higher resolution has increased the entrance apertures of future optical payloads for both Astronomy and Earth Observation most demanding applications, resulting in new opto-mechanical challenges for future systems based on either monolithic or segmented large primary mirrors. Whether easing feasibility and schedule impact of tight manufacturing and integration constraints or correcting mission-critical in-orbit and commissioning effects, Active Optics constitutes an enabling technology for future large optical space instruments at ESA and needs to reach the necessary maturity in time for future mission selection and implementation. We present here a complete updated overview of our current R&D activities in this field, ranging from deformable space-compatible components to full correction chains including wavefront sensing as well as control and correction algorithms. We share as well our perspectives on the way-forward to technological maturity and implementation within future missions.

10401-40, Session 9

Atomic layer deposition and etching methods for far ultraviolet aluminum mirrors

John Hennessy, Jet Propulsion Lab. (United States); Christopher S. Moore, Univ. of Colorado Boulder (United States); Kunjithapatham Balasubramanian, April D. Jewell, Shouleh Nikzad, Jet Propulsion Lab. (United States); Kevin C. France, Univ. of Colorado Boulder (United States)

High performance Al mirrors at FUV wavelengths require the use of transparent dielectric materials as a protective coating to prevent oxidation. Reducing the thickness of this protective layer can result in additional performance gains by minimizing absorption losses, and provides a path toward high Al reflectance in the challenging wavelength range of 90 to 110 nm. We have pursued the development of new atomic layer deposition processes (ALD) for the metal fluoride materials of MgF_2, AlF_3 and LiF. Using an anhydrous HF based approach, these films can be deposited at the

low temperatures required for large area surface-finished optics and can be incorporated onto polymeric diffraction gratings. We also report on the development and application of an atomic layer etching (ALE) procedure implemented to controllably etch native aluminum oxide. Our ALE process utilizes the same chemistry used in the ALD of AlF3 thin films, allowing a combination of high performance evaporated Al layers and ultrathin ALD encapsulation without requiring vacuum transfer or shared-chamber deposition systems. Progress in demonstrating the scalability of this approach, as well as the environmental stability of ALD/ALE Al mirrors will be discussed in the context of possible future applications for NASA LUVOIR and HabEx mission concepts.

10401-41, Session 9

A dense grid of narrow bandpass steep edge filters for the JST/T250 telescope: summary of results

Ulf Brauneck, SCHOTT Suisse SA (Switzerland); Ruediger Sprengard, SCHOTT AG (Germany); Sébastien Bourquin, SCHOTT Suisse SA (Switzerland); Antonio Marín-Franch, Ctr. de Estudios de Física del Cosmos de Aragón (Spain)

On the Javalambre mountain the Centro de Estudios de Fisica del Cosmos de Aragon (CEFCA) has setup a new wide field telescope, the JST/T250: a 2.55m telescope with a plate scale of 22.67" /mm and a 3° diameter field of view.

To conduct a photometric sky survey a 14 CCD large format mosaic camera is used together with filter trays each containing 14 filters of 101.7x96.5mm.

For this project SCHOTT manufactured 56 specially designed steep edged bandpass interference filters which were recently completed. The filter set consists of bandpass filters in the range between 348,5nm and 910nm and a longpass filter at 913nm. Most of the filters have a FWHM of 14.5nm and a blocking from 250 to 1050nm with OD5.

Absorptive color glass substrates in combination with interference filters were used to minimize the residual reflection to avoid ghost images. Inspite of the absorptive elements, the filters show maximum possible transmissions achieved by magnetron sputtered filter coatings. The most important requirement for the continuous photometric survey was the tight tolerancing of the central wavelengths and FWHM of the filters. This insures that each bandpass has a defined overlap with its neighbors. In addition the blocking of the filters is better than OD5 in the range 250–1050nm. A high image quality required a low transmitted wavefront error (<?/8 locally respectively <?/2 globally) which was achieved even by combining 2 or 3 substrates. We report on the spectral and interferometrical results measured on the whole set of filters.

10401-42, Session 9

The study of optimization on process parameters of high-accuracy computerized numerical control polishing

Wei-Ren Huang, Shih-Pu Huang, Tsung-Yueh Tsai, National Taiwan Univ. (Taiwan); Yi-Chun Lin, National Taiwan Univ. (Taiwan); Zong-Ru Yu, Instrument Technology Research Ctr., National Applied Research Labs. (Taiwan); Ching-Hsiang Kuo, Instrument Technology Research Ctr., National Applied Research Labs (Taiwan); Wei-Yao Hsu, Instrument Technology Research Ctr., National Applied Research Labs. (Taiwan); Hong-Tsu Young, National Taiwan Univ. (Taiwan)

Spherical lenses lead to forming spherical aberration and reducing the optical performance. Consequently, in practice optical system shall apply a combination of spherical lenses for aberration correction. Thus, the volume of the optical system increased. For modern optical system, aspherical lenses have been widely used because of its high optical performance with less optical components. However, aspherical surfaces cannot be fabricated by traditional full aperture polishing process due to its various curvature. Sub-aperture computer numerical control (CNC) polishing is adopted for aspherical surface fabrication in recent years. By using CNC polishing process, mid-spatial frequency (MSF) error is normally accompanied during this process. And the MSF surface texture of optics will decrease the optical performance for high precision optical system, especially for short-wavelength applications. Based on a bonnet polishing CNC machine, this study focuses on the relationship between MSF surface texture and CNC polishing parameters, which include feed rate, head speed, path pitch and path direction. The power spectral density (PSD) analysis is used to judge the MSF level caused by those polishing parameters. This study try to find out certain of polishing parameters without MSF surface texture, and the test results show that controlling the removal depth of single polishing path, through the feed rate, can efficiently reduce the MSF error. To verify the optimal polishing parameters, we divided a correction polishing process to several polishing runs with different direction polishing paths. Compare to one shot polishing run, multi-direction path polishing plan could producing better surface quality on the optics.

10401-56, Session 9

Lithographic manufacturing of adaptive optics components

R Phillip Scott, Michael Hart, Tom Milster, Madison Jean, Ryan Bronson, Lauren Schatz, Lee Johnson, University of Arizona (United States)

Adaptive optics systems and their laboratory test environments call for a number of unusual optical components. Examples include lenslet arrays, pyramids, and Kolmogorov phase screens. Because of their specialized application, the availability of these parts is generally limited, with high cost and long lead time, which can also significantly drive optical system design. These concerns can be alleviated by a fast and inexpensive method of optical fabrication. To that end, we are exploring lithographic techniques to manufacture three different custom elements. We report results from a number of prototype devices including 1, 2, and 3 wave Multiple Order Diffractive (MOD) lenslet arrays with 0.75 mm pitch, phase screens with near Kolmogorov structure functions with a Fried length r0 below 1 mm, and a diffractive pyramid that is smaller, lighter, and more easily manufactured than glass versions presently used in pyramid wavefront sensors. We describe how these components can be produced within the limited dynamic range of the lithographic process, and with a rapid prototyping and manufacturing cycle. We discuss exploratory manufacturing methods, including replication, and potential observing techniques enabled by the ready availability of custom components.

Conference 10402: Earth Observing Systems XXII

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Sunday - Thursday 6 –10 August 2017

Part of Proceedings of SPIE Vol. 10402 Earth Observing Systems XXII

10402-1, Session 1

A status update on EUMETSAT programmes and plans

K. Dieter Klaes, EUMETSAT (Germany)

The mandate of EUMETSAT is providing space observations for operational meteorology and climate monitoring. EUMETSAT operates geostationary and sun-synchronous polar orbiting satellites through mandatory programmes. Optional programmes provide further observations for altimetry and oceanography. EUMETSAT makes available data from partner agencies' satellites to the user community through third party programmes. The current fleet of operational geostationary spacecraft comprises Meteosat-7, which is the last satellite of the first generation and the four satellites of the Second Generation of Meteosat (MSG), Meteosat-8, Meteosat-9, Meteosat-10 and Meteosat-11. The EUMETSAT Polar System (EPS) provides data from sun-synchronous polar orbit with currently two satellites: Metop-B, the second of a series of three satellites, launched in September 2012 and currently the prime satellite, and Metop-A, the first of the series, in orbit since October 2006. These satellites are part of the Initial Joint Polar System (IJPS) together with the US. EUMETSAT's first optional programme continues to provide data from the Jason-2 satellite since summer 2008. The follow on satellite Jason-3 was successfully launched and commissioned in 2016 and is now providing the reference altimetry mission. To assure continuity in the mandatory missions the development of Meteosat Third Generation (MTG) is ongoing. The EPS-SG EPS Second generation) programme is now under full development. In the frame of the Copernicus Programme EUMETSAT operates the Sentinel-3A satellite, which was launched in February 2016. EUMETSAT is providing operational marine products from the Sentinel-3A satellite. Sentinel-3B, a second satellite, is scheduled to be launched end of 2017.

10402-2, Session 1

MTG-IRS: From raw measurements to calibrated radiances

Dorothee Coppens, Bertrand Theodore, K. Dieter Klaes, EUMETSAT (Germany); Stefano Gigli, European Organisation for the Exploitation of Meteorological Satellites (Germany)

The Meteosat Third Generation (MTG) series of future European geostationary meteorological satellites consists of two types of satellites, the imaging satellites (MTG-I) and the sounding satellites (MTG-S). The Infrared Sounder (IRS) is one of the two instruments hosted on board the MTG-S satellites. The scope of the IRS mission is to provide the user community with information on time evolution of humidity and temperature distribution, as function of latitude, longitude and altitude. Regarding time and space sampling, the entire Earth disk will be covered, with particular focus on Europe, which will be revisited every 30 minutes.

This paper presents a synthetic overview of the mission and the instrument, and will go through the level 1 processing chain which takes instrument raw data to obtain spectrally and radiometrically calibrated and geolocalised radiances, called level 1b products. A discussion will be presented around the radiances uniformisation in space, spectral range and time and its impact for the users community.

10402-3, Session 1

The EarthCARE mission BBR instrument: Ground testing of radiometric performance

Martin E. Caldwell, William Grainger, Martin S. Whalley, Anthony K. Ward, David Parker, John Delderfield, STFC Rutherford Appleton Lab. (United Kingdom); David Spilling, Nigel Wright, Thales Alenia Space UK Ltd. (United Kingdom); Evangelos Theocharous, National Physical Lab. (United Kingdom); Grant J. Munro, Oliver Poynz Wright, Matthew Hampson, David Forster, ESR Technology Ltd. (United Kingdom)

In ESA's EarthCARE mission the BBR (broad band radiometer) has the role of measuring the net Earth radiance (i.e. total reflected-solar and thermally-emitted radiances), from the same scene as viewed by the other instruments (aerosol lidar, cloud radar and spectral imager). For the methods to measure total Earth radiance the BBR is based on the heritage of previous Earth Radiation Budget (ERB) instruments, and the calibration of this type of sensor is technically similar to other EO instruments that measure in the thermal-IR, but with added challenges: (1) the thermal-IR has to have a much wider spectral range than normal thermal-IR channels, for the whole Earth-emission spectrum of around 4 to 50μm; and (2) the reflected-solar channel must also have a broad response, of around 0.3 to 4μm. Furthermore, this solar channel must be measured on the same radiometric calibration as the thermal channel, and in BBR this is achieved using the same radiometer for both channels. The radiometer has a very broad-band response of 0.3 to 50μm to cover both ranges, with a switchable 4μm short-pass cut-off filter used to separate the channels. The on-ground measurements required for the calibration of absolute responsivity in these channels are described: in the thermal-IR channel this is done using a calibrated black-body test source; and in the solar channel it is by means of a narrow-band (laser) measurement and reference radiometer. A calibration of relative spectral response is also made across this wide range, for the purpose of linking the two channels and converting the narrow-band solar channel measurements to broad-band.

10402-4, Session 1

Focal plane subsystem design and performance for atmospheric chemistry from geostationary orbit tropospheric emissions monitoring of pollution

Angelo S. Gilmore, Robert H. Philbrick, Josh Funderburg, Ball Aerospace & Technologies Corp. (United States)

Diurnal measurements of pollutants are enabled from a satellite in a geostationary orbit containing an imaging spectrometer encompassing the wavelength ranges of 290 - 490 nm and 540 - 740 nm. As the first of NASA's Earth Venture missions, the Tropospheric Emissions: Monitoring of Pollution (TEMPO) program will utilize this instrument to measure hourly air quality over a large portion of North America. The focal plane subsystem (FPS) contains two custom designed and critically aligned full frame transfer charge coupled devices (active area: 1028 x 2048, 18um) within a focal plane array package designed for radiation tolerance and space charging rejection. In addition, the FPS contains custom distributed focal plane electronics that provide all necessary clocks and biases to the sensors, receive all analog data from the sensors and perform 14 bit analog to digital conversion for upstream processing. Finally, the FPS encompasses custom low noise cables connecting the focal plane array and associated electronics. This paper discusses the design and performance of this novel focal plane subsystem with particular emphasis on the optical performance achieved including alignment, quantum efficiency, and modulation transfer function.

10402-5, Session 1

Landsat 9 - OLI 2 focal plane subsystem - design, performance, and status

Kevin J. Malone, Ronald J Schrein, M. Scott Bradley, Ronda Irwin, Barry N Berdanier, Eric Donley, Ball Aerospace & Technologies Corp. (United States)

The Landsat 9 mission will continue the legacy of Earth remote sensing that started in 1972. The Operational Land Imager 2 (OLI-2) is one of two instruments on the Landsat 9 satellite. The OLI-2 instrument is essentially a copy of the OLI instrument flying on Landsat 8. A key element of the OLI 2 instrument is the focal plane subsystem or FPS which consists of the focal plane array (FPA), the focal plane electronics (FPE) box and low-thermal conductivity cables. This paper presents design details of the OLI-2 FPS.

The FPA contains 14 critically-aligned focal plane modules (FPM). Each module contains 6 visible/near-IR detector arrays and three short-wave infrared arrays. A complex multi-spectral optical filter is contained in each module. Redundant pixels for each array provide exceptional operability. Spare detector modules from OLI were re-characterized after six years of storage. Radiometric test results will be presented and compared with data recorded in 2010.

Thermal, optical, mechanical and structural features of the FPA will be described. Special attention is paid to the thermal design of the FPA since thermal stability is crucial to ensuring low-noise and low-drift operation of the detectors which operate at -63°C.

The OLI-2 FPE provides power, timing and control to the focal plane modules. It also digitizes the video data and formats it for the solid-state recorder. Design improvements to the FPA-FPE cables will be discussed and characterization data will be presented. The paper will conclude with the status of the flight hardware assembly and testing.

10402-6, Session 1

Mission studies on constellation of LEO satellites with remote-sensing and communication payloads

Chia-Ray Chen, National Space Organization (Taiwan)

Revisiting time and global coverage are two major requirements for most of the remote sensing satellites. Constellation of satellites can get the benefit of short revisit time and global coverage. Typically, remote sensing satellites prefer to choose Sun Synchronous Orbit (SSO) because of fixed revisiting time and Sun beta angle. The system design and mission operation will be simple and straightforward. However, if we focus on providing remote sensing and communication services for low latitude countries, Sun Synchronous Orbit will not be the best choice because we need more satellites to cover the communication service gap in low latitude region. Sometimes the design drivers for remote sensing payloads are conflicted with the communication payloads. For example, lower orbit altitude is better for remote sensing payload performance, but the communication service zone will be smaller and we need more satellites to provide all time communication service. The current studies focus on how to provide remote sensing and communication services for low latitude countries. A cost effective approach for the mission, i.e. constellation of microsatellites, will be evaluated in this paper.

10402-7, Session 2

Pathway to future sustainable land imaging: The compact hyperspectral prism spectrometer

Thomas U. Kampe, William S. Good, Ball Aerospace & Technologies Corp. (United States)

NASA's Sustainable Land Imaging (SLI) program, managed through the Earth Science Technology Office, aims to develop technologies that will provide future Landsat-like measurements. SLI aims to develop a new generation of smaller, more capable, less costly payloads that meet or exceed current imaging capabilities. One projects funded by this program is Ball's Compact Hyperspectral Prism Spectrometer (CHPS), a visible-to-shortwave imaging spectrometer that provides legacy Landsat data products as well as hyperspectral coverage suitable for a broad range of land science products. CHPS exhibits extremely low straylight and accommodates full aperture, full optical path calibration needed to ensure the high radiometric accuracy demanded by SLI measurement objectives. Low polarization sensitivity in visible to near-infrared bands facilitates coastal water science as first demonstrated the exceptional performance of the Operational Land Imager. Our goal is to mature CHPS imaging spectrometer technology for infusion into the SLI program. Our efforts build on technology development initiated by Ball IRAD investment, and includes laboratory and airborne demonstration, data distribution to science collaborators, and maturation of technology for spaceborne demonstration. CHPS is a three year program with expected exiting technology readiness of TRL-6. The 2013 NRC report Landsat and Beyond: Sustaining and Enhancing the Nations Land Imaging Program recommended that the nation should "maintain a sustained, space-based, land-imaging program, while ensuring the continuity of 42-years of multispectral information." We are confident that CHPS provides a path to achieve this goal while enabling new science measurements while significantly reducing the cost, size, and volume of the VSWIR instrument.

10402-8, Session 2

Design and development of the CubeSat Infrared Atmospheric Sounder (CIRAS)

Thomas S. Pagano, Jet Propulsion Lab. (United States)

The CubeSat Infrared Atmospheric Sounder (CIRAS) will measure upwelling infrared radiation of the Earth in the MWIR region of the spectrum (4.08-5.13μm) with a spatial resolution of 13.5 km (3km in zoom mode) from space on a CubeSat. The observed radiances can be assimilated into weather forecast models and be used to retrieve lower tropospheric temperature and water vapor for climate studies. Multiple units can be flown to improve temporal coverage or in formation to provide new data products including 3D motion vector winds. The CIRAS is currently under development at NASA JPL under the NASA In-space Validation of Earth Science Technologies (InVEST) and scheduled for launch in 2019.

CIRAS incorporates three new instrument technologies. The first is a 2D array of High Operating Temperature Barrier Infrared Detector (HOT-BIRD) material, selected for its high uniformity, low cost, low noise and higher operating temperatures than traditional materials. The detectors are hybridized to a commercial ROIC and commercial camera electronics. The second technology is an MWIR Grating Spectrometer (MGS) designed to provide imaging spectroscopy for atmospheric sounding in a CubeSat volume. The MGS will be built at Ball Aerospace, has no moving parts, and is based on heritage spectrometers developed under the NASA Instrument Incubator Program (IIP) including the SIRAS-G. The third technology is an infrared blackbody developed using Black Silicon developed at JPL. Black silicon has a very high emissivity (<0.2%) over a broad spectral range including the CIRAS band. JPL will develop the mechanical, electronic and thermal subsystems for CIRAS. The spacecraft will be developed by Blue Canyon Technologies (BCT). The integrated system will be a complete 6U CubeSat capable of measuring temperature and water vapor profiles with good lower tropospheric sensitivity. This paper will discuss the design requirements for CIRAS and the current state of development of the instrument, including recent fabrication results for certain subsystems.

10402-9, Session 2

Snow and water imaging spectrometer (SWIS): A CubeSat-compatible instrument

Holly A. Bender, Justin M. Haag, Pantazis Mouroulis, Jet

Propulsion Lab. (United States); Christopher Smith, Sierra Lobo, Inc. (United States)

The Snow and Water Imaging Spectrometer (SWIS) is a fast, high-uniformity, low-polarization sensitivity imaging spectrometer and telescope system designed for integration on a 6U CubeSat platform. Operating in the 350-1700 nm spectral region with 5.7 nm sampling, SWIS is capable of simultaneously addressing the demanding needs of coastal ocean science and snow and ice monitoring. While the SWIS instrument benefits from a rich heritage of imaging spectrometer development at the Jet Propulsion Lab, certain adaptations are required to stay within CubeSat resources. New key technologies that facilitate the development of this instrument include a linear variable anti-reflection (LVAR) detector coating for stray light management, and a single drive on-board calibration mechanism utilizing a transmissive diffuser for solar calibration. We provide an overview of the optomechanical assembly, alignment and performance of the SWIS instrument.

10402-10, Session 2

Design and qualification of the STREEGO multispectral payload

Massimiliano Rossi, Luigina Arcangeli, Giovanni Bianucci, Ruben Mazzoleni, Sebastiano Spinelli, Marco Terraneo, Fabio Emilio Zocchi, Media Lario Technologies S.r.l. (Italy); Giuseppe Capuano, Giuseppe Formicola, Pasquale Longobardi, Techno System Developments S.r.l. (Italy); Luca Maresi, Matteo Taccola, European Space Research and Technology Ctr. (Netherlands)

The increasing number of Earth Observation missions launched over the last decade has fostered the development of a large number of satellite instruments delivering rich imagery supporting ever growing and expanding applications. Recent advances in electronics, optical manufacturing and remote sensing are now enabling smaller instruments that are at the basis of new mission concepts that can affordably be extended to satellite constellations for improved temporal resolution.

We present the development of STREEGO, an innovative multispectral optical payload for Earth Observation from microsatellites. STREEGO is an athermal, fully reflective telescope based on a three mirror anastigmat optical design with 200 mm aperture, 1.2 m focal length, 2° FoV, and 20 kg mass, including electronics. Leveraging on a large format two-dimensional CMOS sensor with a pixel size of 5.5 μm and 9-band multispectral filter, STREEGO delivers a nominal modulation transfer function (MTF) of 64% at Nyquist frequency and a ground sampling distance of 2.75 m from an orbit of 600 km. Extensive straylight and tolerancing analyses and a worst-case thermal model ensure optimal image quality under operational conditions. A fully functional Engineering Model of STREEGO has been built and tested in laboratory with excellent results, such as wavefront error of 43 nm RMS, MTF better than 30% at Nyquist, and 1% linearity. An environmental test campaign has been planned to complete the qualification tests. The design of the instrument and the results of the characterization and qualification tests are presented in details.

10402-11, Session 2

Technical and cost advantages of silicon-carbide telescopes for small-satellite imaging applications

Keith Kasunic, Optical Systems Group LLC (United States); Dave Aikens, Savvy Optics Corp. (United States); Dean Szwabowski, Chip Ragan, Flemming Tinker, Aperture Optical Sciences Inc. (United States)

Small satellites (“SmallSats”) are a growing segment of the Earth imaging market. Designed to be relatively low cost and with performance tailored to specific end-use applications, they are driving changes in optical telescope assembly (OTA) requirements.

OTAs implemented in silicon carbide (SiC) provide performance advantages for space applications but have been predominately limited to large programs. A new generation of lightweight and thermally-stable designs is becoming commercially available, expanding the application of SiC to small satellites. This paper reviews the cost and technical benefits of an OTA designed using SiC for small satellite platforms.

Taking into account faceplate fabrication quilting and surface distortion after gravity release, an optimized open-back SiC design with a lightweighting of 70% for a 125-mm class primary mirror has an estimated area density of 2.8 kg/m2 and an aspect ratio of 40:1. In addition, the thermally-induced surface error of such optimized designs is estimated at ?/150 RMS per watt of absorbed power. Cost benefits of SiC include reductions in launch mass, thermal-management infrastructure, and manufacturing time based on allowable assembly tolerances.

10402-12, Session 3

MOS+P: A combined spectrometer and polarimeter optimized for ocean color

William S. Good, Rainer Illing, Derek Sabatke, Ball Aerospace & Technologies Corp. (United States); Nicholas Tufillaro, Oregon State Univ. (United States)

A significant challenge for ocean color retrievals is atmospheric correction due to the strong atmospheric reflectance and relatively weak ocean color signal. Aerosol measurements coincident with spectral radiance can improve ocean color retrievals by providing appropriate inputs to atmospheric models for aerosol loading and type. Polarimeters provide those aerosol measurements but often are limited in the number of spectral bands and require a separate instrument from the spectral radiance sensor. The Multi-slit Optimized Spectrometer and Polarimeter, MOS+P, includes three linear polarization channels and an un-polarized channel that are all imaged onto a single focal plane. This compact instrument design exhibits low stray light and provides simultaneous measurements of scene polarization across the visible to NIR spectral band. Results from a laboratory characterization will be compared to modeled performance to determine the linear polarization sensitivity of each pixel. This sensitivity can be used to determine scene polarization sensitivity which can provide valuable inputs for atmospheric retrieval models. The MOS+P airborne instrument was flown for NASA in the 2016 KORUS-AQ and OC campaigns based in South Korea. Initial results of measured scene polarizations over the Yellow Sea and Sea of Japan and a comparison of atmospheric retrievals with and without the polarization channels will be presented.

10402-13, Session 3

Radiometric and spectral stray light correction for the portable remote imaging spectrometer (PRISM) coastal ocean sensor

Justin M. Haag, Byron E. Van Gorp, Pantazis Mouroulis, David R. Thompson, Jet Propulsion Lab. (United States)

The airborne Portable Remote Imaging Spectrometer (PRISM) instrument is based on a fast (F/1.8) Dyson spectrometer operating at 350-1050 nm and a two-mirror telescope combined with a Teledyne HyViSI 6604A detector array. Raw PRISM data contain electronic and optical artifacts that must be removed prior to radiometric calibration. We provide an overview of the process transforming raw digital numbers to calibrated radiance values. Electronic panel artifacts are first corrected using empirical relationships developed from laboratory data. The instrument spectral response functions (SRF) are reconstructed using a measurement-based optimization technique. Removal of SRF effects from the data improves retrieval of true spectra, particularly in the typically low-signal near-ultraviolet and near-infrared regions. As a final step, radiometric calibration is performed using

corrected measurements of an object of known radiance. Implementation of the complete calibration procedure maximizes data quality in preparation for subsequent processing steps, such as atmospheric removal and spectral signature classification.

10402-14, Session 3

High altitude hyperspectral remote sensing in the thermal infrared: recent instrument improvements

William R. Johnson, Simon Hook, Jet Propulsion Lab. (United States)

Spectroscopy has been a key part of this scientific exploration because of its ability to remotely determine elemental and mineralogical composition. Mineralogy in particular is critical, because the presence and configuration of minerals within a geologic setting can reveal environmental conditions (e.g., temperature, pressure) at the time of formation and/or evolution. Spectroscopy allows the discrimination of minerals such as olivine, pyroxene, plagioclase, quartz, clays, sulfates, and carbonates. For example, mineralogy can provide key constraints on processes such as internal differentiation and alteration by water. Many key gas species such as methane, ammonia, sulfur, etc. also have vibrational bands which show up in the thermal infrared spectrum above the background response.

The Hyperspectral thermal emission spectrometer (HyTES) has transitioned to NASA's ER-2 platform. We discuss the transition as well as specific challenges faced with installation, operation and calibration. For example, the sensor is outside the pressurized zone of the ER-2 to eliminate a 2nd window. We discuss the large temperature swings and how this affects the calibration (performed pre and post flight on the ground). HyTES uses sensing technology based on the quantum well infrared photodetector (QWIP). The sensor is currently transitioning to a new complementary barrier infrared photodetector (CBIRD) which has a slightly longer wave cut-off and increased sensitivity. We expect this to expand the wide application base of the instrument.

10402-15, Session 3

Imaging spectroscopy using embedded diffractive optical arrays

Michele Hinnrichs, Bradford R. Hinnrichs, Pacific Advanced Technology, Inc. (United States)

We have developed a very small robust infrared imaging spectrometer using and area array of diffractive optical elements embedded in the cold-shield of the sensor and actuated with a piezo motor. This approach allows rapid imaging spectroscopy with multiple spectral images collected and processed each frame of the camera.

This paper will present our optical mechanical design approach including the gray scale photolithographic technique for the fabrication of the diffractive optical elements. And show results of the images collected and processed in real-time on target such as hydrocarbon gases.

The diffractive optical elements are blazed gratings where each lenslet in the array in tuned for a different spectral bandpass. The lenslets are configured in an area array placed a few millimeters above the focal plane and embedded in the cold-shield to reduce the background signal.

We have developed various systems using a different number of lenslets in the area array. Depending on the size of the focal plane and the diameter of the lenslet array will determine the spatial resolution. A 2 x 2 lenslet array will image four different spectral images of the scene each frame and when coupled with a 512 x 512 focal plane array will give spatial resolution of 256 x 256 pixel each spectral image. Another system that we developed uses a 4 x 4 lenslet array on a 1024 x 1024 pixel element focal plane array which gives 16 spectral images of 256 x 256 pixel resolution each frame.

10402-16, Session 3

Assembly and test of a visible and near-infrared imaging spectrometer with a Shack-Hartmann wavefront sensor

Jun Ho Lee, Sung Lyoung Hwang, Kongju National Univ. (Korea, Republic of); Jin Suk Hong, Young Soo Kim, Hanwha Systems Co., Ltd. (Korea, Republic of); Yeon Soo Kim, Hyun Sook Kim, Agency for Defense Development (Korea, Republic of)

We report an assembly procedure and performance evaluation of a visible and near-infrared spectrometer in the region of 400 ~ 900 nm in wavelength, which is later to be combined with a fore-optics i.e. a telescope to form a f/2.5 imaging spectrometer with a field of view of ±7.68°. The detector at the final image plane is a 640?480 pixel charge-coupled device of 24?24 ?m pitch. The spectrometer is an Offner relay configuration consisting of two concentric spherical mirrors, the secondary of which is replaced by a convex grating mirror. A double pass test method with an interferometer is mostly applied in assembly procedures of precision optics but was excluded in our study due to large residual wavefront error (WFE) in optics design i.e. 210nm (0.35? at 600 nm) in root mean squared (RMS). This results in a single-path test method with a Shack-Hartmann sensor. The final assembly was tested to have the RMS WFE increasement of less than 90 nm over the entire field of view, the keystone 0.08 pixel, the smile 0.13 pixel and the spectral resolution 4.32 nm. During the procedure, we confirmed the validity of the use of the Shack-Hartmann as an alignment monitor in the assembly of an Offner-like spectrometer.

10402-17, Session 3

Curved focal plane array for hyperspectral imaging system

Mohammad A. Saleh, Corning Incorporated (United States)

Prior work has demonstrated that curved focal plan arrays (FPA) enable lenses for traditional cameras with improved image quality and fewer elements as compared to existing flat image planes. There is an increasing interest in the development of curved focal planes for other imaging applications using a variety of surface contours. In this work, the potential performance improvements of a hyperspectral imaging system (HSI) with a curved FPA are explored using Corning's existing hyperspectral designs. We evaluated the effect of curved FPAs for spectrometers from the free-space and monolithic Offner class as well as the Dyson form. While these designs are already optimized with aspheric mirrors, the addition of the curved FPA provided additional performance improvements.

Surface types considered for the FPA include aspheric, toroidal, anamorphic and free-forms. The surfaces providing optimum performance offer guidelines for future curved FPA development. We found that multiple design parameters, such as size, weight, f-number, field of view and relative cost can be improved compared with current state-of-the-art flat FPAs. A free-space Offner spectrometer, for example, can be reduced 30% in size, or improved by 20% in f-number. Our initial findings indicate that while a curved FPA improves instrument performance, the aspheric mirror surfaces cannot be removed from the spectrometer designs since they compensate for aberrations that are not diminished by the curved FPA.

10402-18, Session 3

Imaging gratings: Technology and applications for spectrometers

Peter Triebel, Tobias Moeller, Carl Zeiss Microscopy GmbH (Germany); Torsten Diehl, Carl Zeiss Spectroscopy GmbH (Germany); Alexandre Gatto, Alexander Pesch, Lars Erdmann, Matthias Burkhardt, Alexander Kalies, Carl Zeiss Jena GmbH (Germany)

For imaging spectrometers beside the polarization sensitivity and efficiency the imaging quality of the diffraction grating is essential. Low aberration imaging quality of the grating is required not to limit the overall imaging quality of the instrument. The wavefront aberration of an optical grating is a combination of the substrate wavefront and the grating wavefront. During the manufacturing process of the grating substrate different processes can be applied in order to minimize the wavefront aberrations. The imaging performance of the grating is also optimized due to the recording setup of the holography and a special technique to apply blazed profiles also in photoresist of curved substrates.

This technology of holographically manufactured gratings is used for transmission and reflection gratings on different types of substrates like prisms, convex and concave spherical and aspherical surface shapes, free-form elements. All the manufactured gratings are monolithic and can be coated with high reflection and anti-reflection coatings. Prism substrates were used to manufacture monolithic GRISM elements for the UV to IR spectral range preferably working in transmission. Besides of transmission gratings, numerous spectrometer setups (e.g. Offner, Rowland circle, Czerny-Turner system layout) working on the optical design principles of reflection gratings. The present approach can be applied to manufacture high quality reflection gratings for the EUV to the IR.

In this paper we report our latest results on manufacturing lowest wavefront aberration gratings based on holographic processes in order to enable at least diffraction limited complex spectrometric setups over certain wavelength ranges. Beside the results of low aberration gratings the latest achievements on improving efficiency together with less polarization sensitivity and multi-band performance of diffractive gratings will be shown.

10402-19, Session 4

Analysis of a commercial small unmanned airborne system (sUAS) in support of the Radiometric Calibration Test Site (RadCaTS) at Railroad Valley

Jeffrey S. Czapla-Myers, Nikolaus J. Anderson, College of Optical Sciences, The Univ. of Arizona (United States)

The Radiometric Calibration Test Site (RadCaTS) is an automated facility developed by the Remote Sensing Group (RSG) at the University of Arizona to provide radiometric calibration data for airborne and satellite sensors. RadCaTS uses stationary ground-viewing radiometers (GVRs) to spatially sample the surface reflectance of the site. The number and location of the GVRs is based on previous spatial, spectral, and temporal analyses of Railroad Valley. With the increase in high-resolution satellite sensors, there is renewed interest in examining the spatial uniformity the 1-km2 RadCaTS area at scales smaller than a typical 30-m sensor. RadCaTS is one of the four instrumented sites currently in the CEOS WGCV Radiometric Calibration Network (RadCalNet), which aims to harmonize the post-launch radiometric calibration of satellite sensors through the use of a global network of automated calibration sites. A better understanding of the RadCaTS spatial uniformity as a function of pixel size will also benefit the RadCalNet work. RSG has recently acquired a commercially-available small unmanned airborne system (sUAS) system, with which preliminary spatial homogeneity measurements of the 1-km2 RadCaTS area were made. This work describes an initial assessment of the airborne platform and integrated camera for spatial studies of RadCaTS using data that were collected in 2016 and 2017.

10402-20, Session 4

Calibration and use of an ultra-portable field transfer radiometer for automated vicarious calibration

Kurtis J. Thome, NASA Goddard Space Flight Ctr. (United States); Jeffrey S. Czapla-Myers, The Univ. of Arizona (United States); Brian N. Wenny, Science Systems and Applications, Inc. (United States); Nikolaus J. Anderson, The Univ. of Arizona (United States)

A small portable transfer radiometer has been developed as part of an effort to ensure the quality of upwelling radiance at automated test sites used for vicarious calibration in the solar reflective. The test sites, such as the one located at Railroad Valley, are used to predict top-of-atmosphere reflectance relying on ground-based measurements of the atmosphere and surface. The portable transfer radiometer is designed for one-person operation for on-site field calibration of the instrumentation used to determine ground-leaving radiance. The current work describes the laboratory-based calibration of the transfer radiometer highlighting the expected accuracy and SI-traceability. Results from recent field deployments of the transfer radiometer are presented to show how the sensor is to be used for 1) evaluating the health of the automated site radiometers, 2) characterizing the surface being measured at the automated test sites, and 3) assessing the error budget for top-of-atmosphere reflectance prediction from the test site characterization. Additionally, results from using the transfer radiometer for a radiance-based calibration of the Operational Land Imager are presented.

10402-22, Session 5

Updates of MODIS On-orbit calibration uncertainty assessments

Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Amit Angal, Hongda Chen, Science Systems and Applications, Inc. (United States); Kwofu Chiang, Science Systems and Applicaitons, Inc. (United States); Xu Geng, Yonghong Li, Kevin A. Twedt, Zhipeng Wang, Truman Wilson, Aisheng Wu, Science Systems and Applications, Inc. (United States)

Terra and Aqua MODIS have successfully operated for more than 17 and 15 years, respectively, and continuously provided many science products that have significantly improved various studies of the earth's system and its key environmental parameters of land, oceans, and atmosphere. The MODIS level 1B (L1B) calibrated data products include TOA reflectance factors for the reflective solar bands (RSB), radiances for both the RSB and thermal emissive bands (TEB), and the associated uncertainty indices. The uncertainty indices are reported as unsigned integers, which can be converted to the uncertainties in percentage using coefficients provided in the L1B metadata. At launch, most contributors to the L1B uncertainties were estimated from pre-launch calibration and characterization and the use of its on-board calibrators (OBC). Starting from collection 6 (C6), the L1B uncertainties, which are represented via a set of time-dependent parameters, have included contributors estimated from ground observations. As both Terra and Aqua MODIS continue to operate beyond their design lifetime, changes in each instrument's performance and behavior need to be fully characterized and addressed in the L1B algorithms, including the uncertainties. This paper provides an overview of MODIS on-orbit calibration uncertainty assessments, its L1B uncertainty algorithm and implementation, lessons learned for the VIIRS L1B data products. It also discusses the updates resulting from recent changes in sensor characteristics and future improvements.

10402-23, Session 5

Crosstalk effect and its mitigation in Aqua MODIS middle wave infrared bands

Junqiang Sun, Global Science & Technology, Inc. (United States); Sriharsha Madhavan, Science Systems and Applications, Inc. (United States); Menghua Wang, Ctr. for Satellite Applications and Research (United States)

The MODerate-resolution Imaging Spectroradiometer (MODIS) is one of the primary instruments in the National Aeronautics and Space Administration (NASA) Earth Observing System (EOS). The first MODIS instrument was launched in December 1999 on-board the Terra spacecraft. A follow on MODIS was launched on an afternoon orbit in 2002 and is aboard the Aqua

spacecraft. Both MODIS instruments are very akin, has 36 bands, among which bands 20 to 25 are Middle Wave Infrared (MWIR) bands covering a wavelength range from approximately 3.750 ?m to 4.515 ?m. It was found that there was severe contamination in these bands early in mission but the effect has not been characterized and mitigated at the time. The crosstalk effect induces strong striping in the Earth View (EV) images and causes significant retrieval errors in the EV Brightness Temperature (BT) in these bands. An algorithm using a linear approximation derived from on-orbit lunar observations has been developed to correct the crosstalk effect and successfully applied to mitigate the effect in both Terra and Aqua MODIS Long Wave Infrared (LWIR) Photovoltaic (PV) bands. In this paper, the crosstalk effect in the Aqua MWIR bands is investigated and characterized by deriving the crosstalk coefficients using the scheduled Aqua MODIS lunar observations for the MWIR bands. It is shown that there are strong crosstalk contaminations among the five MWIR bands and they also have significant crosstalk contaminations from Short Wave Infrared (SWIR) bands. The crosstalk correction algorithm previously developed is applied to correct the crosstalk effect in these bands. It is demonstrated that the crosstalk correction successfully reduces the striping in the EV images and improves the accuracy of the EV BT in the five bands as was done similarly for LWIR PV bands. The crosstalk correction algorithm should thus be applied to improve both the image quality and radiometric accuracy of the Aqua MODIS MWIR bands Level 1B (L1B) products.

10402-24, Session 5

Improvements to Terra MODIS L2 science products through using crosstalk corrected radiances

Christopher C. Moeller, Richard A. Frey, Eva Borbas, W. Paul Menzel, Cooperative Institute for Meteorological Satellite Studies, Univ. of Wisconsin-Madison (United States); Truman Wilson, Aisheng Wu, Xu Geng, Science Systems and Applications, Inc. (United States)

Terra MODIS PVLWIR band 27 – 30 radiances have been increasingly contaminated by electronic crosstalk through the mission lifetime. In recent years, the contamination has been recognized as compromising the climate quality status of several MODIS L2 science products that depend on the PVLWIR bands. In response to this, the MODIS Characterization Support Team (MCST) has undertaken an effort to generate a crosstalk correction algorithm for use in the operational L1B radiance product algorithm. The correction algorithm has matured and crosstalk corrected L1B radiances have been applied in several Terra MODIS L2 science product algorithms, including MOD35 (Cloud Mask), MOD06 (Cloud Fraction, Cloud Particle Phase, Cloud Top Properties), and MOD07 (Water Vapor). This paper will discuss and document the L1B and L2 product improvements as a result of the crosstalk correction. The crosstalk correction itself is documented in other literature.

10402-25, Session 5

The performance of DC restoration function for MODIS thermal emissive bands

Zhipeng Wang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Ashish Shrestha, NASA Goddard Space Flight Ctr. (United States) and Science Systems and Applications, Inc. (United States)

The DC restore (DCR) process of MODIS instrument maintains the output of a detector at focal plane assembly (FPA) within the dynamic range of subsequent analog-to-digital converter, by adding a specific offset voltage to the output. The DCR offset value is adjusted per scan, based on the comparison of the DN values collected from the blackbody (BB) view with target DN saved as an on-board look-up table. In this work, the MODIS DCR mechanism is revisited, with the trends of DCR offset provided for thermal emissive bands (TEB). Noticeable changes have been occasionally found which coincide with significant detector gain change due to various reasons such as instrument safe-mode anomaly, south Atlantic anomaly and FPA temperature fluctuation. In general, MODIS DCR functionality has been effective and the change of DCR offset has no impact to the quality of MODIS data. One exception is the EV data saturation of Aqua MODIS LWIR bands 33, 35 and 36 during BB warm-up cool-down (WUCD) cycle observed since 2008. The BB view of their detectors saturate when the BB temperature is above certain threshold so the DCR cannot work as designed. Therefore, the dark signal DN fluctuates with the cold FPA (CFPA) temperature and saturate for a few hours per WUCD cycle, which also saturate all data sectors within the scan. The CFPA temperature fluctuation peaked in 2012 and has been reduced in recent years. While the saturation phenomenon has been easing accordingly, it demonstrates the importance of DCR to data production.

10402-26, Session 5

AIRS visible light channels: Lessons from 15 years of using internal calibration sources, vicarious calibration, and the use of deep convective clouds

Steven E. Broberg, Hartmut H. Aumann, Evan M. Manning, Jet Propulsion Lab. (United States)

The Atmospheric Infrared Sounder (AIRS) on the EOS Aqua Spacecraft was launched on May 4, 2002 and is currently fully operational. AIRS, in addition to the infrared system comprised of 2378 channels with wavelengths ranging from 3.7-15.4 um, has 4 Visible/Near-Infrared channels and an on-board calibration source utilizing 3 independent lamps to characterize the change in the visible response over time.

One of the key measurements related to climate change is the measurement of the Reflected Short-Wave Solar radiation (RSW). The AIRS visible light channels can be used to accurately measure the stability of the RSW. We describe our experience from 15 years of AIRS data with using internal calibration lamps, vicarious calibration, MODIS cross-calibration, and Deep Convective Clouds (DCCs) for the calibration and stabilization of the AIRS visible light data. The result is the DCC stabilized anomaly trend of the RSW measured with AIRS.

10402-27, Session 5

A strategy to assess the pointing accuracy of the CERES FM1-FM5 scanners

Nathaniel P. Smith, Z. Peter Szewczyk, Phillip C. Hess, Susan Thomas, Science Systems and Applications, Inc. (United States); Kory J. Priestley, NASA Langley Research Ctr. (United States)

The Clouds and the Earth's Radiant Energy System (CERES) scanning radiometer is designed to measure the solar radiation reflected by the Earth and thermal radiation emitted by the Earth. Five CERES instruments are currently in service; two aboard the Terra spacecraft, launched in 1999; two aboard the Aqua spacecraft, launched in 2002; and one instrument about the Suomi-NPP spacecraft, launched in 2011. Verifying the pointing accuracy of the CERES instruments is required to assure that all earth viewing data is correctly geolocated. The CERES team has developed an on-orbit technique for assessing the pointing accuracy of the CERES sensors that relies on a rapid gradient change of measurements taken over a well-defined and known Earth target, such as a coastline, where a strong contrast in brightness and temperature exists. The computed coastline is then compared with World Bank II map to verify the accuracy of the measurement location. This paper briefly restates the algorithm used in the study, describes the collection of coastline data, and summarizes the results of the study for each of the five CERES instruments currently in operation.

10402-28, Session 6

Initial post-launch radiometric calibration performance of GOES-16 ABI

Fangfang Yu, ERT, Inc. (United States); Xiangqian Wu, NOAA NESDIS Office of Satellite and Product Operations (United States); Hyelim Yoo, National Oceanic and Atmospheric Administration (United States) and ERT, Inc. (United States); Xi Shao, ERT, Inc. (United States)

The first NOAA next-generation geostationary weather satellites, GOES-R was successfully launched on 19 November 2016 and became GOES-16 when it reached the geostationary orbit on 29 November 2016. The satellite is currently parking at 89.5W about 35,000km above the Equator and undergoing intensive instrument performance tests. The main payload instrument on-board is Advanced Baseline Imager (ABI), which has 16 multi-spectral bands covering the spectrum between 0.47μm and 13.3 μm to provide continuous data stream for weather forecasting, disaster monitoring, and long-term climate research. This instrument, for the first time for the NOAA GOES satellites, is housed with a solar diffuser and a temperature-controlled blackbody to provide accurate on-orbit radiometric calibration for the 6 visible and near-infrared (VNIR) bands and 10 infrared (IR) bands, respectively. A series of methods and tools are being used at NOAA/STAR to validate and assess the ABI radiometric calibration accuracy. In this study, we will report the ABI radiometric calibration performance during the post-launch product tests (PLPT) period, including the results of using the ray-matching method to compare the ABI radiance with SNPP/VIIRS for the VNIR bands, and with SNPP/CrIS and Metop/IASI for the IR bands, desert observations to characterize the ABI VNIR imaging bands calibration stability, and lunar tracing images to validate VNIR spatial uniformity. Some other early results related to the instrument performance will also be reported at the meeting.

10402-29, Session 6

Calibration/validation status for GOES-16 products

Jon P. Fulbright, Arctic Slope Technical Services (United States); Elizabeth Kline, Science and Technology Corp. (United States); David R. Pogorzala, Integrity Applications, Inc. (United States); Wayne MacKenzie, Kathryn Mozer, Jamese Sims, Matthew Seybold, NOAA NESDIS Office of Satellite and Product Operations (United States)

The Geostationary Operational Environmental Satellite-R series (GOES-R) will be the next generation of NOAA geostationary environmental satellites. The first satellite in the series, GOES-16, was in November 2016. The satellite carries six instruments dedicated to the study of the Earth's weather (ABI), lightning mapping (GLM), solar observations (EXIS and SUVI), and space weather monitoring (MAG and SEISS). By August 2017, the product calibration/validation and instrument characterization plans for these six instruments should be past the Provisional product maturity threshold. These cal/val plans were created to advance the products through well-characterized states following an aggressive maturity schedule. In this talk, we give an update of the GOES-16 products, the path forward to Full product validation status, and a look forward to any changes to the cal/val plans GOES-S (to be launched in 2018).

10402-30, Session 6

Evaluation of GOES-16 ABI geospatial calibration accuracy using SNO method

Fangfang Yu, Xi Shao, ERT, Inc. (United States); Xiangqian Wu, National Oceanic and Atmospheric Administration (United States) and National Environmental Satellite, Data, and Information Service (United States) and Ctr. for Satellite Application and Research (United States); Vladimir Kondratovich, ERT, Inc. (United States)

The Advanced Baseline Imager (ABI) onboard the GOES-16 satellite is the first next-generation geostationary weather imager operated by NOAA. It has 6 solar reflective and 10 emissive bands for weather forecasting, natural disaster tracking and meteorological and climatic research. Compared to the legacy GOES weather instruments, ABI has improved spectral, spatial and temporal resolutions and the imagery of the 16 spectral bands are produced on a fixed-grid, which is referenced to an ideal location in space located in the earth's equatorial plane. To meet these challenging requirements for accurate geospatial calibration, a set of new technologies are applied for the ABI image navigation and registration (INR) processing. In this study, we evaluate the ABI navigation and band-to-band registration (BBR) accuracies for all the spectrally matched bands between ABI and the Suomi National Polar-orbiting Partnership (SNPP) Visible Infrared Imaging Radiometric Suite (VIIRS), using simultaneous nadir observations (SNO) data between these two instruments. The ABI resampling algorithm and kernels are used to simulate ABI observations using the spectrally matched VIIRS data. The navigation and BBR accuracies at VIIRS I and M band sub-pixel levels are derived using VIIRS geo-location as reference and transfer, respectively. Unlike the traditional INR evaluation method, which relies on clear sky images at coastline or river edges, this method works at heterogenic area with cloudy surface at the sub-satellite area. It will serve as a complementary and independent method to the Landsat imagery based INR algorithms to validate, evaluate and monitor ABI INR accuracies.

10402-31, Session 6

Sentinel 2B: the image quality performances at the beginning of the mission

Thierry L. Trémas, Vincent Lonjou, Arthur Dick, Florie Languille, Angélique Gaudel, Bruno Vidal, Ctr. National d'Études Spatiales (France)

Launched on March 6th, 2017 from Kourou, Sentinel 2B has passed the phase of commissioning. Sentinel 2B will work together with Sentinel 2A launched in June 2015. The building and implementation of the satellite has been realized under the responsibility of ESA, for the European Commission.

The subset of Image Quality commissioning was delegated by ESA to CNES, referring to the experience of the French Space Agency on previous imagers. This phase lasted 4 months after the launch, a little longer than the formal In Orbit Calibration period conducted by ESA, some Image Quality parameters requiring several months before converging to a stable state. This paper presents the status of the satellite, from an IQ prospective, just before it entered its operational phase. The radiometric and geometric performances are listed, including: the absolute radiometric calibration, the equalization, the SNR, the absolute and the multi-temporal location accuracy. The performances of both satellites Sentinel and Sentinel 2B working together, will be addressed. A particular focus will be done on multi-temporal location performances, homogeneity of radiometric inter calibrations. The accomplishment of the Global Reference Image over Europe is evoked as well.

The IQ commissioning phase ended on June 2017. From this date, the monitoring of IQ parameters is under the responsibility of ESA/ESRIN. Nevertheless, CNES continues to support ESA to survey the accuracy of S2A and S2B performances. The article ends by dealing with the prospective offered by the couple Sentinel 2A + Sentinel 2B.

10402-32, Session 6

Compact, on-demand broad spectral range (visible to long wave infrared) calibrator

James Chow, Edward Ward Jr., Raytheon Space and Airborne Systems (United States)

First, the emission wavelengths from visible to short-wave infrared are generated by Light Emitting Diodes (LEDs) and phosphors which spectrally down convert the higher energy photons from the LED to a lower energy photon distribution. This process is analogous to the commercial lighting industry where blue LEDs are down converted into a distribution that resembles variations of white light. Second, several formats of carbon materials have been combined together into a multi-layer structure so that a highly uniform temperature interface feeds a high emissivity surface of vertically aligned carbon nanotubes. Finally, both of these technologies give rise to a thin profile, layered structure which can be easily mounted on a paddle for movement in and out of the optical path.

10402-33, Session 7

Rapid acquisition, processing, and delivery of advanced infrared and microwave sounder data from polar orbiting satellites for numerical weather prediction and other time-sensitive applications

Liam Gumley, Univ. of Wisconsin-Madison (United States)

The current and future satellites of the US Joint Polar Satellite System (JPSS) in low earth orbit provide advanced sounder observations from the Cross-track Infrared Sounder (CrIS) and the Advanced Technology Microwave Sounder (ATMS) for applications including numerical weather prediction, weather forecasting, and aviation hazard detection. NOAA has funded the deployment and operation of a network of satellite ground stations across North America and the Pacific to acquire sounder data from these satellites in real-time, and in conjunction with Cooperative Institute for Meteorological Satellite Studies (CIMSS) at the University of Wisconsin-Madison, has established a system for processing the data with low latency and delivering it to the National Weather Service for assimilation in rapid-refresh numerical weather prediction (NWP) models. The data are also delivered to EUMETSAT for retransmission via satellite to NWP centers in Europe. This presentation will outline the features of the space-borne sensors, the ground receiving stations, the processing system, and the delivery networks which allow advanced infrared and microwave sounder data to be delivered to end users within minutes of the end of a satellite passing over the ground station. This presentation will also describe recent efforts to cut the data latency from the order of minutes to seconds, by using novel processing techniques at the ground station while a satellite is passing overhead.

10402-34, Session 7

Comparison between point-based and line-based parallel-projection transformation models in rectifying satellite images

Ahmed Elaksher, California State Polytechnic Univ., Pomona (United States)

The quick advance in remote sensing technologies established the potential to gather accurate and reliable information about the Earth surface using high resolution satellite images. Remote sensing satellite images of less than one-meter pixel size are currently used in large-scale mapping. Rigorous photogrammetric equations are usually used to describe the relationship between the image coordinates and ground coordinates. These equations require the knowledge of the exterior and interior orientation parameters of the image that might not be available. On the other hand, the parallel projection transformation could be used to represent the mathematical relationship between the image-space and object-space coordinate systems and provides the required accuracy for large-scale mapping using fewer ground control features. This article investigates the differences between point-based and line-based parallel projection transformation models in rectifying satellite images with different resolutions. The point-based parallel projection transformation model and its extended form are presented and the corresponding line-based forms are developed. Results showed that the RMS computed using the point- or line-based transformation models are equivalent and satisfy the requirement for large-scale mapping. The differences between the transformation parameters computed using the point- and line-based transformation models are insignificant. The results showed high correlation between the differences in the ground elevation and the RMS.

10402-35, Session 7

Integrating satellite images and LIDAR data for shoreline mapping

Ahmed Elaksher, California State Polytechnic Univ., Pomona (United States)

Shorelines are imperative for coastal ecosystems and activities. Despite this simplicity, accurate and precise extraction of these features is a challenging task due to the complicity of water bounding zones. Shoreline mapping has been carried out through a variety of techniques such as traditional surveying and aerial mapping. As spatial resolution and geospatial mapping technologies improved in the last few years, satellite images and active remote sensing systems have also been introduced to produce high quality shorelines. The focus of this research is on generating reliable shorelines from satellite images and LIDAR datasets. Different classification algorithms were implemented and tested followed by a number of image processing techniques to vectorize shoreline pixels. The completeness and geometric accuracy of the results are presented and evaluated. They show the benefits of adding ranging data in improving both shoreline recognition quality and mapping accuracy.

10402-36, Session 7

Satellite-based shoreline change detection analysis using operational land imager data

Wasim Pervez, Shoab Ahmad Khan, National Univ. of Sciences and Technology (Pakistan)

Remote sensing change detection remains a challenging problem. Change detection techniques using pre-classification provide changes but do not provide information on the nature of that change. Post classification change detection technique is most commonly used technique due to its inherent advantages as well as its compensation for variation in atmospheric correction. Post classification change detection technique provides its suitability for medium and high resolution data and minimizes impact of misregistration, inconsistencies in classification. Hence is suitable for change detection analysis of Operational Land Imager (OLI) data. This paper investigated OLI suitability for post classification change detection analysis for shoreline changes due to its enhanced features over previous Landsat series. This paper evaluated OLI data classification using support vector machine (SVM) by using data for the four seasons (i.e., spring, summer, autumn and winter) and were compared for the change detection results of the six cases: (1) spring to summer; (2) spring to autumn; (3) spring to winter; (4) summer to autumn; (5) summer to winter; (6) autumn to winter. The results confirmed that OLI SVM classified data is appropriate for shoreline post-classification change detection analysis of the study area.

10402-37, Session 7

Applicability of Distrad technique for downscaling of thermal images in different seasons over Raipur city and its surroundings

Subhanil Guha, Himanshu Govil, National Institute of Technology, Raipur (India); Sandip Mukherjee, TERI Univ. (India)

Land surface temperature (LST) considers a number of biophysical processes associated with the interaction between earth surface features and atmosphere. The present study analysed the applicability of the DisTrad thermal sharpening method to correlate land surface temperature over different types of land surface indices. Water body, Vegetation, Bare land and built-up area were considered as different categories of land cover. Landsat and MODIS satellite data of different seasons having various spatial and temporal resolutions were used for evaluating thermal sharpening. Raipur city and its surroundings were selected for the entire work. High resolution land surface temperature can be retrieved from low resolution sensors using DisTrad based on impervious percentage relationship with the urban land surface temperature. Downscaled land surface temperature at higher resolutions presents a higher correlation compare to the observed land surface temperature. DisTrad technique with impervious percentage always shows a higher correlation with land surface temperature in comparison with NDVI for all the seasons. This thermal sharpening technique allows an improved estimation of urban heat island (UHI) mapping.

10402-38, Session 7

HT-FRTC: Fast radiative transfer using Gaussian processes

Gerald J. Wong, Stephan Havemann, Met Office (United Kingdom)

The Havemann-Taylor Fast Radiative Transfer Code (HT-FRTC) is a principal component (PC) based code that can be used across the whole electromagnetic spectrum to calculate transmittance, radiance and flux spectra. The PCs cover the spectrum at very high spectral resolution, allowing very fast line-by-line, hyperspectral and broadband simulations for satellite-based, airborne and ground-based sensors. The PCs are derived during a code training phase from line-by-line simulations for a diverse set of atmosphere and surface conditions. The derived PCs are sensor independent, with no extra training required to include additional sensors.

The HT-FRTC code is an integral part of the Met Office's Tactical Decision Aids such as NEON, playing an important part in the prediction of environmental impacts on sensors such as IR cameras and night-vision goggles. Moreover, the HT-FRTC has been incorporated into a one-dimensional variational (1D-Var) retrieval system that also works solely in PC space. This reduces the dimensions of the matrices involved, which are important for computational efficiency. Examples of the above applications will be presented, including the retrievals of surface and cloud properties.

10402-40, Session 8

High efficiency signal acquisition

Xiteng Liu, QualVisual Technology (Canada)

This paper presents a new mathematical method for high efficiency signal acquisition. The new method makes revolutionary improvement as compared with compressed sensing. It dispenses with both sparsity and convex optimization on which compressed sensing relies. Convex optimization techniques such as linear programming and orthogonal matching pursuit employ iterative computations and may become very slow and unstable in high dimensional systems. Doing without convex optimization, the new method dramatically improves both computing speed and computing stability. It is eligible for real time applications. Even better, the new method doesn't require signals to have sparse representations. A signal can be recovered in perceptually lossless quality from its as few as 25% samples. Experimental results manifest that our new method may overwhelmingly outperform compressed sensing methods. Demo software and testing data are all downloadable at the website http://qualvisual.net.

10402-41, Session 8

Experimentally validated modification to Cook-Torrance BRDF model for improved accuracy

Samuel D. Butler, Air Force Institute of Technology (United States); James A. Ethridge, Air Force Institute of Technology (United States) and Southwestern Ohio Council for Higher Education (United States); Stephen E. Nauyoks, Air Force Institute of Technology (United States) and Oak Ridge Institute for Science and Education (United States); Michael A. Marciniak, Air Force Institute of Technology (United States)

The bidirectional reflectance distribution function (BRDF) describes material reflectance by relating incident irradiance to scattered radiance. One popular class of BRDF models is the microfacet model, which assumes geometric optics but is computationally simpler than wave optics models, and thus more readily applicable to remote sensing. One drawback of this geometric optics model is the need for a cross section conversion term, which diverges at large angles. This problem is only partially addressed by adding a geometric attenuation (shadowing and masking) term to conserve energy, while still neglecting wave optics effects. In 2003, Matusik measured 100 materials in the MERL database. In 2015, Butler measured several rough materials in the IR at multiple wavelengths with higher fidelity using the SMS CASI®. Butler also proposed a theoretical approximation to replace the geometric attenuation and cross section conversion terms in the microfacet model with the closed-form polarization factor, Q, present in wave optics models such as Rayleigh-Rice. In this work, this theoretical approximation is validated using experimental results from Matusik's MERL measurements and Butler's IR measurements. These BRDFs are fitted to a novel version of the Cook-Torrance model using the polarization factor, and the error in the fits are compared to the standard Cook-Torrance model. The overall error is decreased when using the novel model, particularly for large incident and scattered angles. These experimental results suggest incorporating the polarization factor in the microfacet model in the way previously posited by Butler to improve the quality of fit consistently for several rough materials.

10402-42, Session 8

Wave optics simulation of statistically rough surface scatter

Ann Lanari, Samuel D. Butler, Michael A. Marciniak, Air Force Institute of Technology (United States); Mark F. Spencer, Air Force Research Lab. (United States)

The Bidirectional Reflectance Distribution Function (BRDF) describes optical scatter from surfaces by relating the incident irradiance to the exiting radiance over the entire hemisphere. Laboratory verification of BRDF models and experimentally populated BRDF databases are hampered by sparsity of monochromatic sources and ability to statistically control the surface features. Numerical methods are able to control surface features, have wavelength agility, and via Fourier methods of wave propagation, may be used to fill the knowledge gap. Monte-Carlo techniques, adapted from turbulence simulations, generate Gaussian distributed and correlated surfaces with an area of 1 cm2, RMS surface height of 2.5 μm, and correlation length of 100 μm. The surface is centered inside a Kirchhoff absorbing boundary with an area of 16 cm2 to prevent wrap around aliasing in the far field. These surfaces are uniformly illuminated at normal incidence with a

unit amplitude plane-wave varying in wavelength from 3 μm to 5 μm. The resultant scatter is propagated to a detector in the far field utilizing multi-step Fresnel Convolution and observed at angles from -2μrad to 2μrad. The far field scatter is compared to both a physical wave optics BRDF model (Modified Beckmann Kirchhoff) and two microfacet BRDF Models (Priest, and Cook-Torrance). Modified Beckmann Kirchhoff, which accounts for diffraction, is consistent with simulated scatter for multiple wavelengths for RMS surface heights greater than ?/2. The microfacet models, which assume geometric optics, are less consistent across wavelengths. Both model types over predict far field scatter width for RMS surface heights less than ?/2.

10402-43, Session 9

The Sentinel 4 focal plane subsystem

Rüdiger Hohn, Airbus Defence and Space (Germany); Michael Skegg, Airbus Defence and Space (Germany); Markus Hermsen, Airbus Defence and Space (Germany); Christian Williges, Ralf Reulke, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The Sentinel 4 instrument is an imaging spectrometer, developed by Airbus under ESA contract in the frame of the joint European Union (EU)/ESA COPERNICUS program with the objective of monitoring trace gas concentrations. SENTINEL 4 will provide accurate measurements of key atmospheric constituents such as ozone, nitrogen dioxide, sulfur dioxide, formaldehyde, as well as aerosol and cloud properties.

SENTINEL 4 is unique in being the first geostationary UVN mission. The SENTINEL 4 space segment will be integrated on EUMETSAT's Meteosat Third Generation Sounder satellite (MTG-S). Sentinel 4 will provide coverage of Europe and adjacent regions.

The Sentinel 4 instrument comprises, as a major element, two Focal Plane Subsystems (FPS) covering the wavelength ranges 305nm to 500 nm (UVVIS) and 750 to 775 nm respectively.

The paper describes the Focal Plane Subsystems, comprising the detectors, the optical bench and the control electronics. Further the design and development approach will be presented as well as first measurement results of FPS Qualification Model.

10402-44, Session 9

The Sentinel-4 UVN focal plane assemblies

Jürgen Hinger, Rüdiger Hohn, Airbus Defence and Space (Germany); Ralf Reulke, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The Sentinel-4 UVN Instrument which is a dispersive imaging spectrometer covering the UV-VIS and the NIR wavelength is developed and built under an ESA contract by an industrial consortium led by Airbus DS GmbH.

It will be accommodated on board of the MTG-S (Meteosat Third Generation - Sounder) satellite that will be placed in a geostationary orbit over Europe sampling data for generating two-dimension maps of a number of atmospheric trace gases.

The light reflected by a scan mirror into a common telescope passes a slit and a polarization scrambler and is split by a dichroic beam splitter in the NIR and UV-VIS band. The UV-VIS part of the light (305-500 nm) is dispersed by a combination of a grating and a prism inside the UV-VIS spectrometer and detected by a dedicated CCD accommodated inside the UV-VIS Focal Plane Assembly (FPA).

The near infra-red (NIR) light (750-775 nm) which is dispersed by a reflective grating in the NIR spectrometer is detected by the NIR-CCD inside the NIR FPA. Both CCD detectors acquire spectral channels and spatial sampling in two orthogonal directions and will be operated at about 215 K mainly to minimize random telegraph signal effects and to reduce dark current. Stringent detector temperature as well as alignment stability requirements of less than ±0.1 K per day respectively of less than 2 micrometers/2 arcseconds from ground to orbit are driving the FPA thermo-mechanical design. A special FPA design features is the redundant LED-calibration system for bad pixel detection as well as pixel gain and linearity monitoring.

This paper reports on the design and qualification of the Focal Plane Assemblies with emphasis on thermo-mechanical as well as alignment stability verification.

10402-45, Session 9

The Sentinel-4 detectors: Architecture and performance

Michael Skegg, Markus Hermsen, Rüdiger Hohn, Airbus Defence and Space (Germany); Christian Williges, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Charles Woffinden, e2v technologies plc (United Kingdom); Yves Levillain, European Space Research and Technology Ctr. (Netherlands); Ralf Reulke, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The Sentinel-4 instrument is an imaging spectrometer, developed by Airbus under ESA contract in the frame of the joint European Union (EU)/ESA COPERNICUS program. SENTINEL 4 will provide accurate measurements of trace gases from geostationary orbit, including key atmospheric constituents such as ozone, nitrogen dioxide, sulfur dioxide, formaldehyde, as well as aerosol and cloud properties.

Key to achieving these atmospheric measurements are the two CCD detectors, covering the wavelengths in the ranges 305 nm to 500 nm (UVVIS) and 750 to 775 nm (NIR) respectively. The paper describes the architecture, and operation of these two CCD detectors, which have an unusually high full-well capacity and a very specific architecture and read-out sequence to match the requirements of the Sentinel-4 instrument. The key performance aspects and their verification through measurement are presented, with a focus on an unusual, bi-modal dark signal generation rate observed during test.

10402-46, Session 9

The Sentinel 4 detector electrical system integration

Markus Hermsen, Rüdiger Hohn, Michael Skegg, Airbus Defence and Space (Germany); Christian Williges, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Charles Woffinden, e2v technologies plc (United Kingdom); Ralf Reulke, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The detectors of the Sentinel 4 multi spectral imager are operated in flight at 215K while the analog electronics is operated at ambient temperature. As the cooling power is highly limited no active component has been allowed in the cooled area closest to the detector. Electrically a short connection between detector and electronics is ideal. From mechanical and from thermal point of view the connection requires a certain minimum length. The selected solution supports all these aspects but had to approach the limits of what is electrically feasible. Such constraints manifested a severe challenge in the design as no sacrifice on the technical system performance is acceptable. The physical separation between CCD detector and the Frontend Electronics, the adverse EMI environment in which the instrument will be operated in (the location of the instrument on the satellite is in vicinity to a downlink K-band communication antenna of the S/C and no effective shielding means are given on the satellite to protect from these signals) and the extreme cleanliness requirements for the detector in manufacturing and assembly are some examples for specific challenges to overcome.

This paper describes how in Sentinel 4 the given issues have been overcome, how the limited load drive capability of the detector component

has been considered on a flex length of about 20cm (~8") and how EMC shielding of the highly sensitive analogue signals of the detector has been realized. Also covered are design/manufacturing aspects and a glance on testing results.

The result is an Instrument, based on CCD detectors which are proven to be ruggedized versus strong RF signals and which allows to read out the detector signals with 13,5 bit effective resolution at a pace of 1,42MHz.

10402-47, Session 9

Verification of the Sentinel-4 focal plane subsystem

Christian Williges, Mathias Uhlig, Stefan Hilbert, Hannes Rossmann, Kevin Buchwinkler, Steffen Babben, Llse Sebastian, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Rüdiger Hohn, Airbus Defence and Space (Germany); Ralf Reulke, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The Sentinel-4 payload is a multi-spectral camera system which is designed to monitor atmospheric conditions over Europe. The German Aerospace Center (DLR) Berlin conducted the verification campaign of the Focal Plane Subsystem (FPS) on behalf of Airbus Defense and Space GmbH. The FPS consists of two Focal Plane Assemblies, one for the UV-VIS spectral range (305 nm ... 500 nm), the second for NIR (750 nm ... 775 nm). In this publication, we will present the laboratory set-up of the verification campaign of the Sentinel-4 Qualification Model which will also be used for the upcoming Flight Model verification.

The test campaign consists mainly of radiometric tests performed with an integrating sphere as homogenous light source, as well as a cross-talk test with a 635 nm Diode-Laser as point source. A MTF test will be performed on the Sentinel-4 Engineering Model detector which is identical to the QM.

The FPS has to be operated at 215 K, making it necessary to employ a thermal vacuum chamber (TVC) for the test accomplishment. This publication focuses on the challenge to remotely illuminate both Sentinel-4 detectors as well as a reference detector homogeneously over a distance of approximately 1 m from outside the TVC. Furthermore we will report on the additional set-up for remote illumination with a Laser and the MTF test set-up.

Aside the opto-mechanical test set-up, the publication presents a way to automate numerous tests. Due to the vast amount of measurements to be performed during the test campaign a high grade of automatization is necessary.

10402-48, Session 9

RTS effect detection in Sentinel-4 data

Henrique Candeias, Xavier Gnata, Maximilian Harlander, Markus Hermsen, Rüdiger Hohn, Stefan Riedl, Michael Skegg, Airbus Defence and Space (Germany); Ralf Reulke, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

The future ESA Earth Observation Sentinel-4/UVN is a high resolution spectrometer intended to fly on board a Meteosat Third Generation Sounder (MTG-S) platform, placed in a Geostationary orbit. The main objective of this optical mission is to continuously monitor the air quality over Europe in near-real time.

The Sentinel-4/UVN instrument operates in three wavelength bands: Ultraviolet (UV: 305-400 nm), Visible (VIS: 400-500 nm) and Near-infrared (NIR: 750-775 nm). Two dedicated CCD detector have been developed to be used in the Focal Plane Subsystems (FPS), one for the combined UV and VIS band, the other covering the NIR band.

Being an high resolution spectrometer with challenging radiometric accuracy requirements, both on spectral and spatial dimensions, an effect such the Random Telegraph Signal (RTS) can represent a relevant contribution for the complete system accuracy.

In this work we analyze the RTS effect on data acquired during the FPS testing campaign with qualification models for the Sentinel-4/UVN detectors, performed in late 2016. The strategy for the impact assessment of RTS was to measure the effect at room temperature and then to extrapolate the results to the at instrument operational temperature. This way very-long lasting data acquisitions could be avoided.

A technique for RTS effect detection has been developed in order to characterize the signal levels amplitude and flipping rate frequencies.

We demonstrate the residual impact of the RTS on the global In-Orbit Sentinel-4/UVN instrument performance and products accuracy.

10402-21, Session 10

A reflectance-based cross calibration of the Landsat archive

Cibele Teixeira Pinto, South Dakota State Univ. (United States); Sandeep Chittimalli, NASA Goddard Space Flight Ctr. (United States); Larry Leigh, Timothy Ruggles, Dennis L. Helder, South Dakota State Univ. (United States)

First launched in 1972, the Landsat satellite sensors have provided the longest continuous record of high quality images of the Earth's surface that are used in both civilian and military applications. Extraction of quantitative information (e.g., surface reflectance) from the Landsat image data is only possible through a well-performed absolute radiometric calibration. Typically, this calibration has been performed as a radiance based cross-calibration between sensors. However, to convert radiance to reflectance an accurate estimate of solar exoatmospheric irradiance is critical; and there are several solar models currently available which estimate exoatmospheric irradiance with varying levels of accuracy. A TOA reflectance-based approach, independent of exoatmospheric irradiance, has been developed to provide a consistent cross calibration of the entire Landsat series (from Landsat 8 OLI to Landsat 1 MSS), based on analysis of coincident and near-coincident scene pairs acquired with each sensor. With this method, the Landsat-8 OLI reflectance measurements are used as the starting point (reference), as they are estimated with a 3% uncertainty (compared to the 5% uncertainty associated with radiance measurements). A set of radiometric coefficients has been estimated based on the equations presented in this paper, which allows direct conversion of the digital numbers from the image data to TOA reflectance. The results obtained from application of these coefficients show significant improvement in consistency of reflectance measurements between the Landsat sensors.

10402-49, Session 10

Radiometric characterization of Landsat Collection 1 products

Esad Micijevic, Md. Obaidul Haque, U.S. Geological Survey (United States) and SGT, Inc. (United States); Nischal Mishra, U.S. Geological Survey (United States) and Virtuoso Technologies Inc. (United States)

Landsat data in the U.S. Geological Survey (USGS) archive are being reprocessed to generate a tiered collection of consistently geolocated and radiometrically calibrated products that are suitable for time series analyses. With the implementation of the collection management, no major updates will be made to calibration of the Landsat sensors within a collection. Only calibration parameters needed to maintain the established calibration trends without an effect on derived environmental records will be regularly updated, while all other changes will be deferred to a new collection. This first collection, Collection 1, incorporates various radiometric calibration updates to all Landsat sensors including absolute and relative gains for Landsat 8 Operational Land Imager (OLI), stray light correction for Landsat 8 Thermal Infrared Sensor (TIRS), absolute gains for Landsat 4 and 5 Thematic Mappers (TM), recalibration of Landsat 1-5 Multispectral Sensors (MSS) to ensure radiometric consistency among different formats

of archived MSS data, and a transfer of Landsat 8 OLI reflectance based calibration to all previous Landsat sensors. It is important to note that, although still available for download from the USGS web pages, the products generated using the pre-collection processing do not benefit from the latest radiometric calibration updates.

In this paper, we are assessing radiometry of Landsat Collection 1 products through analysis of trends in pseudo invariant site (PICS) responses and comparisons with the pre-collection products.

10402-50, Session 10

Using earth data to evaluate Landsat 8 collection-1 products radiometric uniformity stability of the focal plane array sensor chips

Raviv Levy, NASA Goddard Space Flight Ctr. (United States) and Science Systems and Applications, Inc. (United States); Brian L. Markham, NASA Goddard Space Flight Ctr. (United States)

The Operational Land Imager (OLI) and Thermal Infrared Sensor (TIRS) aboard the Landsat-8 satellite were rigorously characterized prior to launch to assure flat response at any illumination level and spectra. In this paper we demonstrate how to use in-orbit routine earth data collects processing for extracting information about the sensor chip-to-chip response uniformity across the focal plane array (FPA) field of view (FOV). We evaluate the stability of the response uniformity overtime and against factors such as mean signal level or solar azimuth.

10402-51, Session 10

Statistical relative gain calculation for Landsat 8

Cody Anderson, SGT, Inc. (United States); Dennis L. Helder, Drake Jeno, South Dakota State Univ. (United States)

The Landsat 8 Operational Land Imager (OLI) is an optical multispectral push-broom sensor with a focal plane consisting of over 7000 detectors per spectral band. Each of the individual imaging detectors contributes one column of pixels to an image. It is therefore important to ensure each detector's response is consistent with the responses of each of the other detectors. Any difference in the response between neighboring detectors may result in a visible stripe or band in the imagery. Assuming a detector's response is linear, matching detector responses requires a bias and a relative gain. The gain is called a relative gain since it is matching a detector's response to the spectral band average and not estimating the actual input output response curve. Several methods exist for estimating a detector's relative gain including on-board calibration systems, i.e. a solar diffuser, or special spacecraft maneuvers, i.e. a 90 degree yaw/side slither. This paper describes a procedure for estimating relative gains which uses only normally acquired Earth viewing statistics. The primary idea behind the procedure is that over a "long enough" period of time each detector should receive the same distribution of radiance levels, and if the input is the same for every detector, the output can be equalized by equalizing the means of the output distributions. Things to be considered are how long of time period, i.e. number of scenes, is needed and which scenes provide the best results.

10402-52, Session 10

Landsat-8 TIRS radiometric calibration status

Julia A. Barsi, Brian L. Markham, NASA Goddard Space Flight Ctr. (United States); Matthew Montanaro, Rochester Institute of Technology (United States); Simon Hook, Jet Propulsion Lab. (United States) and NASA Goddard Space Flight Ctr. (United States); John R. Schott, Nina G. Raqueno, Aaron D. Gerace, Rochester Institute of Technology (United States)

The Thermal Infrared Sensor (TIRS) instrument is the thermal-band imager on the Landsat-8 platform. Unlike previous Landsat satellites, there are two thermal bands on Landsat-8 but they are included on a separate instrument from the reflective bands of the Operational Land Imager (OLI). The OLI and TIRS are operated jointly on a single platform to provide a data product continuous with the previous sensors, but the new design of the TIRS instrument has led to calibration problems.

The absolute calibration of the TIRS instrument began immediately after launch by teams from NASA/JPL and the Rochester Institute of Technology. Using measurements from buoys over large water bodies, the predicted sensor-reaching radiance is compared to the radiance provided by TIRS. The initial calibration estimates showed large average errors in both bands, -0.29 and -0.51 W/m2 sr um or -2.1K and -4.4K at 300K in Band 10 and 11, respectively, as well as high variability in the errors, 0.87K (1 sigma) and 1.67K (one sigma), respectively. The average bias error was corrected in operational processing in January 2014, though this adjustment did not account for the variability.

Using scans of the moon as a source , it was determined that stray light originating from far outside the nominal field of view was the origin of the calibration error and variability. An algorithm for modeling the stray light effect was developed and implemented in the Landsat-8 processing system in February 2017. The new process has improved the overall calibration of the two TIRS bands, such that it reduces the residual variability in the calibration from 0.87K to 0.52K at 300K for Band 10 and from 1.67K to 0.91K at 300K for Band 11.

10402-53, Session 10

Landsat 8 TIRS calibration with external sensors

Yue Wang, Emmett J. Ientilucci, Nina G. Raqueno, John R. Schott, Rochester Institute of Technology (United States)

This paper describes a methodology to calibrate stray light error for the Landsat 8 TIRS sensor with data from external sensors, such as Geostationary Operational Environmental Satellite (GOES) and Meteosat Second Generation Satellite (MSG). We utilized the near-coincident thermal image data from these external sensors as the source of stray light radiance (i.e., ghost radiance). Necessary slant path and sensor response corrections were implemented to those sensors before gathering the ghost radiance. Previous studies have proposed an optical model to indicate the ghosting source locations and relative magnitude of the ghost. Once the out-of-field radiance values were collected, two different algorithms are proposed. One method utilizes the magnitude provided by the optical model while the second method uses regression technics to re-estimate stray light errors. Moderate Resolution Imaging Spectroradiometer (MODIS) Sea Surface Temperature (SST) product coupled with water temperatures measured by Buoys were two metrics used to evaluate results. The top-of-atmosphere (TOA) radiance from target water bodies was derived from the measured temperature and the model of the atmosphere at the time of image acquisition. The differences between the calculated TOA radiance and the derived TIRS radiance represents the absolute radiometric calibration error for the sensor. Initial experiments have shown the absolute calibration error has been reduced from 2K to 0.5K when this correction method is implemented.

10402-54, Session 10

Assessing the potential to use the split window technique to retrieve surface temperature with Landsat 8's thermal infrared sensor (TIRS)

Aaron D. Gerace, Matthew Montanaro, Rochester Institute of Technology (United States); Ronald A. Morfitt, U.S. Geological Survey (United States)

Since the launch of the Landsat 8 Thermal Infrared Sensor (TIRS) in early 2013, the utility of its image data for surface temperature retrieval has been hindered by a stray light effect within the instrument. In the subsequent years, a stray light removal algorithm was developed and approved by the Landsat Calibration and Validation team to be incorporated into the USGS ground system. In February 2017, all TIRS data were reprocessed to remove stray light effects, significantly improving the radiometric quality of the data. Considering its dual-band design, and its improved radiometric quality, TIRS exhibits the potential to be used for surface temperature retrieval using the Split-Window technique.

This work investigates the renewed interest for TIRS data to be used to derive surface temperature. A modeling analysis is conducted to assess the accuracy of the Split-Window technique as a function of a sensor's absolute radiometric fidelity. The Split-Window technique is then applied to actual TIRS image data, both before and after the stray light correction, to retrieve surface temperature and compared to MODIS-derived surface temperature. Considering Terra/MODIS is outperforming its absolute radiometric accuracy requirement of 0.5% for the bands corresponding to TIRS, its data is used as a reference. Results of the studies presented here indicate that the stray light removal algorithm significantly improves the utility of TIRS data with surface temperature retrieval accuracies that are in-line with Terra/MODIS.

10402-55, Session 11

JPSS-1 VIIRS RSB sensor spectral response calibration and its applications

Jinan Zeng, Fibertek Inc. (United States) and NASA Goddard Space Flight Ctr. (United States); James J. Butler, Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Hassan Oudrari, Jeffery McIntire, Thomas Schwarting, Qiang Ji, Science Systems and Applications, Inc. (United States)

We present system-level responsivity calibration results of the visible and near infrared channels of JPSS-1 VIIRS in the reflective solar band (RSB) from bands M1(412 nm) to M7 (865 nm). A monochromator-based method based on the Spectral Measurement Assembly (SpMA), and a laser-based calibration method based on Travelling-Spectral Irradiance and Radiance responsivity Calibrations using Uniform Sources (T-SIRCUS) were applied to determine the relative and absolute spectral responses (RSR and ASR). These responsivities are provided for both the single pixel/detector and band-averaged cases for each band. Differences in RSR results from the two methods, SpMA and T-SIRCUS, are compared. The contribution of spectral features in the RSRs is also examined through a comparison to the component-level spectral transmittance of the VIIRS bandpass filters. The potential effects of detector-to-detector RSR variations on image quality are also investigated. The two calibration methods using different configurations provide the opportunity to separate optical and electrical cross-talk as well as contributions from out-of-band which is estimated at about 3 %. We also utilize the ASRs to verify the gain coefficients derived from an independent radiometric calibration test using a broadband source. The system-level responsivity measurement methodologies presented in this paper demonstrate a more accurate, NIST-traceable calibration, which can be used to validate/verify conventional radiometric calibration tests.

10402-56, Session 11

Atmospheric correction for JPSS-2 VIIRS response versus scan angle measurements

Jeffrey McIntire, Science Systems and Applications, Inc. (United States); Christopher C. Moeller, Univ. of Wisconsin-Madison (United States); Hassan Oudrari, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The Joint Polar Satellite System 2 (JPSS-2) Visible Infrared Imaging Radiometer Suite (VIIRS) includes one spectral band centered in a strong atmospheric absorption region. As much of the pre-launch calibration is performed under laboratory ambient conditions, accurately accounting for the absorption, and thereby ensuring the transfer of the sensor calibration to on-orbit operations, is necessary to generate science quality data products. This work is focused on the response versus scan angle (RVS) measurements, which characterize the relative scan angle dependent reflectance of the JPSS-2 VIIRS instrument optics. The spectral band of interest, centered around 1378 nm, is within a spectral region strongly effected by water vapor absorption. The methodology used to model the absolute humidity and the atmospheric transmittance under the laboratory conditions is detailed. The application of this transmittance to the RVS determination is then described including an uncertainty estimate; a comparison to the pre-launch measurements from earlier sensor builds is also performed.

10402-57, Session 11

VIIRS pre-launch near field response characterization

Thomas Schwarting, Jeffrey McIntire, Hassan Oudrari, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) is a scanning radiometer sensor containing 22 spectral bands that is currently taking data aboard the Suomi-NPP satellite. A second flight unit is set to launch aboard the JPSS-1 satellite in the 4th quarter of 2017 followed by a third one aboard JPSS-2 in 2022. The VIIRS sensor is designed to obtain high quality data products over a variety of conditions including high contrast scenes like bright clouds over ocean for example. In the pre-launch test program the vendor, Raytheon, makes measurements to determine the contamination from Near Field Response (NFR), which is scattered light from bright targets, to characterize these features and compare them against the structured scene requirement. As of now prelaunch testing has been completed on the first three VIIRS flight units, S-NPP, JPSS-1 and JPSS-2, with independent analyses performed by the NASA VCST team. We present this NFR characterization including derivation of the Harvey-Shack coefficients and impacts from other contamination such as retro reflections off the dewar to the cold focal planes. Impact of these effects to the on-orbit products will be explored as well.

10402-58, Session 11

Spectralon solar diffuser BRDF variation for NPP, JPSS J1, and JPSS J2

Vijay Murgai, Lindsay H. Johnson, Staci N. Klein, Raytheon Space and Airborne Systems (United States)

The Visible/Infrared Imaging Radiometer Suite (VIIRS) is a key sensor on the Suomi National Polar-orbiting Partnership (NPP) satellite as well as the upcoming Joint Polar Satellite System (JPSS). VIIRS collects Earth radiometric and imagery data in 22 spectral bands from 0.4 to 12.5

?m. Radiometric calibration of the reflective bands in the 0.4 to 2.5 ?m wavelength range is performed by measuring the sunlight reflectance from Spectralon®. Reflected sun light is directly proportional to the Bidirectional Reflectance Distribution Function (BRDF) of the Spectralon®. This paper presents the BRDF measurements of the Spectralon® for JPSS J2 in the 0.4 – 1.63 ?m wavelength using PASCAL (Polarization And Scatter Characterization Analysis of Lambertian materials) with an uncertainty better than 1.2%. PASCAL makes absolute measurements of BRDF in an analogous fashion National Institute of Standards and Technology (NIST) Spectral Tri-function Automated Reflectance Reflectometer (STARR) facility. Unique additional features of this instrument include the ability to vary the sample elevation and roll / clock the sample about its normal allowing measuring BRDF in the as use geometry. Comparison of BRDF in the as use configuration for NPP, J1, and J2 shows variation of up to 3%. The sign of the change from panel to panel depends on the angle of incidence and view angle. The results demonstrate lot to lot variability in Spectralon® and emphasize the necessity of characterizing each panel. A pattern in the BRDF variation is also presented.

10402-59, Session 11

Establishing BRDF calibration capabilities through shortwave infrared

Georgi T. Georgiev, NASA Langley Research Ctr. (United States); James J. Butler, Kurtis J. Thome, NASA Goddard Space Flight Ctr. (United States); Catherine C. Cooksey, National Institute of Standards and Technology (United States)

Satellite instruments operating in the reflective solar wavelength region require accurate and precise determination of the Bidirectional Reflectance Distribution Functions (BRDFs) of the laboratory and flight diffusers used in their pre-flight and on-orbit calibrations. Challenges in making high accuracy BRDF measurements in the ShortWave InfraRed (SWIR) above 1700nm has led to the assumption that Directional Hemispherical Reflectance (DHR), a measurement confidently made with high accuracy, scales linearly with BRDF and can be used to derive BRDF. The work of Yoon et al. questioned the validity of that assumption. This paper advances that initial work and presents a comparison of spectral BRDF and DHR on Spectralon, a common material for laboratory and on-orbit flight diffusers. A new measurement setup for BRDF measurements from 900 nm to 2500 nm located at NASA Goddard Space Flight Center is described. The NASA setup employs an extended indium gallium arsenide detector, bandpass filters, and a supercontinuum light source. Comparisons of the NASA BRDF measurements in the SWIR with those made by the NIST Spectral Tri-function Automated Reference Reflectometer (STARR) are presented. The Spectralon samples used in this study included 2 inch diameter, 99% white pressed and sintered PTFE targets. The control sample was optical grade Spectralon while the second sample was space grade Spectralon. The BRDF results are discussed and compared to empirically generated BRDF data from a linear model based on NIST certified values of 6o DHR from 900 nm to 2500 nm and to NIST BRDF measurements. The NASA/NIST BRDF comparison measurements were made at an incident angle of 0o and viewing angle of 45o. Additional BRDF data not compared to NIST are presented at additional incident and viewing angle geometries. The total combined uncertainty for BRDF in the SWIR range is less than 1% (k=1). This study is in support of current and future NASA remote sensing missions operating across the reflected solar wavelength region.

10402-500, Session Plen

Demonstrating Technologies for Hyperspectral Infrared Remote Sensing from Space on a CubeSat

Thomas S. Pagano, Jet Propulsion Lab. (United States)

CubeSats offer a low cost platform for remote sensing and in-situ measurements in space. Not only is the cost of the spacecraft low, but also the cost of the launch since typically CubeSats are secondary payloads to the primary satellite being launched. Despite the low available volume, mass and power and a typically less than ideal orbit, the platform can be ideal for demonstrating technology and even achieving certain science quality measurements. In this talk we discuss the CubeSat Infrared Atmospheric Sounder (CIRAS) a new project at NASA JPL designed to demonstrate key technologies for hyperspectral infrared measurements of atmospheric temperature and water vapor from space.

10402-60, Session 12

Operational correction and validation of the VIIRS TEB longwave infrared band calibration bias during blackbody temperature changes

Wenhui Wang, ERT, Inc. (United States); Changyong Cao, National Oceanic and Atmospheric Administration (United States) and National Environmental Satellite, Data, and Information Service (United States) and Ctr. for Satellite Applications and Research (United States); Bin Zhang, ERT, Inc. (United States); Likun Wang, Univ. of Maryland, College Park (United States)

The Suomi NPP VIIRS thermal emissive bands (TEB) have been performing very well since the data became available on January 20, 2012. The longwave infrared bands at 11 and 12 um (M15 and M16) are primarily used for sea surface temperature (SST) retrievals. However, a long standing anomaly has been observed during the quarterly warm-up-cool-down (WUCD) events. During such event the SST product becomes anomalous with a warm bias shown as a spike in the SST time series on the order of 0.3K. Analysis shows that this is primarily due to warm biases in M15 (~0.12K) and M16 (~0.07K) during the blackbody cooling phase of the WUCD, which are further amplified by the SST retrieval algorithm. A correction algorithm known as Ltrace has been developed based on analysis of the operational calibration algorithm and traceability to prelaunch. This study presents the evaluation and the implementation of the correction algorithm towards the operational processing in generating VIIRS SDR. Sample reprocessing of the data have been performed with the correction algorithm, and the corrected data have been compared with CrIS observations as independent verification with positive results. Preliminary results from the SST users also indicate positive changes. Our implementation minimizes the impacts to the current operational system and the correction is automatically triggered during the blackbody temperature changes. Analysis of historical data shows that the algorithm is applicable to all WUCD events with the same correction parameters. The algorithm is expected to be implemented in operations in the near future.

10402-61, Session 12

Electronic crosstalk effect in SNPP VIIRS thermal emissive bands

Junqiang Sun, Global Science & Technology, Inc. (United States); Menghua Wang, Ctr. for Satellite Applications and Research (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) onboard the Suomi National Polar-orbiting Partnership (SNPP) spacecraft has been on orbit for more than five years. Pronounced striping in Earth view (EV) images and obvious discontinuity in the EV brightness temperature (BT) of the thermal emissive bands (TEB) during the blackbody (BB) warm-up cool-down (WUCD) calibration have been found since launch but the root-cause of the phenomena has not yet been identified. Meanwhile, recent studies of the MODerate-resolution Imaging Spectroradiometer (MODIS) long-wave infrared (LWIR) photovoltaic (PV) bands demonstrate that crosstalk effect induces the same erroneous features. In this paper, it is shown that there is, indeed, a remarkable crosstalk contamination in SNPP VIIRS TEB. The

crosstalk effect is quantitatively characterized by deriving the crosstalk coefficients from the scheduled lunar observations and the established lunar imagery analysis. Among all SNPP VIIRS TEB, band M14 is shown to have the largest crosstalk contamination from Band M15, while bands M13, M15, M16, and I5 have pronounced crosstalk effect as well. The crosstalk effect is distinctively different for the odd and even detectors within each affected band during to the pattern of the placement of the odd and the even detectors of the band on the focal plane assembly (FPA). The crosstalk coefficients are applied to mitigate the crosstalk effect and the improvements to both the BB calibration and EV retrieval are presented and addressed.

10402-62, Session 12

Suomi-NPP VIIRS thermal emissive bands calibration stability monitoring using Dome C

Zhipeng Wang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Aisheng Wu, Yonghong Li, Science Systems and Applications, Inc. (United States)

The thermal emissive bands (TEB) of VIIRS are radiometrically calibrated on a scan-by-scan basis in reference to an on-board blackbody (BB) regularly operated at approximately 292.5 K. The calibration stability at other temperature ranges can be independently evaluated using remote targets with stable surface properties. Dome Concordia (Dome C), Antarctic (75°06?S, 123°21?E) is a high plateau homogeneous dry scenes with its surface temperatures varying from 190 to 250 K from winter to summer, which are constantly measured on site. Close to South Pole, Dome C is frequently viewed by Suomi-NPP nearly 10 times per day at various scan angles, providing continuous time series TEB data throughout its mission. In this study, the brightness temperatures (BT) of the Dome C surface retrieved from the data generated by NASA Land Science Investigator-led Processing System (SIPS) is trended to monitor the calibration stability of VIIRS TEB. The trending is performed in detector level at various scan angles. Results show that the radiometric calibration of all TEB detectors has been stable since the instrument's launch in 2011. There is also no noticeable BT drift at different scan angles, indicating no significant response versus scan-angle (RVS) drift for TEB. We further analyzed the data by inter-band comparison and in-band (inter-detector) comparison and found no sign of anomaly such as electric crosstalk. The study confirms that Dome C can serve as a valuable calibration reference site at a temperature range far colder than the BB operating temperature.

10402-63, Session 13

Monitoring of VIIRS ocean clear-sky brightness temperatures against CRTM simulation in ICVS for TEB/M bands

Xingming Liang, National Oceanic and Atmospheric Administration (United States) and ERT, Inc. (United States); Ninghai Sun, Quanhua Liu, National Oceanic and Atmospheric Administration (United States); Wenhui Wang, ERT, Inc. (United States) and National Oceanic Atmospheric Administration (United States); Bin Zhang, National Oceanic and Atmospheric Administration (United States) and ERT, Inc. (United States); Taeyoung J. Choi, National Environmental Satellite, Data, and Information Service (United States) and ERT, Inc. (United States); Fuzhong Weng, National Oceanic and Atmospheric Administration (United States); Alexander Ignatov, National Environmental Satellite, Data, and Information Service (United States); Changyong Cao, National Oceanic and Atmospheric Administration (United States)

NOAA Integrated Calibration/Validation System (ICVS) for Long-Term Monitoring is a real-time environmental satellite performance monitoring system. It is used to ensure high-quality satellite imagery and to deliver accurate Sensor Data Record (SDR) products for weather forecasts and environmental monitoring. The Visible Infrared Imaging Radiometer Suite (VIIRS) is one of key sensors monitored in the ICVS. With the development of faster and more accurate radiative transfer models (RTM), validating sensor radiometric accuracy against RTM simulation has become a more important requirement by both SDR and Environmental Data Record (EDR) users. In this presentation, monitoring of VIIRS ocean clear-sky Observations (brightness temperatures, BTs) against the NOAA Community Radiative Transfer Model (CRTM) Simulations (O-S) for thermal emissive M Bands was set up in ICVS. This monitoring builds upon another NOAA system, Monitoring of IR Clear-sky Radiances over Ocean for SST (MICROS) to support VIIRS calibration and validation. To minimize O-S mean biases and uncertainties, model data are calculated on a pixel-by-pixel basis using the CRTM in conjunction with European Center for Medium range Weather Forecasting (ECMWF) atmospheric profiles and Canadian Meteorological Center (CMC) sea surface temperature (SST) analysis as inputs. A modified clear-sky mask employed in the NOAA Advanced Clear-Sky Processor for Oceans (ACSPO) SST system was used to remove cloud contamination. The preliminary results show that the nighttime O-S biases and standard deviations are exemplary stable for all bands. Also the system detects VIIRS warm-up-cool-down (WUCD) event effects in the bands M12, M13 M14 and M15. More efforts are needed to unscramble and fix anomalies in M13, which show large mean biases (~-0.55K) and satellite view zenith angle dependence with an amplitude of ~0.3 K by collaborating with CRTM and VIIRS sensor calibration Teams. Future work will be to extend functionalities to prepare for the upcoming Joint Polar Satellite System 1 (JPSS1, J1) operations.

10402-64, Session 13

Improvements in the calibration of the SNPP VIIRS day-night band

Junqiang Sun, Global Science & Technology, Inc. (United States); Menghua Wang, Ctr. for Satellite Applications and Research (United States)

We present improvements to the on-orbit calibration of the day-night band (DNB) of the Visible Infrared Imaging Radiometer Suite (VIIRS) on the Suomi National Polar-orbiting Partnership (SNPP) satellite. Most important among the improvements is the expansion of the "sweet spot" from 4 o to 7.8o to increase the number of the fully illuminated scans for calcuation. This allows for the completion of the on-orbit calibration using the solar diffuser (SD) within one orbit instead multiple orbits as required in the current standard approach. The bidirectional reflectance factor (BRF) of the SD and the vignetting function (VF) describing the transmission of the attenuation screen in front of the SD port are also examined and improved. Additional enhancements include the analysis of the out-of-band (OOB) contribution of the relative spectral response (RSR) and the adaptation of the previously improved SD degradation. The result shows that the improved DNB calibration coefficients are more stable, smooth and less noisy.

10402-65, Session 13

Prediction of S-NPP VIIRS DNB gains and dark offsets

Chengbo Sun, Global Science & Technology, Inc. (United States); Thomas Schwarting, Hongda Chen, Kwofu Chiang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

We describe the methodology for predicting the S-NPP VIIRS Day-Night-Band (DNB) detector gains and dark offsets. During the first 5 years of

operation, the DNB has shown recognizable patterns in these calibration parameters. These patterns can be decomposed into two distinctive components: degradation and oscillation. We fit the historical data using a periodic function of time superimposed on an exponential function of time to capture both sources of the variation. The results of the fit showed good agreements with historical measured data, indicating the functions may be useful as a forward model for predicting these calibration parameters in operation. As a test, predictions made in April, 2016 were examined against newly obtained measurement data collected at monthly intervals. Through December of 2016, the prediction errors have been smaller than 1.5% and 0.5% in gains and offsets respectively, with the largest errors seen in the end-of-scan aggregation modes of the high-gain stage. The oscillatory features seen in the measured gains will be analyzed to isolate its possible causes and to determine the relevance of its inclusion in the model. Comparisons among the results from using the existing predictions of the gain and offset Look-Up-Tables (LUTs) will be presented.

10402-66, Session 13

Suomi-NPP VIIRS initial reprocessing improvements and validations in the reflective solar bands (RSBs)

Taeyoung J. Choi, National Environmental Satellite, Data, and Information Service (United States); Junqiang Sun, Global Science & Technology, Inc. (United States) and National Oceanic and Atmospheric Administration (United States) and Ctr. for Satellite Application and Resarch (United States); Bin Zhang, National Environmental Satellite, Data, and Information Service (United States) and Univ. of Maryland (United States); Zhuo Wang, National Oceanic and Atmospheric Administration (United States) and Univ. of Maryland (United States); Changyong Cao, National Oceanic and Atmospheric Administration (United States); Fuzhong Weng, National Environmental Satellite, Data, and Information Service (United States); Menghua Wang, National Oceanic and Atmospheric Adminstration (United States) and National Environmental Satellite, Data, and Information Service (United States)

Over five years of the Suomi National Polar orbiting Partnership (S-NPP) Visible Infrared Imaging Radiometer Suite (VIIRS) Sensor Data Records (SDR) production, there were mutual demands of the lifetime VIIRS SDR reprocessing to alleviate operational changes and user oriented suggestions. Meanwhile, the NOAA Ocean Color (OC) team through its independent effort has achieved the robust calibration of the S-NPP VIIR Reflective Solar Bands (RSBs) – including improved radiometric accuracies, minimized annual oscillations and mitigated growing bias for long-term radiometric stability – leading to the institutional decision to use the OC calibration results as the official Look-Up Tables (LUTs) for operational mission-long reprocessing to provide enhanced radiometric accuracy for Environmental Data Records (EDR) productions. The SDR reprocessing team has applied the most recent calibration coefficients LUTs provided by the OC Team to the current VIIRS reprocessing. This paper briefly summarizes the efforts of the SDR reprocessing team, the related entire life reprocessing issues and the initial results in the RSBs. It will show that the quality and accuracy of the SDR reprocessed with the new LUTs are significantly improved. It will also demonstrate the remarkable improvements of the VIIRS EDR for various applications and higher-level science products by using the reprocessed SDR as their inputs.

10402-67, Session 14

Reflective solar bands calibration improvements and look up tables for SNPP VIIRS operational mission-long SDR reprocessing

Menghua Wang, Ctr. for Satellite Applications and Research (United States); Junqiang Sun, Global Science & Technology, Inc. (United States)

The Suomi National Polar-orbiting Partnership (SNPP) Visible Infrared Imaging Radiometer Suite (VIIRS) has been on orbit for more than five years. Through independent efforts by the NOAA OC Team, the radiometric calibration of reflective solar bands (RSBs) recently has reached a mature stage. Numerous improvements have been made in the standard RSB calibration methodology for the sensor data records (SDR), which is the starting for the higher-level environmental data records (EDR) and science products. These improvements have helped the EDR ocean color products that demand stringent accuracy to reach maturity. The success of the OC EDR performance has further led to the institutional decision to use the calibration results generated by the OC Team, in the form of the look-up-tables (LUTs), as the official input for the operational SDR reprocessing, which are to be the official release to be used by all science groups and communities. The OC LUTs delivered for the operational SDR reprocessing is the latest update containing further improvements over the current LUTs used for the OC reprocessing and forward processing. This presentation will address the following: the good performance of the SNPP VIIRS RSBs, the inadequacies in the current operational forward SDR generated by the Interface Data Processing Segment (IDPS), the RSB calibration improvements made by the NOAA OC Team, the success of the RSB SDR reprocessing for ocean color EDR using the improved RSB LUTs, and finally, the use of the OC LUTs as the official LUTs for VIIRS RSB SDR operational reprocessing.

10402-68, Session 14

On-orbit noise characterization of the SNPP VIIRS reflective solar bands

Kevin A. Twedt, Ning Lei, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) aboard the Suomi National Polar-orbiting Partnership satellite has 14 reflective solar bands (RSBs) covering a spectral range from 410 nm to 2250 nm. We provide an overview of the noise characterization of the VIIRS RSB from pre-launch through more than five years of on-orbit operation. On orbit, the noise is measured as the variation in the signal level observed at the sunlit solar diffuser (SD) within each instrument scan. The SD signal level changes from scan to scan as the solar angle changes during the SD illumination time period of each orbit, allowing us to establish a functional dependence of the noise on signal level. The signal-to-noise ratio for all RSB has been slowly decreasing on-orbit, but remains above specification performance values (given at fixed typical radiance for each band) and is projected to remain above specification for at least five more years based on the current trends in the performance of the electronic and optical sub-systems. We show a comparison to pre-launch measurements, and also discuss the importance of data quantization and sample aggregation in the interpretation of the SNR values.

10402-69, Session 14

RSB calibration of SNPP VIIRS using solar diffuser illuminated by scattered light

Junqiang Sun, Global Science & Technology, Inc. (United States) and Ctr. for Satellite Applications and Research (United States); I-Wen Mike Chu, Menghua Wang, Ctr. for Satellite Applications and Research (United States)

We present a different approach to the on-orbit calibration of the reflective solar bands (RSBs) using solar diffuser (SD) for SNPP VIIRS. Instead of following the standard methodology that uses full solar illumination occurring in the short window of time right before the satellite reaches the terminator, we use light scattered off the earth scenes coming through the nadir port as the source of the illumination for the SD. This alternative to the standard approach is shown to be viable, and in fact demonstrates more stable calibration results due to having more data volume. We describe the methodology, present the results, make comparison with the current standard method, and discuss its advantages. The methodology is applicable to other instruments employing a similar SD-based calibration strategy, such as MODIS, and can serve as a viable replacement.

10402-70, Session 14

Suomi-NPP visible infrared imaging radiometer suite (VIIRS) calibration uncertainty its effect on trends in the ocean color data record

Kevin R. Turpie, NASA Goddard Space Flight Ctr. (United States) and Univ. of Maryland (United States); Robert E. Eplee Jr., NASA Goddard Space Flight Ctr. (United States) and SAIC (United States); Gerhard Meister, Bryan A. Franz, NASA Goddard Space Flight Ctr. (United States)

The NASA Ocean Color calibration team continued to reanalyze and improve on their approach to the on-orbit calibration of the Visible Infrared Imaging Radiometer Suite (VIIRS), aboard the Suomi National Polar-orbiting Partnership (NPP) satellite, now five years into its Earth Observation mission. As the calibration was adjusted for changes in ocean band responsitivity with time, the team also observed the variance and autocorrelation properties of calibration trend fit residuals, which appeared to have a standard deviation within a few tenths of a percent. Autocorrelation was observed to be different between bands at the blue end of the spectrum and bands at the red/NIR end, which are affected by significant changes in responsitivity stemming from mirror contamination. This residual information offered insight into the effect of small calibration biases, which can cause significant trend uncertainties in regional time series of surface reflectance and derived products. This work involves modeling spurious trends that are inherent to the calibration over time and that also arise between reprocessing efforts because of extrapolation of the time-dependent calibration table. Uncertainty in calibration trends was estimated using models of instrument and calibration system trend artifacts and correlated noise models using Monte Carlo techniques. Combined table reprocessing and extrapolation biases are presented for the first time. Calibration trend uncertainty is then propagated through to ocean color remote sensing reflectance and chlorophyll-a concentration time series. The results quantify the smallest trend observable in these oceanic parameters. This quantification furthers our understanding of uncertainty in measuring regional and global biospheric trends in the ocean using VIIRS, and better defines the roles of records in climate research.

10402-71, Session 14

Advances in the on-orbit calibration of SNPP VIIRS for ocean color applications

Robert E. Eplee Jr., NASA Goddard Space Flight Ctr. (United States); Kevin R. Turpie, Univ. of Maryland, Baltimore (United States); Gerhard Meister, Frederick S. Patt, Bryan A. Franz, NASA Goddard Space Flight Ctr. (United States)

The NASA Ocean Biology Processing Group has continued monitoring the SNPP VIIRS on-orbit calibration since the derivation of the calibration for Reprocssing 2014.0 of the VIIRS ocean color data set. A key technique involves evaluation of globally-derived anomaly plots of remote sening reflectance for the ocean color bands. Updates to the on-orbit calibration have produced ocean color data retrievals that show trends in the anomaly plots for bands M1 (412 nm), M4 (555 nm), and M5 (672 nm). Consequently, the OBPG has re-examined the effects of the prelaunch calibration (counts-to-radiance conversion) of SNPP VIIRS on the on-orbit calibration. Two cases were compared to the baseline linear function of counts: a quadratic function of counts, and a focal plane temperature-dependent quadratic function of counts. The quadratic function, compared to the baseline, showed a 0.2% effect on band M7 (862 nm) over the mission. The temperature-dependent quadratic function, compared to the baseline, showed the following effects over the mission: 0.5% on band M1 (412 nm), 0.6% on band M4 (555 nm), 0.2% on band M6 (748 nm) and 0.6% on band M7 (862 nm). The OBPG has produced an on-orbit calibration based on the temperature-dependent quadratic counts-to-radiance conversion and has reprocessed the mission-long solar and lunar calibration time series using our standard approach for deriving lunar adjustments to the solar-derived radiometric gains. The impact of this new on-orbit calibration of SNPP VIIRS on global ocean color data retrievals will be reported.

10402-72, Session 14

Assessment of S-NPP VIIRS band-to-band registration using Earth-scene features

Daniel Link, Zhipeng Wang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) is currently operating onboard the Suomi National Polar-orbiting Partnership (S-NPP) spacecraft. VIIRS records Earth imagery with spectral bands ranging from 0.4 to 12.2 micrometers at a combination of resolutions. Five imaging bands (I1-5) have a 375 m spatial resolution at nadir, which is half of the 750 m resolution of the 16 moderate resolution bands (M1-16). These bands are mounted according to their wavelengths among three separate Focal Plane Assemblies (FPA).

The proper spatial registration between imaging bands is required to create multi-spectral images and analyses. Measurement of the band-to-band registration (BBR) is a determination of how well these bands are coincident. Using an external target such as the moon has proven to be a valid method and has been thoroughly investigated using VIIRS raw data record (RDR). Calibrated VIIRS radiometric data has been investigated using normalized mutual information (NMI) for BBR and shown stable results, by focusing on high-contrast shoreline sites. However, these results focus on a relatively small number of observations. We have previously reported analyses using earth-scene targets to determine BBR for MODIS instruments. This approach focuses on an African Desert site with high contrast spots generated through agricultural pivot irrigation. Using the near-daily observations provided by the VIIRS instrument, we investigate a large data set and track the BBR stability over the VIIRS mission. We discuss our results as they relate to pre-launch measurements and design specifications.

10402-85, Session PWed

Design and implementation of JOM-3 Overhauser magnetometer analog circuit

Xiao Zhang, Xue Jiang, Jianchang Zhao, Shuang Zhang, Xin Guo, Tingting Zhou, Jilin Univ. (China)

Overhauser magnetometer, a kind of static-magnetic measurement system based on the Overhauser effect, has been widely used in archaeological exploration, mineral resources exploration, oil and gas basin structure detection, prediction of engineering exploration environment, earthquakes and volcanic eruotions, object magnetic measurement and underground buried booty exploration. Overhauser magnetometer plays an important role in the application of magnetic field measurement for its characteristics of small size, low power consumption and high sensitivity. This paper researches the design and the application of the analog circuit of JOM-3 Overhauser magnetometer. First, the Larmor signal output by the probe is very weak. In order to obtain the signal with high SNR, the design of pre-amplifier circuit is the key to improve the quality of the system signal. Second, in this paper, the effectual step which could improve the frequency characters of bandpass filter amplifier circuit were put forward, and theoretical analysis was made for it. Third, the shaping circuit shapes the amplified sine signal into a square wave signal which is suitable for detecting the rising edge. Fourth, this design elaborated the optimized choice of coordination capacitor circuit, so the measurement range of the magnetic field can be covered. Last, integrated analog circuit testing system was formed to obtain waveform of each module. By calculating the standard deviation, the sensitivity of the improved Overhauser magnetometer is close to 0.05nT for Earth's magnetic field observation. Experimental results show that the new magnetometer is sensitive to earth field measurement.

10402-86, Session PWed

The curious case of the intersensor radiometric comparison of SNPP VIIRS M11 with Aqua MODIS B7

I-Wen Mike Chu, Ctr. for Satellite Applications and Research (United States) and Cooperative Institute for Research in the Atmosphere (United States) and ERT, Inc. (United States); Junqiang Sun, Global Science & Technology, Inc. (United States) and Ctr. for Satellite Applications and Research (United States); Menghua Wang, Ctr. for Satellite Applications and Research (United States)

The radiometric performance of the Visible Infrared Imaging Radiometer Suite (VIIRS) onboard the Suomi National Polar-orbiting Partnership (SNPP) satellite is often carried out against the Moderate-resolution Imaging Spectrometer (MODIS) onboard Aqua satellite utilizing simultaneous nadir overpasses (SNOs). The comparison of SNPP VIIRS Band M11 (2257 nm) versus Aqua MODIS B7 (2130 nm), however, suffers from widely varying and inconsistent result unusable for further evaluation of the radiometric performance. This investigation presents the first successful radiometric comparison between SNPP VIIRS M11 and Aqua MODIS B7. It is shown that the non-overlapping relative spectral responses (RSRs) are the cause of the widely varying comparison coming from the mix of snow and cloudy scenes with each having different reflectance in different part of the spectrum. A targeted selection procedure using both geolocation and statistics seek out the more stable surface snow scenes as the viable targets of comparison. The resulting comparison time series, with about 50 sufficiently robust SNO events, of Aqua MODIS B7 radiance over the SNPP VIIRS M11 radiance is shown to be stable at 0.4 with a ~5% range and no obvious drift.

10402-87, Session PWed

Bridging the thermal band comparison between LEO-LEO sensors and between GEO-GEO sensors

Tiejun Chang, Graziela R. Keller, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The MODIS onboard the Terra and Aqua satellites have operated since 1999 and 2002, respectively. The inter-comparison between their thermal emissive bands is a useful tool in assessing their calibration consistency and enhancing their product quality. One application of the comparison is to assess the MODIS thermal band cross-talk. However, the comparison is hindered by the time difference of their measurements, since Terra is in the morning orbit and Aqua is in the afternoon orbit.

GOES-R was launched on November 19, 2016 and Himawari 8 was launched on October 7, 2014. The Advanced Baseline Imager (ABI) onboard GOES-R and the Advanced Himawari Imager (AHI) onboard Himawari are in the same class and have almost identical thermal spectral bands. Their comparison will be very useful for sensor calibration assessment. However, the comparison is challenged by the fact that they image different regions of the Earth.

This work focuses on bridging the thermal band comparison between LEO-LEO sensors and between GEO-GEO sensors. The double difference method is applied to assess the BT measurements between the two MODIS instruments using the GOES imager as a bridge. The comparison between ABI and AHI can also be performed with bridging by either MODIS or VIIRS measurements. GOES-R and Himawari are both positioned over tropical ocean regions. Thus, the comparison with simultaneous nadir overpass can provide assessments for BT measurements for this type of scenery. The comparison can also be extended to simultaneous off-nadir measurement for various types of sites and for a broad BT range.

10402-88, Session PWed

Status of the MODIS spatial and spectral characterization and performance after recent SRCA operational changes

Daniel Link, Zhipeng Wang, Kevin A. Twedt, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

There are two nearly identical MODIS instruments currently operating on-board the NASA EOS Terra and Aqua spacecraft. Each MODIS is equipped with several on-board calibrators (OBCs) including a Spectro-Radiometric Calibration Assembly (SRCA). The SRCA is a multi-configuration calibrator that aids in determining the performance parameters of MODIS detectors on-orbit. Depending on its configuration, scheduled operations of the SRCA provide measurements to assess the on-orbit radiometric, spatial, and spectral performance. The SRCA was designed to utilize various combinations of three 10 Watt lamps and one 1 Watt lamp and included a spare of each type. Lamp failures reduced the available number of 10 Watt lamps from four to two for each mission by 2006.

Over the past year, each instrument experienced an issue on-orbit. The nadir door of Terra MODIS closed as the instrument was autonomously commanded into safe-mode after a spacecraft commanding issue. The instrument and spacecraft were successfully recovered. For Aqua, a failure occurred for one of the two remaining 10 Watt lamps. We investigate each issue as it relates to the SRCA's operation and its ability to properly characterize MODIS detector performance. For Terra MODIS, we present changes in MODIS spectral and spatial performance due to changes in the instrument environment. In the case of Aqua MODIS, losing a lamp reduces the output potential of the SRCA. We present the results from this impact and the adjustments made to calibration activities to maximize the effectiveness of the remaining lamps.

10402-89, Session PWed

CrIS sub-pixel level VIIRS radiance clustering analysis

Haibing Sun, I. M. Systems Group, Inc. (United States); Walter Wolf, Ctr. for Satellite Applications and Research (United States); Thomas S. King, Shanna Sampson, I. M. Systems Group, Inc. (United States)

The Visible Infrared Imaging Radiometer Suite (VIIRS) and Cross-track Infrared Sounder (CrIS) are two key infrared instruments onboard JPSS for observing the Earth's weather, climate, and environment. Their observations and products provide information with different spectral and spatial resolution. NOAA/NESDIS/STAR satellite observation collocation algorithms are used to spatially match observations or products from different sensors. The spatially matched and integrated satellite datasets are widely used in integrated satellite retrievals, satellite instrument inter-calibration and satellite observation validation. The VIIRS instrument has multi-band imaging capabilities to support the acquisition of high-spatial resolution atmospheric imagery. The VIIRS measurements collocated within the CrIS file of view (FOV) can provide sub-pixel level scene VIIRS radiances and cloud information. These data have been used for CrIS cloud-clearing algorithms and sub-pixel observation selection. The currently operational CrIS and VIIRS collocation processing algorithm was updated to generate a radiance clustering analysis. This analysis is performed on the co-located VIIRS pixels to identify localized areas of similar radiance clusters within the CrIS FOV, the assumption being that these clusters correspond to different scene types. The algorithm is based on the K-means clustering method using all available VIIRS channels. The CrIS sub-pixel VIIRS clustering product consists of the mean radiance, the standard deviation, and the coverage of the class within the CrIS FOV. The radiance clustering analysis product provides the inhomogeneity knowledge within the CrIS field of view. This knowledge is helpful to define the scene type and provide an accurate guess estimate of the decomposition parameters for the cloud clearing processing. In this paper, the CrIS sub-pixel radiance clustering algorithm and its operational implementation is presented. The product, parameter selection, and the validation results are presented in detail.

10402-90, Session PWed

MTF analysis using lunar observations for Himawari-8/AHI

Graziela R. Keller, Tiejun Chang, Zhipeng Wang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The modulation transfer function (MTF) is a common measure of image fidelity, which has been historically characterized on-orbit using high contrast images of the lunar limb obtained by remote sensing instruments onboard both low-orbit and geostationary satellites.

Himawari-8, launched in 2014, is a Japanese geostationary satellite that carries the Advanced Himawari Imager (AHI), a near-identical copy of the Advanced Baseline Imager (ABI) instrument onboard the GOES-16 satellite. In this paper, we apply a slanted-edge method for deriving the MTF from lunar images, first verified by us on simulated test images, to Himawari-8/AHI L1A and L1B data. The MTF is derived along both the North/South and East/West directions separately and we assess the impact of the relative movement between the Moon and the spacecraft on the edge profiles.

The AHI L1A images used in the characterization of the MTF are obtained from scheduled lunar observations routinely acquired for validating the radiometric calibration. The L1B data, on the other hand, come from serendipitous lunar observations where the Moon appears close to the Earth's disk and spanning different Moon phases. We developed and implemented an algorithm to identify such occurrences using the SPICE/Icy package to predict the times where the Moon is visible in the L1B imagery and demonstrate their use for MTF derivation. AHI L1B data is spatially re-sampled and this application allows the impact of the AHI re-sampling algorithm on the MTF to be assessed at different North/South and East/West positions on the images.

10402-91, Session PWed

Prediction of S-NPP VIIRS DNB stray light correction

Chengbo Sun, Global Science & Technology, Inc. (United States); Thomas Schwarting, Hongda Chen, Kwofu Chiang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The VIIRS Day-Night-Band (DNB) is a panchromatic band with three gain stages used for delivering imagery under a variety of conditions ranging from daylight to low light nighttime scenes. Early in the S-NPP mission a gray haze was observed in some nighttime DNB imagery with the cause determined to be stray light contamination. This effect was characterized along with a proposed correction algorithm. The correction algorithm was subsequently included in operational data processing and re-processing. However, in order to process real-time data, prediction of the stray light correction is necessary. In this paper we present a new method to predict the DNB stray light correction Look-Up-Tables (LUTs). Since measurements suitable for characterizing the stray light contamination are sparse (about once a month during new-Moon), and because some of the measurements might not be accurate due to the presences of unaccounted light sources, such as algae glow and lightening, we have applied additional constraints to the model by assuming that certain patterns of the stray light are repeatable. Comparisons of the LUT parameters produced by the prediction algorithm with those from the measurements will be presented along with the impact on the derived Earth View products.

10402-92, Session PWed

MODIS solar diffuser degradation at short-wave infrared band wavelengths

Kevin A. Twedt, Amit Angal, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Xu Geng, Hongda Chen, Science Systems and Applications, Inc. (United States)

The MODIS instruments aboard the Terra and Aqua spacecraft have 20 reflective solar bands (RSB) with wavelengths spanning 0.412 μm to 2.13 μm. The primary on-board calibration source for the RSB is a sunlit solar diffuser (SD), with its degradation tracked by a SD stability monitor (SDSM). The SDSM measurements show that the decrease in SD reflectance over time has a strong wavelength dependence, with longer wavelengths showing less degradation. The SDSM has 9 detectors to track the SD degradation at wavelengths from 0.412 μm to 0.936 μm, but is not designed to track the degradation at SWIR wavelengths. In recent years, the SDSM has measured non-negligible degradation in the SD reflectance at 0.936 μm for both Terra (>2%) and Aqua (>0.5%) MODIS. In addition, comparison of SD calibration results to earth view targets suggests that smaller but non-negligible SD degradation also exists at the SWIR band wavelengths.

In this paper, we review the current status of the MODIS SD degradation as measured by the SDSM, and discuss the challenges involved in calibration. We present efforts to extend the SD degradation measurements to the SWIR band wavelengths (1.2 μm to 2.1 μm) by fitting a wavelength-dependent model to the SDSM results from the NIR wavelength detectors. The predicted degradation results are used to correct the MODIS SWIR band degradation, and comparisons are made with that determined using the pseudo-invariant earth targets. Results are presented for both Terra and Aqua MODIS.

10402-93, Session PWed

Prism spectrometer analysis for field use

Adam Abdelatif, Nikolaus J. Anderson, College of Optical

Sciences, The Univ. of Arizona (United States); Oscar Hernandez, The Univ. of Arizona (United States); Jeffrey S. Czapla-Myers, College of Optical Sciences, The Univ. of Arizona (United States)

The Spectrometer Arduino Mega (SpAM) is a prism spectrometer that has been designed and fabricated by the Remote Sensing Group (RSG) at the College of Optical Sciences of the University of Arizona. SpAM is designed to be a low budget, stand alone, solar powered field spectrometer. RSG plans to use SpAM to measure the reflectance of natural surfaces in the field. After verification of the accuracy and performance of SpAM, it will be deployed to the Radiometric Calibration Test Site (RadCaTS) at Railroad Valley, where network capabilities and data logging devices will allow RSG to remotely download spectral radiance measurements.

SpAM measures and records the spectral composition of a light source or light reflected from a surface. The prism inside of SpAM refracts the input light on to a linear array of 512 silicon detectors. The detector-prism combination produces a spectral resolution of ~2 nm, and the overall spectral range is 433–760 nm. The spectral radiometric measurements produced by SpAM are stored and processed by an Arduino mega micro controller with network capabilities for field applications. SpAM will be used to analyze the spectral reflectance of Railroad Valley, Nevada, and its accuracy and performance will be determined by a comparison with more precise radiometers that have been produced by RSG.

This work presents the design and instrumentation of SpAM, and an assessment of its ability to provide radiometric results for satellite calibration and other radiometric measurement applications.

10402-94, Session PWed

Site selection and characterization at Uyuni desert for the calibration and validation of GOES solar reflective bands

Hyelim Yoo, National Oceanic and Atmospheric Administration (United States); Fangfang Yu, ERT, Inc. (United States) and National Oceanic and Atmospheric Adminstration (United Kingdom); Xianqian Wu, National Oceanic and Atmospheric Administration (United States)

Uyuni desert (-20.8 to -19.6 in latitude, -68.2 to -66.8 in longitude) covered by a few meters of salt can be a good target for Earth observation satellite with its flatness and high altitude. Also, the Uyuni desert is the closest desert to the sub-satellite point of GOES-East satellites and we can validate the accuracy of GOES-16 ABI visible and near-IR bands using the Uyuni desert as a reference. An selection of uniform scenes over the Uyuni desert using a number of space-borne observational datasets is a main objective.

It is critical to identify the geospatially, temporally, and spectrally uniform area with at least 3 km x 3 km in size for ABI band 2 and 7 km x 7 km for ABI band 1,3,4,5,and 6. For radiometric and temporal stability, GOES-15 Imager visible data obtained near the satellite noon time is used. Reflectance is calculated by applying the post-launch calibration for each image using calibration coefficients generated by Yu et al.(2014) and projected them to the ABI fixed grid position in order to identify the area with low standard deviation reflectance pixels. In terms of spatial stability, SNPP Visible Infrared Imaging Radiometer Suite (VIIRS) data is compared to find the uniform scenes with low coefficient of variance of reflectance over the radiometric and temporal stable areas. The Hyperion data is used to minimize atmospheric effect and examine the desert spectral variability over a long-term period. The spectral band adjustment factor is calculated as the ratio of GOES-13 Imager visible and VIIRS I band 1 reflectance.

Such findings are expected to help validate the accuracy of ABI visible and near infrared bands by providing high and stable reflectance information. We will cross-check these results with the results of the Sonoran desert.

10402-95, Session PWed

The space-borne hyperspectral imager (SPARK) based on curved prisms

Juanjuan Jing, Jinsong Zhou, Academy of Opto-Electronics, CAS (China) and Univ. of Chinese Academy of Sciences (China); Lei Feng, Academy of Opto-Electronics, CAS (China) and Univ. of Chinese Academy of Sciences (China); Guifeng Zhang, Academy of Opto-Electronics, CAS (China)

The space borne hyperspectral imager, SPARK, the payloaded of microsatellite, has been developed by Academy of Opto-electronics, Chinese Academy of Sciences, China. It has been launched on 22, Dec, 2016, and now deployed for commercial operations around the world. The compact Offner spectrometer featuring two curved prisms are designed to disperse the incident light in optical system with the benefits of low smile, keystone and lateral distortion. All surfaces of mirrors and prisms are spherical. It features a pushbroom imaging spectrometer with more than 148 channels covering a spectral range from 420 to 1000nm. The ground sampling distance is as low as 50m @700km, and the swath width is 100km. But the weight is only 12.8kg, the outer dimensions of SPARK are 362mm (X)* 343mm (Z)*139 mm (Y). The spectrometer has an F-number of 4.5. Because prisms are used for imaging spectrometry, the spectral sampling distance varies with wavelength. The width of the spectral response function varies from 1nm to 12nm. The mean bandwidth is less than 5nm. The SPARK sensor has achieved high performance levels in terms of signal to noise ratio(SNR), spectral calibration and image quality. The SNR is better than 110, the relative calibration precision is better than 5%, and the absolute calibration precision is better than 10%. It can be used for environmental and disaster monitoring.

10402-96, Session PWed

El Niño southern oscillation: Nonlinear modeling, satellite data, and Fourier analysis

Nour Hadjih, Ahmed Hassebo, The City College of New York (United States); Yasser Y. Hassebo, The City College of New York (United States) and LaGuardia Community College (United States); Frank Wang, LaGuardia Community College (United States) and The City College of New York (United States)

The El Niño Southern Oscillation (ENSO) is considered one of the most prominent signal of interannual climate variability. For instance, an investigation provided evidence of the El Niño events impact in determining the ecosystem conditions. El Niño events are characterized by positive Sea Surface Temperature (SST). In this study, Sixty six-year of SST anomalies data of the Niño 3.4 region were analyzed to understand the El Niño-Southern Oscillation (ENSO) phenomenon quantitatively through an elementary nonlinear model using Fast Fourier Transform (FFT) algorithm. A key element in this model is the inclusion of the effects of equatorially trapped oceanic waves (Kelvin and Rossby waves) propagating in a closed basin through a time delayed element. The relationship between this element and the temporal oscillation variability was examined. Results showed that when the time delay was small, there was no oscillation; which explain the lack of El Niño in the Atlantic Ocean compared to the Pacific Ocean. FFT of the Oceanic Niño Index revealed multiple peaks centered on a period of 3.7 years. Range of parameters that cause drastic qualitative changes in the climate system, i.e. bifurcation, was investigated. The model was extended by including external influences such as annual forcing, global warming, and stochastic effects. Study revealed that when the global warming rate was too high, the oscillations disappeared. Self-sustained oscillations under certain conditions was discussed. To validate the model results, four stages of data correction of 5-year Satellite data of Earth Surface Temperature (EST) for Niño 3.4 (5N-5S, 170W-120W) were performed.

10402-97, Session PWed

Principle and analysis of a rotational motion Fourier transform infrared spectrometer

Qisheng Cai, Huang Min, Wei Han, Yixuan Liu, Lulu Qian, Xiangning Lu, Academy of Opto-Electronics, CAS (China)

Fourier transform infrared spectroscopy is an important technique in studying molecular energy levels, analyzing material compositions, and environmental pollutants detection. A novel rotational motion Fourier transform infrared spectrometer with high stability and ultra rapid scanning advantages is proposed in this paper. The basic principle, the optical path difference calculations, and the tolerance analysis are elaborated. The optical path difference of this spectrometer varies with the continuously rotational motion of a pair of parallel mirrors instead of the translational motion in traditional Michelson interferometer. Because of the rotational motion, it avoids the tilt problems occurred in the translational motion Michelson interferometer. There is a cosine function between the optical path difference and the rotating angle of the parallel mirrors. The NUFFT (Non-Uniform Fast Fourier Transform) needs to be used to recover the input spectrum. The vibration of the parallel mirrors, the parallelism of the two rotating mirrors, and the alignment of the two fixed end mirrors are analyzed. The vibration of the parallel mirrors is the main error during the rotation. An optical model is setup in non-sequential mode of the ZEMAX software, and the interferogram of a monochromatic light is simulated using ray tracing method. The simulated interferogram is consistent with the theoretically calculated interferogram. This high stability and ultra rapid scanning Fourier transform infrared spectrometer is a suitable candidate for airborne and space-borne remote sensing spectrometer.

Impact of fluorescence on the underwater polarized light field: Comparison of theory and field measurements

Ahmed El-Habashi, Robert Foster, Carlos Carrizo, Thomas Legbandt, Sam Ahmed, The City College of New York (United States)

We have examined, in earlier work, the relationship between naturally induces chlorophyll fluorescence and the underwater polarized oceanic light field. This shows the un-polarized fluorescence causes a reduction in the degree of polarization over the fluorescence spectral range. Theory shows that the peak of the reduction in polarization occurs at or near the fluorescence peak. Furthermore, it also shows that the magnitude of this reduction in degree of polarization can be related to both the magnitude of the fluorescence as well as the intensity of the underwater light field over the fluorescence spectral range. To examine this relationship in detail, a vector radiative transfer code (VRTE) for the coupled atmosphere-ocean system was employed for a variety of oligotrophic and eutrophic water conditions. The VRTE used measured inherent optical properties (IOPs) for these water conditions as inputs to simulate the complete elastic and in-elastic components of the underwater light field, as well as the degree of linear polarization (DoLP) associated with it. These theoretical predictions were then compared with the results of DoLP measurements carried out using by our multi-angular hyperspectral polarimeter. A comparison of the measured reduction in degree polarization of the underwater light field over the fluorescence spectral range, and the magnitude of the fluorescence causing it, confirmed the validity of our theoretical relationship, and the feasibility of determining the natural fluorescence existing in an underwater light field from polarization measurements.

10402-73, Session 15

The updated intersensor radiometric comparison of SNPP VIIRS M1-M8 with Aqua MODIS bands through June 2017

I-Wen Mike Chu, Ctr. for Satellite Applications and Research (United States) and Cooperative Institute for Research in the Atmosphere (United States) and ERT, Inc. (United States); Menghua Wang, Ctr. for Satellite Applications and Research (United States)

The radiometric inter-sensor comparison of the Visible Infrared Imaging Radiometer Suite (VIIRS) onboard Suomi National Polar-orbiting Partnership (SNPP) satellite with the Moderate-resolution Imaging Spectrometer (MODIS) onboard Aqua satellite in the visible and near-infrared spectral range (410 – 1238 nm) is updated and presented. The methodology and statistical analyses have been improved since the preceding report. The radiometric comparison time series are updated and extended through June 2017, and are shown to be more robust and complete. All comparison time series achieve an overall precision under 1% with no obvious long-term drift. The SNPP VIIRS SDR version generated by the NOAA Ocean Color Team, with numerous important calibration improvements, demonstrates through inter-sensor comparison with Aqua MODIS the continual radiometric stability of SNPP VIIRS Bands M1?M8 bands as well as the very robust calibration achieved. The inter-sensor comparison of SNPP VIIRS M11 (2257 nm) versus Aqua MODIS B7 (2130 nm), the first-ever successful comparison achieved via a targeted study over the snowy scene, is a new result included in this report. The overall result demonstrates the long-term radiometric stability of the SNPP VIIRS bands that are presented in this update.

10402-74, Session 15

GEO-LEO reflectance band inter-comparison with BRDF and atmospheric scattering corrections

Tiejun Chang, Science Systems and Applications, Inc. (United States); Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Graziela R. Keller, Science Systems and Applications, Inc. (United States); Xiangqian Wu, National Oceanic and Atmospheric Administration (United States) and Ctr. for Satellite Applications and Research (United States)

The inter-comparison of reflective solar bands between the sensors onboard a geostationary orbit satellite and a low Earth orbit satellite is very helpful to assess their calibration consistency. GOES-R was launched on November 19, 2016 and Himawari 8 was launched October 7, 2014. Unlike previous GOES instruments, the Advanced Baseline Imager on GOES-R and the Advanced Himawari Imager on Himawari have onboard calibrators for the reflective solar bands. The assessment of calibration is important for their product quality enhancement. MODIS and VIIRS provide good references. The SNO and ray-matching are widely used inter-comparison methods for reflective solar bands.

In this work, the inter-comparisons are performed over pseudo-invariant targets. The use of stable and uniform calibration sites provides comparison with appropriate reflectance level, accurate adjustment for band spectral coverage difference, reduction of impact from pixel mismatching, and consistency assessment from long-term trending. The sites in this work include deserts in Australia, New Mexico, and Mexico. Due to the difference in solar and view angles, two corrections are applied to have comparable measurements. First, the satellite sensor measurements are top of atmosphere reflectance. The scattering, especially Rayleigh scattering, should be removed allowing the ground reflectance to be derived. Secondly, the angle differences magnify the BRDF effect. The ground reflectance should be corrected to have comparable measurements. The atmospheric correction is performed using a vector version of the Second Simulation of a Satellite Signal in the Solar Spectrum modeling and BRDF correction is performed using a semi-empirical model.

10402-76, Session 15

Validation of VIIRS with CrIS by taking into account the sub-pixel cloudiness and viewing geometry

Jun Li, Univ. of Wisconsin-Madison (United States); Changyong Cao, National Environmental Satellite, Data, and Information Service (United States); Zhenglong Li, Xinya Gong, Univ. of Wisconsin-Madison (United States); Wenhui Wang, ERT, Inc. (United States); Christopher C. Moeller, Univ. of Wisconsin-Madison (United States)

The Cross-track Infrared Sounder (CrIS) onboard Suomi NPP (SNPP) and JPSS series has high radiometric accuracy, which can be used for validating some infrared bands of Visible Infrared Imaging Radiometer Suite (VIIRS) onboard the same platform. The collocated CrIS and VIIRS sensor data record (SDR) along with the VIIRS cloud mask product from 19 to 21 September 2016 (during a period of blackbody warm-up cool-down, or WUCD) are used for inter-comparisons. This study addresses the questions on how the sub-pixel cloud presence and the local zenith angle impact the radiometric differences between CrIS and VIIRS. Both VIIRS brightness temperature (BT) bias and standard deviation for I5, M13, M15 and M15 whose spectral response functions (SRFs) have the full coverages over the CrIS spectral regions, are analyzed over the clear and cloudy skies, respectively. Results show good agreement between VIIRS and CrIS, cloud presence has substantial impact on STD, and also impact on BIAS, local zenith angle has also substantial impact on STD, but impact on bias is small. Both bias and STD are large in DCC (deep convective cloud) areas. The study clearly shows the VIIRS scene temperature bias during WUCD, as well as the bias removal after reprocessing the M15 and M16 with the improved calibration bias correction algorithm. The methodology can be applied to monitor and validate the imager with advanced infrared (IR) sounder onboard the same platform, such as CrIS for VIIRS (SNPP, JPSS), IASI for AVHRR (Metop), and GIIRS for AGRI (FengYun-4).

10402-77, Session 15

Using AIRS level-1c for AIRS/CrIS full-resolution longwave band comparisons

Evan M. Manning, Hartmut H. Aumann, Jet Propulsion Lab. (United States)

In order to make long-term records from AIRS and CrIS radiance spectra, the spectra must first be made compatible in spectral resolution and sampling. We illustrate this with the CrIS LW band, which has resolution comparable to AIRS. The first step is to use the new AIRS Level-1C product to eliminate spectral gaps and bad channels in the AIRS data. We illustrate this with real AIRS data. The second step is to re-sample the AIRS spectra on the CrIS sample grid. The third step is to match the AIRS and CrIS (apodized) spectral resolution. We illustrate and provide a statistical evaluation of the second and third steps with calculated clear spectra.

10402-78, Session 15

AIRS/CrIS data continuity: Evaluation for extreme conditions

Hartmut H. Aumann, Evan M. Manning, Jet Propulsion Lab. (United States)

AIRS and CrIS have been in the same orbit, with the same footprint size and the same scan pattern for the past four years. On average, and for spatially homogeneous scenes, AIRS and CrIS radiometry agrees at the 100 mK level. This agreement does not assure that the measurements of extremes agree. We evaluate daily extremes using data from the 900 cm-1 channel of AIRS and CrIS. The choice of the 900 cm-1 channel suppresses spectral resolution and sampling differences. For measurements of extremes AIRS and CrIS statistically disagree significantly. For example, the daily frequency of clouds colder than 225K in the tropical zone identified by CrIS is 5% larger that than for AIRS. The daily maximum 900 cm-1 brightness temperature is typically 330K for day tropical land, but for CrIS it is 0.3±0.1 K warmer than for AIRS. If AIRS and CrIS data were not obtained for the same time period, the observed differences would be misinterpreted as climate change effects. The differences are significant for the continuity of the data record established by AIRS, to be continued with CrIS on NPP and future satellites. We evaluate if the observed differences are related to scene temperature or scene contrast dependent radiometric calibration differences or due to more subtle differences in what appear to be "the same" conditions.

10402-79, Session 15

Intercomparisons of IASI on METOP and infrared multi-spectral instruments

Bertrand Theodore, Mayte Vasquez, Dorothee Coppens, K. Dieter Klaes, EUMETSAT (Germany)

Since the launch of the second Metop platform in September 2012, two IASI (Infrared Atmospheric Sounding Interferometers) instruments are flying on the same orbit, overflying the same area with 50 minutes delay. This provides a unique opportunity to perform multiple inter-comparisons and cross-monitoring. To do so, different methodologies have been implemented to provide complementary results giving qualitative and quantitative information on both instruments in terms of radiometric and spectral inter-calibration. This includes comparisons between the two IASI but also with other instruments covering infrared regions flying on the same platform like AVHRR and HIRS; comparisons with CrIS flying on Suomi/NPP have also been performed both using SNOs which occur every seven weeks and also on a daily basis using double differences.

We will present an overview this monitoring which, besides giving us confidence on the intercalibration of both IASI, provides a way to detect the slightest differences between IASI and other infrared multispectral instruments

10402-80, Session 16

The stars: An absolute radiometric reference for the on-orbit calibration of PLEIADES-HR satellites

Aimé Meygret, Gwendoline Blanchet, Ctr. National d'Études Spatiales (France); Flore Mounier, Capgemini Sud (France); Christian Buil, Ctr. National d'Études Spatiales (France)

The accurate on-orbit radiometric calibration of optical sensors has become a challenge for space agencies who gather their effort through international working groups such as CEOS/WGCV or GSICS with the objective to insure the consistency of space measurements and to reach an absolute accuracy compatible with more and more demanding scientific needs. Different targets are traditionally used for calibration depending on the sensor or spacecraft specificities: from on-board calibration systems to ground targets, they all take advantage of our capacity to characterize and model them. But achieving the in-flight stability of a diffuser panel is always a challenge while the calibration over ground targets is often limited by their BDRF characterization and the atmosphere variability. Thanks to their agility, some satellites have the capability to view extra-terrestrial targets such as the moon or stars. The moon is widely used for calibration and its albedo is known through ROLO (RObotic Lunar Observatory) USGS model but with a poor absolute accuracy limiting its use to sensor drift monitoring or cross-calibration. Although the spectral irradiance of some stars is known with a very high accuracy, it was not really shown that they could provide an absolute reference for remote sensors calibration. This paper shows that high resolution optical sensors can be calibrated with a high absolute accuracy using stars. The agile-body PLEIADES 1A satellite is used for this demonstration. The star based calibration principle is described and the

results are provided for different stars, each one being acquired several times. These results are compared to the official calibration provided by ground targets and the associated error budget is discussed.

10402-81, Session 16

Absolute, SI-traceable lunar irradiance tie-points for the USGS Lunar Model

Steven W. Brown, Keith R. Lykke, National Institute of Standards and Technology (United States); Robert E. Eplee Jr., Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States)

The USGS ROLO model predicts the top-of-the atmosphere lunar irradiance as a function of lunar phase and libration angles over the spectral range from 350 nm to 2350 nm. The current uncertainties in the lunar irradiance predicted by the ROLO model are too large for the Moon to be used as an absolute, exo-atmospheric, satellite sensor calibration source. In this work two low uncertainty, absolute SI-traceable top-of-the atmosphere measurements of the lunar irradiance at phase angles of 7o and 17o are used to scale the output of the ROLO model in the visible to near infrared spectral region. The corrected ROLO output is SI-traceable with quantified uncertainties an order of magnitude less than the estimated uncertainties in the current ROLO model.

In addition, empirical corrections to the phase and libration angle dependence of the output of the ROLO model using lunar observation data from Earth remote sensing satellite sensors are presented. Including corrections in the output of the ROLO model for lunar phase and libration angles enables the development of an empirical correction to the output of the ROLO model for phase and libration angles relevant to Earth remote sensing sensors over this wavelength range.

Implications of the empirical correction to the output of the ROLO Model for transitioning the Moon toward an absolute, exo-atmospheric, SI-traceable satellite sensor calibration source with uncertainties commensurate with science data product requirements will be discussed.

10402-82, Session 16

Improving ROLO lunar albedo model using PLEIADES-HR satellites extra-terrestrial observations

Aimé Meygret, Gwendoline Blanchet, Ctr. National d'Études Spatiales (France); Stéphane Colzy, Capgemini Sud (France)

The accurate on orbit radiometric calibration of optical sensors has become a challenge for space agencies which have developed different technics involving on-board calibration systems, ground targets or extra-terrestrial targets. The combination of different approaches and targets is recommended whenever possible and necessary to reach or demonstrate a high accuracy. Among these calibration targets, the moon is widely used through the well-known ROLO (RObotic Lunar Observatory) model developed by USGS. A great and worldwide recognized work was done to characterize the moon albedo which is very stable. However the more and more demanding needs for calibration accuracy have reached the limitations of the model. This paper deals with two mains limitations: the residual error when modelling the phase angle dependency and the absolute accuracy of the model which is no more acceptable for the on orbit calibration of radiometers.

Thanks to PLEIADES high resolution satellites agility, a significant data base of moon and stars images was acquired, allowing to show the limitations of ROLO model and to characterize the errors. The phase angle residual dependency is modelled using PLEIADES 1B images acquired for different quasi-complete moon cycles with a phase angle varying by less than 1°. The absolute albedo residual error is modelled using PLEIADES 1A images taken over stars and the moon. The accurate knowledge of the stars spectral irradiance is transferred to the moon spectral albedo using the satellite as a transfer radiometer.

This paper describes the data set used, the ROLO model residual errors and their modelling, the quality of the proposed correction and show some calibration results using this improved model.

10402-83, Session 16

MODIS and VIIRS reflective solar calibration inter-comparisons using lunar observations

Xiaoxiong J. Xiong, NASA Goddard Space Flight Ctr. (United States); Junqiang Sun, Global Science & Technology, Inc. (United States); Zhipeng Wang, Amit Angal, Science Systems and Applications, Inc. (United States); Jon P. Fulbright, ASTS (United States)

The reflective solar bands (RSB) of both MODIS and VIIRS, covering wavelengths from 0.41 to 2.1 microns, are calibrated on-orbit by a sunlit solar diffuser (SD) panel placed behind an attenuation screen (optional for MODIS). In addition, near-monthly scheduled lunar observations have been performed through the entire mission of each instrument and used to validate and improve its RSB on-orbit calibration, particularly in term of its long-term radiometric calibration stability. MODIS and VIIRS lunar observations have also been used for other applications, including characterization of crosstalk, optical leak, and sensor spatial performance. In this paper, we provide an overview of MODIS and VIIRS solar and lunar calibration strategies and methodologies and present calibration inter-comparison results based on their lunar observations. A lunar irradiance model, such as the USGS ROLO model, is used in the lunar calibration inter-comparisons to correct for the differences due to sensors' relative spectral response (RSR) and their lunar viewing geometries. Also discussed in this paper are key uncertainty contributors associated with current lunar calibration inter-comparisons and potential improvements in future work.

10402-84, Session 16

In-orbit verification of MHS spectral channels co-registration using the moon

Roberto Bonsignori, European Organisation for the Exploitation of Meteorological Satellites (Germany)

In-orbit verification of the co-registration of channels in a scanning microwave or infrared radiometer can in principle be done during normal in-orbit operation, by using the regular events of lunar intrusion in the instrument cold space calibration view. A technique of data analysis based on best fit of data across lunar intrusions has been used to check the mutual alignment of the spectral channels of the MHS instrument. MHS (Microwave Humidity Sounder) is a cross-track scanning radiometer in the millimetre-wave range flying on EUMETSAT and NOAA polar satellites, used operationally for the retrieval of atmospheric parameters in numerical weather prediction and nowcasting.

This technique does not require any special operation or manoeuvre and only relies on analysis of data from the nominal scanning operation. The use of earth landmarks for this purpose would not be possible on the sounding channels due to the effect of the atmosphere.

The analysis reported in this paper shows an achievable accuracy below 0.5 mrad against a beam width at 3dB and spatial sampling interval of about 20 mrad. In-orbit results for the MHS instrument on Metop-B are also compared with the pre-launch instrument characterisation, showing a good correlation.

Conference 10403: Infrared Remote Sensing and Instrumentation XXV

Monday - Tuesday 7 –8 August 2017

Part of Proceedings of SPIE Vol. 10403 Infrared Remote Sensing and Instrumentation XXV

10403-1, Session 1

Integrated optical filters on chip for miniature spectrometer *(Invited Paper)*

Shao-Wei Wang, Wei Lu, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China) and Shanghai Engineering Research Ctr. of Energy-Saving Coatings (China)

We proposed the concept of integrated narrow bandpass filter array in 2003 and realized in 2004, which can totally match with detectors array with very high spectral resolution and high structure & spectrum flexibility. The structure of corresponding spectrometer or imaging is simple with small volume and high reliability. We developed the combinatorial etching technique and combinatorial deposition technique for fabrication of such devices. A concept of a high-resolution miniature spectrometer has been demonstrated by using an integrated filter array. Such a device has already been successfully used in a multi-spectral luminescence imaging for plant growth research setup of Shijian ten satellite launched in 2016.

10403-2, Session 1

Research on active imaging information transmission technology of satellite borne quantum remote sensing

Siwen Bi, Institute of Remote Sensing and Digital Earth (China) and Beijing Institute of Space Mechanics and Electricity (China); Ming Zhen, Institute of Remote Sensing and Digital Earth (China); Song Yang, Xuling Lin, Zhiqiang Wu, Beijing Institute of Space Mechanics and Electricity (China)

According to the needs of the development and application of Remote Sensing Science and technology, Prof. Siwen Bi proposed quantum remote sensing. Firstly, the background of Quantum Remote sensing, The research status of quantum remote sensing theory, information mechanism, imaging experiments and principle prototype, the related research at home and abroad are briefly introduced. Then, the basic principles of the squeezing operator and the single mode squeezing operator of the quantum remote sensing radiation field are, Active imaging experiment of information transmission and preparation of quantum optical field squeezed light imaging experiments are described. Finally, the scheme of satellite active imaging information transmission is proposed, The composition and working principle of the active imaging system of the satellite borne quantum remote sensing are mainly included, Active imaging compression light preparation and injection device and quantum noise amplifying device. In order to realize the active imaging technology of satellite borne quantum remote sensing, the scheme and technical basis are provided. The use of quantum field technology is higher than that of coherent light imaging resolution results of 2-3 times, it can significantly improve the quantum information transmission of the remote sensing image SNR and spatial resolution. It provides the technical basis for the development of quantum remote sensing imaging engineering prototype.

10403-3, Session 1

Narrowband infrared emitter constructed with metal-DBR cavity

Shao-Wei Wang, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China) and Shanghai Engineering Research Ctr. of Energy-Saving Coatings (China); Mingfei Wu, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China) and Shanghai Engineering Research Ctr. of Energy-Saving Coatings (China) and Shanghai Normal Univ. (China); Jialiang Lu, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China); Xingxing Liu, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China) and Shanghai Engineering Research Ctr. of Energy-Saving Coatings (China); Zhiwei Li, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China); Huafen Li, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China) and Shanghai Engineering Research Ctr. of Energy-Saving Coatings (China); Jiaming Hao, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China); Wei Lu, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China) and Shanghai Engineering Research Ctr. of Energy-Saving Coatings (China)

We developed a narrowband infrared emitter constructed with Metal and Dielectric Bragg Reflector (DBR) cavity. The center wavelength and Q factor of emitter can be easily tuned by changing the thickness of dielectric cavity layer and the number of DBR stack. It was demonstrated that an infrared emitter centered at 10.4 ?m with emission of 92% and Q factor larger than 100, fabricated with thin film deposition equipment on 4 inch Si substrate. Such a simple structure can be easily fabricated in a large scale and can be applied in many fields.

10403-4, Session 2

Long wavelength interband cascade lasers on GaSb substrates *(Invited Paper)*

Anne Schade, Julius-Maximilians-Univ. Würzburg (Germany); Sven Höfling, Julius-Maximilians-Univ. Würzburg (Germany) and Univ. of St. Andrews (United Kingdom)

Interband Cascade Lasers (ICLs) are semiconductor laser sources emitting photons in the mid-infrared wavelength region. In the GaSb material system, ICLs cover the ~2.7 μm to ~5.6 μm wavelength range operating in continuous wave mode. In this spectral region, the low power consumption of ICLs is unrivaled compared to diode lasers and quantum cascade lasers emitting in this region. Many important gases like hydrocarbons have strong absorption lines in this wavelength region. ICLs are therefore suitable for gas sensing applications like tunable laser absorption spectroscopy (TLAS) for the detection of various gases. ICLs combine the cascading of active stages from quantum cascade lasers with interband transitions of diode lasers enabled by the semimetallic interface between InAs and GaSb. Beyond 5.6 μm important gases like nitrogen oxides have strong absorption lines making long wavelength GaSb ICLs interesting. We show the realization of long wavelength emitting ICLs optimized by reducing the number of electron injector quantum wells and improving doping in the active region, increasing thicknesses of the separate confinement layer and cladding layer. The devices emit at 5.72 μm and 6.00 μm, with pulsed mode characteristic temperatures of 47 K and threshold current densities of 1194 A/cm2 and 778 A/cm2 with voltage drops of 1.29 V and 1.33 V respectively.

10403-5, Session 2

Antimonide-based resonant tunneling photodetectors for mid infrared wavelength light detection *(Invited Paper)*

Fabian Hartmann, Andreas Pfenning, Georg Knebl, Robert Weih, Andreas Bader, Monika Emmerling, Martin Kamp, Julius-Maximilians-Univ. Würzburg (Germany); Sven Höfling, Julius-Maximilians-Univ. Würzburg (Germany) and Univ. of St. Andrews (United Kingdom); Lukas Worschech, Julius-Maximilians-Univ. Würzburg (Germany)

The semiconductors of the so-called 6.1 Å family, GaSb, InAs and AlSb, enable a broad range of bandgap energies and bandgap alignments which make them particularly suitable for mid-infrared optoelectronic devices. Resonant tunneling diode (RTD) photodetectors based on 6.1 Å family semiconductors allow to transfer the photodetection principle of RTDs from the visible and near infrared to the mid-infrared wavelength region. The RTD photodetection principle originates from the modulation of the majority carrier resonant tunneling current via Coulomb interaction of photogenerated minority charge carriers with the benefit of low voltage operation, high amplification factors and low noise operation. Here, we show room temperature operation of antimonide-based resonant tunneling photodetectors with GaSb/AlAsSb double barrier structures and pseudomorphically grown prewell emitter structures comprising the ternary compound semiconductors GaInSb and GaAsSb. The AlSb/GaSb double barrier RTS resembles conventional GaAs based RTDs and provides a type-I band alignment with large band offsets. We show that the electronic transport properties of AlSb/GaSb RTDs with emitter prewells lead to large peak-to-valley current ratios that are caused by an increased ?-L-valley energy separation and consequently an increased population of electrons at the ?-point. At room temperature the peak-to-valley current ratios reaches up to 2.4 for samples with incorporation of GaAsSb prewell emitters. RTD photodiodes with cut-off wavelength up to 3 μm are realized by integration of a lattice-matched quaternary GaInAsSb absorption layer. Due to the well-pronounced region of negative differential conductance, we are able to demonstrate a variety of different operation modes of the RTD photodetectors.

10403-6, Session 2

Trace gas spectroscopy using state-of-the- art mid-infrared semiconductor laser sources: Progress, status, and applications *(Invited Paper)*

Frank K. Tittel, Rice Univ. (United States)

Broadband spectroscopy is a useful tool for measuring trace gas species simultaneously. In this report basic techniques and their implementation as well as applications for laser absorption spectroscopy (LAS) and quartz-enhanced photoacoustic spectroscopy (QEPAS) will be reviewed. The design and performance characteristics of sensor systems based on absorption spectroscopy including laser sources, absorption cells and detection methods will be described. Potential future advances in techniques and applications of LAS and QEPAS relevant to the petrochemical industry, in life sciences and biomedical applications as well as environmental monitoring, atmospheric chemistry will be described.

The authors acknowledge the support from National Science Foundation (NSF) (ERC MIRTHE award), USA Robert Welch Foundation (C-0586), NSF Phase II SBIR (IIP-1230427DE DE), DOE ARPA-E awards (DE-0000545, DE-0000547).

10403-7, Session 2

Mid infrared DFB interband cascade lasers *(Invited Paper)*

Johannes Koeth, Robert Weih, Marc O. Fischer, nanoplus Nanosystems and Technologies GmbH (Germany); Martin Kamp, Sven Höfling, Julius-Maximilians-Univ. Würzburg (Germany)

The mid infrared spectral range (MIR) is of great interest for a variety of industrial, medical and environmental applications since numerous molecules have strong absorption lines therein. Interband cascade lasers (ICLs) have the ability to cover the entire MIR almost independently from the bandgap of the utilized semiconductors. Combined with a DFB technology which is applicable for most kinds of interband transition based semiconductor lasers the spectral range between 2.8 and 5.9 μm could be covered with application grade single mode devices with low power consumption. Recent optimizations regarding the layer design as well as the device processing yielded DFB laser chips with improved performance that will pave the way for a variety of applications that benefit from reasonable output power.

10403-8, Session 2

A GaAs-based up-converter for mid-infrared detection utilizing quantum cascade transport

Zhibiao Hao, Lili Xie, Chao Wang, Yaqi Liu, Lai Wang, Jian Wang, Bing Xiong, Changzheng Sun, Yanjun Han, Hongtao Li, Yi Luo, Tsinghua Univ. (China)

The next generation infrared (IR) detection technology demands for very-large-format focal plane arrays (FPAs) with high performance. Semiconductor up-converters can convert IR photons to near-infrared (NIR) photons, and can be a potential candidate for large-format IR imaging since the mechanical bonding with read-out circuit can be avoided. However, previously reported up-converters and corresponding up-conversion systems suffer from low detectivity because of the trade-off between responsivity and dark current. To solve this issue, a cascade infrared up-converter (CIUP) is demonstrated in this work. Based on a quantum cascade transport mechanism, higher IR responsivity is achieved while the dark current is maintained fairly low. A 4-?m InGaAs/AlGaAs CIUP has been fabricated, and both the CIUP and up-conversion system are under background-limited infrared performance (BLIP) regime below 120 K. The up-conversion efficiency is 2.1 mW/W at 3.3 V and 78 K. Taking shot noise as the main noise in the up-conversion system, the BLIP detectivity of the system is 2.4E9 Jones at 3.3 V and 78 K, higher than the semiconductor up-converters at similar wavelengths reported so far. To further improve the CIUP performance, AlInP hole-blocking layer is introduced taking place of AlAs layer . AlInP/GaAs has larger valence band discontinuity than AlAs/GaAs, showing the advantage of tightly confining injected holes into the emission quantum well. By adopting the AlInP hole-blocking layer, the quantum efficiency and detectivity of the up-conversion system can be enhanced.

10403-9, Session 3

High bit depth infrared image compression via low bit depth codecs *(Invited Paper)*

Evgeny A. Belyaev, Claire Mantel, Søren O. Forchhammer, Technical Univ. of Denmark (Denmark)

Future infrared remote sensing systems, such as monitoring of the Earth's environment by satellites, infrastructure inspection by unmanned airborne vehicles etc., will require 16 bit depth infrared images to be compressed and stored or transmitted for further analysis. Such systems are equipped with

low power embedded platforms where image or video data is compressed by a hardware block called video processing unit (VPU). However, in many cases using two 8-bit VPUs can provide advantages compared with using one higher bit depth image compression directly. We propose to compress 16 bit depth images via 8 bit depth codecs in the following way. First, an input 16 bit depth image is mapped into 8 bit depth images, e.g., the first image contains only the most significant bytes (MSB image) and the second one contains only the least significant bytes (LSB image). Then each image is compressed by an image or video codec with 8 bits per pixel input format. We analyze how the compression parameters for both MSB and LSB images should be chosen to provide the maximum objective quality for a given compression ratio. Finally, we apply the proposed infrared image compression method utilizing JPEG and H.264/AVC codecs, which are usually available in efficient implementations, and compare their rate-distortion performance with JPEG2000, JPEG-XT and H.265/HEVC codecs supporting direct compression of infrared images in 16 bit depth format. A preliminary result shows that two 8 bit AVC codecs can achieve similar result as 16 bit HEVC codec for far-IR images.

10403-10, Session 3

Observation and analysis of modulation and noise in visible and near-infrared diffuse ambient daylight

John Kielkopf, Elijah Jensen, Frank O. Clark, Univ. of Louisville (United States); Jeff Hay, RDI Technologies (United States)

We report on observations of low level noise and modulation in natural sky light and in sunlit scenes. Data were taken with various clear sky and partly cloudy conditions of the sky itself, as a function of altitude and angular resolution, and of naturally illuminated scenes. Different optical and sensor configurations were employed to explore the contributions of natural signal fluctuation to the remote sensing of vibrations through modulation of optical and near infrared diffusely scattered light and temporal imaging of partially resolved high contrast features. Low noise InGaAs high dynamic range photodiodes and cameras, and silicon image sensors were used with real time and post-processing to identify the noise floor, and to establish practical limits on light level and viewing distance in the use of these methods for remote structural health and vibration monitoring.

10403-11, Session 3

Flexible thermistors: MCNO films with low resistivity and high TCR deposited on flexible organic sheets by RF magnetron sputtering

Jing Wu, Zhiming Huang, Yanqing Gao, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China)

Because of its large temperature coefficient of resistivity and good chemical stability, Mn-Co-Ni-O (MCNO) spinel is an attractive ternary system for thermistor applications, and for infrared detecting bolometers. However, conventional MCNO chip or ceramic thermistors are usually be fabricated using a solid-state reaction and sintering above 1100 ? high temperature.1 Although there are many reports on MCNO film deposition techniques, including pulsed laser deposition, chemical solution deposition, sputtering, screen printing,2-5 all those methods require 600-1200 ? high temperature treatment ((including post-annealing) to achieve sufficient crystal quality and good properties for high performance. High temperature treatment has severely hindered MCNO films to be used in standard semiconductor industry process, and also have prevented MCNO thermistor from being prepared on flexible organic substrates so as to develop wearable healthcare devices.

Meanwhile, in order to achieve lower noise and higher responsivity of bolometers, researchers have made a great effort to pursue MCNO films expected to have lower resistivity and higher TCR. For the past several decades, people considered that MCNO ternary system has a resistivity minimum as ~250?cm at room temperature.

In this work, we have used $MnCO_3$, Co_2O_3, Ni_2O_3 as original materials to sinter MCNO target under an oxygen-enriched ambient and employed RF magnetron sputtering method to directly deposit MCNO on polyethylene terephthalate (PET) and polyimide (PI) sheets at room temperature. For the first time, we have reached the lowest resistivity among the results have ever been reported for MCNO ternary system. We have achieved flexible MCNO film thermistor with resistivity 110?cm and TCR -3.1% at 295 K.

10403-12, Session 3

Nanoantenna integrated infrared pixels

Fei Yi, Huazhong Univ. of Science and Technology (China)

The concept of the antenna is widely used in the microwave regime to convert freely propagating electromagnetic waves into localized energy, and vice versa. By simple scaling down of antennas, through “scale-invariance” of Maxwell’s equations and ignoring kinetic inductance, one gets an antenna for light that has nanoscale dimensions commensurate with the much shorter optical wavelengths. Unlike conventional photonic devices (lenses, mirrors and diffractive elements) which redirect the wave front of optical radiation through the reflection and refraction of electromagnetic waves, resonantly excited optical antennas support localized surface plasmon resonances(LSPR), or the collective oscillation of electron plasma at the surface of nanostructured metals. Since metals are usually not perfect conductors at optical frequencies, the oscillating electron plasma in the optical antenna can cause high losses to the electromagnetic energy and the high optical absorption has led to the demonstration of absorbers for radiation from THz frequencies to the visible region. The electromagnetic energy dissipated in plasmonic absorber is eventually turned into heat and the thermal effects of plasmonic absorbers have enabled the investigation of such structures as nanoscale heat sources in many applications.

In this presentation I will talk about our recent works on nanoantenna integrated thermomechanical infrared pixels towards spectral selective mid-infrared detector free of discrete optics such as optical filters and polarizers. I will also talk about our proposed thermal infrared pixel array integrated with narrowband nanoantenna absorbers towards on-chip infrared spectroscopy.

10403-13, Session 4

Assessing the GOES-16 ABI onboard calibration using deep convective cloud *(Invited Paper)*

Hyelim Yoo, National Oceanic and Atmospheric Administration (United States) and ERT, Inc. (United States); Fangfang Yu, ERT, Inc. (United States) and National Oceanic and Atmospheric Administration (United States); Xianqian Wu, Ctr. for Satellite Applications and Research (United States) and National Oceanic and Atmospheric Administration (United States)

Tropical deep convective clouds (DCCs) are thick, bright, and cold and their reflectance is considered stable. Thus, DCCs can be used to calibrate visible/near infrared channels of satellite instruments. Previous studies report that how DCCs are identified by providing specific brightness temperature thresholds and are used for calibration purpose as an invariant target for solar channels.

On 19 November 2016, the Geostationary Operational Environment Satellite-R Series (GOES-R) has been successfully launched and became GOES-16 after reached the geostationary orbit on 29 November 2016. The Advanced Baseline Imager (ABI) instrument on-board GOES-R has 16 multi-spectral bands (0.47 - 13.3 um) which can provide more accurate and frequent radiometric calibration information than previous GOES satellite series.

Assessment and monitoring of the GOES-16 ABI visible/near infrared channel calibration using DCC method is a main objective of this study. The calibration stability of the ABI visible/near infrared channels will be examined and compared the results with other method (e.g., ray-matching, desert). In this study, we use the improved DCC identification method and characterize DCC temporal and spatial variation by selecting the identification thresholds to get only DCC cores. The target region is a 20°N-20°S and 109.5°W-69.5°W centered on the GOES-16 ABI check-out spatial domain. This work can be expected to provide useful information of the ABI radiometric calibration stability.

10403-14, Session 4

Preliminary study of the on-orbit radiometric traceability and artifacts for the VIIRS longwave infrared channels during blackbody temperature changes

Changyong Cao, National Environmental Satellite, Data, and Information Service (United States); Wenhui Wang, ERT, Inc. (United States)

The Longwave infrared channels (thermal emissive bands or TEB) of the Suomi NPP VIIRS are primarily used for retrieving sea surface temperatures globally. Since the VIIRS TEB data became available in January, 2012, its calibration has gone through several stages and the data reached validated maturity on March 18, 2014. While overall the validation has shown that these channels are very stable based on comparisons with CrIS, MODIS, and aircraft campaigns, with an estimated absolute uncertainty on the order of 0.1K, there is a remaining issues that persisted over the years. A calibration bias on the order of 0.1 K is introduced during the quarterly blackbody warm-up-cool-down (WUCD), and the bias is further amplified by the SST retrieval algorithm up to 0.3K in the SST products which causes an apparent spike in the SST time series. Our investigation reveals that this bias is related to a fundamental and theoretical assumption in the radiometric traceability of the VIIRS calibration equation, which states that the shape of the calibration curve is assumed unchanged from prelaunch to postlaunch, although not supported by test data from either prelaunch or postlaunch. On the other hand, the VIIRS calibration is otherwise stable when the blackbody temperature is well maintained at the designed 292.5K, during which this assumption has limited effects. In this study, after extensive analysis, we present a correction algorithm (known as Ltrace) to reconcile the calibration curve shape assumption so that the calibration bias is removed during the WUCD with minimal impacts to the operations.

10403-15, Session 4

Millikelvin thermal dynamics of infrared scenes

Nathan Hagen, Utsunomiya Univ. (Japan)

Imaging the thermal changes in a scene at the millikelvin level reveals a fascinating world that we normally cannot see. Wind passing over the ground produces dynamic striations that indicate the wind direction and speed. A person's pulse rate and blood flow can be seen from the thermal changes visible even at the surface of the skin. Material defects normally invisible to the eye become visible through the changes they induce in a surface's dynamic thermal response. We show example videos and discuss the underlying measurement principles.

10403-45, Session 4

Utilizing the precessing orbit of TRMM to produce hourly corrections of geostationary infrared imager data with the VIRS sensor

Benjamin R. Scarino, Science Systems and Applications, Inc. (United States); David R. Doelling, NASA Langley Research Ctr. (United States); Conor O. Haney, Science Systems and Applications, Inc. (United States); Kristopher M. Bedka, Univ. of Wisconsin-Madison (United States); Patrick Minnis, NASA Langley Research Ctr. (United States); Arun Gopalan, Rajendra Bhatt, Science Systems and Applications, Inc. (United States)

It is important that consistent calibration coefficients across satellite platforms are made available to the remote sensing community, and that calibration anomalies are recognized and mitigated. One such anomaly is the infrared imager brightness temperature (BT) drift that is caused by solar heating of some geostationary satellite (GEOsat) instruments near local midnight. Currently the GSICS community uses hyperspectral IASI data to uniformly inter-calibrate GEOsat IR imagers to a common reference. The IASI sensors are located on the MetOp sun-synchronous satellites, which have a local equator crossing time (LECT) of 21:30 hours on the ascending node. Similarly, the hyperspectral AIRS sensor, another viable reference, on the Aqua platform has a 01:30 LECT. Thus, the combination of IASI and AIRS observations is unable to completely resolve the GEOsat midnight BT bias. The precessing orbit of the TRMM VIRS sensor, however, allows sampling of all local hours over 46 days. Thus, VIRS has the capability of providing hourly temperature adjustments in order to mitigate the midnight anomaly observed in the 3.8-, 11-, and 12-?m channels of concurrent GEOsat sensors. In order to achieve this goal, the VIRS IR measurements are first assessed for temporal stability between 2002 and 2012 via direct comparisons with Aqua-MODIS. Furthermore, VIRS IR calibration artifacts are corrected by inter-calibrating with the IASI GSICS reference standard. The validity of this methodology is tested through direct comparisons of GEOsat and VIRS hourly-adjusted temperatures with measurements from IASI and AIRS, as well as with GEOsat measurements resulting from official GSICS calibration.

10403-32, Session PMon

Thermal pulse propagation in the search of subcutaneous masses

Marija Strojnik, Centro de Investigaciones en Óptica, A.C. (Mexico)

The irradiation of matter with laser pulse is important for determining the material surface characteristics and to form them, upon absorption of energy. The knowledge of the physical phenomena, taking place during the surface interaction with radiation directly impacts the amount of energy transmitted through the interface. This is of particular interest when assessing the tissue non-homogeneities with a probing propagating pulse, for tissue growth with modified characteristics. We simulate the thermal pulse propagation in a partially absorbing and in a partially scattering material. We compare the results to the case of pulse propagation inside the non-absorbent and non-scattering medium.

10403-33, Session PMon

Noncoding sequences classification based on wavelet transform analysis

Omar Paredes, Rebeca Romo Vázquez, Hugo Vélez Pérez, J. Alejandro Morales, Univ. de Guadalajara (Mexico); Radu Ranta, Univ. de Lorraine (France) and Ecole Nationale

Supérieure d'Electricité et de Mécanique - Nancy (France); Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico); Marija Strojnik, Univ. de Guadalajara (Mexico) and Centro de Investigaciones en Óptica, A.C. (Mexico)

DNA sequences in human genome can be divided into the coding and noncoding ones. Coding sequences are those that are read during the transcription. The identification of coding sequences is widely described in literature due to its much studied periodicity. Noncoding sequences represent the majority of the human genome. They play an important role in gene regulation and differentiation among the cells. However, noncoding sequences do not exhibit periodicities that correlate to their functions. The ENCODE (Encyclopedia of DNA elements) and Epigenomic Roadmap projects have cataloged the human noncoding sequences into specific functions. We study characteristics of noncoding sequences with wavelet analysis of genomic signals. We hypothesize that noncoding sequences have characteristic periodicities related to their function. We describe identification of these characteristic periodicities using wavelet analysis. Our results show that three groups of noncoding sequences, each one with different biological function are differentiated by their wavelet coefficients within specific frequency range.

Optical spectral characterization of leaves for endemic species from La Primavera forest

Roberto Carlos Barragan Campos, Antonio Rodríguez Rivas, Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico); Francisco Javier González Contreras, Univ. Autónoma de San Luis Potosí (Mexico); Marija Strojnik, Univ. de Guadalajara (Mexico) and Centro de Investigaciones en Óptica, A.C. (Mexico)

La Primavera forest is the main climate regulator in the metropolitan area of Guadalajara, the second most populated megalopolis in Mexico with approximately 4.4 million people. This forest area has been a focus of fires in the last decade and it is deteriorating the quality of life of the inhabitants. Leaves from the endemic forest provide information about their biochemical composition and physiology. This information is enclosed in the spectral range of the visible band to the middle infrared (400 nm at 2500 nm). In this paper we examine the reflectance of six endemic species leaves of La Primavera forest, considering the measurement in fresh and dry samples. Measurements will be obtained with a Vis-NIR spectrometer which uses a calibrated light source. A formal collection of the optical properties of tree leaves in La Primavera forest does not exist, but it is important to classify about the type of vegetation in the area. In addition, it will provide information to generate vegetation inventories, provide data to the forest fire prevention systems, pest control and erosion in the area.

Solar irradiance forecasting with an artificial vision system for Shor-time horizons

Cesar Mauricio M. Peña Martinez, Manuel I. Peña-Cruz, Centro de Investigaciones en Óptica, A.C. (Mexico)

Solar resource assessment is a subject of great importance for any technological application that wants to exploit this resource; e.j, photovoltaic technology, solar thermal, agriculture, meteorology, etc. In this paper, detailed information about solar irradiance and its variations due to climate conditions is given for Aguascalientes, Mexico. This development was achieved through an artificial vision system that analyse earth-sky dynamics. The prototype consist of image acquisition system mounted on a convex mirror that reflects the sun and sky dome over the CCD sensor. The prototype was designed with the intention of capturing wide horizon images and sun position at all times. From the images taken, shape, thickness and cloud displacements (cloud vector) can be identified, as well as the positions of the sun throughout the day. A digital image processing algorithm was designed to obtain Global Horizon Irradiance values (GHI) and compare it through a correlation with data from a traditional thermopile pyranometer. From cloud classification and cloud vector, mathematical expressions that predicts overlapping between clouds and sun was found. The developed prototype is capable of obtaining the value of GHI as accurate as those sensors in highly sophisticated solarimetric stations. It also provides a great tool for solar irradiance short-time forecasting.

High precision phase shifter modulator in a shearing interferometric system

Alejandro Reynoso Alvarez, Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico); Marija Strojnik, Univ. de Guadalajara (Mexico) and Centro de Investigaciones en Óptica, A.C. (Mexico); Jorge Luis Flores Nuñez, Univ. de Guadalajara (Mexico)

Shearing interferometers measure small angular variations such as the angle between a star and a planet measured from the Earth. The detected intensity pattern usually presents few fringes or less, often just a fraction of a fringe that may be interpreted as a misalignment error. Exact alignment is a challenge in the calibration of an interferometer. The optical components frequently introduce tilt making it very difficult to retrieve the phase. Spatial light modulators (SLM) are traditionally used to shift the phase to compensate small amounts of tilt, improving the accuracy of the phase measurement. We implement a phase retrieving algorithm to evaluate the accuracy of the phase shifter based on a SLM in a vectorial shearing interferometer (VSI). Our VSI is based on a Mach-Zehnder configuration. With the SLM we are able to compensate the phase error due to the alignment and the fabrication errors. Our results also demonstrate that we may correct error in the OPD and the magnitude of the tilt in the observation plane.

10403-37, Session PMon

Differential shearing interferometer

Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico); Marija Strojnik, Univ. de Guadalajara (Mexico) and Centro de Investigaciones en Óptica, A.C. (Mexico); Azael Mora-Nuñez, Beethoven Bravo-Medina, Univ. de Guadalajara (Mexico)

We present a novel interferometer that we call the differential shearing interferometer (DSI). It incorporates a set of Risley prisms in a Sagnac interferometer. The Risley prisms deviate the beam in both directions. This interferometer interferes two beams displaced in the same direction, but with different magnitudes. The resultant interferogram is the directional derivative of the wavefront. The interferometer sensitivity depends on the difference between the beam deviations. This deviation is controlled by the position of the Risley prisms inside the path and their angular orientation. The advantages of quasi-common-path configuration include its low sensitivity to vibrations.

10403-38, Session PMon

Alignment of a shearing interferometer for faint sources detection using a spatial light modulator

Guillermo Garcia-Torales, Marija Strojnik, Roberto Carlos Barragan Campos, Alejandro Reynoso Alvarez, Jorge Luis

Flores Nuñez, Univ. de Guadalajara (Mexico)

Perfect alignment of shearing system is crucial for the optimal detection and analysis of wave fronts from faint and remote sources. This paper describes a method for optical misalignment detection using an intensity pattern obtained in the calibration process using a spatial light modulator. The key of the misalignment correction is the comparison of a reference intensity pattern, against a sheared interferogram. We apply digital filters used in a numerical correlator, which results in a simple and robust calibration system. Experimental and simulated work is presented.

10403-39, Session PMon

Tracking pointer using Risley Prisms

Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico); Marija Strojnik, Univ. de Guadalajara (Mexico) and Centro de Investigaciones en Óptica, A.C. (Mexico); Anuar B. Beltran-Gonzalez, Jorge Luis Flores Nuñez, Univ. de Guadalajara (Mexico)

Risley prisms system has been used in scientific and technological approaches and pointing for alignment. This system is able to mark the path of a moving object by the proper combination of the angular position of a prisms pair. In this work the performance of the Risley prism model is compared with a robotic arm with two degrees of freedom model. The system is able to track an object in movement with precision and obtain the spatial coordinates in near real time.

10403-40, Session PMon

Three-dimensional shape profiling by projection of binary patterns: generated by a deterministic optimization approach

Adriana Silva, Antonio Muñoz, Jorge Luis Flores Nuñez, Univ. de Guadalajara (Mexico); Jesus Villa, Univ. Autónoma de Zacatecas (Mexico)

Three-dimensional shape profiling by sinusoidal phase-shifting methods are affected by the non-linearity of the projector. To overcome this problem, the defocused projection of binary patterns has become an important alternative to generate sinusoidal fringe patterns. In this paper, we present an efficient technique to generate binary fringe patterns where we use the symmetry and periodicity properties of binary-coded sinusoidal wavefront. This reduces the search-space for the optimization problem. The patterns are projected out-of-focus to generate quasi-sinusoidal patterns, which can be used together with a phase-shifting algorithm to retrieve 3D shape measurements. Simulations and experimental results show the feasibility of the proposed scheme.

10403-41, Session PMon

Online 3D measurement by an efficient iterative algorithm

Jorge Luis Flores Nuñez, Antonio Muñoz, Guillermo Garcia-Torales, Sotero Ordoñes Nogales, Adán Cruz, Univ. de Guadalajara (Mexico)

Online three-dimensional shape measurement has been an important procedure in many fields of the science and technology. In this work, we propose a novel technique to retrieve the 3D shape of dynamic objects by the simultaneous projection of a fringe pattern and a homogeneous white light pattern, they are both coded in an RGB image. The first one is used to retrieve the phase by an iterative least-square method. The last one is used to match pixels from the object in consecutive images, which are acquired at different positions. The proposal successfully overcome the requirement of projecting different frequency fringes: one to extraction of the object information and the other to retrieve phase. Simulations and experimental results show the feasibility of the proposed method.

10403-42, Session PMon

Piezoresistive method for a laser induced shock waves detection on solids

J. R. Gonzalez Romero, Guillermo Garcia-Torales, Gilberto Gomez-Rosas, Univ. de Guadalajara (Mexico); Marija Strojnik, Univ. de Guadalajara (Mexico) and Centro de Investigaciones en Óptica, A.C. (Mexico)

A laser shock wave is a mechanical high-pressure impulse with a duration of a few nanoseconds induced by a high power laser pulse. We performed wave pressure measurements in order to build and check mathematical models. They are used for wave applications in material science, health, and defense, to list a few. Piezoresistive methods have been shown to be highly sensitive, linear, and highly appropriate for practical implementation, compared with piezoelectric methods employed in shock wave pressure measurements. In this work, we develop a novel method to obtain the sensitivity of a piezoresistive measurement system. The results shows that it is possible to use a mechanical method to measure pressure of a laser induced shock wave in nanosecond range. Experimental pressure measurements are presented.

10403-43, Session PMon

Experiments to measure salient feature characteristics of laser-induced shock waves

Gilberto Gomez Rosas, J. R. Gonzalez Romero, Guillermo Garcia-Torales, Univ. de Guadalajara (Mexico)

Laser induced shock waves are mechanical waves of pressure of extraordinary magnitude with duration of a few nanoseconds that travel at high velocities through a material. Shock waves have been used extensively in material science to improve physical properties of material as to fatigue, strength, wear resistance, corrosion resistance, to list just a few. The shock wave induces a compressive residual stress on the target material that plastically deforms it. In this work, a piezoelectric method is used for superficial shock wave characterization near the area of the incidence of the laser pulse. It can be shown that the shock wave propagation is spherical and the velocity reduction is not linear. Experimental results with different geometrical configuration of the sensor are presented.

The detection of heat emission to solar cell using drone-based thermal infrared sensor and GIS technology

Geun Sang Lee, VISION Univ. of Jeonju (Korea, Republic of)

Many studies have been implemented to manage solar plant being supplied widely in recent years. This study analyzed heat emission of solar cell using UAV-based thermal infrared sensor, and major conclusions are as below. Firstly, orthomosaic image and DSM data were acquired using UAV-based RGB sensor, and solar light module layer necessary to analyze the heat emission of solar cell was constructed by these data. Also as a result of horizontal error into validation points using VRS survey for evaluating the location accuracy of solar light module layer, higher location accuracy could be acquired like standard error of dx=±2.4cm and dy=±3.2cm. And this study installed rubber patch to test the heat emission of solar cell and could analyzed efficiently the location of rubber patch being emitted heat using UAV-based thermal infrared sensor. Also standard error showed as

±3.5% in analysis between calculated cell ratio by rubber patch and analyzed cell ratio by UAV-based thermal infrared sensor. Therefore, it could be efficiently analyzed to heat emission of solar cell using UAV-based thermal infrared sensor. Also efficient maintenance of solar plant could be possible through extracting the code of solar light module being emitted of heat automatically.

10403-16, Session 5

Rosetta's studies of comet 67P: A review after the end of the mission *(Invited Paper)*

Gabriele E. Arnold, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

ESA's cornerstone mission Rosetta ended with landing the orbiter at comet 67P/Churyumov-Gerasimenko in September 2016. It acquired an enormous amount of scientific data, which have increased our knowledge about these pristine Solar system objects. The paper summarizes some the outstanding results of this mission.

10403-17, Session 5

The Venus emissivity mapper *(Invited Paper)*

Joern Helbert, Gabriele E. Arnold, Ingo Walter, Dennis Wendler, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany); Thomas Widemann, Lab. d'Etudes Spatiales et d'Instrumentation en Astrophysique (France); Gabriel Guignan, Emmanuel Marcq, LATMOS (France); Anko Börner, Judit Jänchen, Deutsches Zentrum für Luft- und Raumfahrt e.V. (Germany)

Based on experience gained from using the VIRTIS instrument on Venus Express to observe the surface of Venus and the new high temperature laboratory experiments, we have developed the multi-spectral Venus Emissivity Mapper (VEM) to study the surface of Venus. VEM imposes minimal requirements on the spacecraft and mission design and can therefore be added to any future Venus mission. Ideally, the VEM instrument will be combined with a high-resolution radar mapper to provide accurate topographic information, as for example the NASA Discovery VERITAS mission or the ESA EnVision M5 proposal.

10403-18, Session 5

Fourier spectrometer TIRVIM/ACS aboard ExoMars 16 orbiter *(Invited Paper)*

Alexei V. Grigoriev, Alexey Shakun, Boris E. Moshkin, Dmitry V. Patsaev, Alexander V. Zharkov, Victor Shashkin, Andrey S. Kungurov, Alexander Santos-Skripko, Fedor G. Martynovich, Igor A. Stupin, Dmitry Merzlyakov, Vladislav Makarov, Oleg M. Sazonov, Yuryi Nikolskyi, Nikolai I. Ignatiev, Igor A. Maslov, Dmitry Gorinov, Elena Efremenkova, Alexander Terentiev, Oleg Korablev, Space Research Institute (Russian Federation)

Fourier-spectrometer TIRVIM is a part of ACS spectral complex aboard Mars-Express orbiter spacecraft. TIRVIM spectral range is 2–16 micron. It can operate as a spectrometer – with the Sun as a standard radiation source ("occultation" mode) or as a spectro-radiometer ("nadir" mode). In occultation mode the spectral resolution is 0.2 cm-1, in nadir mode – 1.3 cm-1. The main scientific objective of the occultation mode is to search for atmosphere minor constituents, of the nadir mode – to monitor the Mars atmosphere vertical thermal profile (by 15-micron CO_2 band). The occultation mode is self-calibrated. For absolute calibration in the nadir mode TIRVIM has a rotating inlet flat mirror (single-axis foreoptic) able to point the FOV (2º) to nadir, space, built-in black-body or to another direction in the plane. TIRVIM mass is 12 kg, the power consumption is 15 W.

10403-19, Session 6

Directional ringlet intensity feature transform (DRIFT) based object tracking in IR imagery *(Invited Paper)*

Theus H. Aspiras, Evan W. Krieger, Vijayan K. Asari, Univ. of Dayton (United States)

Current object tracking implementations utilize different feature extraction techniques to obtain salient features to track objects of interest which change in different types of imaging modalities and environmental conditions. Challenges in infrared imagery for object tracking include object deformation, occlusion, background variations, and smearing, which demands high performance algorithms. We propose the directional ringlet intensity feature transform to encompass significant levels of detail while being able to track low resolution targets. The algorithm utilizes a weighted circularly partitioned histogram distribution method which outperforms regular histogram distribution matching by localizing information and utilizing the rotation invariance of the circular rings. The image also utilizes directional edge information created by a Frei-Chen edge detector to improve the ability of the algorithm in different lighting conditions. We find the matching features using a weighted Earth Mover's Distance (EMD), which results in the specific location of the target object. The algorithm is fused with image registration, motion detection from background subtraction and motion estimation from Kalman filtering to create robustness from camera jitter and occlusions. It is found that the DRIFT algorithm performs very well under different operating conditions in IR imagery and yields better results as compared to other state-of-the-art feature based object trackers. The testing is done on two IR databases, a collected database of vehicle and pedestrian sequences and the Visual Object Tracking (VOT) IR database.

10403-20, Session 6

Automatic building change detection through linear feature fusion and difference of Gaussian classification

Daniel Prince, Vijayan K. Asari, Univ. of Dayton (United States)

Many applications in infrastructure planning and maintenance are currently aided by the collection of aerial image data and manual examination by human analysts. The increasing availability and quality of this image data presents an opportunity for computer vision and machine learning techniques to aid in infrastructure planning and maintenance. Due to the immense effort required for human analysts to view and organize the data, there is great demand for computer automation of these tasks. A strategy for detecting changes in known building regions in multi-temporal visible and near-infrared imagery based on a linear combination of independent features and a difference of Gaussian based classification approach is being developed. Initial building candidates are discovered using a linear combination of features representing vegetation intensity, image texture, shadow intensity and distance from known road areas. The resulting building candidates are classified by shape using a unique difference of Gaussians technique and a standard Support Vector Machine classifier. Building regions reported in the reference data set from the prior observation time are revisited using the same classification approach to minimize the number of false positive detections from the feature fusion strategy. The effectiveness of the proposed technique is evaluated on five wide area real-world images. Ground truths for the building regions in all five images are manually created and used to measure the accuracy of the building detection and change detection results. Detection statistics and visualized results of the proposed algorithm are presented, and it is observed that the results are promising compared to the manually created ground truth.

10403-21, Session 6

Spectrum modeling of mid-infrared flare considering realistic measurement environment

Kiwook Han, Yonsei Univ. (Korea, Republic of); Wondong Lee, Korea Military Academy (Korea, Republic of) and Yonsei Univ. (Korea, Republic of); Jae W. Hahn, Yonsei Univ. (Korea, Republic of)

Evaluating the performance of infrared (IR) flare as an active countermeasure, the similarity between an actual signal of flare and emission of an aircraft exhaust plume is important. In order to predict the actual signal of flame, exact knowledge of theoretical modeling of the flare spectrum considering realistic measurement environment is required. In this study, we conduct a line-by-line modeling of IR flare. We calculate the spectral line parameters of IR flare using high-temperature molecular spectroscopic database (HITEMP) and chemical parameters using ICT thermodynamic code in thermodynamic equilibrium condition. We consider a collisional broadening of the spectral lines under atmospheric pressure, and instrument function of spectrometer. Also, we apply an atmospheric transmission with varying altitudes, measurement angles, and humidity based on moderate resolution atmospheric transmission database (MODTRAN). Finally, we verify our modeling of IR flare by comparing with experimental results. The normalized RMS deviation between the measured and modeled data is calculated to be about 6.7%.

Acknowledgement: This work was supported by the Low Observable Technology Research Center program of Agency for Defense Development (ADD).

10403-22, Session 6

Object parameters optimization on pure and mixed pixels in thermal hyperspectral imagery

Xinyuan Miao, Ye Zhang, Junping Zhang, Sheng Wei Zhong, Harbin Institute of Technology (China)

The hyperspectral image in thermal infrared domains provide information, such as temperature and emissivity, about different kinds of materials. These information can be used for a wide number of applications such as mineral mapping, bathymetry, indoor and outdoor detection of chemicals. But because of the limitation of spatial resolution and the characteristics of thermal infrared sensor, there are many mixed pixels in the data, whose temperature?emissivity and abundance of different components can be hard to estimated. In this paper, a new method to estimate the parameters in pure and mixed pixels is proposed based on linear and nonlinear optimization. Firstly, the standard temperature and emissivity separation (TES) algorithm is applied on pure pixels of different materials selected by supervise or unsupervised methods to get the initial temperature. Secondly, the emissivity in different bands can be retrieved by minimizing the reconstruction error, which the more accurate temperature is optimized with. The emissivity in one band is trained by the samples in the same band but in different pixels, while the temperature is trained by different bands in one pixel. Lastly, the abundance and temperature of components in mixed pixels are estimated based on a linear mixture model of the bottom of atmosphere radiance as full constraint linear optimization problem and nonlinear optimization problem. The method is also analyzed with respect to sensitivity to the noise and different parameters' influences on estimation errors.

10403-23, Session 7

Sentinel-5, the new generation European operational atmospheric chemistry mission in polar orbit *(Invited Paper)*

Abelardo Pérez Albiñana, Didier D. Martin, Matthias Erdmann, Norrie Wright, European Space Research and Technology Ctr. (Netherlands); Markus Melf, Peter Bartsch, Wolfgang Seefelder, Airbus Defence and Space (Germany)

Sentinel-5 is an Earth Observation instrument to be flown on the MetOp Second Generation satellites with the fundamental objective of monitoring atmospheric composition from polar orbit. The Sentinel-5 instrument consists of five spectrometers to measure the solar spectral radiance backscattered by the earth atmosphere in five bands within the UV (270nm) to SWIR (2385nm) spectral range. The data obtained with Sentinel-5 will allow obtaining the distribution of important atmospheric constituents such as ozone on a global daily basis and at a finer spatial resolution than its precursor instruments on the first generation of MetOp satellites. The launch of the first MetOp Second Generation satellite is foreseen for 2021. The Sentinel-5 instrument is being developed by Airbus DS under contract to the European Space Agency. The Sentinel-5 mission is part of the Copernicus program Space Component, a joint initiative by ESA, EUMETSAT and the European Commission. The Preliminary Design Review (PDR) for the Sentinel-5 development was successfully completed in 2015. This paper provides a description of the Sentinel-5 instrument design and data calibration.

10403-25, Session 7

Design and characterization of a low cost CubeSat multi-band optical receiver to map water ice on the lunar surface for the Lunar Flashlight mission

Quentin Vinckier, Jet Propulsion Lab. (United States); Karlton Crabtree, Photon Engineering LLC (United States); Christopher G. Paine, Paul O. Hayne, R. Glenn Sellar, Jet Propulsion Lab. (United States)

The Lunar Flashlight mission is an innovative NASA CubeSat mission dedicated to mapping water ice in the permanently shadowed regions of the Moon, which may act as cold traps for volatiles. To this end, a multi-band reflectometer will be sent to orbit around the Moon. This instrument consists of an optical receiver aligned with four lasers, each of which emits sequentially at a different wavelength in the near-infrared between 1μm and 2μm. The receiver measures the laser light reflected from the lunar surface and continuum/absorption band ratios are then analyzed to quantify water ice in the illuminated spot. Here we present the current state of the optical receiver design. To optimize the optical signal-to-noise ratio, we have designed the receiver so as to maximize the laser signal collected, while minimizing the stray light reaching the detector from solar-illuminated areas of the lunar surface outside the FOV, taking into account the lunar topography. Calibration and test plans are also discussed. This highly mass- and volume-constrained mission will demonstrate several firsts, including being one of the first CubeSats performing science measurements beyond low Earth orbit.

10403-30, Session 7

Tissue characterization by transillumination interferometry

Brenda Guzman Valdivia, Marija Strojnik, Centro de Investigaciones en Óptica, A.C. (Mexico)

In this research, we demonstrate the feasibility of an optical method, based on transillumination interferometry, to detect anomalies in biological tissues. By light tissue interference, tree phenomena may occur when a light beam interacts with a tissue: absorption, scattering, and the un-deviated passage of light through the sample (ballistic photons). The method uses the ballistic photons property to preserve their coherence and phase, so they can participate in interference. We develop equations that describe the transmission of a beam light that pass through multiple tissues. We obtain the expressions that describes the interference pattern between both beams of an interferometer. We simulate the transillumination and the interference by considering biological tissues. The interference pattern contains information about the tissue transmission characteristics. With this information, we determine the existence of anomalies within the tissue. An experimental setup, that consist in a modified Mach-Zehnder interferometer, is presented. Such an arrangement is used to obtain the interference pattern when using a simulated tissue. The simulation results demonstrate that the method can detect anomalies in absorption and scattering coefficients in tissues. The experimental results show that the experimental arrangement is capable to characterize biological tissues. The potential of the method to be used in detecting abnormalities in biological tissues is demonstrated.

10403-27, Session 8

Millimeter-wave/terahertz detection and photonic double-mixing by transistors *(Invited Paper)*

Akira Satou, Taiichi Otsuji, Tohoku Univ. (Japan)

Development of high-performance devices for millimeter-wave (MMW)/terahertz (THz) frequencies is emerging for MMW/THz wireless communication networks and remote sensing networks. For this purpose, two-dimensional (2D) plasmons in the channels of transistor structures, specifically, InP HEMTs and graphene FETs, have been extensively investigated. The detection of MMW/THz waves can be accomplished by excitation of the 2D plasmons with the generation of rectified photocurrent due to their hydrodynamic nonlinearities as well as the nonlinear transfer characteristics of the transistors. Also, the downconversion of an optical data signal to an MMW/THz IF signal, the so-called photonic double-mixing, can be accomplished by the transistors. A local MMW/THz signal is generated in the channel of a transistor by the photomixing of the optical data and an optical subcarrier signal as a beat note signal, and then the LO signal is input to the gate, leading to the mixing of the beat note and LO signal due to the nonlinearities and, in turn, leading to the generation of the MMW/THz IF signal.

In this paper, we review the two types of MMW/THz devices we have developed; the grating-gate InP HEMTs for detection and single-gate InP HEMTs/graphene FETs for photonic double-mixing. We experimentally demonstrate the ultra-high internal responsivity of the detectors, and we discuss about their response speed to modulated data signals. For photonic double-mixing, we experimentally verify the down-conversion of 10-Gbps-class optical data to the MMW IF band using InP HEMTs and graphene FETs. We also address a possibility of photonic double-mixing in the THz frequencies.

10403-28, Session 8

Generation of ultra-stable signal twins and idler twins by coupled optical parametric oscillators: Applications in remote sensing *(Invited Paper)*

Pengda Hong, Yujie J. Ding, Lehigh Univ. (United States)

We will summarize the progress made on investigation of coupled optical parametric oscillators using a single pair of nonlinear-optical crystals forming the twins. A single signal is split into signal twins whereas a single idler is split into two idler twins. Such twins are ultrastable since their frequency difference is insensitive to the change of the pump wavelength and temperature fluctuation. It exhibits the inverse proportionality of the frequency separation on the length of each of the crystals and difference of the group indices of the signal and idler waves. What is unique about such coupled optical parametric oscillators lies in the fact that the frequency separation can be scaled to a few 100 GHz from a few THz by using just a single pair of the twins. Such a significant reduction opens up novel applications of such coupled optical parametric oscillators in remote sensing by heterodyning the output beams generated by the ultrastable twins in a photodiode.

Conference 10404: Infrared Sensors, Devices, and Applications VII

Wednesday - Thursday 9 –10 August 2017

Part of Proceedings of SPIE Vol. 10404 Infrared Sensors, Devices, and Applications VII

10404-2, Session 1

Noise and detectivity of InAs/GaSb T2SL 4.5 um IR detectors

Andrzej Kolek, Lukasz Ciura, Rzeszów Univ. of Technology (Poland); Krzysztof Czuba, Iwona Sankowska, Janusz B. Kaniewski, Institute of Electron Technology (Poland); Jaroslaw Jurenczyk, Institute of Electron Technology (Poland) and VIGO System S.A. (Poland); Agata Jasik, Institute of Electron Technology (Poland)

Infrared detectors operating under bias may suffer from 1/f noise in the low frequency (LF) range. Then, their LF detectivity is no longer determined by thermal or shot noise but instead by 1/f noise. This noise must be experimentally determined because there is no universal model allowing for its theoretical estimation. In the paper, the measurements of LF noise of type-II superlattice (T2SL) detectors are reported and used to describe detectors' performance and gain the knowledge on noise phenomena in these devices. Devices under test (DUTs) have p-i-n architecture and were formed from 10 ML/10 ML InAs/GaSb T2SL material grown using MBE technology. They reach maximum responsivity of 0.8 A/W, with 50% cutoff at 4.5 um.

The noise versus temperature and bias voltage was measured with low-noise transimpedance amplifier. These measurements enable one to draw a maps of noise limitations and frequency/voltage-dependent detectivity of DUTs. It occurs that the common approach to describe detectivity, based on theoretical estimation of shot or thermal noise, is valid only in a very limited region. Much more wider are the areas, where detector is limited by either 1/f noise or noise of the amplifier. The latter has the performance (1 nV/Hz^1/2/15 fA/Hz^1/2) better than modern read-out integrated circuits, so this limitation holds in real detection systems.

The insights into phenomena governing the noise in the studied devices, were gained employing the modeling to decompose dark current into its components and correlating them with the measured 1/f noise. We have found no 1/f noise related to the diffusion current. The generation-recombination and shunt currents contribute to the total 1/f noise power as ?_gr*I_gr^2 and ?_sh*I_sh^2, and the coefficients ?_gr, ?_sh were estimated. The coefficient ?_sh can be so large that shunt-originated noise dominates even in the high temperature region, in which current is limited by generation-recombination and diffusion components. Tunneling currents also add a contribution to 1/f noise (at high reverse bias); however, its dependence on the bias current is weaker, i.e. noise power ~ ?_tun*I_tun.

One more issue connected with the LF noise is the possibility of detecting traps that generate random processes. In our DUTs, the traps were found, that generate processes with thermally activated kinetics. The activation energies of these traps were determined.

10404-3, Session 1

Resonantly enhanced infrared detectors based on type-II superlattice absorbers

Michael D. Goldflam, Emil A. Kadlec, Benjamin V. Olson, John F. Klem, Samuel D. Hawkins, S. Parameswaran, Wesley T. Coon, Gordon A. Keeler, Torben R. Fortune, Anna Tauke-Pedretti, Joel R. Wendt, Eric A. Shaner, Paul S. Davids, Jin K. Kim, David W. Peters, Sandia National Labs. (United States)

Recent improvements in measured dark current and minority carrier lifetimes in type-II superlattice infrared detectors have positioned these materials as possible competitors to mercury cadmium telluride. We have demonstrated a resonantly enhanced sub-2 ?m thick type-II superlattice long-wavelength infrared detector with gold nanoantennas on its top surface. Enhanced quantum efficiency in this device results from increased fields from both the patterned metal surface, as well as the Fabry-Pérot cavity formed by the active region of the detector structure. Coupling of these two resonances results in spectral selectivity of the detector, as well as a peak quantum efficiency exceeding 50%, nearly four times that of a comparable non-resonant device. This increase in quantum efficiency is possible in spite of the thin active region, which has a thickness a fraction of the free-space light wavelength. Through modification of only the nanoantenna structure, the device spectral response can be tailored to include multiple peaks or to shift a single peak by up to 2 ?m. Ultimately, use of thinned detector structures has the potential to reduce dark current, thereby improving signal-to-noise, while alleviating the expected decrease in quantum efficiency that results from a smaller absorbing volume. The mechanisms used here to improve detector functionality are detector-material agnostic suggesting their utility with alternative materials such as mercury cadmium telluride. These resonantly enhanced detectors show promise for future applications as sensitive frequency-agile solid-state sensors as well as two-color detector systems.

10404-4, Session 1

Theoretical simulation of mid-wave type-II InAs/GaSb superlattice interband cascade photodetector

Piotr Martyniuk, Klaudia Hackiewicz, Jaros?aw Rutkowski, Tetina Manyk, Andrzej Kowalewski, Wojskowa Akademia Techniczna im. Jaroslawa Dabrowskiego (Poland)

In this paper, the performance of a HOT interband type-II mid-wave (MWIR) InAs/GaSb superlattice (T2SLs) cascade detector is presented. Detailed analysis of the detector's performance (dark current and detectivity) versus bias voltage and operating temperatures reached by thermoelectrical cooling T= 200?230 K is shown. The bulk analytical base model to include surface current contribution is used while absorption coefficient and carrier effective masses are calculated by APSYS platform. It was assumed that cascade detector is composed of N stages where active layer length, d ~156 nm in each stage are equal to the same value. The carrier's diffusion length, L and absorber's length meet the requirement d << L. Simulated structure exhibits a cut-off wavelength ~ 4.8 μm at 200 K. The absorber region is non-intentionally doped and is made of 9 ML InAs/9 ML GaSb T2SLs. Responsivity, and detectivity, of the structure without immersion lens and zero bias reaches ~ 0.25 A/W and ~ 3e9 Jones for T = 230 K respectively. The proper compatibility between experimental and measured results was reached.

10404-5, Session 1

Effects of 4.5 MeV and 63 MeV proton irradiation on carrier lifetime of InAs/InAsSb type-II superlattices

Emil A. Kadlec, Michael D. Goldflam, Edward Bielejec, Jin K. Kim, Benjamin V. Olson, John F. Klem, Samuel D. Hawkins, Johnathan Moussa, Peter A. Schultz, Sandia National Labs. (United States); Christian P. Morath, Geoffery D. Jenkins, Vincent M. Cowan, Air Force Research Lab. (United States); Eric A. Shaner, Sandia National Labs. (United States)

Type-II strained-layer superlattices (T2SLs) are receiving increased interest as mid-wave infrared (MWIR) and long-wave infrared detector absorbers due to their potential Auger suppression and ability to be integrated into

complex device structures. Although T2SLs show promise for use as infrared detectors, further investigation into the effects of high energy particle radiation is necessary for space-based applications. In this presentation, the effects of both 4.5 MeV and 63 MeV proton radiation on the carrier lifetime of MWIR InAs/InAsSb T2SLs will be shown. The 63 MeV proton radiation study will focus on the carrier lifetime of MWIR InAs/InAsSb T2SL samples of varying donor density. These results reveal a Shockley-Read-Hall (SRH) lifetime associated with a radiation induced defect level, which is not dependent on the donor density of the T2SL. Using 4.5 MeV proton radiation, the dependence of carrier lifetime on relative trap density in MWIR T2SLs samples is studied by varying the particle fluence. A comparison of these two radiation studies shows similar lifetime effects that will be discussed in detail. These results give insight into the viability of Ga-free T2SLs for space applications.

10404-6, Session 1

Extraction of minority carrier diffusion length of MWIR type-II superlattice nBp detector

Zahra Taghipour, The Univ. of New Mexico (United States); Alireza Kazemi, The Ohio State Univ. (United States); Stephen Myers, SKINfrared LLC (United States); Priyalal S. Wijewarnasuriya, U.S. Army Research Lab. (United States); Sen Mathews, The Univ. of New Mexico (United States); Elizabeth Steenbergen, Christian P. Morath, Vincent M. Cowan, Gamini Ariyawansa, John Scheihing, Air Force Research Lab. (United States); Sanjay Krishna, The Ohio State Univ. (United States) and Univ. of New Mexico (United States) and SKInfrared LLC (United States)

We present a model to extract the minority carrier diffusion length (Ln) of an unipolar nBp InAs/GaSb Type II superlattice (T2SL) mid-wave infrared (MWIR) detector. The detector consists of a p-doped 10ML InAs/10ML GaSb SL absorber with a 50% cut-off wavelength of 4.5 μm at 80 K and zero bias. The detector was designed with an n-type doped InAs/AlSb SL barrier to reduce the operating bias. The device was fully turned on at 0 V. The external quantum efficiency (EQE) was measured to be 62% at 80 K, using front side illuminated devices with no anti-reflection (AR) coating. The dark current density, at the same temperature and operating bias, was measured to be 3.05?10-8 A/cm2. By fitting the experimentally measured EQE data to the theoretically calculated QE based on Hovel expressions, Ln can be extracted if the absorption coefficients are known accurately. The absorption coefficient was measured using an FTIR microscope and found to be 1600 cm-1 at 4.5 μm at 80 K. In addition, a reduced background concentration of 1.6?1016 cm?3 and a built-in potential of 150 meV were extracted by utilizing a capacitance-voltage measurement technique. Combining these results with the minority carrier lifetime measured via time-resolved-photoluminescence (TRPL), we were able to obtain an estimate of the diffusion length in this T2SL detector with a 4 μm thick absorber. This work was sponsored by the Army Research Office (ARO) under the contract W911NF-16-2-0068.

10404-7, Session 2

Active modulation of surface plasmon polaritons at degenerate semiconductor interfaces

Raj K. Vinnakota, Dentcho A. Genov, Louisiana Tech Univ. (United States)

The prospective of plasmonics to bridge the gap between electronics and photonics is well recognized by the scientific community with a large number of investigators working in the field of plasmonics. The Surface Plasmon Polaritons (SPPs), charge-density waves propagating at metal-dielectric and/or semiconductor-dielectric interfaces have tighter spatial confinement and higher local field intensity, can possess the key to offer the bandwidths of photonic devices and physical dimensions shared with nanoscale electronics. Here, we present an opto-electric switching element for plasmonic interconnects and circuits by electronically controlling highly confined SPPs at the metallurgic interfaces of degenerate semiconductor materials. The opto-electric SPP switch uses heavily doped sandwich of p and n-type semiconductor. In the operation the SPPs propagating at the interface of the p-n junction are switched by forward biasing the p-n junction by an external voltage. Two figure of merits are introduced and parametric study has been performed identifying the device optimal operation range. For high optical confinement, reduced system size and fast operation Indium Gallium Arsenide (In0.53Ga0.47As) is identified as the best semiconductor material. The opto-electric SPP switching element is shown to operate at signal modulation up to -24dB and switching rates surpassing 100GHz, thus possibly providing a path towards bridging the gap between photonic and electronic devices.

10404-8, Session 2

Distance and temperature dependent plasmon-enhanced carrier generation and diffusion in InAs/InGaAs/GaAs near-infrared photodetectors

Terefe Habteyes, Sharmin Haq, Sadhvikas Addamane, Ganesh Balakrishnan, The Univ. of New Mexico (United States); Danhong Huang, Air Force Research Lab. (United States)

Compared to the highly sensitive silicon based affordable visible light detectors, infrared photodetectors require significant improvement. Localized surface plasmon resonances of metal nanoparticles can be utilized for increasing the absorption efficiency of semiconductors suited for detection of infrared radiation. In this presentation, plasmonic gold nanorods (AuNRs) are used to enhance generation of charge carriers and photon emission by InAs/InGaAs/GaAs quantum dots-in-a-well structures. Comparison of measured and calculated scattering spectra reveals that the AuNRs on GaAs exhibit red to green colors depending on their proximity to the GaAs surface. On the other hand, theoretical and experimental near-field optical characterization show that the electric field is tightly localized at the AuNR-GaAs interfacial regions, creating a convenient platform for investigating localized carrier generation and diffusion by monitoring the emission of InAs QDs. The carrier generation and photon emission enhancement is studied as a function of the GaAs thickness (distance) and temperature. Analysis of the InAs quantum dot emission enhancement as a function of distance reveals a Förster radius of 3.85 ± 0.15 nm, a near-field decay length of 4.8 ± 0.1 nm and an effective carrier diffusion length of 64.0 ± 3.0 nm. These distance parameters indicate two emission enhancement mechanisms: plasmon enhanced carrier generation inside the GaAs layer and diffusion to the InAs quantum dots, and direct near-field excitation of the InAs/InGaAs. The emission enhancement increases with temperature, confirming the importance of charge carrier diffusion from the GaAs to the InAs quantum dots, where recombination and photon emission takes place.

10404-9, Session 3

The photonic device for integrated evaluation of collateral circulation of lower extremities in patients with local hypertensive-ischemic pain syndrome

Volodymyr S. Pavlov, Vinnitsa State Technical Univ. (Ukraine); Yurii O. Bezsmernyi, SRI of Invalid Rehabilitationon on the base of National Pirogov Memorial Medical University (Ukraine); Sergey M. Zlepko, Vinnitsa State Technical Univ. (Ukraine); Halyna V. Bezsmertna, SRI of Invalid Rehabilitationon on the base of National Pirogov Memorial Medical University (Ukraine)

Non-invasive diagnostic methods with optical registration and transformation of biomedical information extensive have been extensively developed for the last few years. Laser photoplethysmography (LPPG) relates to one method of non-invasive optical diagnostics peripheral circulation.

The purpose is the evaluation of LPPG diagnostic value in examination of patients with chronic ischemia of lower extremities.

Method can improve the reliability of the control and peripheral circulation diagnostics and identify the effects on the autonomic nervous system, can serve for evaluation of sympathetic innervations of the skin, can be used in the diagnostics of Reynaud's disease, early forms of atherosclerosis, thrombosis, etc. Besides, LPPG has additional diagnostic and prognostic value in the study of many cardiovascular and neurological diseases that are the most common causes of death and disability in young age. Therefore, effective processing of LPPG information is very important.

Photonic device is developed to determine the level of the peripheral blood circulation, which determines the basic parameters of peripheral blood circulation and saturation level. Device consists of two sensors: infrared sensor, which contains the infrared laser radiation source and photodetector, and the red sensor, which contains the red radiation source and photodetector. The outputs of amplifiers connected to the inputs of the microcontroller.

LPPG method allows to determined pulsatility of blood flow in different areas of the foot and lower leg, the degree of compensation and conservation perspectives limb and of amputation level. LPPG is the highly informative method to evaluation the pulsatility of blood flow in a specific area.

10404-10, Session 3

In vivo noninvasive detection of blood glucose by near-infrared spectroscopy with machine learning techniques

Siman Zhang, Siqi Liu, Ting Xie, Peng Sun, Chang Wang, Huaye Li, Zhenrong Zheng, Zhejiang Univ. (China)

Blood glucose level (BGL) has been regarded as an indicator of diabetes mellitus, hypoglycemia and metabolism disorders for patients. In this paper, we presented a system for in vivo noninvasive BGL detection using near-infrared (Near-IR) diffuse-reflectance spectroscopy combined with machine learning (ML) algorithms. Compared with conventional BGL detection devices, this system could release the pain of patients associated with the frequent pricking of skin for taking blood samples. The system was consisted of an illumination module, a noninvasive detection module based on Near-IR spectrometer and a data processing module. Method underlying the system was that there was functional relationship between Near-IR spectra and BGL. Near-IR spectra were collected separately from thirty volunteers at the fingertip during glucose tolerance tests. Calibration models were generated from two-thirds of the spectra data to predict BGL using multilayer perceptron neural network, support vector machine and random forest ML techniques. Unlike traditional chemometrics methods which were used to model linear relationships, ML algorithms performed better in representing BGL via Near-IR spectra due to the presence of nonlinearity. The performance of the calibration models were examined by evaluating the accuracy of glucose predictions from the remaining third spectral data using correlation coefficient of prediction, mean error percentage of prediction and root mean square error of prediction (RMSEP). The best results were obtained with random forest technique. Results showed that with the designed system, blood glucose could be detected with a high correlation coefficient of 92.4%, mean error percentage of 14.49% and RMSEP of 0.52 mmol/L.

10404-11, Session 3

Photoacoustic signal detection using interferometric fiber-optic ultrasound transducers

Amanda D. Salas-Caridad, Geminiano Martinez-Ponce, Rodolfo Martinez Manuel, Centro de Investigaciones en Óptica, A.C. (Mexico)

Photoacoustics is a hybrid technique driven by the photoacoustic effect. This effect is based on the sensitive detection of acoustic waves launched by the absorption of pulsed or modulated radiation by means of transient localized heating and expansion in a gas, liquid, or solid. This effect is due to the transformation of at least part of the excitation energy into kinetic (translational) energy by energy exchange processes between different degrees of freedom. Consequently, the absorption of pulsed radiation generates an acoustic signal that is acquired by an ultrasonic piezoelectric transducer or optically with a contact-free method. It is an interesting technique which combines the advantages of optics and acoustics. The optics field provides with high resolution, while acoustics provides higher spreading range. The technique caught the special attention of biomedical researchers, as the optical absorption of some tissue components such as hemoglobin, oxy-hemoglobin, melanin, bilirubin, lipids and water, allows them to process information regarding their presence.

This work aims to propose the design of a fiber-optic interferometric sensors array which localizes the origin of an acoustic signal generated by an infrared light absorption center inside the volume of a semi-opaque medium. The characterization and evaluation of the performance for ultrasonic transductors (hydrophones) based in fiber-optic interferometric sensors must be made in order to develop an accurate inverse algorithm for the localization of an acoustic signal from its spatial and temporal behavior. Also, an experimental method to determine the optimal distribution of four ultrasonic transductors can be developed as well.

10404-13, Session 4

Improved performance of GaAs photocathodes using effective activation technique

Yijun Zhang, Jingzhi Zhang, Cheng Feng, Nanjing Univ. of Science and Technology (China); Hongchang Cheng, Science and Technology on Low-Light-Level Night Vision Lab. (China); Xiang Zhang, Yunsheng Qian, Nanjing Univ. of Science and Technology (China)

Up to now, negative-electron-affinity (NEA) GaAs-based photocathodes have found widespread applications in photoelectric detectors for night observation and electron sources for high-energy physics. To achieve NEA state, the atomically clean cathode surface is usually activated by cesium and oxygen. In view of the required computer-control of evaporation flow rates, the solid oxygen dispenser instead of gaseous oxygen is used just as the regular Cs dispenser. Two types of solid oxygen dispensers composed of barium peroxide powder and silver oxide powder are chosen to activate GaAs photocathodes. By residual gas detection during degassing, it is found that the barium peroxide-based O dispenser can release more oxygen than silver oxide-based one. The appropriate evaporation current passing through the O dispenser of silver oxide should exceed 7.8A. Through a series of Cs-O activation experiments, there exists an unsatisfactory feature that the silver oxide-based O dispenser released effectual oxygen gas more slowly than the barium peroxide-based O dispenser, which was adverse to the first Cs/O alternate activation. Therefore, an effective activation technique was proposed to ameliorate the unfavorable phenomenon for silver oxide-based O dispenser, which could bring out the desired symmetry of photocurrent curve shape during the whole Cs/O alternate activation process. Whereas, compared with the silver oxide-based O dispenser, the barium peroxide-based one can bring a higher activation photocurrent for GaAs photocathodes, which accordingly resulted in a better spectral response. The effective activation technique using solid dispensers can provide guidance for the optimization of activation craft.

10404-14, Session 4

Extended wavelength InGaAs SWIR FPAs with high performance

Xue Li, Xiu-Mei Shao, HaiMei Gong, Xianliang Zhu, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China)

The extended InGaAs short wavelength infrared (SWIR) detector covers 1.0-2.5μm wavelength, which plays an important role in weather forecast, resource observation, low light level systems, and astronomical observation and so on. In order to fabricate the high performance extended InGaAs detector, materials structure and parameters were characterized by using Scanning Capacitance Microscopy(SCM), Scanning Spreading Resistance Microscopy (SSRM) and Photoluminescence Spectroscopy(PL), the spreading of minority carriers and lattice quality were obtained. Mesa etching parameters, etching damage restoration and low temperature passivation were used in the fabrication of the extended InGaAs detector. The improvement of material structure and device process was studied by using different perimeter-to-area (P/A) photodiodes and MIS structure device, respectively. The dark current of the extended InGaAs detector obviously decreases, about 1nA/cm2 at 170K temperature. The 512?256 FPAs were fabricated, the peak detectivity and the quantum efficiency of which are 5?1011cmHz1/2/W and 80% , respectively. The staring image yielded of the 512?256 FPAs is shown, which demonstrates very good imaging quality.

10404-15, Session 4

640x512 pixel InGaAs FPAs for short-wave infrared and visible light imaging

Xiu-Mei Shao, Bo Yang, Songlei Huang, Yang Wei, Xue Li, Xianliang Zhu, Tao Li, HaiMei Gong, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China)

The spectral irradiance of moonlight and air glow is mainly in the wavelength region from visible to SWIR band. The imaging for very low background applications during this wavelength range is of great significance in civil safety and defense field. In this paper, 640?512 visible-SWIR InGaAs FPAs were studied for night vision and short-wave infrared (SWIR) imaging. A special epitaxial wafer structure with etch-stop layer was designed and developed. Planar-type 640?512 InGaAs detector arrays were fabricated. The photosensitive arrays were bonded with readout circuit through Indium bumps. The FPAs were tested at the temperature of 293K. The relative spectral response is in the range of 900nm to 1700nm. Then, the InP substrate was removed with low damage by mechanical thinning and chemical wet etching. Multilayer anti-reflection films were designed and deposited on the backside-illuminated surface. The quantum efficiency is approximately 15% at 500nm, 30% at 700nm, 50% at 800nm, 90% at 1550nm. The visible irradiance can reach InGaAs absorption layer and then to be detected. As a result, the detection spectrum of the InGaAs FPAs has been extended toward visible spectrum from 500nm to 1700nm. The average peak detectivity is higher than 3?10^12cm•Hz^1/2/W at room temperature with a integrated time of 10ms.The Visible-SWIR InGaAs FPAs were applied to an imaging system with good resolution for SWIR and visible light imaging.

10404-16, Session 4

Life test of the InGaAs focal plane arrays detector for space applications

Xianliang Zhu, HaiYan Zhang, Xue Li, ZhangCheng Huang, HaiMei Gong, Shanghai Institute of Technical Physics of the Chinese Academy of Sciences (China)

Compared to tactical applications, IR detectors for space applications require far fewer quantities, and reliability and photoelectric performances must be extraordinarily high. Therefore, the research of its reliability is very difficult because of the little amount and high price.

Hybrid Infrared focal plane array (IRFPA) is the core component of the third generation infrared detection systems, which consists of infrared detector chip, readout integrated circuit (ROIC), and flip-chip bonding interconnection by Indium bump. In order to satisfy space application requirements for failure rates or Mean Time to Failure (MTTF), which can only be demonstrated with the large number of detectors manufactured, the single pixel in short-wavelength infrared InGaAs focal plane array is chose as the research object in this paper.

As the InGaAs FPAs are usually operated around room temperature, they will not go through thousands times of temperature cycles, so hot temperature is the suitable accelerated stress. Through step-stress accelerated life test, the maximum temperature stress of InGaAs FPAs under the same failure mechanism has been obtained, and it was found that Indium bump is the most possible weakness of the FPAs. According to the results of step-stress accelerated life test, choosing the single pixel in InGaAs FPAs as research object, the constant-stress accelerated life test has been carried out at 70??80??90?and100?. The bad pixels increased gradually during more than 10000 hours at each elevated temperatures. Statistical analysis on the experimental data shows that the activation energy is about 0.46eV, and the average lifetime of a single pixel in InGaAs FPAs will be more than 1E+7h at the operating temperature(5?).

10404-17, Session 5

Mid-infrared photo detector using pyroelectric response of LiNbO3

Kavitha K. Gopalan, ICFO - Institut de Ciències Fotòniques (Spain); Davide Janner, Politecnico di Torino (Italy); Sebastien Nanot, Romain Parret, Mark B. Lundeberg, Frank H. L. Koppens, Valerio Pruneri, ICFO - Institut de Ciències Fotòniques (Spain)

Photodetectors (PDs) in the mid infrared (mid-IR) wavelength region are of great interest as they are essential components in many applications, e.g. vibrational spectroscopy and thermal imaging. The majority of current PDs in the mid-IR are limited by the fact that they operate at cryogenic temperatures. We demonstrate a room temperature photodetector working in the 6-10 ?m range based on graphene on z-cut LiNbO3 pyroresistive platform. Infrared radiation absorbed in the LiNbO3 crystal leads to an increase in temperature, which subsequently induces polarization (bound) charges at the crystal surface via the pyroelectric effect. These cause doping into graphene which in turn changes its carrier density and hence the electrical conductivity.The characteristics of such pyro-resistive detectors are in between conventional pyroelectric detectors and bolometers that are used in IR detection, thus enabling an optimum trade-off between both these classes of detectors. Detectivities of about 10^5cm√HzW-1 in the 6 to 10 ?m region are demonstrated. We also show that up to two orders of magnitude larger detectivity can be achieved by optimising the geometry and operating in vacuum, thus opening the path to a new class of mid-IR photo-detectors that can challenge classical HgCdTe devices, especially in real applications where cooling is to be avoided and low cost is crucial.

10404-18, Session 5

Low dark current p-on-n technology for space applications

Nicolas Péré-Laperne, SOFRADIR (France); Nicolas Baier, Cyril Cervera, Jean-Louis Santailler, Clément Lobre, CEA-LETI (France); Christine Cassillo, Jocelyn Berthoz, Vincent Destefanis, Diane Sam-Giao, Adrien Lamoure, SOFRADIR (France)

Space applications are requiring low dark current in the long wave infrared at low operating temperature for low flux observation. The applications

envisioned with this type of specification are namely scientific and planetary missions. Within the framework of the joint laboratory between Sofradir and the CEA-LETI, a specific development of a TV format focal plane array with a cut-off wavelength of 12μm at 40K has been carried out.

For this application, the p on n technology has been used. It is based on an In doped HgCdTe absorbing material grown by Liquid Phase Epitaxy (LPE) and an As implanted junction area. This architecture allows decreasing both dark current and series resistance compared to the legacy n on p technology based on Hg vacancies.

In this paper, the technological improvements are briefly described. These technological tunings led to a 40% decrease of dark current in the diffusion regime. CEA-LETI and Sofradir demonstrated the ability to use the p on n technology with a long cutoff wavelength in the infrared range.

10404-19, Session 5

Germanium photodetectors fabricated on 300 mm silicon wafers for near-infrared focal plane arrays

Ashok K. Sood, John W. Zeller, Magnolia Optical Technologies, Inc. (United States); Caitlin Rouse, Pradeep Haldar, Harry Efstathiadis, SUNY Polytechnic Institute (United States); Nibir K. Dhar, U.S. Army Night Vision & Electronic Sensors Directorate (United States)

Germanium near-infrared (NIR) photodetectors operating a room temperature have certain advantages compared to conventional III-V and HgCdTe based infrared detectors in relation to ease of fabrication, cost, and size, weight and power (SWaP), aided by recent improvements in techniques for epitaxially depositing layers of pure Ge. While Ge based detectors have traditionally been limited to operating up to ~1.6 ?m, this detection limit may be extended to longer wavelengths through incorporation of tensile strain. Scanning transmission electron microscopy (STEM) based fast Fourier transform (FFT) modeling of atomic-scale lattice periodicity of the cross-sectional device structure has been performed to determine the location and extent of tensile strain in the detectors, as well as the nature of material coalescence at the Si-Ge junction. Ge-based p-i-n photodetectors have been fabricated on 300 mm silicon wafers, taking advantage of complementary metal-oxide semiconductor (CMOS) technology. The fabrication is based on a specialized two-step low/high temperature growth process taking into account the significant difference in thermal expansion coefficients between Ge and Si, designed to minimize formation of threading dislocations. Bright-field STEM analysis showed the Ge seed and intrinsic layers to be of high quality with limited defects and dislocations. In addition, measured I-V photoresponse behavior of photodetector devices at room temperature under dark and illuminated conditions demonstrated significant photocurrent enhancement for visible-NIR radiation at reverse biases, and relatively high zero-bias response. These Ge p-i-n detectors were designed to function as elements in an NIR imager focal plane array (FPA).

10404-1, Session PWed

Effect of antimony segregation on the electronic properties of InAs/InAsSb superlattices

Heather J. Haugan, Frank Szmulowicz, John J. Hudgins, Logan E. Cordonnier, Gail J. Brown, Air Force Research Lab. (United States)

There has been great progress in recent years in advancing the state-of-the-art of Ga-free InAs/InAsSb superlattice (SL) materials for infrared detector applications, spurred by the observation of long minority carrier lifetimes in this material system. However, compositional and dimensional changes through Sb segregation alter the detector properties from those originally designed. Therefore, in this work, epitaxial conditions that can mitigate this segregation were explored in order to produce high-quality SL materials for optimum detector performance. A nominal SL structure of 7.7 nm InAs/3.5 nm InAs0.7Sb0.3 tailored for an approximately six-micron response at 5 K was used to optimize the epitaxial parameters. Since the growth of mixed AsSb alloys is complicated by the potential reaction of As with Sb surfaces, the authors vary the substrate temperature (Ts) in order to control the As surface reaction on a Sb surface. Experimental results indicate that the SL sample grown at the lowest investigated Ts produces the highest Sb-mole fraction x of ~0.3 in InAs1-xSbx layers, which then decreases by 21 % as the Ts increases from 395 to 440 °C. This reduction causes an approximately 30 meV blueshift in the position of the excitonic photoluminescence (PL) peak. This finding differs from the results obtained from the Ga-containing InAs/GaSb SL equivalents, where the PL peak position remains constant at about 220 meV, regardless of Ts. The Ga-free SLs generally generate a broader PL linewidth than the corresponding Ga-containing SLs due to the higher spatial Sb distribution at the hetero-interfaces engendered by Sb segregation.

10404-12, Session PWed

Improved calibration-based non-uniformity correction method for uncooled infrared camera

Chengwei Liu, Xiubao Sui, Nanjing Univ. of Science and Technology (China)

With the latest improvements of microbolometer focal plane arrays (FPAs), uncooled infrared (IR) cameras become the most widely devices in thermography, especially in handheld devices. While the influences derived from changing ambient condition and the non-uniform response of the sensors make it more disturbing to correct the non-uniformity of uncooled infrared camera. In this paper, based on the infrared radiation characteristic in the TEC-less uncooled infrared camera, a novel model was proposed for calibration-based non-uniformity correction. In this model, we introduce the FPA temperature, together with the responses of microbolometer under different ambient temperature to calculate the correction parameters. Based on the proposed model, we can work out the correction parameters with the calibration measurements under controlled ambient condition and uniform blackbody. All correction parameters can be determined after the calibration process and then be used to correct the non-uniformity of the infrared camera in real time. This paper present the detail of the compensation procedure and the performance of the proposed calibration-based non-uniformity correction method. And our method was evaluated on realistic IR images obtained by a 384?288 pixels uncooled long wave infrared (LWIR) camera operation under changed ambient condition. The results show that our method can exclude the influence caused by the changed ambient condition, and ensure that the infrared camera has a stable performance.

Chalcogenide based rib waveguide for compact on-chip supercontinuum sources in mid-infrared domain

Than Singh Saini, Umesh K. Tiwari, Central Scientific Instruments Organisation (India); Ravindra K. Sinha, Delhi Technological Univ. (India)

Mid-infrared supercontinuum generation (i.e the broadening in the intense laser pulses when they pass through the highly nonlinear medium) is very exciting research field because of its applications in diverse fields such as spectroscopy, medical imaging, security and sensing. The broadening of the supercontinuum spectrum depends on both strong nonlinearity and dispersion characteristic, which leads to solitonic effects and efficient four-wave mixing. The highly nonlinear materials such as chalcogenide glasses are promising platform for the realization of compact, on-chip mid-infrared supercontinuum sources. To date, various chalcogenide glass systems have been explored and their potential applications have been estimated. Recently, a novel chalcogenide glass system, Ga–Sb–S, is reported which has a very high nonlinearity (n2 = ~12.4?10–14 cm2/W at 1.55 μm) and wide

transparent window of ~0.8–14 μm. Because of these favorable properties this chalcogenide glass system supposed to be promising materials for mid-infrared nonlinear applications such as thermal imaging, nonlinear optics, and mid-infrared lasers. In this work, we have designed and analyzed a highly nonlinear rib waveguide structure in recently reported Ga-Sb-S based chalcogenide glass for mid-infrared supercontinuum generation ranging from 2 – 10 μm. The proposed waveguide structure possesses a very high nonlinear coefficient and can be used for compact on-chip supercontinuum sources in mid-infrared domain.

10404-37, Session PWed

High security Infrared biometrics authentication system for financial application

Xiaofeng Jin, Sun Yat-Sen Univ. (China); Tiancai Liang, Research Institute of GRG Banking Equipment Co., Ltd. (China); Biao Wang, Sun Yat-Sen Univ. (China); Ming Li, Jun Xu, Research Institute of GRG Banking Equipment Co., Ltd. (China); Jianfeng Sun, Shanghai Institute of Optics and Fine Mechanics (China)

Based on infrared Finger-vein Recognition technology, security chip and hardware encryptor, this paper provides secure and trusted solution for identity authentication. In order to guarantee the safe running environment of the Finger-vein device, a security chip was embedded to process triple DES algorism for sensitive biometric information encryption and storage. And the device to be self-defensive, once destructed, all the information inside the chip will gone. Besides the hardware encryptor was adopted to be with the server of the platform, to generate all the keys running in the system and decryption the key during communication. The digital signature was applied to guarantee the integrity of biometric information, which is unable to be manipulated. So we can support the process of Finger-vein authentication to meet with financial-level security standard.

10404-38, Session PWed

A comparison of approximate and exact modes in few-mode micro-optical fibres

José Á. Flores-Bravo, Fernando Martínez-Piñón, Ctr. de Investigación e Innovación Tecnológica (Mexico); Grethell G. Pérez-Sánchez, Univ. Autónoma Metropolitana (Mexico)

An analysis of different cases of few-mode micro-optical fibers from 10 to 1 microns in diameter is performed based on solving the eigenvalue equation using both the weak guidance approximation (scalar LP modes) when the refractive index difference is small, and the exact full eigenvalue equation (vector TE, TM, HE and EH modes), when the refractive index difference is large, for example having air or a gas as the surrounding medium. One of the objectives of this analysis is to show at what point the propagation constant and optical field intensity of the fundamental modes LP01 and HE11 differ significantly depending of the refractive index difference, the other objective is to find out the evolution of the other modes along the final tapered section in a few mode fiber taper. The graphical behavior of the solutions of the eigenvalue equation is presented and the optical intensity distributions are calculated for different sizes, as for example in adiabatic tapers to evaluate the extent of the evanescent field. In general, the propagation constant and effective refractive index depends on the size of the core waveguide diameter, the refractive index difference and the wavelength. This analysis is useful to calculate the extension of the evanescent field in liquids or gases for optical fiber sensors that can be used to model, for example, fluorescent optical fiber sensors for biological or industrial applications. Additionally, the propagation characteristics of the few-mode micro optical fiber could be controlled or tuned by changing the refractive index of the surrounding media by changing, for example, its temperature.

Elongation-based fiber optic tunable filter

Grethell G. Pérez-Sánchez, José A. Mejía-Islas, Edgar A. Andrade-González, Univ. Autónoma Metropolitana (Mexico); José R. Pérez-Torres, Tecnológico de Estudios Superiores de Coacalco (Mexico)

Fiber optic filters are devices that allow selecting certain wavelengths transmitted in a fiber optic and rejecting the others. Such devices are highly used in both fiber optic communications networks, and in fiber optic testing and monitoring systems as sensors. The main applications of optical filters in optical communication systems include: elimination of noise; equalization of the response of optical amplifiers, selection of channels in WDM systems. Communications systems have the need of tunable filters to be able to select different wavelengths that are propagated in the same transmission medium, also require devices with a large dynamic range that allow to explore of effects and system responses at different wavelengths.

This paper focuses on introducing the results of a model using a control system for an optical fiber Bragg grating filter with central wavelength at 1557 nm that can be tuned, using a solution that employs, an elongation control system. At the first stage, the optical characterization of the filter was made, then the stepper motors were chosen for the desired wavelength selection with a couple of pulleys which produce the grating elongation and, as a consequence, the wavelength shifting The pulleys diameters were calculated to produce 0.08 nm shift for each step on the stepper motors. At the last stage the user can define the filtering wavelenght using a control program.

Laser goniometer used for remote non-contact measurement of angular position and movement

Nkpoikanke Eno, Saint Petersburg Electrotechnical Univ. “LETI” (Russian Federation)

Laser Goniometer and other standard devices operate in remote non-contact mode of measuring object’s angular positions. This article is devoted to error’s analysis, results and new methods of measuring wider angles of 15-30degs with 0.1arcs accuracy

10404-21, Session 6

Wave study of compound eyes for efficient infrared detection

Takiyettin O. Kilinc, Roketsan A.S. (Turkey) and TOBB Univ. of Economics and Technology (Turkey); Zeki Hayran, Hamza Kurt, TOBB Univ. of Economics and Technology (Turkey)

Improving sensitivity in the infrared spectrum is a challenging task. Detecting or imaging infrared light over wide band width and at low power consumption is very important. Novel solutions can be acquired by mimicking biological eyes such as compound eye with many individual lenses inspired from nature. Nature provides many ingenious approaches of sensing and detecting the surrounding environment. Even though compound eye consists of small optical units, it can detect wide-angle electromagnetic waves and it has high transmission and low reflection loss. Insects have eyes that are superior compared to human eyes (single-aperture eyes) in terms of compactness, robustness, wider field of view, higher sensitivity of light intensity and being cheap vision systems. All these desired properties are accompanied by an important drawback: lower spatial resolution. The first step to investigate the feasibility of bio-inspired optics in photodetectors is to perform light interaction with the optical system that gather light and detect it. The most common method used

in natural vision is ray analysis. Light wave characteristics are not taken into consideration in such analyses, such as the amount of energy at the focal point or photoreceptor site, the losses caused by reflection at the interfaces and absorption cannot be investigated. In this study, we present a bio-inspired wave analysis of infrared detection of light. We numerically model the wave analysis based on Maxwell equations from the viewpoint of efficient light detection and reveal the light journey after intercepting the first interface of the eye towards the photoreceptor site.

10404-22, Session 6

Probing infrared detectors through energy-absorption interferometry

Dan Moinard, Stafford Withington, Christopher N. Thomas, Univ. of Cambridge (United Kingdom)

We introduce an interferometric technique capable of fully characterizing the optical response of few-mode and multi-mode detectors, including the amplitude and phase patterns of their individual modes, using solely power measurements. Describing detectors' outputs as the contraction of the external field correlation tensor and detector response tensor representing their respective coherence states, the latter can be recovered using Energy-Absorption Interferometry. EAI is essentially a generalization of holography, and allows the reconstruction of the individual degrees of freedom through which the detector can absorb energy, including their relative sensitivities and spatial forms. Coupling mechanisms into absorbing structures and their underlying solid-state phenomena can therefore be studied, with direct applications in improving current infrared detector technology. In particular, material properties such as the absorber's spatial coherence length are directly obtained.

EAI yields an experimental procedure where the system under test is excited with two external coherent sources, and the fringe in the total power dissipated is measured as the relative phase between the sources is varied. Iterating for multiple source positions, the fringes' complex visibilities allow the two-point detector response function to be retrieved: this correlation function can then be decomposed into a set of natural modes.

We describe the theoretical basis of EAI, examine a room-temperature 1550nm-wavelength infrared experiment we have constructed and present our preliminary results. Finally, we discuss how EAI is applicable to detector arrays, and more broadly to many-body structures as varied as spin systems and energy-harvesting absorbers.

10404-24, Session 6

Frequency-selective surfaces for infrared imaging

Emeline Lesmanne, François Boulard, CEA-LETI (France); Roch Espiau de Lamaestre, MINATEC (France); Giacomo Badano, CEA-LETI (France)

In the past decade, the infrared detector industry has developed a multitude of solutions for multicolor detection. The general idea behind them is to stack up two or more diodes per pixel, each tuned to the target wavelength range. That involves the fabrication of multilayer structures and results in quite complex and expensive devices of superior performance. Bayer matrices have attracted attention as an inexpensive albeit less performant approach, whereby wavelength selection is achieved by filters deposited on top of an existing detector. In this work, we developed a 4 color Bayer matrix of filters that operates in the mid-infrared range (MWIR). Our filters consist of metasurfaces of transverse-electric resonators : a thin metallic sheet is punctured with apertures filled with a high-index dielectric material. Each aperture behaves as a separate resonator. The aperture size determines the transmission waveband. Two or more arrays of such apertures can be juxtaposed to create a multicolor filter, without cross-talk between the adjacent colors. Using an original approach based on the temporal coupled mode theory, we show that metallic loss is negligible in the infrared range, as long as the filter bandwidth is large enough (typically >?/10). To get this result, we develop closed form expression for the radiative and dissipative loss rates and show that the transmission of the filter depends solely on their ratio. Next, we present a prototype infrared detector functionalized with one such array of filters and characterize it by electro-optical measurements.

10404-25, Session 6

Plasmo-thermomechanical suspended nanowire array detectors for mid-infrared spectrum

Qiancheng Zhao, Mohammad W. Khan, Univ. of California, Irvine (United States); Parinaz Sadri-Moshkenani, Univ. of California Irvine (United States); Rasul Torun, Imam-Uz Zaman, Ozdal Boyraz, Univ. of California, Irvine (United States)

We propose a plasmo-thermomechanical mid-infrared detector operating at 4.3 μm wavelength. The design utilizes an array of the bimetallic fishbone nanowires that are suspended 50 nm above a 1.5 μm x 0.3 μm silicon nitride waveguide to create a leaky wave radiation. Moreover, the thermo-mechanically actuated nanowire will induce evanescent wave modulation that can be detected by the leaky wave or transmitted power of the waveguide. The antenna has a strip length of 1.76 μm and can yield an absorption coefficient of 35.57% with a period of 3.1 μm. Six unit cells are connected by a nanowire, and the fishbone-like nanowires are clamped at the two ends, leaving the center free to bend. The mid-infrared energy is absorbed by the resonant metallic antennas, resulting in a temperature increment. The mismatch of the thermal expansion coefficients of the bimetallic materials, gold and nickel, actuates the nanowire, and thus changes the gap between the nanowire and the waveguide. The deformation of the nanowire modulates the waveguide evanescent field, and hence alternates the transmitted power as well as the leak wave power. With a normal incident power of 10 μW/μm2, the temperature in the center of the nanobridge can be increased over 133 K above the ambient temperature, leading to an elevation of 29.9 nm in the center and thus weakening the evanescent modulation strength. The difference of S21 caused by the gap change is 0.111. This methodology can be applied in other spectrums and the fabrication progress will be reported later.

10404-26, Session 6

PbS and HgTe quantum dots for SW IR devices

Witold Palosz, Sudhir Trivedi, Brimrose Corp. of America (United States); Gregory Meissner, Kimberley Olver, Eric DeCuir Jr., Priyalal S. Wijewarnasuriya, U.S. Army Research Lab. (United States); Janet Jensen, U.S. Army Edgewood Chemical Biological Ctr. (United States)

HgTe and PbS Colloidal Quantum Dots with first excitonic absorption peak of about 2 ?m and shorter (down to about 1 ?m) have been synthesized and characterized. A wide range of growth conditions, in particular the growth temperature and temperature timeline, type and concentration of the reagents, and growth time, were tested. Post-growth purification conditions and procedures were also investigated. The synthesized CQDs were characterized using FTIR spectroscopy and TEM technique. The nanomaterials were tested for photo-electrical properties with PC devices. The devices were fabricated by drop-casting a suspension of the QDs on a fan-out, followed by solid ligand exchange, and then spectral and electrical photoresponse of the device was measured. The device fabrication parameters were the number of deposited layers, the thickness of individual layers, the type of the substituting ligand, and the ligand exchange duration. The solid ligand exchange process was evaluated thru absorption spectra of test samples. (The tests were done by forming QD layers on a CdF2 substrate and then conducting the ligand exchange.) For selected devices Quantum Efficiency was also determined.

10404-27, Session 7

Innovations in imaging technology and NASA/ESTO investments in technology development *(Invited Paper)*

Sachidananda R. Babu, NASA Goddard Space Flight Ctr. (United States)

Imaging technology is one of the fastest evolving areas in the consumer market, due to the penetration of imaging instruments into our everyday life. NASA has specific interest in space and earth imaging requirements. Therefore, there is a big push in consumer needs that is advancing the technology at explosive rate. Some of the technologies of particular interest to NASA applications are dual gain pixel design, wafer level integration of the imagers and mass production of high resolution imagers. We are also looking at ways to operate the existing imaging sensors in innovative ways to extract more information.

This talk will focus on the imaging technology developments in professional and consumer application areas and its relevance to NASA imaging needs. Some of the ESTO investments in innovative use of existing technology and our recent investments in new technology applications will be also presented.

10404-28, Session 7

Target detection in sun glint using the improved MWIR polarization technique

Ji Zheng, Huijie Zhao, Yansong Li, BeiHang Univ. (China); Xiaofeng Sun, Pengfei Song, Shitao Wang, China Academy of Space Technology (China); Chi Cheng, BeiHang Univ. (China)

When detecting target in sun glint by a mid-infrared detector, the target could be submerged in its intense background noises due to detector saturation.The traditional technique based on the single horizontal linear polarizer was one of the common methods to reduce the sun glint by eliminating its s-polarized component, nevertheless, the residual p-polarized component of sun glint could be still too strong to saturate the detector in some cases. Therefore, we further improve the sun glint countermeasure and propose the sun glint suppression method based on two rotatable polarizers, which is presented in this paper. Firstly, the brief theoretical analysis methods employed in different detection scenarios that whether the single or two polarizers should be used to further eliminate the p-polarized component of the sun glint is described. Secondly, the formula and its derivation for the optimum angle between the two polarizers is provided in case that the second polarizer is required. Thirdly,the MWIR polarization imaging system design with two rotatable and dismountable polarizers is described. Then, the field experiments and results under two different experimental conditions are presented, demonstrating that the improved polarization technique can significantly reduce sun glint and can enhance the contrast of target images in both cases. Combined with the commonly used image processing algorithm,the targets in sun glint can be identified, confirming the effectiveness of the improved MWIR polarization technology.

10404-29, Session 7

Temperature measurements on fast-rotating objects using a thermographic camera with an optomechanical image derotator

Bettina Altmann, Christian Pape, Eduard Reithmeier, Leibniz Univ. Hannover (Germany)

Increasing requirements concerning the quality and lifetime of machine parts in industrial and automotive applications require comprehensive investigations of the components in conditions close to the application. Irregularities in heating of mechanical parts reveal regions with increased loading of pressure, draft or friction. In the long run this leads to damage and failure of the component. Thermographic measurements of rotating objects like roller bearings, brakes and clutches present an approach to investigate those defects. However, it is challenging to measure fast-rotating objects accurately. Currently one contact-free approach is performing stroboscopic measurements using an aerial infrared sensor. The data acquisition would be triggered so that the image is taken once per revolution. This leads to a huge loss of information on the majority of the movement and motion blur. The objective of this research is using an optomechanical image derotator together with a thermographic camera. The derotator follows the rotation of the measurement object so that quasi-stationary thermal images of the whole movement can be acquired by the infrared sensor. Unlike conventional derotators which use a glass prism to achieve this effect, the derotator within this work is equipped with a sophisticated mirror-assembly. These mirrors are made of aluminum to transfer infrared radiation emitted by the rotating object. Because of the resulting stationary thermal image, the operation can be monitored seamlessly even for fast-rotating objects. The field of view can also be set to a small off-axis region of interest which then can be investigated with higher resolution or frame rate. To depict the potential of this approach, thermographic measurements on various roller bearings and their rolling elements are presented to show differences in the heating and problem areas during different operating states.

10404-30, Session 7

Modeling of IR spectra for nerve agent-sorbent binding

Michael R. Papantonakis, Courtney A. Roberts, Andrew Shabaev, Youngchan Kim, R. Andrew McGill, Christopher A. Kendziora, Robert Furstenberg, Samuel G. Lambrakos, U.S. Naval Research Lab. (United States)

An inverse analysis of experimentally measured absorption spectra for the custom sorbent polymer SiFA4H, nerve agent simulant DMMP and molecular structure SiFA4H-DMMP is presented. These molecular structures and their associated IR spectra provide general understanding of the process of nerve agent detection based on spectral analysis. The inverse analysis presented provides estimates of permittivity functions, which when combined with the Claussius-Mossotti relation, can predict molecular polarizabilities associated with the SiFA4H-SiFA4H and SiFA4H-DMMP interactions. Molecular polarizabilities deduced from measured absorption coefficients are modeled using molecular dynamics simulations.

10404-31, Session 8

NDIR gas sensing using high performance AlInSb mid-infrared LED as light source

Edson G. Camargo, Yuji Goda, Osamu Morohara, Hromi Fujita, Hirotaka Geka, Koichiro Ueno, Yoshihiko Shibata, Naohiro Kuze, Asahi Kasei Microdevices Corp. (Japan)

Global warming has become a pressing issue worldwide and high performance sensors for environmental gas monitoring have being required. Particularly, CO2 sensors have been used for optimal control of indoor air quality reducing around 30% the energy consumption in heating, ventilation and air conditioning systems. An important element of these gas sensors is low power consumption, which is possible to be achieved by short current pulse driving of the light source.

To allow pulsed driving, we developed a high performance mid-infrared LEDs using MBE grown AlInSb active/barrier layers. The structure was grown on a semi-insulating GaAs (001) substrate using a Riber MBE-49 system, having a 0.5 μm thick n+-InSb buffer layer which improved the crystal quality of the AlxIn1-xSb (0.039≤x≤0.076) active layer. The LED consists on several junctions connected in series and its design was optimized so that maximum efficiency could be achieved at a desirable voltage/current condition.

The developed LEDs showed the highest performance until reported (75% higher emission than commercial LEDs for the 4.2 μm wavelength) and together with already reported mid-infrared photovoltaic detectors [1] allowed the realization of high performance and low power consumption CO2 gas sensors.

Moreover, a new technique was developed for temperature and/or output drift compensation, by referencing the LED output with a detector on the same substrate, leading us to realize high precision and long term stability measurements.

The developed technology is believed to be promising not only for CO2 but also for other environmental gas sensing systems.

[1] E. G. Camargo; K. Ueno; Y. Kawakami; Y. Moriyasu; K. Nagase; M. Sato; H. Endo; K. Ishibashi; N. Kuze, Opt. Eng. 47(1) (2008)

10404-33, Session 8

Development of nanostructured antireflection coatings for infrared technologies and applications

Gopal G. Pethuraja, John W. Zeller, Roger E. Welser, Ashok K. Sood, Magnolia Optical Technologies, Inc. (United States); Pradeep Haldar, Harry Efstathiadis, SUNY Polytechnic Institute (United States); Eric DeCuir Jr., Priyalal Wijewarnasuriya, U.S. Army Research Lab. (United States); Nibir K. Dhar, U.S. Army Night Vision & Electronic Sensors Directorate (United States)

Infrared (IR) sensing technologies and systems operating from near-infrared (NIR) to long-wave infrared (LWIR) spectrum are being developed for a variety of defense and commercial system applications. Loss of a significant portion of the incident optical signal due to reflection limits the performance of IR sensing systems. One critical technology that will overcome this limitation and enhance the performance of IR sensing systems is the development of advanced antireflection (AR) coatings. Magnolia is actively working on the development and advancement of ultra-high performance AR coatings for a wide variety of defense and commercial applications. Ultrahigh performance nanostructured AR coatings have been demonstrated for ultraviolet (UV) to LWIR spectral bands on various substrates. The AR coatings enhance the transmission of light through optical components and devices by significantly minimizing reflection losses, a substantial improvement over conventional thin-film AR coating technologies.

Nanostructured AR coatings have been fabricated using a tunable self-assembly process on substrates transparent for a given spectrum of interest, ranging from UV to LWIR. The nanostructured multilayer structures have been designed, developed and optimized for various optoelectronic applications. The optical properties of AR-coated optical components and sensor substrates have been measured and fine-tuned to achieve a predicted high level of performance. In this paper, we review our latest work on high quality nanostructure-based AR coatings, including recent efforts for the development of the nanostructured AR coatings on IR-transparent substrates.

10404-34, Session 8

Long wavelength infrared (LWIR) acousto-optical (AOTF) and acousto-optic modulators (AOM) using Hg2Br2 crystals *(Invited Paper)*

Priyanthi Amarasinghe, Joo-Soo Kim, Feng Jin, Sudhir Trivedi, Brimrose Technology Corp. (United States); Syed Qadri, U.S. Naval Research Lab. (United States); Jolanta Soos, Mark Diestler, Brimrose Technology Corp. (United States); Neelam Gupta, U.S. Army Research Lab. (United States); Janet Jensen, James O. Jensen, U.S. Army Edgewood Chemical Biological Ctr. (United States)

High quality large single crystals of mercurous bromide were grown by physical vapor transport method (PVT). The crystalline quality and the orientation of the crystals were determined using high resolution x-ray diffraction (HRXRD) technique. The full width at half maximum (FWHM) of the rocking curve of mecurous iodide crystals was measured as 0.13 degrees for (004) reflection, which is the best that has been achieved so far. Due to their high figure of merit and wide transmission range (0.35 um – 30 um) mercurous bromide is considered as an excellent material for acousto-optic tunable filter (AOTF) and Acousto-optic modulators (AOM) operating in strategic long wavelength infrared (LWIR) region. The paper will discuss performance of the crystals as acousto-optic tunable filter (AOTF) and acousto-optic modulator (AOM). Application of the AOTF for the long wavelength infrared (LWIR) imaging will be discussed. The results indicate the grown mercurous halide crystals are excellent materials for above device fabrication. The diffraction efficiencies of the AOTF device was found to be 26% at 10.6 um wavelength which to the best of our knowledge is the highest ever, reported.

10404-35, Session 8

Overview of detector technologies and IRFPA's for various sensor applications *(Invited Paper)*

Siva Sivananthan, Univ. of Illinois at Chicago (United States) and EPIR Technologies Inc. (United States)

No Abstract Available

Thermal sensitivity of the fundamental natural frequency of a resonant MEMS IR detector pixel

Sedat Pala, Kivanc Azgin, Middle East Technical Univ. (Turkey)

This paper presents the effect of temperature on the natural frequency of (1,1) mode shape of a resonant MEMS IR detector pixel in the range of 295-340 K. For the first time in literature, closed form equation of the temperature effect on the frequency of mode (1,1) is presented for silicon as the structural material.

The resonating plate is supported at its geometric center, enabling more robust pixels with 98% fill factor and less complicated fabrication process. In this work, we focused on the thermal sensitivity of the frequency of the fundamental (1,1) mode shape of the pixel structure shown in Figure 1. Higher mode shapes and corresponding frequency equations can also be derived with an acceptable error compared to FE simulations and test results [1]

Mechanical structure of the pixel is composed of a plate and a post as shown in Figure 2. It is shown that mode shapes and corresponding frequencies can be found using Rayleigh-Ritz energy method including electrostatic softening effect [1]. Inserting the thermal coefficient of mechanical properties (e.g. thermal coefficient of expansion and the thermal coefficient of Young's modulus) into the frequency equation, thermal effects are modelled as well (Eqn. 1).

Fabrication flow is given in Figure 5 as they can be found in [2]. Figure 3 shows SEM images of the fabricated pixels. Temperature range of 295-340 K is tested and selected frequency sweeps are presented in Figure 6. Test results and the model behave in the same manner (Figure 4), with some expected discrepancy due to undamped mathematical model.

10405-1, Session 1

Use of artificial neural network and satellite data to predict Boro rice yield in Bangladesh

Kawsar A. Akhand, The City Univ. of New York (United States); Mohammad Nizamuddin, Leonid Roytman, The City College of New York (United States); Felix Kogan, National Oceanic and Atmospheric Administration (United States)

Rice is the main staple food that plays a crucial role in the agro-based economy of Bangladesh. Due to increasing population and decreasing agricultural land in every year, rice production plays a key role in national economy because this sector is in under pressure of increasing demand of food to maintain food security for its large population of Bangladesh. In addition, Bangladesh is faced with production constraints such as drought, flooding, salinity, lack of irrigation facilities and lack of modern technologies. To maintain self sufficiency in rice, Bangladesh will have to continue to expand rice production by increasing yield at a rate that is at least equal to the rate of population growth until the demand of rice has stabilized. The first and foremost responsibility of the country is to ensure an uninterrupted supply of food to all people at all times to ensure dependable food security. At present, rice yield prediction is an important area of study because its potential contribution to food security to ensure adequate and stable supply of safe and nutritious food at all times for an active and healthy life. This paper tries to develop a reliable rice yield prediction model by using Artificial Neural Network (ANN) and satellite data. Advanced Very High Resolution Radiometer (AVHRR)-based vegetation health (VH) indices (Vegetation Condition Index (VCI) and Temperature Condition Index (TCI)) are used as input variables and official statistics of Boro rice yield is used as target variables for ANN prediction model. The result obtained with ANN method shows a great promise and the error of prediction is less than 10%. Therefore, this prediction model can serve as an important tool to the planners, policy makers, economists, analysts, academics, educationists, researchers, and others stakeholders.

10405-2, Session 1

Using deep recurrent neural network for direct beam solar irradiance cloud screening

Maosi Chen, John M. Davis, Zhibin Sun, Colorado State Univ. (United States); Chaoshun Liu, East China Normal Univ. (China); Melina Maria Zempila, Wei Gao, Colorado State Univ. (United States)

Cloud screening is an essential procedure for in-situ calibration and atmospheric properties retrieval on Multi-Filter Rotating Shadowband Radiometer (MFRSR). Previous study has explored a cloud screening algorithm for direct-beam MFRSR raw voltage measurements based on the stability assumption on a long time period (typically a half day or a whole day). Although the algorithm was not too complex, to design such an algorithm and to implement it on codes was not a trivial task. It requires the detailed understanding of physical properties and the delicate strategy of data manipulation. Recent rapid developments on deep neural network and GPU have opened a window for modeling complicated End-to-End systems with a standardized strategy. In this study, a three-layer dynamic bidirectional Long Short-Term Memory was chosen for determining the cloudiness on each point based on the daily raw direct beam voltages and the corresponding airmasses inputs. This sequence to sequence network was trained and tested at two stations of the USDA UV-B Monitoring and Research Program. The size of the training set was around 6000 days per station, while the size of testing set was around 500 days per station. The final accuracy of the network was around 95-97% depending on the testing station.

10405-3, Session 1

Comparison of two satellite imaging platforms for monitoring quasi-circular vegetation patch in the Yellow River Delta, China

Qing-sheng Liu, Li Liang, Gaohuan Liu, Chong Huang, Institute of Geographic Sciences and Natural Resources Research (China)

Vegetation often exists as patch in arid and semi-arid region throughout the world. Vegetation patch can be effectively monitored by remote sensing images. However, not all satellite platforms are suitable to study quasi-circular vegetation patch. This study compares fine (GF-1, launched in Jiuquan Satellite Launch Center on April 26, 2013) and coarse (CBERS-04, launched in Taiyuan Satellite Launch Center on December 7, 2014) resolution platforms, specifically focusing on the quasi-circular vegetation patches in the Yellow River Delta (YRD), China. Vegetation patch features (area, shape and location) were extracted from GF-1 and CBERS-04 imagery using unsupervised classifier (K-Means), supervised classifier (Maximum Likelihood) and object-based approach in order to analyze vegetation patterns. These features were then compared using image overlay and differencing, and the Root Mean Squared Error (RMSE) was used to determine if the mapped vegetation patches were significantly different. It was found that CBERS-04 is a sufficient data source when studying patch patterns within a regional scale, but smaller vegetation patches identified from GF-1 data were not capable of being extracted in the data sourced from CBERS-04. This means that for studies concerned with the quasi-circular vegetation patch patterns in the YRD, CBERS-04 is sufficient. But in studies where the area, shape and dynamics of small patches are required, a fine resolution such as GF-1 is required. However, in the future, finer resolution platforms such as Worldview are needed in order to gain more detailed insight on the patch structures and components and to study the formation mechanism.

10405-41, Session 1

Retrieval of crop leaf area index from SPOT-5 data using a look-up-table approach based on PROSAIL

Xiaohua Zhu, Academy of Opto-Electronics, CAS (China)

Leaf Area Index (LAI) is a key structural characteristic of vegetation and plays a significant role in global change researches. Several methods and remotely sensed data have been evaluated for LAI estimation. The objective of this article is to study on retrieval and scale effect analysis of crop LAI based on PROSAIL model and SPOT-5 data, mainly focusing on: i) establishment and evaluation of a new LUT approach for crop LAI estimation in northwestern China; ii) scale effect analysis during LAI retrieval from different scale data; and iii) integration of scale information into LUT to improve accuracy of LAI estimation. The LAI inversion result of LUT method was validated by in-situ LAI measurements, indicating that the LUT generated based on PROSAIL model was suitable for crop LAI estimation, with a root mean square error (RMSE) of approximately 0.31 m2/m2 and determination coefficient (R2) of 0.65. The spatial scale effect of crop LAI was analyzed based on Taylor expansion theory, indicating that when the SPOT data aggregated by 200 by 200 pixel, the relative error is significant with 13.7%. Finally, a new LUT method integrated with scale information was proposed in this article, improving the inversion accuracy with RMSE of 0.20 m2/m2 and R2 of 0.83.

10405-4, Session 2

Using feature information in neural networks for ultraviolet retrieval in the USA

Zhibin Sun, Colorado State Univ. (United States); Ni-Bin Chang, Univ. of Central Florida (United States); Wei Gao, Maosi Chen, Melina Maria Zempila, Colorado State Univ. (United States)

In neural networks, the training/predicting accuracy and algorithm efficiency can be improved significantly via accurate input feature extraction and weight determination. In this study, some spatial features of several important factors in retrieving surface ultraviolet (UV) are extracted, and the input weights are determined via the local information of those factors. A single hidden layer feedforward network (SLFN) is used to retrieve the surface UV of 2013 in the United States, using the extracted features and input weights. The results are analyzed by comparing with the retrieval results using extreme learning machine (ELM).

10405-5, Session 2

Introducing a new total ozone column retrieval algorithm: Evaluation at Mauna Loa station

Melina Maria Zempila, USDA UV-B Monitoring and Research Program (United States); Konstantinos Fragkos, National Institute of R&D for Optoelectronics (Romania); John Davis, Zhibin Sun, Maosi Chen, Wei Gao, USDA UV-B Monitoring and Research Program (United States)

The USDA UV-B Monitoring and Research Program (UVMRP) comprises of 36 climatological sites along with 4 long-duration research sites, in 27 states, one Canadian province, and the south island of New Zealand. Each station is equipped with an Ultraviolet multi-filter rotating shadowband radiometer (UV-MFRSR) which can provide response weighted irradiances at 7 wavelengths (300, 305.5, 311.4, 317.6, 325.4, and 368 nm) with a nominal full width at half maximun of 2 nm. These UV irradiance data from the long term monitoring station at Mauna Loa, Hawaii, are used as inputs to a retrieval algorithm in order to derive high time frequency total ozone columns. The sensitivity of the algorithm to the different wavelength inputs is tested and the uncertainty of the retrievals is assessed based on error propagation methods. For the validation of the method, collocated hourly ozone data from the Network for the Detection of Atmospheric Composition Change (NDACC) for the period 2010-2016 are used.

Acknowledgement: MMZ. would like to thank Dr. Russell C. Schnell as the MAUNA LOA station representative.

10405-6, Session 2

An integrated hyperspectral and SAR small satellite constellation for environment monitoring

Jinnian Wang, CHINARS SHENZHEN Institute for Satellite Applications Innovation (China)

A fully-integrated, Hyperspectral optical and SAR (Synthetic Aperture Radar) constellation of small earth observation satellites will be deployed over multiple launches from last December to next five years. The Constellation is expected to comprise a minimum of 16 satellites (8 SAR and 8 optical) flying in two orbital planes, with each plane consisting of four satellite pairs, equally-spaced around the orbit plane. Each pair of satellites will consist of a hyperspectral/mutispectral optical satellite and a high-resolution SAR satellite (X-band) flying in tandem. The constellation is expected to offer a number of innovative capabilities for environment monitoring. As a pre-launch experiment, two hyperspectral earth observation minisatellites, Spark 01 and 02 were launched as secondary payloads together with Tansat in December 2016 on a CZ-2D rocket. The satellites feature a wide-range hyperspectral imager. The ground resolution is 50 m, covering spectral range from visible to near infrared (420 nm - 1000 nm) and a swath width of 100km. The imager has an average spectral resolution of 5 nm with 148 channels, and a single satellite could obtain hyperspectral imagery with 2.5 million km2 per day, for global coverage every 16 days. This paper describes the potential applications of constellation image in environment monitoring.

10405-7, Session 3

Deep and fast learning for feature extraction of merged or fused satellite remote sensing images to observe lake eutrophication *(Invited Paper)*

Ni-Bin Chang, Univ. of Central Florida (United States)

In this presentation, two advanced feature extraction methods with fast and deep learning algorithms will be discussed for environmental monitoring in all-weather conditions with convergent and divergent thinking. One is the newly developed novel Spectral Information Adaptation and Synthesis Scheme (SIASS) and the other is the newly invented SMart Information Reconstruction (SMIR) method to support the Integrated Data Fusion and Mining (IDFM) research. Whereas the former is organized to generate cross-mission consistent ocean color reflectance by merging observations from several different satellites to recover the cloudy pixels, the latter is designed to reconstruct cloud contaminated pixel values from the time-space-spectrum continuum with the aid of a machine learning tool. For the purpose of demonstration, Lake Nicaragua located at Central America is selected as a study site which is a very cloudy area year round. In this case study, merging observations from MODIS-Terra, MODIS-Aqua, and VIIRS over Lake Nicaragua will be presented for the 2012-2015 time period. Then the performance of SMIR will be performed after the merging operation by reconstructing the missing remote sensing reflectance values derived from the Moderate Resolution Imaging Spectroradiometer (MODIS) on board the Terra satellite over Lake Nicaragua. The SIASS algorithm is proven to have the capability not only in eliminating incompatibilities for those matchup bands but also in reconstructing spectral information for those mismatching bands among sensors. For the recovery of those missing pixel values after merging three satellite images, experimental results from SMIR show that the extreme learning machine may perform well with simulated memory effect due to linking the complex time-space-spectrum continuum between cloud-free and cloudy pixels. Final water quality assessment will be generated based on the integrative algorithm of the two with bio-optical models for eutrophication assessment in Lake Nicaragua.

10405-8, Session 3

Quality assurance of the UV irradiances of the UV-B monitoring and research program: the Mauna Loa test case

Melina Maria Zempila, John M. Davis, George T. Janson, Elizabeth Olson, Maosi Chen, Bill Durham, Scott Simpson, Jonathan Straube, Zhibin Sun, Wei Gao, USDA UV-B Monitoring and Research Program (United States)

The USDA UV-B Monitoring and Research Program (UVMRP) is an ongoing effort aiming to achieve a better understanding of climate change driven variations in the Ultra Violet (UV) solar radiation, and their impacts on agriculture. By providing high quality radiometric measurements of UV solar radiation, UVMRP is focusing on advancing science for agricultural, forest, and range systems in order to mitigate climate impacts. Within these foci, the goal of the present study is to validate the accuracy of the erythemal measurements and response-weighted irradiances at 6 UV channels from a

YES UVB-1 radiometer and an ultraviolet multi-filter rotating shadowband radiometer (UV-MFRSR) respectively at the calibration site of Mauna Loa. Uncertainties during the calibration procedures are discussed, while collocated ground-based measurements from a Brewer spectrophotometer along with model simulations are used as a baseline for the validation of the data. Besides this quantitative research, the limitations and merits of the existing UVMRP methods are considered and further improvements are analyzed.

Acknowledgements: M.M.Z would like to thank Drs. R. McKenzie and V. Fioletov for providing the Brewer data used in this study.

10405-9, Session 3

Spatio-temporal anomaly detection for environmental impact assessment: A case of an abandoned coal mine site in Turkey

Hilal Soydan, Alper Koz, Hafize Sebnem Duzgun, Middle East Technical Univ. (Turkey)

The main purpose of this research is to determine the anomalies regarding with the coal mining operations in an abandoned coal mine site in central Anatolia by multi-temporal image analysis of Landsat 4-5 surface reflectance data. A well-known hyperspectral anomaly detection algorithm, Reed-Xioli (RX), which calculates Mahalanobis distance metrics to calculate the likelihood ratios by normalizing the difference between the test pixel and the background to allocate anomaly pixels, was implemented across the time series.The high score anomaly pixels in the output image sets are selected using multi-thresholding technique based on Otsu method, as the technique presents extra information of segmentation metric for performance evaluation.An additional false alarm removal was applied with the baseline anomaly signal calculated with pre-mining imagery anomaly pixels. The high score abnormalities in the region with this additional removal of false alarms are appointed as the deviations due to mining operations. According to the initial results, the anomaly scores are allocated in the open-pit, coal storage, excavations & area of disturbances of the land, dumpsites starting with the mining operations throughout the multi-temporal images, which reveal the differentiations on earth surface across the years. The preliminary studies point out especially the profound land use – land cover change in the field in time series, exposing some critical regions that need an immediate rehabilitation action. Presenting such an invaluable potential to observe the anomalies in multi-temporal fashion, Landsat reflectance images seem to be bringing out the abnormalities with a great contrast despite its spatial resolution limitations.

10405-10, Session 3

Remote hybrid electro-optic biosensor with fluorescent fiber optic for cephalosporins determination in water

Ramona M. Galatus, Technical Univ. of Cluj Napoca (Romania); Cecilia Cristea, Bogdan Feier, Iuliu Hatieganu Univ. of Medicine and Pharmacy (Romania); Nunzio Cennamo, Luigi Zeni, Seconda Univ. degli Studi di Napoli (Italy)

Antibiotics are extensively used not only in human, for prophylactic and treatment purposes, but also in animals and in agriculture and it leads gradually to environmental contamination and drug resistance. The present research propose a hybrid electro-optical platform capable of sensitive detection for one major class of most used drugs in water (drinking water and waste water), ?-lactams antibiotics (cephalosporines). The analytical technique is based on an integrated solution with Raspberry Pi with remote analysis capabilities of the results. The platform integrates the results from the D-shape surface plasmon resonance plastic optical fiber (SPR-POF) [R. Galatus et.al, SAS-2016], with the electrochemical sensors, for flow injection analysis of cephalosporines in water [Bogdan Feier, Cecilia Cristea, et.al, Analytica Chimica Acta-2017, under review]. This new approach use multiplexed fluorescent plastic optical fibers, as light source for SPR, instead of the halogen lamp, for broadband wavelength biosensing analysis. The solution assure low-power consumption and low-heating capabilities of the sensing platform. For direct electrochemical detection, due to the extreme oxidation potential of antibiotics only boron-doped-diamond (BDD) could be used as working electrode, that is a quite expensive method. For label-free fast low-cost SPR-POF method, the effective refractive-index variations of the sample (water) are determined by the resonance wavelength and related to the binding of non–labeled molecules on the sensing area. The bioreagents for the detection of ?-lactams are CCK-BSA (cholecystokinin receptor ligands bind to bovine serum albumin); RSA (rat serum albumin), bioreceptor; anti-RSA, polyclonal antibody from rabbit. SPR sensitivity is about 1,200(nm/RIU).

10405-11, Session 3

Effects of microphysics parameterization on simulations of summer heavy precipitation in the Yangtze-Huaihe Region, China

Yu Kan, East China Normal Univ. (China); Bo Chen, Air Traffic Management Bureau of East China (China); Tao Shen, Shanghai Shixi High School (China); Chaoshun Liu, Fengxue Qiao, East China Normal Univ. (China)

The Yangtze-Huaihe region (YHR) is an extremely important area in China, densely populated and economically developed, but during the summer, heavy rainfall events frequently occur over this region causing devastating damages and considerable socio-economic consequences. However, it is still a challenge for current weather/climate models to accurately predict the summer precipitation over this region due to model uncertainty related to key precipitation processes such as microphysics parameterization. This study first examines all the weather patterns causing regional persistent heavy precipitation in summer over the YHR during 2008-2012, and classifies them into three types of rain: the type I associated with stationary front, the type II directly associated with typhoon or with its spiral rain band, and the type III associated with strong convection along the edge of Subtropical High. Sixteen groups of comparative experiments are conducted for three representative cases from the above different types, using the WRF v3.5.1 model with eight different microphysics schemes (Kessler, Purdue Lin, WSM3, WSM5, Eta Ferrier, WSM6, Goddard and Thompson) and two cumulus parameterization schemes (KF and BMJ). The study focuses on examining the effects of microphysics parameterization on the simulation of different type of heavy precipitation over the YHR with respect to different cumulus schemes. A local short-time rainstorm event in Shanghai is used to compare with the regional persistent heavy rainfall events. Major results are: (1) Two cumulus parameterization schemes have systematic but different impacts on the simulations of different type of rain. The BMJ cumulus scheme shows better capability than the KF scheme in simulating the spatial pattern of precipitation for the type I and III, while the KF scheme is better than the BMJ scheme for the type II. (2) The microphysics parameterization has large but different impacts on the location and intensity of regional heavy precipitation centers. For type I, Ferrier-BMJ scheme most realistically simulates the pattern of rainbands with the rain center location and intensity. For type II, Thompson-KF scheme not only accurately simulates the precipitation areas, center position and intensity, but also has higher predictive skills than others for daily precipitation. For type III, Lin-BMJ scheme shows clear advantages over others in simulating the rainbands and heavy rain centers for regional persistent heavy rainfall events, while WSM5-BMJ scheme shows better capability than others in simulating the heavy rain centers for the short-time rainstorm in Shanghai with the similar weather pattern of type III.

10405-12, Session 3

Assessment and verification of rainfall threshold through antecedent soil-moisture model in Lambagarh and Pipalkoti landslides (Chamoli District) of Garhwal Himalaya, in Gis & remote sensing environment

Mahesh K. Tripathi, Himanshu Govil, National Institute of Technology, Raipur (India); Prashant K. Chamapatiray, Indian Institute of Remote Sensing (India); Monkia Besoya, National Institute of Technology, Raipur (India)

Landslide is among the major hydro-geological hazards that affect the large part of India; especially the Himalayas. Landslide inventory is a major way of assessment of study of landslide hazard. Geospatial techniques and satellites images providing many advantageous information about landslides along with some other factors like as rainfall, soil-moisture, geological, geographical, climatological and anthropogenic which initiate the order of increment of occurrences of landslides. In this study landslide inventory of Alaknanda catchment was prepared with the help of LISS III, LISS IV satellite images for subsequent years (2007, 2008, 2009, and 2010). A soil-moisture index table was prepared through TRMM rainfall data (25x25 km.) to assess and verify, rainfall threshold for initiation of landslides occurrences. Assessment of rainfall threshold (3-days prior and 15-days cumulative) with soil-moisture shows a direct relationship among landslides occurrence, regolith thickness, drained porosity, porosity, evapotranspiration, rainfall, of the study area. The regolith thickness, drained porosity, total porosity, evapotranspiration, effective rainfall, directly interrelated to initiation of landslide occurrences, as well as intensity of rainfall and soil-moisture is also main important variable of intensity of occurrences of landslides in the study area. A process based (soil- moisture) approach verify the rainfall threshold in initiation of landslide.

10405-13, Session 3

Watershed management using geospatial data: A case study of Beas upper catchment of India

Monkia Besoya, Himanshu Govil, National Institute of Technology, Raipur (India); Sagar Salunkhe, Regional Remote Sensing Service Ctr. (India) and National Remote Sensing Ctr., Government of India (India); Mahesh K. Tripathi, National Institute of Technology, Raipur (India)

Watershed play a critical role in the natural functioning of the Earth, thus consider as one of the primary planning units in the field of natural resource Management.

In this study watershed delineation and morphometric analysis of Beas Upper Catchment in India was carried out using Geospatial Techniques. ASTER DEM & Cartosat-1 version 3 DEM (30m) used for watershed delineation and morphometric analysis and satellite image of IRS LISS-IV (Resourcesat-2) was used for study area map preparation, threshold analysis and morphometric analysis. Different morphometric parameters i.e. stream, basin, relief parameters (highest & lowest point, drainage density,etc.) including slope and aspect analyses were carried out through measurement of linear, aerial and relief aspects of the catchment.

Total 10 watersheds were delineated using ASTER & Cartosat DEM using Arc GIS hydrological tool. Using ASTER DEM areas were found to be ranging from 324.51 to 850.34 km2 and using Cartosat DEM 322.27 to 850.03 km2. The basin area is found to be 5800 m and 5412 m delineated and the catchment is of 7th order and 8th order in drainage map prepared using ASTER and Cartosat DEM respectively. By calculating Drainage density, Bifurcation ratio, Ruggedness number etc. indicates the area is moderate drainage, extremely rugged with high relief and is more prone to soil erosion.

Hence, from the research, it can be concluded Digital Elevation Model and Satellite data coupled with GIS techniques have proven as a robusting tool in watershed management.

10405-14, Session 3

The relationship of Aleutian low and sea surface heat flux

Junqiang Gong, East China Normal Univ. (China)

Using the observed data from NCEP, this paper evaluates the climate features of Aleutian low, heat flux in winter. SVD method has been used to analyse the relations between Aleutian low and heat flux in north Pacific. The results show that the intensity of Aleutian low and heat flux in central north pacific have positive correlation, while having negative correlation with heat flux in western coast of north America.

10405-15, Session PWed

Remote sensing estimates of reclamation-induced carbon loss in coastal wetland of Yangtze River estuary

Jinquan Ai, East China Normal Univ. (China); Wei Gao, Colorado State Univ. (United States); Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China); Runhe Shi, Chao Zhang, East China Normal Univ. (China); Fuxiang Xu, Yantai Institute of Coastal Zone Research (China); Debin Song, Yantai Institute of Coastal Zone Researches, (China)

Coastal wetland reclamation directly changes the structure and function of wetland ecosystem, causing potential ecological consequences. In this study, we estimated the total emissions and carbon sequestration of the coastal wetlands in the Yangtze River before reclamation and after reclamation to other land cover types using GF-1 WFV imagery. Results showed that the converted coastal wetland area occupied up to 55.5% between 2013 and 2016. Carbon estimation indicated that the coastal wetland before reclamation had greater contribution to the global warming mitigation than the wetland reclamation to other land cover types. This study further demonstrated that the coastal wetland loss in the Yangtze River would lead to 3.2 ?104 CO2 eq/yr of net sequestration loss and may cause the further climate warming.

10405-16, Session PWed

Comparison of snow depth retrieval algorithm in Northeastern China based on AMSR2 and FY3B-MWRI data

Xintong Fan, Lingjia Gu, Ruizhi Ren, Tingting Zhou, Jilin Univ. (China)

The snow accumulation has a very important influence on the natural environment and human activities. Meanwhile, the high-precision passive microwave snow depth retrieval has been a hotspot currently. Northeastern China is a typical snow study area including a large area of farmland, forest and other surface types. Especially, there is relatively stable snow accumulation in January. With the Global Change Observation Mission 1st Water (GCOM-W1) launched on May 18, 2012?Japan Standard Time?, the 2-year (2013-2014) observations of brightness temperature by the Advanced Microwave Scanning Radiometer 2 (AMSR2) on GCOM-W1 and those by the FengYun3B Microwave Radiation Imager (FY3B-MWRI) in the same period are selected in the research. Snow depth retrieval algorithms, considering different land cover types, are used in this paper. Therefore, the results of snow depth retrieval using AMSR2 standard algorithm and Jiang's FY operational algorithm are compared in the research. To further validate the accuracy of the two algorithms, the retrieval results are compared with

the snow depth data observed at the national meteorological stations in Northeastern China. In order to analyze the difference between the retrieval results and the standard snow products, the retrieval snow depth (SD) using AMSR2 and FY3B-MWRI data are compared with AMSR2 and FY standard snow depth products, respectively.

10405-17, Session PWed

Research on snow cover monitoring of northeast China using Fengyun geostationary satellite

Tong Wu, Jilin Univ. (China); Lingjia Gu, Ruizhi Ren, TIngting Zhou, Jilin Univ. (China)

Snow cover information has great significance for monitoring and preventing snowstorms. With the development of satellite technology, geostationary satellites are playing more important roles in snow monitoring. Currently, cloud interference is a serious problem for obtaining accurate snow cover information. Therefore, the cloud pixels located in the MODIS snow products are usually replaced by cloud-free pixels around the day, which ignores snow cover dynamics. FengYun-2(FY-2) is the first generation of geostationary satellite in our country which complements the polar orbit satellite. The snow cover monitoring of Northeast China using FY-2G data in January and February 2016 is introduced in this paper. First of all, geometric and radiometric corrections are carried out for visible and infrared channels. Secondly, snow cover information is extracted according to its characteristics in different channels. Multi-threshold judgment methods for the different land types and similarity separation techniques are combined to discriminate snow and cloud. Furthermore, multi-temporal data is used to eliminate cloud effect. Finally, the experimental results are compared with the MOD10A1 (MODIS daily snow cover) product. The MODIS product can provide higher resolution of the snow cover information in cloudless conditions. Multi-temporal FY-2G data can get more accurate snow cover information in cloudy conditions, which is beneficial for monitoring snowstorms and climate changes.

10405-18, Session PWed

Analysis of relationships between NDVI and land surface temperature in coastal area

Jicai Ning, Yantai Institute of Coastal Zone Research (China)

Relationships between NDVI and Land Surface Temperature (LST) variations were analyzed using Landsat imagery in the Yellow River Delta (YRD). The area has increased substantially due to the deposited sediment carried by the Yellow River from upper reach during nearly 30 years. Qin's mono-window algorithm was used to retrieve the regional LST. There was a regular connection between LST, NDVI, ANDVI, SAVI and other relevant vegetation indices, and there was a positive correlation, as well as a negative correlation, between different threshold ranges.

10405-19, Session PWed

Study of waterline extraction based on object-oriented method

Yuanyuan Zhang, Yantai Institute of Coastal Zone Research (China)

The coastal zone is a dynamic land reserve resource. Taking Shandong Bohai rim as the study area, the paper combined with TM and HJ1A/1B satellite images under the help of time series built by MODIS images, using Ecognition software platform to realize the waterline extraction based on object-oriented method. The result shows that this method can make full use of the existing image resources to realize the batch processing of the waterline extraction, and the accuracy is well which means that the method is applicable and can be popularized.

10405-20, Session PWed

Temporal and spatial characteristics of macroalgae blooms in the Yellow Sea based on MODIS data

Fuxiang Xu, Yantai Institute of Coastal Zone Research (China); Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China) and East China Normal Univ. (China); Jicai Ning, Xiangyu Zheng, Yantai Institute of Coastal Zone Research (China); Jinquan Ai, Yantai Institute of Coastal Zone Research (China) and East China Normal Univ. (China); Debin Song, Yantai Institute of Coastal Zone Research (China)

We conducted a comprehensive utilization of aerial images, in situ data, and MODIS dynamic monitoring of the green tide in 2016, to reveal the source and spatial-temporal characteristics of green tide in the Yellow Sea. The dynamic monitoring of green tide by MODIS indicates that the Yellow Sea green tide first moved northwards, then moved in the northeast direction along the coastline of Shandong Peninsula, and finally became stranded in the sea areas near Qingdao and Weihai in 2016. Our goal is to provide a reference for monitoring, prevention, control and research of green tide.

10405-21, Session PWed

Multi-resource data-based research on remote sensing monitoring over the green tide in the Yellow Sea

Zhiqiang Gao, Yantai Institute of Coastal Zone Research (China)

This paper conducted dynamic monitoring over the green tide (large green alga—Ulva prolifera) occurred in the Yellow Sea in 2014 to 2016 by the use of multi-source remote sensing data, including GF-1 WFV, HJ-1A/1B CCD, CBERS-04 WFI, Landsat-7 ETM+ and Landsta-8 OLI, and by the combination of VB-FAH (index of Virtual-Baseline Floating macroAlgae Height) with manual assisted interpretation based on remote sensing and geographic information system technologies.

10405-22, Session PWed

Correlation analysis between green tide evolution and secchi disk depth variation in south Yellow Sea

Xuerong Li, Qianguo Xing, Yantai Institute of Coastal Zone Research (China)

Secchi disk depth (SDD), which can directly reflect the clarity and turbidity of coastal seawater, is a measure of seawater visibility and an important parameter to describe the optical properties of water. Green tides is the marine algae in the formation of explosive growth and aggregation of algal blooms phenomenon. 2007-2016, the south Yellow Sea for 10 years outbreak of Enteromorpha algae species as the green tide disaster. The outbreak of enteromorpha cannibalis seriously damaged the ecological balance of the southern Yellow Sea and brought serious impact to the economic and social development of the southern coast of Shandong Peninsula. Based on the MODIS remote sensing reflectance data and the three-band model, the SDD was analyzed and the green-tide drift trajectory was formed to form the SDD change images based on year, month and week. In the spring, the

Enteromorpha proliferates first in the form of small-scale floating green algae in the north of Jiangsu, and gradually drifts northwards and under the effect of wind and sea current, and finally accumulates in the coast of Shandong Peninsula in August. In 2008, large-scale Macroalgal blooms broke out in Qingdao, focusing on the changes of SDD from the origin to the end of the green-tide outbreak. And the change rule of SDD in the process of green tide evolution is revealed.

10405-23, Session PWed

Spectrum analysis of plants growing in the oil-fields

Ekaterina A. Selezneva, Elena V. Timchenko, Pavel E. Timchenko, Nikolay V. Tregub, Yana Fedorova, Anna S. Tyumchenkova, Samara Univ. (Russian Federation)

Currently, for the oil industry of many countries more and more raises the matter of replenishment of hydrocarbon resource base and discovery of new energy feedstock sources. Exploration activity of hydrocarbon accumulation is a difficult task and, above all, expensive. Therefore, the development of quick and cheap way to detect oil and gas fields is priority. For operational evaluation of oil-and-gas content with minimal cost and time use biogeochemical technique. Biogeochemical prospecting of mineral deposits based on the research study of the chemical composition of biological objects, usually plants.

The studies were carried out in two phases. First of all were carried out laboratory experiments based on the theory that oil affects on the plants Raman spectra. Then, field studies have been carried out.

Raman spectroscopy method was used as a method of research, realized with the help of experimental stand described in the work. Processing of Raman spectra were carried out in software environment Mathematica'8. Method of error did not exceed 5.84%. The highest statistical dispersion of the optical parameters of plant facilities within a single zone of investigation is 7.93%.

Green pea (Pisum sativum) and soft wheat (Tríticum aestívum) was chosen as the object of laboratory tests. The samples were divided into five groups; each group was grown in 3 pots. The first and second group of samples was a control; plants were grown in soil (without adding hydrocarbons). These groups of samples were located near the samples of the third and fourth groups. Into the pots with plants of third and fourth groups was added pure oil at a concentration of 1 g / kg. This concentration of oil is equal to the MRL for pure oil in the soil. The fifth group of plants had been growing in 6 pots in separate rooms in order to eliminate the influence of oil vapor on the spectral characteristics of plants. Dandelion ordinary (Taráxacum officinále) was chosen as the object of field research. Plants of this type are good bioindicators of environmental conditions.

The features of Raman spectra of plants growing in the field of oil deposits were obtained as a result of research studies. Major changes were documented at wave numbers 605 cm-1, 1440 cm-1 and 1547 cm-1 corresponding to the stretching vibrations of bromide ions, boron and chlorophyll "a" in plant leaves.

On the basis reasoning from two-dimension analysis of optical coefficients (H1, H2 and H3) were input criteria of plants separation growing in the oil-field area and outside of the oil-field area.

The extraction of coastal windbreak forest information based on UAV remote sensing images

WeiTao Shang, Zhiqiang Gao, XiaoPeng Jiang, Yantai Institute of Coastal Zone Research (China)

Unmanned aerial vehicle(UAV) have been increasingly used for natural resource applications in recent years as a result of their greater availability, the miniaturization of sensors, and the ability to deploy UAV relatively quickly and repeatedly at low altitudes. UAV remote sensing offer rich contextual information, including spatial, spectral and contextual information. In order to extract the information from these UAV remote sensing images, we need to utilize the spatial and contextual information of an object and its surroundings. If pixel based approaches are applied to extract information from such remotely sensed data, only spectral information is used. Thereby, in Pixel based approaches, information extraction is based exclusively on the gray level thresholding methods. To extract the certain features only from UAV remote sensing images, this situation becomes worse. To overcome this situation an object-oriented approach is implemented. By object-oriented thought, the coastal windbreak forest information are extracted by the use of UAV remote sensing images. Firstly, the images are segmented. And then the spectral information and object geometry information of images objects are comprehensively applied to build the coastal windbreak forest extraction knowledge base. Thirdly, the results of coastal windbreak forest extraction are improved and completed. The results show that better accuracy of coastal windbreak forest extraction can be obtained by the proposed method, in contrast to the pixel-oriented method. In this study, the overall accuracy of classified image is 0.94 and Kappa accuracy is 0.92. The classification overall accuracy is based on TTA mask (training and test area mask) and it is 0.98 and Kappa accuracy is 0.96.

10405-25, Session PWed

A GIS-based health assessment of marine ecosystem in the Bohai Sea

Debin Song, Zhiqiang Gao, Fuxiang Xu, Xiangyu Zheng, Yantai Institute of Coastal Zone Research (China); Jinquan Ai, East China Normal Univ. (China)

Based on the index system of 22 indicators including water environment, sedimentary environment, ecosystem obtained from the investigation data of several voyage in the Bohai Sea during 2014 to 2016, the ecosystem health in the Bohai Sea was assessed by using Analytic Hierarchy Process (AHP) method and GIS technology. The results show the CEI value of marine ecosystem health is 0.643 and its health level is middle, which indicate the ecosystem health around the Bohai Sea are in an sub-health state. The maritime area with poor ecosystem performance were mainly located in Laizhou Bay, Bohai Bay and its adjacent area of the Yellow River Delta. The ecosystem health of offshore waters and high-seas area nearby Tangshan, Qinhuangdao and Huludao generally in an intermediate level. The central study area along with Bohai Straits displayed a relatively better health state. Be familiar with the assessment result, this paper carried out analysis on the health stress factors in Laizhou Bay and Bohai Bay, and obtained the following result: land-based input and reclamation. Based on these stress factors, countermeasures is studied to provide decision support in the management of the Bohai Sea.

10405-26, Session PWed

Monitoring of coastal zone pollution using unmanned aerial vehicle remote sensing system

XiaoPeng Jiang, Zhiqiang Gao, WeiTao Shang, Yantai Institute of Coastal Zone Research (China)

As an important complement to satellite observation, the technique of Unmanned Aerial Vehicle (UAV) shows great advantages because of its high spatiotemporal resolutions, low cost and risk. With the development of technology related to UAV, its research was increasingly enhanced and has been applied to many fields such as environmental monitoring. Taking a coastal zone of Yantai city as study area, this paper utilized the UAV system to capture aerial images and monitor the pollutant status of the study area, then analyzed the effects to coastal environment. The results showed that there were some different types of pollution in the study area, including solid waste (industrial refuse, house refuse), waste water (industrial and living sewage), which had a bad effect on the air, sea and

beach environment. This research on the application of UAV will provide the good base for coastal environment protection.

The trend of the Tropospheric NO2 over the Yangtze River delta and the impact of the rapid urbanization on it

Ming-Liang Ma, East China Normal Univ. (China); Yue Song, Shanghai Shixi High School (China); Qiyang Liu, Runhe Shi, Wei Gao, East China Normal Univ. (China)

Over the past few decades, China has experienced a rapid increase in urbanization, especially in the Yangtze River delta. The urban built-up areas (population) in this region increase a lot from 1995 to 2015. In the same time, the dramatic economic development also has led to tremendous increases in energy consumption and put millions of cars on the roads. In this paper, we use satellite retrieval data to quantify the trend of the Tropospheric NO2 over the Yangtze River delta and the effects of rapid urbanization on the yearly and seasonal changes in tropospheric nitrogen dioxide (NO2) over this area.

Remote sensing of atmospheric aerosols by MFRSR

Xiaoli Wei, Wei Gao, Runhe Shi, East China Normal Univ. (China)

Multi-filter rotating shadow-band radiaometer (MFRSR)is a ground-based instrument and it is used to measure irradiance and aerosol. It use automated rotating shadow-band technique to alternatively measure total horizontal and diffuse horizontal irradiance at seven wavelengths simultaneously, and then deduce direct normal irradiance. This paper uses two ground-based stations' data which avoid the influence of cloud. It is necessary to use the satellite data and AERONET data to check its accuracy.

10405-29, Session PWed

A study of long-term ground settlement behavior of muddy coastal lands in Shanghai with time-series InSAR

Hongbin Dong, Shanghai Shixi High School (China); Qing Zhao, East China Normal Univ. (China) and ECNU-CSU Joint Research Institute for New Energy and the Environment (China)

As the global warming problem is becoming seriously in recent decades, the global sea level is continuously rising. This will cause damages to the coastal deltas with the characteristics of low-lying land, dense population, and developed economy. Continuously reclamation costal intertidal and wetland areas is making Shanghai, the mega city of Yangtze River Delta, more vulnerable to sea level rise. In the paper, we investigate the ground settlement temporal evolution of patterns and processes on a stretch of muddy coast located between the Yangtze River Estuary and Hangzou Bay with differential synthetic aperture radar interferometry (DInSAR) analysis. By exploiting a set of 31 SAR images acquired by the ENVISAT/ASAR sensor from February 2007 to May 2010 with persistent scatters and small baseline approaches, coherent point targets with ground settlement velocity and time series are identified and densely distributed in the coastal region. The ground settlement time series and velocity are analyzed with multiple regression analysis and regression equation by SPSS to obtain a time-dependent settlement model. With the DInSAR constrained ground settlement model, we predict the ground settlement trend and the expected cumulative settlement in 2015 and 2020. Ground settlements retrieved with the high resolution SAR sensor, X-band COSMO-SkyMed, are used for validation purpose. With the ground settlement predictions and digital elevation model (DEM), we analyze the combined risk of ground settlement and sea level rise on the coastal areas of Shanghai. The potential flooded areas are mapped under different scenarios.

Effects of climate change on peanut's yield in China

Hanqing Xu, Shanghai Institute of Technology (China) and Shanghai Climate Ctr., Shanghai Meteorological Bureau (China); Zhan Tian, Shanghai Institute of Technology (China) and Shanghai Climate Ctr., Shanghai Meteorological Bureau (China); Dongli Fan, Shanghai Institute of Technology (China); Runhe Shi, East China Normal Univ. (China)

Peanut production is one of the main sources of edible vegetable oil and feed protein in China. In recent years the demand for peanut products has been increasing much faster than its domestic production, which has resulted in massive imports and reduced self-reliance. Peanut cultivation faces a wide range of production conditions in china and is rather sensitive to climate change. It is critical to evaluate the climate change impact on peanut and production and its impact to the oil industry and security in China. In this research, we calibrate DSSAT based on available research data covering 31 years (1981-2011) of site-specific observations of peanut growth and development. We simulate the peanut production under climate projections from 5 General Circulation Models (GCMs) with 4 representative concentration paths (RCPs) in 2011-2040 (2020s), 2041-2070 (2050s) and 2071-2010 (2080s). Then we develop a probabilistic estimation to present an analysis that combines outputs from a wide range of General Circulation Models (GCMs) with observational data to produce more detailed projections of local climate suitable for assessing the impact on peanut yield. This assessment will help to evaluate the climate change impact on peanut and production and its in the food security of China.

Residual settlements detection of ocean reclaimed lands with multi-platform SAR time series and SBAS technique: A case study of Shanghai Pudong International Airport

Lei Yu, East China Normal Univ. (China) and ECNU-CSU Joint Research Institute for New Energy and the Environment (China); Tianliang Yang, Ministry of Land and Resources (China) and Shanghai Institute of Geological Survey (China); Hongbin Dong, Shanghai Shixi High School (China); Qing Zhao, East China Normal Univ. (China) and ECNU-CSU Joint Research Institute for New Energy and the Environment (China); Antonio Pepe, Istituto per il Rilevamento Elettromagnetico dell'Ambiente (Italy)

Shanghai Pudong International airport(PVG) is one of three major international airports in china. The airport is located at the Yangtze estuary which is a sensitive belt of sea and land interaction region. The majority of the buildings and facilities of Pudong International airport are built on ocean reclaimed lands and silt tidal flat. Residual ground settlement could probably occur after the completion of the airport construction. The current status of the ground settlement at PVG and whether it is within a safe range are necessary to be investigated. In order to continuously monitor the ground settlement of the airport, we employed with high resolution SAR satellite TerraSAR-X(TSX) and the new generation SAR satellite Sentinel-1, which was launched by European Space Agency(ESA) in April 2014. Three

SAR time series, acquired by C-band TerraSAR-X(TSX) and TanDEM-X (TDX) sensor from December 2009 to December 2010 and from April 2013 to July 2015, and C-band Sentienl-1A(S1A) from February 2015 to December 2016, were used for obtaining the ground deformation of PVG with SBAS/DInSAR technique. The maximum ground settlement rate of the three SBAS results are as high as -48, -42, and -35 mm/y respectively. Ground settlement maps of the Pudong International Airport are generated with the multiplatform SBAS results. It shows continuous ground settlement occurred in this region. The results are consistent with field surveying records and implying that attention should be paid to impacts of ocean processes on the stability of newly reclaimed lands in recent years.

The estimation model of chlorophyll content based on spectral index of Spartina alterniflora leaf

Jiapeng Wang, Runhe Shi, Chao Zhang, Pudong Liu, Yuyan Zeng, East China Normal Univ. (China)

The content of chlorophyll is an indicator of photosynthesis ability ?growth and development for vegetation. It is one of the important indexes to monitor the health status of vegetation growth. Spartina alterniflora is one of the most important invasive species in the coastal wetland in China, its chlorophyll content information is an important basic data for the research of wetland ecosystem. Taking Chongming Dongtan wetland, the Yangtze Estuary as the study area, we measured the leaf spectral reflectance with Field SpecHandHeld spectrometer and the content of chlorophyll with spectrophotometer indoor. In the base of these data sources, the relationship model(linear, logarithmic, exponential, quadratic, cubic, power model) is established by using correlation analysis and univariate fitting analysis, including the model of chlorophyll content and spectral index as well as trilateral parameters, then Cross Validation was used to test the accuracy of the estimation model.

10405-33, Session PWed

Calculation of mean solar exo-atmospheric irradiances of GF-4 data

Chunying Guo, Runhe Shi, East China Normal Univ. (China)

Mean Solar Exo-atmospheric Irradiances (ESUN) is an important parameter to calculate the appearance reflectance according the DN value of satellite receiving.GF-4 were launched in 2015.However,the ESUN of this satellite has not been released publicly. To determine which solar spectrum curves is good for GF satellite, this paper calculated the ESUN of GF-1,using 7 solar spectrum curves and spectral response curve of GF-1.And we compared and verified the result with official results. At last we calculate the ESUN of GF-4 with this solar spectrum curve.

10405-34, Session PWed

Vegetation dynamics and their response to climatic variability in Yangtze River watershed region

Bowen Zhang, Shanghai Institute of Technology (China); Linli Cui, Jun Shi, Shanghai Meteorological Bureau (China); Peipei Wei, Shanghai Institute of Technology (China)

Based on SPOT/NDVI and meteorological data, NDVI and their response to temperature and precipitation in the watershed region between Changjiang River and Huaihe River were investigated over the period 1998--2013 by using the maximum value composite, linear regression and the method based on Pearson correlation coefficient. The results show that the average value of NDVI have a significant increasing trend for the whole area in the past 16 years. And the annual mean temperature of Yangtze River watershed region has a slightly increasing, while the annual average precipitation has a slightly decreasing in the past 16 years. Accordingly the values exist evidently variations in month and season. Correlation analysis shows that monthly averaged NDVI variations are generally determined by temperature but not precipitation. Positive correlations appear between NDVI and temperature, and the correlations are more significant in spring and autumn. Significant negative correlations are found in summer and winter between NDVI and precipitation. Spatial heterogeneity analysis shows that NDVI is more vulnerable to climate change for the middle basin than other regions. Finally, it can be demonstrated that NDVI can currently responds to temperature with a lag of 1 month. With respect to precipitation, the strongest response may occur 2 months. In addition, human activities also had profound effect to the NDVI trends in some regions. This study contributes to ongoing investigations of the effects of climate change on vegetation activity.

10405-35, Session PWed

Effects of distribution density of 3D vegetation model on canopy NDVI simulation

Zhu Tao, Runhe Shi, East China Normal Univ. (China)

The 3D model is an important part of simulated remote sensing for earth observation. In the study of small-scale spatial extent of DART software, both the details of the model itself and the number of models of the distribution have an important impact on the scene canopy NDVI. Taking the phragmites australis of Changjiang Estuary wetland as an example, this paper studied the effect of the phragmites model on the canopy NDVI, based on the previous studies of the model precision, mainly from the cell dimension of the DART software and the density distribution of the phragmites model in the scene , As well as the choice of the density of the phragmites model under the cost of computer running time in the actual simulation. The DART Cell dimensions and the density of the scene model were set by using the optimal precision model in the existing research results. The simulation results of NDVI with different model densities under different cell dimensions were analyzed by error analysis. By studying the relationship between relative error, absolute error and time costs, we have mastered the density selection method of phragmites model in the simulation of small-scale spatial scale scene. Experiments show that the number of phragmites in the simulated scene need not be the same as in the real environment due to the difference between the 3D model and the real plant. The best simulation results can be obtained by keeping the density ratio of about 40 trees per square meter, simultaneously, of the visual effects.

The preliminary analysis of the occultation atmospheric products of FY-3C satellite

Zhenxiang Shen, Chaoshun Liu, East China Normal Univ. (China); Yan Chen, Shanghai Shixi High School (China)

FY-3 is the second-generation polar orbit meteorological satellite in China and the purpose is to realize all-weather, multi-spectral and three-dimensional observation of the global atmospheric and geophysical elements. The FY-3C successfully launched in Taiyuan on the morning of September 23, 2013. The Global Navigation Satellite System Occultation Sounder (GNOS) is the first new civilian payload to detect the neutral atmosphere and ionospheric atmosphere by occultation in FY-3C. The detector can realize the atmospheric and ionospheric detection and it can be more comprehensive and accurate determination of the atmospheric and ionospheric profiles, so as to provide more high-precision technical support to China's space weather monitoring and weather forecasting. GNOS can receive Global Positioning System (GPS) navigation satellites and China's Beidou navigation satellite signal and we can get a global range of atmospheric products (including refractive index, density, temperature and humidity profile) of the neutral atmosphere and ionospheric atmosphere after inversion. In this paper, the atmospheric products (including refractive index, density, temperature, and humidity profile) of the GNOS receiver is examined by the ECMWF profile data. The results show that the difference in temperature was very small between the 200 hPa and 600 hPa near the mid-troposphere, and significantly different in temperature at the tropospheric top at 200 hPa and above. The basic range of bias is between -2% and 1%. In the whole troposphere, the bias of humidity a greater degree of dispersion and basically maintained at -40% to 40%.

Assessing the potential productivity of summer maize using WOFOST in north China plain

Mingnuo Jiang, Chaoshun Liu, East China Normal Univ. (China)

The North China Plain(NCP) region is an important maize producing area in China.This study simulated the potential and water-limited yield of summer maize in the region using the reanalysis data of 30 yrars with the help of WOFOST model, and analyzed the yield gaps between the actual and potential production.The aims are to reveal the yield potential and its spatial and temporal variation,identify the limiting facters affecting crop growth, and indicate room to increase the yield of summer maize.The results show that:1)potential and water-limited yield of summer maize in the NCP region 5384-11876kg/ha and 2987-7798kg/ha.respectively. 2)Annual variation of potential yield is relatively lower in the middle and southern parts,while it is higher in the northeastern region. 3)The region has a high potential room to increase the yield of summer maize by improving the crop managemment and irrigation systems.

Satellite observations of autumn-winter floating brown macroalgae blooms drifted from the Yellow Sea to the East China Sea

Qianguo Xing, Xuerong Li, Yantai Institute of Coastal Zone Research (China)

At the end of December, 2016, massive macroalgae blooms caused by floating brown macroalgae (Sargassum honeri) beat the seaweed aquaculture at the Jiangsu Shoal, China, and led to the largest direct economic loss due to Sargassum honeri blooms in China. In this study, high resolution satellite images were used to monitor the drifting path and development of the brown macroalgae blooms. For the first time, we showed that brown macroalgal blooms first occurred at the middle of October in the western Yellow Sea (YS) near the south coast of the Shandong Peninsula, arrived at the Jiangsu Shoal and damaged the local seaweed aquaculture at the middle of December, and finally drifted into the East China Sea (ECS). This kind of southward drifting path from the YS to the ECS, is also verified by the winter-spring macroalgal blooms in previous years.

Measurement of changes in the land cover and classification of regions of interest

Wendy Barrera Garcia, Juan Carlos Valdiviezo Navarro, Univ. Politécnica de Tulancingo (Mexico); César Joel Camacho Bello, Univ. Tecnológica de Tulancingo (Mexico)

The study and interpretation of changes on Earth´s surface have become the main topic of interest for different researches around the globe. Thanks to the availability of satellite data acquired by different missions, now a days it is possible to analyze the evolution of land surface changes at a certain interval of time as satellite time series. The research here outlined presents a novel technique to analyze satellite time series registered from natural reserves and water bodies in Mexico. With the aim to delineate land use changes, our method is applied to various collections of Landsat images acquired in the period from 1980 to 2015. For this purpose, each satellite image set is analyzed by means of two different approaches. Fist, the Hurst Exponent (H), which measures the distortion in the curve of some time series through windows of different dimensions, is computed. In a previous research we demonstrated the relation between Hurst exponent values and changes in land use. Hence, a decreasing H value can be associated with alterations in land surface. Second, the well known normalized difference vegetation index (NDVI) and the normalized difference water index (NDWI) are computed for each image in the series to segment areas of the corresponding natural resources. The segmented images are then compared at small windows, located at the same position along the series, in order to mark out the differences. At the end of the procedure we have a global estimation of H, NDVI, and NDWI values for each image in the set. In addition, an image indicating the positions where land use changes occurred is also produced by the algorithm. According to our preliminary results, decreasing H, NDVI, and NDWI values state that the Earth´s surface has been significantly modified. We remark that our method facilitates precise classification of the regions analyzed, minimizing confusion in any interpretation of the data.

A sampling strategy based on CGM for LAI measurements over non-uniform surface

Xiaohua Zhu, Lingling Ma, Yongguang Zhao, Academy of Opto-Electronics, CAS (China)

Currently, the remotely sensed product compared by measurements of field reference targets is still the basic means for validation. Limited by the representativeness of point sampling, all of the field measurements covering the whole region should be collected, which is impossible. Taking the cost of field measurement into account, more representative points with minimum number should be selected during remotely sensed product validation. There are several sampling strategies are used for remotely sensed product validation, including simple random sampling strategy, spatial uniform sampling strategy, Prior knowledge-based sampling strategy and so on. However, without fully considering the influence of the surface spatial heterogeneity, those sampling strategies often reduce the reliability of products validation. In this paper, a new sampling strategy based on computational geometry model (CGM) is proposed for leaf area index (LAI) ground measurement over non-uniform surface, as shown in Figure 1. Firstly, a correlation index (CI) is calculated based on high-resolution LAI image to choose the points of field measurement. Secondly, based on the first selected field measurements, the CGM model is used for simulating low-resolution LAI. Thirdly, the points of field measurement are decided according to the gaps between the simulated LAI and the aggregated LAI from high resolution. If the gap is accepted, the sampling strategy is finally established for field measurement. Otherwise, the field measurements should be re-selected and analyzed until the gap is accepted.

10405-43, Session PWed

About remote monitoring systems for aquatic environment

Ferdenant A. Mkrtchyan, Kotel'nikov Institute of Radio Engineering and Electronics of Russian Academy of Sciences (Russian Federation)

The technique of detection offered in given work and identification of the abnormal phenomena in the aquatic environment (microwave and optical) combines presence with application of possibilities of remote measurements algorithmic and the software, allowing to solve measurement and detection problems in real time. The effective decision of these problems is impossible without wide introduction in practice of researches of the automated systems of gathering, storage and data processing on the basis of modern computer systems with application of technology of open systems. Already created methods and algorithms possess ability to overcome such difficulties, as scantiness and not stationary information, presence small statistically non-uniform samples. It is obvious that complex research of the given land and remote measurements can raise reliability of estimations of parameters of natural systems and solve a problem of planning of these measurements. Application of means of remote monitoring in many cases is connected with acceptance of the statistical decision on presence on a surveyed part of studied space of this or that phenomenon. One of features of conditions of gathering of the information for such decision is the impossibility of reception statistical samples great volumes. Therefore working out and research of optimum algorithms of distinction of the casual signals characterized by samples of the limited volume, in the conditions of parametrical aprioristic indefinite are necessary.

Conference 10406: Lidar Remote Sensing for Environmental Monitoring 2017

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Tuesday - Wednesday 8 –9 August 2017

Part of Proceedings of SPIE Vol. 10406 Lidar Remote Sensing for Environmental Monitoring 2017

10406-1, Session 1

A survey of enabling active remote sensing technologies for NASA's Earth science observations *(Keynote Presentation)*

George J. Komar, NASA Headquarters (United States)

Recently conducted NASA Earth Science Technology Office (ESTO) review of current science challenges related to NASA's Earth science measurement goals highlighted the technology needs that would make future Earth observations possible. New investments in lidar technology and a review of state-of-the-art transmitter, receiver, and information technologies as they pertain to lidar systems will enable successful new capabilities that will give researchers a better understanding of the Earth system. This presentation will cover the needs and technology advancements that will make advanced science measurements from space possible.

10406-2, Session 2

Progress on development of an airborne two-micron IPDA lidar for water vapor and carbon dioxide column measurements *(Invited Paper)*

Upendra N. Singh, Mulugeta Petros, Tamer Refaat, Jirong Yu, Charles W. Antill, Bryant D. Taylor, Ruben G. Remus, Teh-Hwa Wong, Karl Reithmaier, Jane Lee, Syed Ismail, NASA Langley Research Ctr. (United States)

An airborne 2-?m triple-pulse integrated path differential absorption (IPDA) lidar is currently under development at NASA Langley Research Center (LaRC). This lidar targets both atmospheric carbon dioxide (CO2) and water vapor (H2O) column measurements, simultaneously. Advancements in the development of this IPDA lidar are presented in this paper. Updates on advanced two-micron triple-pulse high-energy laser transmitter will be given including packaging and lidar integration status. In addition, receiver development updates will also be presented. This includes a state-of-the-art detection system integrated at NASA Goddard Space Flight Center. This detection system is based on a newly developed HgCdTe (MCT) electron-initiated avalanche photodiode (e-APD) array. Future plan for IPDA lidar system for ground integration, testing and flight validation will be discussed.

10406-3, Session 2

GreenLITE: A new laser-based tool for near-real-time monitoring and mapping of CO2 and CH4 concentrations on scales from 0.4-25 km2

Jeremy T. Dobler, Nathan Blume, Michael Braun, Harris Corp. (United States); Scott Zaccheo, Timothy G. Pernini, Atmospheric and Environmental Research, Inc. (United States)

In 2013, Harris and Atmospheric and Environmental Research developed the greenhouse-gas laser imaging tomography experiment (GreenLITE™) under a cooperative agreement with the National Energy Technology Laboratory of the Department of Energy. The system uses a pair of high precision intensity modulated continuous wave (IMCW) transceivers and a series of retroreflectors to generate overlapping atmospheric density measurements from absorption of a particular greenhouse gas (e.g. CO2 or CH4), to provide an estimate of the 2-D spatial distribution of the gas within the area of interest. The system is capable of making the measurements over areas from approximately 0.4 to 25 km2 (~200 m X 200 m, up to ~5 km X 5 km). Multiple GreenLITE™ CO2 demonstrations have been carried out to date, including a full year, November 04, 2015, to November 14, 2016, deployment over ~25 km2 area of downtown Paris, France. In late 2016 the GreenLITE™ system was converted to provide similar measurements for CH4. Recent experiments showed that GreenLITE™ CH4 concentration retrievals agreed with an in situ instrument, calibrated with World Meteorological Organization traceable gas purchased from the NOAA Earth Systems Research Laboratory, to within approximately 0.5% of background or ~10-15 parts per billion. Several experiments are planned in 2017 to further evaluate the accuracy of the CH4 and CO2 retrieved concentration values compared to the calibrated in situ instrument and to demonstrate the feasibility of GreenLITE™ for environmental and safety monitoring of CO2 and CH4 in industrial applications.

10406-4, Session 2

New semiconductor laser technology for gas sensing applications in the 1650nm range

Milan L. Mashanovitch, Gordon Morrison, Paul O. Leisher, Jeremy Thomas, Freedom Photonics, LLC (United States); Mark Stephen, Kenji Numata, Stewart Wu, Haris Riris, NASA Goddard Space Flight Ctr. (United States)

Atmospheric methane (CH4) is the second most important anthropogenic greenhouse gas with approximately 25 times the radiative forcing of carbon dioxide (CO2) per molecule. CH4 also contributes to pollution in the lower atmosphere through chemical reactions leading to ozone production. Recent developments of LIDAR measurement technology for CH4 have been previously reported by Goddard Space Flight Center (GSFC). The instrument has a tunable, narrow-frequency light source and photon-sensitive detector to make continuous measurements from orbit, in sunlight and darkness, at all latitudes and can be relatively immune to errors introduced by scattering from clouds and aerosols. To further improve and simplify the instrumentation used, advances in tunable laser technology used are required.

In this paper, we report on a novel, high-performance tunable semiconductor laser technology developed by Freedom Photonics for the 1650nm wavelength range operation, and for LIDAR detection of CH4. Devices described are monolithic, with simple control, and compatible with low-cost fabrication techniques. They are based on distributed Bragg reflector laser implementations, and exhibit >70nm of tuning. They can thus also be used for CO2 and water vapor detection. The fabrication platform is radiation hard, allowing for simplified space deployment.

10406-5, Session 2

Compact, highly efficient, single-frequency 25W,2051nm Tm Fiber-based MOPA for Co2 trace-gas laser space transmitter

Doruk Engin, Fibertek, Inc. (United States); Ti Chuang, Fibertek (United States); Mark Storm, Fibertek, Inc. (United States)

Fibertek has developed and demonstrated a high output power, low risk, low SWAP (size, weight and power) 2051nm laser design meeting the lidar requirements for satellite-based global measurement of CO2. The laser design provides a path to space for either a coherent lidar approach being developed by NASA JPL or an Integrated Path Differential Absorption (IPDA) lidar approach. The IPDA approach has been implemented using RF

modulation and is being flown as part of a NASA Earth Venture suborbital mission - NASA's Atmospheric Carbon and Transport – America. The thulium fiber laser amplifies a < 500 kHz linewidth DFB laser up to 25W average power in a polarization maintaining fiber. The design manages and suppresses deleterious non-linear effect that can cause linewidth broadening or amplified spontaneous emission and meets the laser transmitter requirements for the identified lidar programs. We believe the core laser components, architecture and design margins can support a coherent or IPDA lidar for a 10 year space-based mission. We would be able to adapt an existing space-based, TRL-6, 20 W erbium fiber laser package for this thulium design and enable a near term space mission with an electrical to optical efficiency of > 20 %.

10406-6, Session 2

Wide area methane emissions mapping with airborne IPDA lidar

Jarett Bartholomew, Philip Lyman, Carl Weimer, Lyle Ruppert, Ball Aerospace & Technologies Corp. (United States)

Methane emissions from natural gas production, storage and transportation are a potential source of greenhouse gas emissions. Leaks also constitute revenue loss potential from operations. Since 2013, Ball Aerospace has been developing advanced airborne sensors using integrated path differential absorption (IPDA) LIDAR instrumentation to identify methane, propane and longer-chain alkanes in the lowest region of the atmosphere. Additional funding has come from the U.S. Department of Transportation, Pipeline and Hazardous Materials Administration (PHMSA) to upgrade instrumentation to broader swath coverage of 0.3 km while maintaining high spatial sampling resolution and geolocation accuracy. Wide area coverage allows efficient mapping of emissions from gathering and distribution networks, processing facilities, landfills, natural seeps, and other distributed methane sources. This paper summarizes benefits of advanced instrumentation for aerial methane emission mapping, describes the operating characteristics and design of this upgraded IPDA instrumentation, and reviews technical challenges encountered during development and deployment.

10406-7, Session 2

Single frequency Er:YAG methane/water vapor DIAL source

Patrick M. Burns, Moran Chen, Dave Pachowicz, Jeremy E. Young, Fran Fitzpatrick, Nicholas Sawruk, Fibertek, Inc. (United States)

Fibertek is developing injection locked, resonantly pumped Er:YAG laser systems for use in methane and water vapor differential absorption lidar (DIAL) systems. Accurate measurements of methane and water vapor are critical to understanding global energy transport and climate change. Current state-of-the-art lidar sources for DIAL measurements of these constituents are based on less efficient non-linear parametric conversion of diode pumped Nd:YAG systems. Er:YAG offers an avenue for a more compact, efficient system that can interrogate both methane and water vapor spectra. Fibertek's approach uses VBG stabilized 1532nm fiber coupled diodes minimizing the quantum defect and thermal loading while generating tunable single frequency output at 1.645 to 1.646μm. Single frequency operation is achieved through an injection seeded ring laser architecture with a Pound Drever Hall (PDH) locking technique. Laser systems from 1kHz to 10kHz are being studied with powers in the 4 to 10W range at the fundamental. Further work is being done on doubling this output to the 822nm regime for water vapor Lidar with a target of 3-5W.

10406-8, Session 3

Application of Doppler wind lidar observations to hurricane analysis and prediction *(Invited Paper)*

Robert M. Atlas, National Oceanic and Atmospheric Administration (United States); George D. Emmitt, Simpson Weather Associates, Inc. (United States); Lisa Bucci, Kelly Ryan, Jun A. Zhang, National Oceanic and Atmospheric Administration (United States)

Winds are among the most important variables in the atmosphere. They transport all the other variables of the atmosphere and govern the exchanges of mass, energy, and momentum. Currently, winds make up a very small fraction of the observations that are used in data assimilation systems. Many of the winds that are available are created by tracking features in the cloud or water vapor field. These atmospheric motion vectors are valuable, but they are an indirect measurement and have inherent height uncertainties. In contrast, Doppler Wind Lidars (DWLs) directly measure the line-of-sight wind by observing the Doppler shift in the lidar signal returned by a volume of atmospheric scatterers.

Impact experiments with real data, termed Observing System Experiments (OSEs), are conducted with and without one observing system to quantify the impact of that observing system. Similar experiments with simulated data are termed Observing System Simulation Experiments (OSSEs). In OSSEs a long forecast is taken to be the "truth" or nature run. The present study complements previous space-based DWL OSSEs by examining the impact of DWL observations on hurricanes and by beginning to evaluate the impact of having an existing DWL on NOAA's Hurricane Hunter aircraft. An airborne DWL was flown for the first time in 2015 on the NOAA P3 Orion Hurricane Hunter aircraft into Atlantic Tropical Storms Danny and Erika, and then again during the 2016 hurricane season. The impacts of the airborne DWL data that was obtained will be presented at the conference.

10406-9, Session 3

Status of pulsed coherent-detection wind lidars at NASA LaRC and recent airborne science campaign results

Michael J. Kavaya, NASA Langley Research Ctr. (United States); George D. Emmitt, Simpson Weather Associates, Inc. (United States); Zhaoyan Liu, Upendra N. Singh, NASA Langley Research Ctr. (United States)

NASA LaRC is developing high-energy 2-micron lasers and coherent-detection wind lidar systems to advance technology that is needed for global wind measurements from space. The wind measurements have been endorsed by the NRC in its Earth Science "Decadal Survey", and by NOAA for improved forecasting. LaRC began laser development in the 1990s, wind lidar development with the high-energy lasers in 2002, and airborne wind lidar systems in 2005. The wind lidar systems utilized the advanced laser technology available at the time in the development progress. The first 2-micron airborne wind lidar system was developed over 2005 – 2010. The Doppler Aerosol WiNd (DAWN) lidar system featured a 250 mJ, 10 Hz, 190 ns laser, an optical wedge-based conical scanner approximately centered on nadir, and a 15-cm receiver aperture. DAWN has flown in three science campaigns to date: the NASA hurricane Genesis and Rapid Intensification Processes (GRIP) in 2010, the NASA Polar Winds campaign based at Greenland in 2014, and the Polar Winds campaign based in Iceland in 2015. We are planning to fly DAWN in NASA's Convective Processes Experiment (CPEX) in May-June 2017. In preparation for CPEX, DAWN is being upgraded to improve its photon efficiency and to permit more operator test and alignment options in the field. NASA LaRC is also developing a second generation airborne lidar system that will have a different laser operating point to reduce risk, to greatly decrease the heat to be removed from the laser, and to improve the science product from future use in space. The status of the wind lidar systems, and aircraft science campaign results will be presented.

10406-10, Session 3

Efficient, space-based, 100W thulium fiber laser for pumping Q-switched 2um Ho:YLF for global winds and carbon dioxide lidar

Doruk Engin, Brian Mathason, Mark Storm, Fibertek, Inc. (United States)

Space-based global wind and CO2 measurements are critically needed to improve and extend NOAA weather forecasting that impacts U.S. crop production, hurricane forecasting, flooding, and FEMA disaster planning. NASA, NOAA, and the 2007 National Research Council (NRC) Earth Science Decadal Survey have identified space-based, global wind measurements as critical for improving both weather prediction as well as longer term climate change research. Researchers at NASA Langley have conducted aircraft-based coherent wind lidar measurements using 2 um Ho:YLF lasers that have demonstrated the ability of the lidar system to provide both wind and CO2 measurements. Extending the lidar system design to a space-qualifiable version requires the development of a robust and efficient pump source for the required 2 μm laser. Fibertek has designed and demonstrated a high-efficiency, 100 W average power continuous wave 1940 nm thulium-doped fiber laser breadboard system that meets the performance requirements for a space-qualifiable, 2 μm Ho:YLF pump laser source. Our preliminary design shows that it is possible to package the pump laser for high reliability, spaceflight operation in an ultra-compact ~2”x8”x14” volume and weight <8.5 lbs. Our 100 W polarization maintaining Tm laser provides a key component for the development of a space-qualified, Q-switched, 2 μm Ho:YLF laser with 30-80 mJ/pulse at 100-200 Hz repetition rates.

10406-11, Session 3

Fast widely-tunable single-frequency 2-micron laser for remote sensing applications

Sammy W. Henderson, Charles P. Hale, Beyond Photonics (United States)

We describe a fast frequency–tunable diode-pumped solid-state laser we have developed, called the SWIFT laser. The laser architecture is compatible with operation using many different solid state laser crystals for access of various emission lines between 1 and 2.1 micron. We initially demonstrated the laser using a Tm,Ho:YLF laser crystal near 2.05 micron wavelength and achieved up to 100 mW of output power and up to 50 GHz fast PZT-actuated tuning range. The fast frequency tuning range can be centered at any wavelength from 2047-2059 nm using the Tm,Ho:YLF crystal, making the laser compatible with path-integrated or range-resolved differential absorption lidar systems for atmospheric CO2 or H20-vapor concentration measurements. Other laser crystals will allow access to other molecular absorption lines, e.g., Er:YAG for CH4. The frequency stability and power are sufficient to serve as the local oscillator laser in long-range (e.g., space-based) coherent lidar systems for measurement of atmospheric winds or tracking and characterization of hard targets.? The SWIFT laser and its performance will be described in detail in the paper and presentation. We also have demonstrated that a miniature Q-switched laser of similar design to the SWIFT laser can produce 20 microJoule pulses at 5-10 kHz PRF. We will also describe lidar modeling which predicts that such low energy laser pulses are sufficient to allow for range-resolved wind measurements in the atmospheric boundary layer to a few km range.

10406-12, Session 4

First principle calibration of water vapor Raman lidars *(Invited Paper)*

Valentin B. Simeonov, Ecole Polytechnique Fédérale de Lausanne (Switzerland)

Raman lidars exploit the proportionality between the intensity of scattered by Raman process laser radiation and the number density of scattering molecules. Water vapor-air mixing ratio is proportional to the ratio of the measured intensities of Raman scattering from water vapor and nitrogen molecules. The coefficient of proportionality, denoted as calibration constant, depends on instrument parameters and spectroscopic parameters of the scattering molecules and is primary factor defining lidar measurement accuracy. Derivation of the calibration constant using above mentioned parameters is possible but leads to high uncertainty. Therefore Raman lidars are calibrated against reference instrument- radio sonde or microwave radiometer. The accuracy of such calibration is thus limited by the accuracy of the reference instrument.

The new method for calibration of water vapor Raman lidars proposed here is based on first principles. The calibration constant is derived from set of water vapor and nitrogen Raman backscatter signals measured with the lidar receiver in a cell filled with reference humidity mixture.

The reference humidity mixture is prepared gravimetrically. The water vapor mixing ratio is calculated directly as a ratio of the mass of water to the mass of air. Since mass is a fundamental quantity, this method yields an absolute value of water vapor mixing ratio which translates to the lidar calibration constant.

A lidar calibrated with the method has the potential to become reference instrument for atmospheric profiling of water vapor and can be used for validation and calibration of other instruments, such as microwave radiometer, balloon sonde, and GPS.

10406-13, Session 4

Greater than 2mJ pulse energy and 65kW peak power single frequency fiber laser at 1.03 micron

Shibin Jiang, AdValue Photonics, Inc. (United States)

All-fiber monolithic laser sources are highly desirable for airborne and space borne applications because fiber laser sources offer a much more compact and robust solution compare to free-space solid state lasers. However, the pulse energy and peak power of the fiber amplifiers are limited because of the stimulated Brillouin scattering (SBS). The pulse energy is generally limited to near 0.5mJ level.

We developed multi-component non-silica glasses as the host of the rare-earth ions, which permit a higher doping concentration because of their less-defined glass network as compared to silica glass. Yb doped glasses were fabricated as the core glasses, and a large core single mode fiber was developed. A singe frequency fiber laser with pulse energy of greater than 2mJ and peak power of greater than 65kW will be presented.

10406-14, Session 4

Stabilized diode seed laser for flight and space-based remote lidar sensing applications

Shirley McNeil, Phillip Battle, AdvR, Inc. (United States); Floyd Hovis, Joe Rudd, Fibertek, Inc. (United States)

AdvR, through support of the NASA SBIR program, has developed fiber-based components and sub-systems that are routinely used on NASA’s flight-based missions, and is now developing an environmentally hardened, diode-based, locked wavelength, seed laser for future space-based high

spectral resolution lidar applications. The seed laser source utilizes a fiber coupled diode laser, a fiber coupled calibrated iodine cell module to provide an absolute wavelength reference, and an integrated dual-element nonlinear optical waveguide component for second harmonic generation, spectral formatting and wavelength locking. The seed laser operates over a range close to 1064.5nm, provides for stabilization of the seed to the desired iodine transition and allows for a highly efficient, fully integrated seed source that is well-suited for use in flight and space-based environments. A summary of component level environmental testing and spectral purity measurements with a seeded Nd:YAG laser will be presented. A direct diode, wavelength locked seed laser will reduce the overall size weight and power (SWaP) requirements of the laser transmitter thus directly addressing the need for developing compact, efficient, lidar component technologies for use in flight and space-based environments.

10406-15, Session 4

Development of a wing-beat-modulation scanning lidar system for insect studies

Martin J. Tauc, Montana State Univ. (United States); Kurt M. Fristrup, U.S. National Park Service (United States); Joseph A. Shaw, Montana State Univ. (United States)

The spatial distributions of flying insects are not well understood since most sampling methods -- Malaise traps, sticky traps, vacuum traps, light traps -- are not suited to documenting movements or changing distributions of various insects on short time scales. These methods also capture and kill the insects. To noninvasively monitor the spatial distributions of flying insects, we developed and implemented a scanning lidar system that measured wing-beat-modulation. Transmitting and receiving optics were mounted to a telescope that was attached to a scanning mount. As it scanned, the lidar collected and analyzed the light scattered from insect wings of various species. Mount position and pulse time-of-flight determined spatial location and spectral analysis of the backscattered light provided clues to insect identity. During one day of a four day field campaign at Grand Teton National Park in June of 2016, 76 insects were detected, with a maximum range to the insect of 87.6 m.

10406-16, Session 4

1550 nm eye-safe wavelength watt-level laser transmitter for space communication and lidar

Ray R. Y. Tang, Ramadas Pillai, NuPhoton Technologies, Inc. (United States)

A master-oscillator power amplifier (MOPA) based 1550 nm wavelength fiber laser transmitter has been developed for Space-to-Earth communication application, utilizing Telcordia rated 1550 nm seed laser, pump lasers, and fiber optics. With adequate pre-screening of electrical components, the fiber laser transmitter has been in operation since its original launch in April 2014 for more than 28 months. This presents as a relatively cost-effective route for low-earth-orbit optical communication as well as LIDAR application.

10406-17, Session 4

The Scheimpflug lidar method

Mikkel Brydegaard, Elin Malmqvist, Samuel Jansson, Jim Larsson, Sandra Török, Lund Univ. (Sweden); Guangyu Zhao, South China Normal Univ. (China)

The recent several years we developed the Scheimpflug lidar method. We combined an invention from the 19th century with modern optoelectronics such as diode lasers and CMOS array from the 21st century. The approach exceeds expectations of background suppression, sensitivity and resolution beyond known from time-of-flight lidars. We accomplished multiband elastic atmospheric lidars for resolving single particles and aerosol plumes from 405 nm to 1550 nm. We pursued hyperspectral differential absorption lidar for molecular species. We demonstrated a simple method of inelastic hyperspectral lidar for profiling aquatic environment and vegetation structure. Not least, we have developed polarimetric Scheimpflug lidar with multi-kHz sample rates for remote modulation spectroscopy and classification of the aerofauna. All these advances thanks to the scheimpflug principle. Here we give a tour of how far we came, we shed light on the limitations and opportunities for future directions. In particular we show how the biosphere can be resolved with unsurpassed resolution in space and time, and share our expectation on how this can revolutionize ecological analysis and management in relation to agricultural pests, disease vectors and pollinator problematics.

10406-18, Session PWed

A photon-efficient method based on curve fitting for photon counting 3D imaging lidar

Ling Ye, Guohua Gu, Weiji He, Wenye Yin, Jie Lin, Jian Fang, Nanjing Univ. of Science and Technology (China)

For using Geiger mode avalanche photodiode (Gm-APD) and the technique of time correlated single photon counting (TCSPC), a direct-detection 3D imaging lidar has high sensitivity in low-light-level (LLL) scene. Conventionally, traditional method needs long fixed dwell time to collect thousands of photons to find accurate range and mitigate Poisson noise at each pixel. We present a new method, which acquires accurate depth images using much less detected photons and has quantitative analysis to estimate whether results are in the confidence interval. Based on the shape of emitted laser and the response curve of the detector, we use one order of magnitude back-reflected photons less than traditional method, fitting a curve of laser-return pulse by nonlinear least-squares fitting to obtain the range. The condition of moving to next pixel in our method is acquiring a fixed number of back-reflected photons, instead of sampling for a fixed time. Low-reflection areas have more time to acquire enough photons. This adaptive jump condition is able to speed up the scanning without generating distortion. The results are analyzed with chi-square test to determine whether the curve we fit has enough credibility. This quantitative analysis provides a important judgment condition for our method to recover the depth image. Experimental results demonstrate our method obtained the millimeter-accuracy depth image in the confidence interval using one tenth photons of traditional method each pixel. Thus our method will be of considerable value to fast 3D imaging in LLL scene, such as remote sensing and military reconnaissance.

10406-19, Session PWed

11 years of Rayleigh lidar observations of gravity wave activity above the southern tip of South America (Río Gallegos, Argentina, 51.6ºS, 69.3ºW)

Jacobo O. Salvador, Instituto de Investigaciones Científicas y Técnicas para la Defensa (Argentina) and CONICET (Argentina); Pablo Llamedo Soria, Univ. Austral (Argentina); Jonathan Quiroga, Consejo Nacional de Investigaciones Científicas y Técnicas (Argentina); Eduardo Quel, Instituto de Investigaciones Científicas y Técnicas para la Defensa (Argentina); Peter Alexander, Univ. de Buenos Aires (Argentina); Rodrigo Hierro, Alejandro de la Torre, Univ. Austral (Argentina)

Gravity wave (GW) activity is analyzed using Temperature (T) data retrieved from a Rayleigh Lidar at Río Gallegos, Argentina (51.6ºS, 69.3ºW). GW characteristics are derived from 302 observations providing more than 960

of high-resolution lidar data between 20 km and 56 km height between August 2005 and December 2015.

Temperature measurements from the Rayleigh scattering are evaluated through a DIAL system (Differential Absorption Lidar). Rayleigh backscattered photons are emitted by an Excimer (XeCl) laser at 308 nm (300 mJ maximum energy) and the third harmonic of Nd-YAG laser at 355 nm (130 mJ maximum energy). This lidar is the southernmost outside Antarctica. Located 300 km leeward of the southern Andes and 70 km North of the strait of Magellan. Río Gallegos is an exceptional place to observe large amplitude GW where the principal sources are the orography and the spontaneous adjustment processes around the jet in the stratosphere.

During the spring (September to November) the polar vortex weakens and advances northward surpassing Río Gallegos and rapidly changing the conditions for GW.

The mean specific potential energy (PE) is a proxy for GW activity. PE statistical differences inside, outside and in the edge of the polar vortex are analyzed. Also, the sensitivity of T perturbation to different integration time of backscattered signals is studied.

10406-20, Session PWed

Potential of UAV LIDAR systems for geospatial mapping

Ahmed Elaksher, Subodh Bhandari, California State Polytechnic Univ., Pomona (United States)

Shorelines are imperative for coastal ecosystems and activities. Despite this simplicity, accurate and precise extraction of these features is a challenging task due to the complicity of water bounding zones. Shoreline mapping has been carried out through a variety of techniques such as traditional surveying and aerial mapping. As spatial resolution and geospatial mapping technologies improved in the last few years, satellite images and active remote sensing systems have also been introduced to produce high quality shorelines. The focus of this research is on generating reliable shorelines from satellite images and LIDAR datasets. Different classification algorithms were implemented and tested followed by a number of image processing techniques to vectorize shoreline pixels. The geometric accuracy and the completeness of the results are presented and evaluated. Results show the benefits of adding ranging data in improving both shoreline recognition and accuracy.

10406-21, Session PWed

Lidar observations of long range dust transport over Mauna Loa Observatory

Jalal-ud-din Butt, Nimmi C. P. Sharma, Central Connecticut State Univ. (United States); John E. Barnes, National Oceanic and Atmospheric Administration (United States)

A bistatic CCD camera lidar (CLidar) was used at the National Oceanic and Atmospheric Administration's Mauna Loa Observatory (MLO) to map aerosol light scattering. Laser light from a 532 nm, 20 watt, Nd:YAG laser was vertically transmitted into the atmosphere and the scatter off clouds, aerosols and air molecules was detected using a CCD camera with wide angle optics and a laser line filter. The intensity of each CCD camera pixel imaging the beam was normalized to a molecular scattering model in an aerosol free region for subtraction of molecular scattering. Aerosol extinction was derived using a column average aerosol phase function derived from AERONET sun photometer measurements at MLO. The CLidar design allows measurements of aerosol scattering all the way to the ground without an overlap correction. MLO, at 3397 m.a.s.l., typically receives free tropospheric air. Though during spring months, prevailing winds can transport dust from Asian sources with high dust activity over MLO. Aerosol scattering measurements were taken by the CLidar during spring months at MLO and revealed extinction peaks at mid-range altitudes. Back trajectories of these peaks were conducted using NOAA's Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) model and found their origins to be Eastern Asian sources of high dust activity. Relative humidity data from radiosondes and the NOAA lidar's water vapor channel were examined to differentiate aerosol scattering from tenuous cloud scattering. This paper presents aerosol extinction data with observations of Asian dust as measured by the CLidar during spring months at MLO.

Applications of synergistic combination of remote sensing and in-situ monitoring of urban air quality

Adrian Diaz Fortich, NOAA-CREST (United States)

Understanding the spatial distribution of aerosols can shed light on atmospheric dynamics, aerosol transport and particulate pollution. Moreover, due to the harmful effects of particulate pollution on human health, it is of special interest to monitor air quality at high resolution in populated urban areas. In this study, multiple remote sensing and in-situ measurements are combined in order to obtain a more comprehensive understanding of the aerosol distribution in New York City. Measurement of the horizontal distribution of aerosols is performed using a scanning eye-safe elastic-backscatter mini micro-pulse lidar. Vertical distribution of aerosols is measured with a multi-wavelength lidar. Wind measurements are obtained from multiple meteorological stations and available wind profiler data for New York City. Our analysis also includes in-situ measurements of particulate matter (PM2.5) from sampling stations throughout the area of interest. These observations are combined to understand dynamics of the boundary layer and inhomogeneous distribution and transport of aerosols.

Conference 10407: Polarization Science and Remote Sensing VIII

Tuesday - Wednesday 8 –9 August 2017

Part of Proceedings of SPIE Vol. 10407 Polarization Science and Remote Sensing VIII

10407-1, Session 1

A fast Stokes polarimeter

Israel J. Vaughn, The Univ. of New South Wales (Australia); Andrey S. Alenin, J. Scott Tyo, UNSW Canberra (Australia)

Designing polarimetric systems directly in the channel space has provided insight into how to design new types of polarimetric systems, including systems which use carriers in hybrid domains of space, time, or spectrum. Utilizing linear systems theory, we present a full Stokes imaging polarimeter design which has the potential to operate at the full frame rate of the imaging sensor of the system by utilizing a hybrid spatio-temporal carrier design. The design places channels on the faces and the edges of the Nyquist cube resulting in the potential for the temporal Nyquist limit to be achieved, provided that the spatial frequency of the objects being imaged are bandlimited to less than 0.25 cycles per pixel. If the objects are not spatially bandlimited, then the achievable temporal bandwidth is more difficult to analyze. However, a spatio-temporal tradeoff still exists allowing for increased temporal bandwidth. We present the design of a ``Fast Stokes'' polarimeter and some simulated images using this design.

10407-2, Session 1

Real-time Stokes polarimeter using three polarized beam splitter

Shuhei Shibata, Utsunomiya Univ. (Japan); Shuichi Kawabata, Tokyo Polytechnic Univ. (Japan); Yukitoshi Otani, Utsunomiya Univ. (Japan)

This paper describes real-time, very small and cheap Stokes polarimeter using three polarized beam splitters (PBSs). Each s1, s2 and s3 of Stokes parameters is measured by the PBSs. However this technique has to separate three beams keeping unknown incidental polarization state. To overcome this problem, three same normal beam splitters (BSs) are possible to separated two beams keeping polarized state. An alignment of three BSs is set orthogonal in transmission part and reflection part. In transmission part, the polarization state after two BSs can be canceled change of polarization state of first BS by change of second orthogonal BS. In reflection part is same theory. If you set two pear of this keeping polarization beam splitter, you can separate three beams keeping incidental polarization state. After separated beams, three PBS can measure Stokes parameters easily. At first we checked effect of the keeping polarization beam splitter using spectoscopic Mueller matrix polarimeter. We got Mueller matrixes having max 3.3% value of transmission and reflection from unit matrix during from 450nm to 700nm. In second we checked Stokes parameters after a rotating polarizer and a quarter wave plate in this Stokes polarimeter. In two condition results, an error had 5.6%. Finally we checked measurement speed of this real-time Stokes polarimeter using rotating quarter wave plate. From this result this Stokes polarimeter is possible to measure Stokes parameter in 15Hz. This measurement speed depends on detection speed of six PIN photodiodes and transfer speed of AD convertor.

10407-3, Session 1

Snapshot spatially heterodyned imaging Fourier transform spectropolarimeter

Eddie J. Youngs, Michael W. Kudenov, Michael J. Escuti, North Carolina State Univ. (United States); Jim Schwiegerling, The Univ. of Arizona (United States)

The development, calibration, and implementation of a snapshot spatially heterodyned imaging fourier transform spectropolarimeter (SHIFT) is detailed. While conventional scanning, imaging fourier transform spectroscopy techniques incorporate a Michelson interferometer and modulation mirrors, the described SHIFT utilizes a set of common-path, mechanically robust birefringent prisms to generate a set of interference fringes. By leveraging the data provided by these fringes, per pixel spectral and polarimetric data across the entire imaged scene is obtained. Incident light is first passed through an analyzer array, which directs the top-half of the imaged scene through a quarter-wave plate and the bottom-half through a linear polarizer. A lenslet array then images both halves into a series of subimages. These subimages are propagated through a set of common-path birefringent prisms to generate interference fringes which overlay onto the subimages. These fringes are heterodyned by a pair of polarization gratings and passed onto a focal plane array. Mathematically, the set of subimages can be rearranged into a cube. Each x,y location on this cube represents a pixel location, whereas the z-axis at this location corresponds to a sampled version of the interferogram for this pixel. The sample locations in the interferogram are different for each pixel, with the same sampled resolution providing identical spectral information. By leveraging the data provided by these fringes, per pixel spectral and polarimetric data across the entire imaged scene is obtained. To achieve this, a theoretical model for the system was developed and validated with data from proof of concept experiments. With this model, a prototype assembly has been designed and calibrated via multiple techniques, including exposing the sensor to a target spectrum of monochromatic light in multiple polarization states. A variety of scenes was then measured with the calibrated prototype to demonstrate its functionality. Applications for this sensor includes high-resolution spectroscopy and polarimetry in biomedical imaging, remote sensing, and machine vision.

10407-4, Session 1

Intrinsic coincident full-Stokes polarimeter using stacked organic photovoltaics and architectural comparison of polarimeter techniques

Ruonan Yang, Pratik Sen, Brendan T. O'Connor, Michael W. Kudenov, North Carolina State Univ. (United States)

An intrinsic coincident full-Stokes polarimeter is demonstrated by using stain-aligned polymer-based organic photovoltaics (OPVs) which can preferentially absorb certain polarized states of incident light. The photovoltaic-based polarimeter is capable of measuring four stokes parameters by cascading four semitransparent OPVs in series along the same optical axis. Two wave plates were incorporated into the system to modulate the S3 stokes parameter so as to reduce the condition number of the measurement matrix. The model for the full-Stokes polarimeter was established and validated from radiometric calibration which showed an average RMS error of 0.84%. The optimization based on minimizing the condition number of the 4-cell OPV design showed that a condition number of 2.4 is possible. The performance of this in-line polarimeter concept was compared with other polarimeter techniques (Division of Time (DoT), Division of Amplitude (DoAm), Division of Focal Plane (DoFP) and Division of Aperture (DoA) Polarimeter) from signal collection abilities and signal-to-noise ratio (SNR) perspective. This in-line polarimeter concept has the potential to enable both high temporal (as compared with DoT polarimeter) and high spatial resolution (as compared with DoFP and DoA polarimeter) at the same time. It has the same SNR advantage as the DoAm polarimeter theoretically, twice as much as other techniques, but the former is significantly more compact than the latter.

10407-5, Session 1

Characterization of cameras for all-sky polarization measurements during the 2017 solar eclipse

Taiga Hashimoto, Hokkaido Univ. (Japan); Laura M. Dahl, Seth A. Laurie, Joseph A. Shaw, Montana State Univ. (United States)

A solar eclipse is one of the most famous natural phenomena and on 21 August 2017 we will measure the skylight polarization during a total solar eclipse in Rexburg, Idaho. Previous research has shown that during totality the sky polarization pattern is altered significantly to become nominally symmetric about the zenith. However, there are still questions remaining about the details of how surface reflectance near the eclipse observation site and aerosol properties influence the totality sky polarization pattern. We will study how skylight polarization in a solar eclipse changes through each phase and how surface and atmospheric features affect the measured polarization signatures. During this solar eclipse, the estimated time for totality is under three minutes. With the short window of time to take measurements and the drastic change from day to totality conditions, instrument limitations can be problematic. Therefore, fully characterizing the cameras and fisheye lenses is critical. These measurements include finding the camera sensitivity and its relationship to the required exposure times, the camera's spectral response function, and angular pixel mapping with the fisheye lens. Additional steps include comparing daytime polarimetric images to an existing polarimetric radiative transfer model and taking measurements during twilight and nighttime.

10407-6, Session 2

Advances in modeling polarimeter performance *(Invited Paper)*

Russell A. Chipman, College of Optical Sciences, The Univ. of Arizona (United States) and Airy Optics, Inc. (United States)

Polarization modeling methods developed for the NASA MSPI, MAIA, and several Mueller matrix imaging polarimeters will be discussed. This algorithm development culminated in the Polaris-M polarization analysis program. Polarimeter design requires attention to issues of wavelength and angle sensitivities of polarization elements, as well as target or sample polarization, polarization aberrations of imaging systems, and thermal and mechanical effects. The realistic modeling of polarization elements involves precise crystal optics models, rigorous coupled wave analysis with anisotropic materials, ghost reflection analysis, and the athermalization of polarization properties such as retardance.

Artifacts in polarimeters are apparent polarization features which are not real but result from the systematic errors in the polarimeter. The polarization artifacts are very different between division of focal plane, spectral, and time modulation polarimeters. Artifacts result from many sources such as source properties, micropolarizer arrays, coatings issues, vibrations, and stress birefringence. Modeling examples will be presented including the athermalization of retarders and polarization aberration analyses for polarimeters.

10407-7, Session 2

Modeling the polarization aberrations of optical elements

Kyle Hawkins, Russell A. Chipman, Airy Optics, Inc. (United States)

Conventional ray tracing calculates the shape of wavefronts, but not their amplitudes or polarization states. Thin films, polarizers, diffraction gratings, crystals and even lenses, in addition to affecting the shape of wavefronts make contributions to the relative phase and amplitude of the light in an Optical System.

These contributions will vary with polarization, field, and pupil position, adversely affecting the system performance. For sensitive optical systems, it is necessary to design around these effects with polarization ray tracing algorithms which are not only related to the optical path length, but include polarization dependent surface effects. This is done by supplementing the optical path length with calculations of the polarization ray tracing matrix (PRT).

The adverse effects can then be described as the deviations from an identity Jones Pupil (polarization aberration), and Zernike polynomials can then be used to provide a simplified generalization of the polarization aberration that is still accurate. The Zernike terms will describe the amplitude transmission along the ray paths, the amplitude aberration, which is normally unavailable with a geometrical ray trace, and the Zernike terms will have the relative phase accumulations along ray paths, that describe phase variation with polarization state.

Three different optical elements will be modeled: a wire grid polarizer, an anisotropic diffraction grating, and an injection molded lens with the polarization ray tracing software, Polaris-M. For each optical element, the polarization aberrations will be calculated and fit to Zernike polynomials. The effects of the aberrations on system performance will then be discussed and categorized.

10407-8, Session 2

End-to-end multi-scale simulations of optical systems containing isotropic and anisotropic components with arbitrary geometries using full vector wave propagation

Steven Bos, Sebastiaan Haffert, Christoph Keller, Leiden Observatory (Netherlands)

Precise three-dimensional modelling of the (off-axis) point spread function (PSF) to identify geometrical and polarization aberrations is important for many optical systems. In order to characterise the PSF of the system in all Stokes parameters, an end-to-end multi-scale simulation has to be performed that includes all relevant physics.

We present the first results of a python code that we are developing to perform end-to-end wave propagation (no ray-tracing), including all relevant physics: vector diffraction in isotropic and anisotropic materials, reflection and refraction of arbitrary surfaces and interference effects. The code will operate on multiple scales: from meter size (e.g. telescope mirrors) to structures on the order of wavelengths (e.g. waveguides). Current capabilities of the code are: near- and far-field vector diffraction effects of propagating waves in homogeneous isotropic and anisotropic materials, refraction and reflection of flat parallel surfaces. Next steps in the development are to include reflection and refraction of arbitrarily shaped surfaces and interference effects in thin films.

An example application is the accurate modelling of the PSFs of future space and ground-based telescopes. These will try to perform the first observations of Earth-like exoplanets ten billion times fainter than their host star. To evaluate the performance of the entire system including advanced coronagraphic, spectroscopic, polarimetric and adaptive optics techniques, where an end-to-end characterisation on all scales is needed.

10407-9, Session 2

Polarization fringe modeling for the DKIST retarders

David M. Harrington, National Solar Observatory (United States)

We present polarization fringe models based on a new application of the Berreman calculus. The new 4m Daniel K. Inouye Solar Telescope has very challenging specifications for retarders. The optic must operate in a 300W beam with flux from <320nm to >25 micron wavelength and a clear aperture over 105mm. Thermal performance and polarization fringes represent a major challenge for accurate calibration of instruments operating at 380nm to 5000nm wavelength and large fields of view. Predicting fringe behavior, field dependence, temperature dependence and allowing trade studies on the impacts of various anti-refelction coatings have been enabled with the new fringe models. We also create models for retarders other solar and night-time spectropolarimeters and compare with observations to verify the models.

10407-10, Session 3

Statistics for linear Stokes polarimetry

Nathan Hagen, Utsunomiya Univ. (Japan)

We present a method of calculating analytic formulas for the second-order statistics --- the signal, variance, and SNR --- of a variety of linear Stokes polarization measurement techniques. The advantage of the method is that it is easy to perform and produces simpler formulas than previously published methods. Using the resulting formulae, we compare a number of different polarimetric designs and discuss how these can be used to optimize instrumentation.

10407-11, Session 3

Single image super-resolution via regularized extreme learning regression for imagery from microgrid polarimeters

Garrett C. Sargent, Univ. of Dayton (United States); Bradley M. Ratliff, Univ. of Dayton Research Institute (United States); Vijayan K. Asari, Univ. of Dayton (United States)

The advantage of division of focal plane imaging polarimeters is their ability to obtain temporally synchronized intensity measurements across a scene; however, they sacrifice spatial resolution in doing so due to their spatially modulated arrangement of the pixel-to-pixel polarizers and often result in aliased imagery. This shortcoming is largely overcome through advanced demosaicing strategies that minimize the effects of false polarization while preserving as much high frequency content as possible. While these techniques can yield acceptable imagery, they tend to be computationally complex and the spatial resolution is often reduced below the native capabilities of the focal plane array. Here we propose a super resolution method based upon previously trained extreme learning machines (ELM) that attempt to recover missing high frequency content beyond the spatial resolution of the sensor while suppressing false polarization signatures resulting from pixel-to-pixel misalignment. For each channel of an image, the proposed method utilizes two ELM models: the first predicts the missing high frequency components, whereas the second predicts the pixel-to-pixel alignment errors associated with the low frequency components of each channel. Adding the results of the two ELM models together yields a sharper image with minimized false polarization artifacts. This provides a fast and computationally simple way of demosaicing raw microgrid polarimetric imagery while simultaneously improving image resolution. The technique is applied to both visible and long-wave infrared data.

10407-12, Session 3

Channeled linear imaging polarimetry using iterative reconstruction

Dennis J. Lee, Charles F. LaCasse IV, Julia M. Craven, Sandia National Labs. (United States)

Channeled linear imaging polarimeters amplitude modulate the linear stokes parameters onto spectrally broadband interference fringes. The Stokes parameters are demodulated by performing a 2D Fourier transform on the intensity pattern and applying 2D filters to isolate channels for further processing. A disadvantage of processing the fringes in the frequency domain is that reconstruction of the Stokes parameters suffers from high sensitivity to noise. Noise or cross talk between channels will degrade the quality of reconstruction. We propose an iterative reconstruction approach to improve on Fourier domain processing and achieve a more accurate and noise robust calculation of the Stokes parameters. This work will outline the theoretical approach and demonstrate simulated results.

10407-13, Session 4

Moving towards more intuitive display strategies for polarimetric image data

Bradley M. Ratliff, Univ. of Dayton Research Institute (United States); J. Scott Tyo, UNSW Canberra (Australia)

The display of polarimetric image data has been a subject of considerable debate. Display strategies range from direct display of the Stokes vector images (or their derivatives) to false color representations. In many cases, direct interpretation of polarimetric image data using traditional display strategies is not intuitive and can at times provide confusion as to what benefit polarimetric information is actually providing. Here we investigate approaches that attempt to augment the s0 image with polarimetric information, rather than directly display it, as a means of enhancing the baseband s0 image. The benefit is that the polarization-enhanced visible or infrared image maintains a familiar look without the need for complex interpretation of the meaning of the polarimetric data, thus keeping the incorporation of polarimetric information transparent to the end user. We take a more subjective approach to image enhancement than current techniques employ by simply seeking to improve contrast and shape information for polarized objects within a scene. We find that such approaches provide clear enhancement to the imagery when polarized objects are contained within the scene without the need for complex interpretation. We investigate these display strategies using both visible and infrared data.

10407-14, Session 4

Engaging Montana high school students in optical sciences with a polarization photo contest

Martin J. Tauc, Montana State Univ. (United States); Jim Boger, Flathead Valley Community College (United States); Andrew Hohne, Laura M. Dahl, Paul W. Nugent, David W. Riesland, Benjamin Moon, Carol L. Baumbauer, Orrin Boese, Joseph A. Shaw, Wataru Nakagawa, Montana State Univ. (United States)

Getting students interested in science, specifically in optics and photonics, can be a significant challenge. We developed and implemented an outreach campaign which sought to engage high school students in the science of polarized light. The outreach was motivated and paid for by a NASA-sponsored project to investigate the use of nanostructure-based, polarization-selective bandpass filters for atmospheric science applications. Over the course of a few months, we traveled to Montana high schools and gave a presentation on the polarization of light. The presentation covered the physics of light, the ways that it becomes polarized, how polarization is useful, and how to take pictures with linear polarizers to see polarization. Students were given polarizers and instructions to take pictures that show polarization in either a natural setting or a contrived scene. Each participant submitted his or her entry - a photo along with an explanation of how polarization was involved - for evaluation by a panel of judges. A good photograph illustrated polarization in a well composed and interesting manner. The paragraph-long writing component was judged on how the photo was taken, the scientific explanation of how polarization was present, and why it was interesting. The contest was open to all high school students in the state. We visited 13 high schools, and presented live to approximately 450 students. A video version of the presentation and other resources for the contest were also made available online through the Montana Space Grant Consortium website.

10407-16, Session 5

Polarization-selective infrared bandpass filter based on a two-layer subwavelength metallic grating

Andrew Hohne, Benjamin Moon, Carol L. Baumbauer, Tristan Gray, James Dilts, Joseph A. Shaw, David L. Dickensheets, Wataru Nakagawa, Montana State Univ. (United States)

We present the design, fabrication, and optical characterization of a polarization-selective infrared bandpass filter based on a two-layer subwavelength metallic grating for use in cloud polarimetric imaging. Gold nanowires were deposited via physical vapor deposition (PVD) onto a silicon surface-relief grating that was fabricated using electron beam lithography. Optical characterization with a broad-spectrum tungsten halogen light source and a grating spectrometer showed normalized peak TM transmission of 53% with a full-width half-maximum (FWHM) of 122 nm, which was consistent with rigorous coupled-wave analysis (RCWA) simulations. The peak TM transmission wavelength was shifted by as much as 200 nm by changing the period of the grating by less than 100 nm. This device was designed to operate at a wavelength of 1.55-μm, but by altering only the lithography step, multiple gratings sensitive to different wavelengths can be created on the same substrate. Simulation results suggested that device operation relies on suppression of the TM transmission caused by surface plasmon polariton (SPP) excitation at the gold-silicon interface and an increase in TM transmission caused by a Fabry-Perot (FP) resonance in the cavity between the gratings. TE rejection occurs at the initial air-gold interface. We also present simulation results of an improved design based on a two-dielectric grating where two different SPP resonances allowed us to improve the shape of the passband by suppressing the side lobes. This newer design resulted in improved side-band performance, increased peak TM transmission, and a more reliably fabricated device.

10407-17, Session 5

Achromatic and chromatic liquid crystal polymer films at near-infrared wavelengths

Nathaniel Z. Warriner, Michael J. Escuti, Shuojia Shi, Kathryn J. Hornburg, North Carolina State Univ. (United States)

Certain wavelengths bands, especially Y, J, H, and K, have become the main measurement pathway for many of the world's largest telescopes. Additionally, the study of stellar light within of near-infrared (NIR) bands has become the staple in the field of direct imaging. Because of this, there is a growing necessity for customized broadband optics in the near infrared to meet the needs of the astronomers and allow for more precise measurements. We report on complex birefringent films developed for NIR operation, useful to implement wave-plates, vector apodizing phase plates, and polarization gratings. The combination of multi-twist retarders (MTRs) with both direct-write laser scanning or holographic lithography, and allows us to fabricate arbitrary phase patterns via a geometric phase effect and achromatic, super-achromatic, and highly chromatic (dual-band) spectra from 0.5 to 5 microns. MTRs are complex birefringent films with an optic axis variation along 1D/2D/3D. They consist of two or more chiral liquid crystal (LC) layers on a single substrate and with a single photo-alignment layer. Importantly, subsequent LC layers are aligned directly by prior layers, allowing simple fabrication, achieving automatic layer registration, and resulting in a monolithic film with a continuously varying optic axis. MTRs can be used for a wide range of remote optical sensing, both earth- and space-based. Here, we will review our current and prior MTR films being used for NIR astronomical observation, and discuss the realistic opportunities and limitations ahead for improved precision and design-complexity for retardation and wavefront(phase).

10407-18, Session 5

Polarization conversion systems based on geometric-phase microlenses

Jihwan Kim, Michael W. Kudenov, Michael J. Escuti, North Carolina State Univ. (United States)

Many optical devices and systems require polarized light for operation. However, preferable light sources are unpolarized, including LED, CCFL, incandescent lamps, and natural light. While many polarizing elements, including sheet polarizers or various birefringent prisms, can convert unpolarized light into polarized, they are inherently lossy, since they operate by either absorbing the unwanted light or redirecting it in an unwanted direction, which leads to more than 50% loss of optical power. We report on a new polarization conversion system (PCS) based on geometric phase holograms (GPHs) and a patterned retarder (PR). The first GPH acts essentially as thin-film polarizing lens that can separate (i.e., converge/diverge) unpolarized light into two orthogonal circular polarizations with high efficiency. The PR is a birefringent optical element having two patterned regions, designed to alter the separated polarization states into a target output polarization. The second GPH located next to the PR homogenizes and recollimates the output light. A simple arrangement of these elements results in a thin, monolithic, and flat surface device, with the ability to convert unpolarized input into linearly polarized output across most of the visible bandwidth. We experimentally demonstrate GPH-PCS that manifests about 70% conversion efficiency for ±10 degrees input light divergence. Here, we describe the concept and characterize our first prototypes by evaluating conversion efficiency, correct polarization transmittance, and divergence/uniformity of the output light. We also discuss the realistic opportunities and limitations for this approach.

10407-19, Session 5

Fraunhofer line optical correlator for improvement of initial orbit determination

Brett A. Pantalone, Michael W. Kudenov, North Carolina State Univ. (United States)

The design of a Fraunhofer line optical correlator is detailed. The instrument described herein correlates a reflected solar spectrum against multiple Fraunhofer absorption lines to estimate the velocity of the reflecting body. By using a spatial light modulator (SLM) as a photomask for known solar absorption lines in the range of 512-552 nm, the ratio of Doppler shifted solar energy to the total received energy can be calculated. Although the reflected light from targets in high orbit is relatively weak, signal-to-noise ratio (SNR) is enhanced by the measurement of multiple Fraunhofer lines in a single snapshot image. Simulations indicate that prediction of orbital parameters is improved by incorporation of this velocity information, and in some cases the number of line-of-sight measurements can be reduced from three to two.

10407-40, Session 5

Adaptive display strategies for polarization data

J. Scott Tyo, UNSW Canberra (Australia); Bradley M. Ratliff, Univ. of Dayton Research Institute (United States); Andrey S. Alenin, Israel J. Vaughn, UNSW Canberra (Australia)

Display of polarization information has always been a challenge. Since the human vision system cannot directly perceive polarization, systems are forced to represent polarization information in a visual channel that is

normally used for something else: e.g. color, texture, or motion. A handful of strategies are widely used with polarization data, one of which is a mapping that places angle of polarization (AOP), degree of linear polarization (DoLP), and s0 into the color channels hue saturation and value. We recently presented an extension of that mapping that provides significant benefits in areas of a polarization scene that have high DoLP but low s0. The circumstance of high DoLP and low s0 is relatively common in both emissive and reflective polarimetry, so this problem can be important. Our new strategy uses the local spatial statistics of AOP as metric of confidence in the polarization measurement; regions of high AOP variability tend to imply noisy polarization measurements. In this poster presentation, we will demonstrate our new system with data from several different sensors, and we will compare its properties with other popular polarization rendering schemes.

10407-20, Session 6

A nine-channeled partial Mueller matrix polarimeter

Andrey S. Alenin, Israel J. Vaughn, J. Scott Tyo, UNSW Canberra (Australia)

We have recently introduced channeled-partial Mueller matrix polarimeters as a potential design for measuring a limited number of Mueller elements for remote sensing discrimination. Because the polarization information in such systems is modulated in space or spectrum, the corresponding carrier domain ends up sharing two different types of information, thus leading to a reduction of bandwidth for each. In this work, we concentrate on an efficient nine-channel/nine-reconstructables design, which reduces the noise power in the reconstructed measurements and limits the associated resolution loss by limiting the overall complexity of the system. Employing structured decomposition techniques allows us to produce a system description that provides an analytically deducible set of reconstructables that include m00, any two linear combinations of the elements within the diattenuation vector, any two linear combinations of the elements within the polarizance vector, as well as the linear combinations specified by the Kronecker product of the diattenuation and polarizance vectors. Finally, we optimize the available polarimeter parameters to align the nine reconstructables with the desirables derived from sample data. Though class separability is impacted, the ability to discriminate between different objects is maintained.

10407-21, Session 6

Hyperspectroscopic Mueller-matrix polarimeter based on channeled polarimetry

Kazuhiko Oka, Kodai Sayama, Hiroshi Michida, Hokkaido Univ. (Japan)

We describe the principle and the demonstrative experiment of a novel hyperspectroscopic Mueller-matrix polarimeter based on channeled polarimetry. The channeled polarimetry is a method for measuring polarimetric parameters using a cosinusoidally-modulated spectrum. We previously reported on a snapshot spectroscopic Mueller-matrix polarimeter based on channeled polarimetry. In this presentation, we describe its expansion for the hyperspectroscopic Mueller-matrix measurement. The developed method uses both spectrally and spatially modulated spectrum. A light from a polychromatic source first passes through a spectral polarization state modulator, consisting of a polarizer and two high-order retarders, and is then impinges upon a sample under measurement. The light emerging from the sample is fed into a polarization state analyzer using spatial carriers, including two Savart plates. The hyperspectral image obtained from the system is cosinusoidally modulated along both wavenumber- and space-axes, and the respective spatio-spectral frequency components carry the information of the sixteen Mueller-matrix elements of the sample. The Fourier analysis of the hyperspectral image allows us to demodulate the spatio-spectrally resolved Mueller matrix of the sample. This method has a feature that it requires neither mechanical nor active components for polarization modulation. For the experimental demonstration, two different types of experimental systems were assembled. The first system uses a pushbroom-type hyperspectrometer using a grating spectrometer with a two-dimensional CCD sensor, whereas the second system is based on the wavelength-scanning type hyperspectrometry using a wavelength-scanning laser. Both systems demonstrated the feasibility of the present principle in the visible region.

10407-22, Session 7

Remote sensing of atmospheric aerosols and clouds using the AirMSPI imaging polarimeter

Gerard van Harten, David J. Diner, Feng Xu, Brian E. Rheingans, Jet Propulsion Lab. (United States); Mick Tosca, The School of the Art Institute of Chicago (United States) and Jet Propulsion Lab. (United States); Felix C. Seidel, Jet Propulsion Lab. (United States)

Ambient particulate matter is a major global environmental risk factor, causing millions of premature deaths per year. In addition, the direct interaction of aerosols with sunlight, and the indirect effect through their impacts on cloud formation, contribute large uncertainties to the degree of warming expected in a future climate. The spatial heterogeneity of aerosols and short atmospheric lifetimes motivate the need for global observations of their amount and spatial distribution, their optical and microphysical properties (such as particle size distribution), and composition. Particle abundances, microphysical properties, and optical proxies for composition (such as the complex refractive index) are retrievable from multi-angle, multi-wavelength, radiometric and polarimetric observations of scattered sunlight. High spatial resolution enables observations of aerosol spatial gradients. A key technical challenge is high polarimetric accuracy (~0.005 in the degree of linear polarization) in a multispectral imager over a broad spectral range. JPL's Airborne Multiangle SpectroPolarimetric Imager (AirMSPI) instrument has demonstrated the capability of meeting this objective using a dual photoelastic-modulator-based measurement technique. The data processing pipeline, on-ground and in-flight polarimetric calibrations, and performance comparisons with the NASA Research Scanning Polarimeter (RSP) and the SRON Spectropolarimeter for Planetary EXploration (SPEX) will be discussed, along with example aerosol and cloud droplet size retrievals from recent airborne field campaigns. The AirMSPI modulated polarization technique is employed in JPL's future Multi-Angle Imager for Aerosols (MAIA) satellite instrument, currently in development. MAIA is scheduled for launch around 2020-2022 and will study the health effects of different aerosol components in major cities across the globe.

10407-23, Session 7

Cloud thermodynamic phase detection using an all-sky polarimeter

Laura M. Dahl, Martin J. Tauc, Joseph A. Shaw, Montana State Univ. (United States)

Clouds strongly influence weather and climate, as they shade the surface from direct sunlight, increase the greenhouse effect, and regulate surface precipitation, thereby contributing to a net warming or cooling effect on the Earth's radiation budget. Knowing the cloud thermodynamic phase, if the cloud is composed of ice crystals or liquid particles, can help in accurately simulating the cloudy atmosphere to better understand how clouds influence Earth's climate. Clouds containing liquid particles, such as cumulus clouds, are generally optically thick and tend to have a net cooling effect. Thin cirrus clouds on the other hand, have a net warming effect on the Earth's radiation budget. Knobelspiesse et al. (Atmos. Meas. Tech., 8, 1537–1554, 2015) showed that for zenith observations, the direction of linear polarization (the sign of the S1 Stokes parameter) can be used to detect cloud thermodynamic phase when observed with a ground-based passive polarimeter. A positive S1 value indicates a liquid cloud, while a negative S1 values indicates an ice cloud. In this paper, we show results from a ground-based, all-sky imaging Stokes polarimeter used to detect cloud thermodynamic phase by analyzing the sign of the measured S1 parameter. We used our all-sky polarimeter, operating in 10 nm band wavelengths at 450 nm, 530 nm, and 780 nm, to detect liquid, ice, and mixed layered clouds. The thermodynamic phase was independently verified with a dual-polarization lidar.

10407-24, Session 7

Polarimetric time-lapse imaging of aurorae with DSLR color cameras

Frans Snik, Michael J Wilby, Louis Martin, Felix C. M. Bettonvil, Leiden Observatory (Netherlands); Michiel Rodenhuis, Ramón Navarro, Netherlands Research School for Astronomy (Netherlands); Hervé Lamy, Belgian Institute for Space Aeronomy (Belgium)

We present the design and first results from a polarimetric instrument for time-lapse imaging of the aurora. The auroral red line is polarized because of the anisotropic electron flux that bombards the upper atmosphere during a geomagnetic storm, and can therefore be used to study the local effects of such a storm. The aurora consists of three main spectral features: the green and red lines (due to atomic oxygen), and the blue band (due to molecular nitrogen). Regular color cameras with RGB filters can therefore constrain the spectral content of the auroral signal. We have constructed a polarimeter from two synchronized Canon 6D cameras with regular polarization filters in front of the identical objective lenses to deliver the first two Stokes parameters. We use the background stars to map pairs of frames onto each other, and bin down to reduce the effects of pixel gain variations to the polarimetric sensitivity. We have performed auroral observations at Skibotn Observatory (Norway) in March 2016, and detect a clear polarization signal for the red line at a level of ~2%, perpendicular to the magnetic field lines. This low-cost set-up therefore provides the first imaging polarimetry of aurorae, and can easily be upgraded to furnish tomographic measurements from several locations.

10407-25, Session 8

The hand-hold polarization-sensitive spectral domain optical coherence and its applications

Hao Liu, Nanjing Univ. of Science and Technology (China)

The advantages of polarization-sensitive spectral domain optical coherence tomography (PSOCT) include that PSOCT is able to measure the polarization properties of samples, such as phase-retardation, diattenuation, depolarization, and optical axis orientation. In contrast to conventional OCT, PSOCT provide a convenient method to distinguish the differences between the diseased area and normal area in tissues with additional contrast in images. Conventionally, the sample arm of PSOCT is fixed on the stage where biomedical tissues or models is placed, and the OCT images is acquired by scanning with galvanomer-based mirrors. While this method provides accurate imaging quality, the clinical experiments are limited by stationary of sample arm. To be applied in the practical diagnosis, a promising way is to design a hand-hold device. To this end, it is required that probe is assembled with a small volume to allow for comprehensively imaging large tissues areas at a microscopic scale, and is available to move on different samples to be acquired quickly with negligible motion artifacts. Meanwhile, the probe should be manufactured wih well stability to avoid system jitter error while it is used to detect the biological tissues in vivo. In this work, a design of a hand-hold fiber-based PSOCT is described, the parameters that influence the performance of the system are considered. The images of several examples are presented to demonstrate the capability of the system.

10407-26, Session 9

Polarimetric LIDAR with FRI sampling for target characterization

Erandi Wijerathna, Charles D. Creusere, David G. Voelz, New Mexico State Univ. (United States); Juan Castorena, Ford Motor Co. (United States)

Polarimetric LIDAR is a significant tool for current remote sensing applications. Extensive developmental and field studies have been conducted with polarimetric LIDARs such as MAPL (Multiple-wavelength Airborne Polarimetric LIDAR) for target identification and characterization in agriculture and vegetation settings. The conventional Nyquist sampling used in most implementations, however, requires vast data collection and storage to achieve satisfactory depth and spatial resolutions. To address this problem, we previously introduced an FRI (Finite Rate of Innovations) model for application to third generation full-waveform (FW) LIDAR systems. The concept is to detect time resolved 1D signals produced by laser pulses reflecting from the intercepted targets and use the FRI approach to effectively sample and record the signals at sub-Nyquist rates. We have demonstrated that laboratory targets within the beam footprint can be identified and ranged with high accuracy (i.e. sub spot-size target localization). Here, we describe the latest results with the FRI approach and extend the capability of the laboratory system to characterize targets with differing polarization signatures. Targets with different retardance characteristics are illuminated by a linearly polarized laser beam and the return pulse intensities are observed with a 3-channel, time division, polarimetric setup. The return signals are resolved using the FRI model analysis and Stokes vectors are constructed. The Stokes vectors are then used to identify the retardance properties of the targets within limitations. Hence, the proposed FRI based LIDAR approach can be used to achieve sub laser spot size target localization and to resolve target characteristics within the spot.

10407-27, Session 9

Active infrared polarimetric imaging demonstrator by orthogonality breaking sensing

Francois Parnet, Julien Fade, Institut de Physique de Rennes (France); Noé Ortega-Quijano, Deneb Medical, S.L. (Spain); Ludovic Frein, Goulc'hen Loas, Mehdi Alouini, Institut de Physique de Rennes (France)

Polarimetric imaging systems are likely to reveal contrasts that are not visible on classical intensity images. This ability is especially important in target detection applications where manufactured objects are hidden in a surrounding natural environment. Since their polarization behavior differs strongly from the background, polarimetry may enhance their visibility and improve detection performances. Standard active techniques are mainly based on a fixed polarization state at the illumination and several polarization orientations at the analysis by performing either sequential (division of time techniques) or simultaneous acquisitions (division of amplitude, division of focal plane techniques). We have developed an alternative approach to probe polarization effects, which revisits the standard way of performing polarimetric images.

We report the design of a free-space active infrared polarimetric imaging demonstrator based on the orthogonality breaking technique. With this non-conventional approach, a scene is enlightened by raster scanning with a specific Dual-Frequency Dual-Polarization beam, obtained from a fibered source developed at 1.55 μm. The light backscattered and detected on an avalanche photodiode in a confocal configuration produces an intensity signal comprises a continuous part and a modulated part (beatnote at the frequency difference between the two optical frequencies) whose amplitude is directly linked to the polarization behavior of the targeted point on the scene. Finally, Raw images are built-up digitally on a computer and, polarimetric contrast maps are obtained on homemade scenes within limited acquisition time (~1s). Based on experimental test scenes, we

compare this technique with standard full-field approaches and discuss its benefits and drawbacks.

10407-28, Session 9

Polarization vector signatures for target identification

Diane Beamer, Ujitha A. Abeywickrema, Partha P. Banerjee, Univ. of Dayton (United States)

Objects distant enough to be unresolved images have been studied and manipulated in different ways to attempt to recognize the object based on various characteristics. Most of the effort to recognize objects from space or in space has focused on imaging and spectral analysis, and only a fraction of work has been performed using polarimetry for target identification. Yet in the work that has been performed, it has been demonstrated that polarization signatures do exist, and appear to carry more information and can more easily differentiate between unresolved objects. In recent work, it has been demonstrated that polarization signatures are more distinctive than intensity signatures alone. This work was based on using two of the four Stokes parameters, S0 and S1, to create a vector signature which could be obtained from recording polarization states of reflected sunlight. This work proposes to use full Stokes polarimetry to create vector spaces that can be associated with the object observed. A novel analysis is proposed based on astronomy's color-color technique of analyzing wavelength band intensity of reflected light from objects in space. The proposed vector-vector spaces will provide a method to analyze and statistically compare polarization signatures to a library of objects so that target recognition can be obtained. This work will be based on experimental observations of near field objects to demonstrate the signature methodology.

10407-29, Session 9

Surface parameter based image estimation from application of a scattering model to polarized light measurements

Hanyu Zhan, New Mexico State Univ. (United States) and Research Institute of Highway, Ministry of Transport (China); Hanwan Jiang, New Mexico State Univ. (United States) and Research Institute of Highway, Ministry of Transportation (China); David G. Voelz, New Mexico State Univ. (United States); Zhan Li, Research Institute of Highway, Ministry of Transportation (China); Pengfei Li, Research Institute of Highway, Ministry of Transportation (China); Shoushan Cheng, Research Institute of Highway, Ministry of Transportation (China)

An importance task for remote sensing applications is the characterization of material properties, which can be accomplished by estimating physics-based parameters from optical scattering off a target's surface. In a recent paper, we present a theoretical development of a modified polarimetric bidirectional reflectance distribution function (pBRDF) incorporating both surface and diffuse scattering components.The model is applied to Stokes parameters measurements of scattered light for jointly estimating the complex refractive index (?), slope variance roughness (?2) and diffuse scattering coefficient (?d) of a surface. The parameter estimation results and synthetic Stokes parameters curves generated by the proposed pBRDF models shows close correspondence to the associated measurement values. In the work presented here, we describe a novel approach to estimate surface parameters and generate parameter-based images by extending the modified pBRDF model to the multispectral Stokes parameter-based imaging measurements collected with the University of Arizona's MultiangleSpectroPolarimetric Imager (MSPI). In particular, we analyze the measured Stokes parameters values as a function of time of day and wavelength. Values for ?, ?2 and ?d for each pixel are jointly estimated and statistics associated the estimated values are presented. Multispectral imagesconsisting of the parameter values are generated by using the relevant results for each pixel at different wavelengths and optimized by contrast-ratio enhancement algorithms. The approach offers significant potential for remote targets analysis and novel imaging technology development.

10407-30, Session 10

High contrast observations of circumstellar disks with the Gemini Planet Imager's polarimetry mode *(Invited Paper)*

Maxwell A. Millar-Blanchaer, Jet Propulsion Lab. (United States); Marshall D. Perrin, Space Telescope Science Institute (United States); Bruce A. Macintosh, Stanford Univ. (United States); James R. Graham, Univ. of California, Berkeley (United States); Michael P. Fitzgerald, Univ. of California, Los Angeles (United States); Paul R. Kalas, Univ. of California, Berkeley (United States); Jeffrey K. Chilcote, Dunlap Institute for Astronomy & Astrophysics (Canada); Jason J. Wang, Univ. of California, Berkeley (United States); Li-Wei Hung, Univ. of California, Los Angeles (United States); Sloane J. Wiktorowicz, The Aerospace Corp. (United States); Sebastian Bruzzone, Western Univ. (Canada)

The Gemini Planet Imager (GPI) is a near-infrared high-contrast imager on the 8-m Gemini South telescope, optimized for the direct detection and characterization of extrasolar Jovian-mass planets and circumstellar disks. The instrument includes a dual-channel polarimetry mode designed to image the inherently polarized light scattered off faint debris disks and protoplanetary disks. In the three and half years that it has been operational, GPI has imaged over two dozen circumstellar disks — detecting some for the first time in scattered-light — and carried out polarimetric measurements of brown dwarfs and exoplanets. These observations have let us study the locations and conditions in which exoplanets form in protoplanetary disks, increased our understanding of the composition of extrasolar debris disks, and allowed for the characterization of disk-planet interactions. Here, we review the design, implementation and performance of GPI's polarimetry mode, and highlight a selection of significant scientific results it has enabled.

10407-31, Session 10

Visible, near infrared spectropolarimeter for characterization of the DKIST optical system and polarization properties

Stacey R. Sueoka, David M. Harrington, National Solar Observatory (United States)

We have developed a laboratory spectropolarimeter built to characterize the transmissive and reflective polarization properties of the Daniel K. Inouye Solar Telescope (DKIST) optical components. This includes the full Mueller matrix of retarders, polarizers, mirrors, dichroic coatings, and other optical elements that introduce polarization effects. Characterization is performed at various angles of incidence from 400nm to 1650nm with ~9nm spectral resolution and statistical noise limits >5000 using many automated stages. With this data set, we present tolerance analysis of typical as-built DKIST optics.

10407-32, Session 11

Controlling the spatial coherence and polarization of a quasi-homogeneous, planar electromagnetic source for remote sensing applications

Oscar G. Rodríguez-Herrera, Univ. Nacional Autónoma de México (Mexico)

We present the design and characterization of a quasi-homogeneous, planar electromagnetic source to produce beam-like optical fields with controllable spatial coherence and polarization properties. Dynamic control of the second-order correlation properties of an optical beam is achieved by controlling the spectral density and polarization state distributions at the source plane, as described by the generalized van Cittert-Zernike theorem for the cross-spectral density matrix of a quasi-homogeneous, planar electromagnetic source.

In the proposed design, the spectral density distributions of orthogonal linear polarization components at the quasi-homogeneous source are controlled using a spatial light modulator. The beam generated in this way propagates to the far-field region yielding the desired spatial coherence and polarization state distributions. With this source we can generate an optical beam that is unpolarized in the usual one-point polarization sense, but polarized in the two-point mutual polarization sense. That is, the beam has a polarization distribution where two orthogonal linear polarization components at two points, within the aperture of the beam, separated by a set vector, given by the spectral density distribution at the source, are fully correlated. A beam with that polarization distribution may be used to perform the measurements required by variable coherence polarimetry, which can be applied to estimate the polarimetric bidirectional reflectance distribution function from monostatic measurements, with promising applications in remote sensing.

10407-33, Session 11

Statistics of partially-polarized fields: Beyond the Stokes vector and coherence matrix

Mikhail I. Charnotskii, Consultant (United States)

Traditionally, the partially-polarized light is characterized by the four Stokes parameters. Equivalent description is also provided by correlation tensor of the optical field. These statistics specify only the second moments of the complex amplitudes of the narrow-band two-dimensional electric field of the optical wave. Electric field vector of the random quasi monochromatic wave is a nonstationary oscillating two-dimensional real random variable. We introduce a novel statistical description of these partially polarized waves: the Period-Averaged Probability Density Function (PA-PDF) of the field. PA-PDF contains more information on the polarization state of the field than the Stokes vector. In particular, in addition to the conventional distinction between the polarized and depolarized components of the field PA-PDF allows to separate the coherent and fluctuating components of the field. We present several model examples of the fields with identical Stokes vectors and very distinct shapes of PA-PDF. In the simplest case of the nonstationary, oscillating normal 2-D probability distribution of the real electrical field and stationary 4-D probability distribution of the complex amplitudes, the newly-introduced PA-PDF is determined by 13 parameters that include the first moments and covariance matrix of the quadrature components of the oscillating vector field. PA-PDF can be measured by simultaneous heterodyne detection of the optical field. It provides additional information about the polarization state of the wave that is hidden from the classic Stokes vector description. Potential application of this theoretical development include terrestrial and atmospheric remote sensing, environmental monitoring, radar meteorology, biomedical optics particle characterization and astrophysics.

10407-34, Session 12

Estimating the relative water content of leaves in a cotton canopy

Vern C. Vanderbilt, NASA Ames Research Ctr. (United States); Craig S. T. Daughtry, U.S. Dept. of Agriculture (United States); Meredith K. Kupinski, Christine L. Bradley, College of Optical Sciences, The Univ. of Arizona (United States); Andrew N. French, Kevin Bronson, U.S. Arid-Land Agriculture Research Ctr. (United States); Russell A. Chipman, College of Optical Sciences, The Univ. of Arizona (United States); Robert P. Dahlgren, NASA Ames Research Ctr. (United States)

Remotely sensing plant canopy water status remains a long term goal of remote sensing research. Established approaches to estimating canopy water status — the Crop Water Stress Index, the Water Deficit Index and the Equivalent Water Thickness — involve measurements in the thermal or reflective infrared. Here we report plant water status estimates based upon analysis of polarized visible imagery of a cotton canopy measured by ground Multi-Spectral Polarization Imager (MSPI). Such estimators potentially provide access to the plant hydrological photochemistry that manifests scattering and absorption effects in the visible spectral region.

Twice during one day, +/- 3 hours from solar noon, we collected polarized imagery and relative water content data on a cotton test plot located at the Arid Land Agricultural Research Center, United States Department of Agriculture, Maricopa, AZ. The test plot, a small portion of a large cotton field, contained stressed plants ready for irrigation. The evening prior to data collection we irrigated several rows of plants within the test plot. Thus, ground MSPI imagery from both morning and afternoon included cotton plants with a range of water statuses.

Data analysis includes classifying the polarized imagery into sunlit reflecting, sunlit transmitting, shaded foliage and bare soil. We estimate the leaf surface reflection and interior reflection based upon the per pixel polarization and sun/view directions. We compare our cotton results with our prior polarization results for corn and soybean leaves measured in the lab and corn leaves measured in the field.

10407-35, Session 12

A high-sensitivity circular spectropolarimeter for remote sensing of homochirality in photosynthetic organisms

Lucas Patty, Vrije Univ. Amsterdam (Netherlands); Frans Snik, Luuk Visser, Leiden Observatory (Netherlands)

We describe the design and performance of a spectropolarimetric instrument, called TreePol, that is dedicated to remote sensing of the circular polarization signatures due to homochirality in photosynthetic organisms. To ensure high polarimetric sensitivity to observe such signatures, we combine rapid modulation offered by a Ferroelectic Liquid Crystal with a dual-beam spectrometer that incorporates fast line-detectors. The latter also furnishes relatively short measurement times through spectral multiplexing. We introduce several mitigation steps to correct for potential cross-talk from much stronger linear polarization signals into the measured circular polarization spectra. We present first laboratory results for (decaying) leaves and microbes, and we provide an outlook for field-work. In addition to providing a unique look into chiral photosystems of life on Earth, we aim to pave the way towards a unique detection method for extraterrestrial life.

10407-36, Session PWed

Passive millimeter-wave polarization characteristics of several common structures

Yayun Cheng, Fei Hu, Liangqi Gui, Huazhong Univ. of Science and Technology (China)

Passive millimeter-wave (PMMW) imaging has been widely adopted in security and military applications. Objects emit and reflect the MMW radiation just as they do in the visible and infrared regimes. Polarization is an important feature of electromagnetic waves and is affected by surface features, shapes, shading, materials, local curvature, and roughness. To obtain more information about the interested objects, polarimetric measurement is an important approach. In this paper, the polarization characteristics of several common structures (e.g., sphere, cone, and periodic surface) have been analyzed theoretically and the corresponding physical meanings have been revealed. The analyzed polarization feature parameters include Stokes vector, angle of polarization, degree of linear polarization, degree of polarization, linear polarization ratio and so on. The considered structure parameters include the radius of sphere, the radius and height of cone, and the curve function of periodic surface.

The ambient radiation can affect the polarization characteristics in PMMW imaging, which may be from sky, ground, water, building, mountain, or human. Different ambient radiations not only have different brightness temperatures, but also may have different polarization states. The indoor and outdoor simulations have been conducted to investigate the effect of ambient radiation. The relationship between polarization feature parameters and ambient polarization states are obtained.

The polarization characteristics discussed in this paper can provide some intrinsic mechanisms to acquire objects information (e.g., three-dimensional feature, contour, and material composition). In future work, we will further investigate the extraction methods of object information for several practical applications.

10407-37, Session PWed

Active polarization imaging system based on optical heterodyne balanced receiver

Qian Xu, Jianfeng Sun, Zhiyong Lu, Yu Zhou , Zhu Luan, Peipei Hou, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Active polarization imaging technology has recently become the hot research field all over the world, which has great potential application value in the military and civil area. By introducing active light source, the Mueller matrix of the target can be calculated according to the incident light and the emitted or reflected light. Compared with conventional direct detection technology, optical heterodyne detection technology have higher receiving sensitivities, which can obtain the whole amplitude, frequency and phase information of the signal light. In this paper, an active polarization imaging system will be designed. Based on optical heterodyne balanced receiver, the system can acquire the real part and imaginary part of reflected optical field simultaneously, which contain the polarization characteristic of the target. Besides, signal to noise ratio and imaging distance can be greatly improved.

10407-38, Session PWed

A partial Mueller matrix polarimeter using two photoelastic modulator and polarizer pairs

Nia Natasha Tipol, Utsunomiya Univ. (Japan); Shuichi Kawabata, Tokyo Polytechnic Univ. (Japan); Yukitoshi Otani, Utsunomiya Univ. (Japan)

A partial Mueller matrix polarimeter using two photoelastic modulators and polarizer pairs is introduced. Photoelastic modulators (PEMs) are commonly used in various kinds of polarization measurement techniques for many years. The advantage of instruments that works using PEMs is the high-sensitivity and high-speed measurement of polarization properties due to its light modulation by specific resonant frequency. A polarized light beam passing through the center of the fused quartz bar will experience a periodic phase retardation because of the photoelastic effect which is the basis operation of PEM. In the two PEM-polarizer pairs, Mueller matrix elements of a sample are determined based on the analysis of the frequencies of the time-dependent light beam. Each PEM is operated at different resonant frequencies of 50 kHz and 60 kHz and are oriented 45° apart. Mueller algebra is used to analyze the optical configuration of the proposed system. The changing variables inside the proposed system will be only the orientations of the azimuthal angle of polarizer and analyzer whereas orientations for both PEMs are fixed. The polarization information that are to be represented by Mueller matrix is distributed based on combinations of two resonant frequencies of operating PEMs. Polarization information such as total retardation can be retrieved instantaneously by using the partial Mueller matrix information based on the proposed polarimeter. Experimental results of a quarter wave plate and a variable linear retarder will be presented showing the characteristics of the implementation.

10407-39, Session PWed

System of Mueller-Jones matrix polarizing mapping of blood plasma films in breast pathology

Natalia I. Zabolotna, Kostiantyn O. Radchenko, Mykola H. Tarnovskiy, Vinnytsia National Technical Univ. (Ukraine)

With the latest laser polarimetry methods used for the diagnosis of optical-anisotropic objects, it's possible to obtain fundamentally new results on the structure and condition of facilities, including blood plasma.

The combined method of Jones-Mueller matrix mapping and blood plasma films analysis based on the system that proposed in this paper. Based on the obtained data about the structure and state of blood plasma samples the diagnostic conclusions can be made about the state of breast cancer patients (“normal” or “pathology”).

The proposed method of mapping of blood plasma films is to receive, in particular algorithm, the coordinate distributions of real and imaginary components of the Jones matrix and Mueller matrix elements.

Then, by using the statistic and correlation analysis obtain statistical and correlational moments for every coordinate distributions; these indicators are served as diagnostic criterias. The final step is to comparing results and choosing the most effective diagnostic indicators.

This method is implemented on the existing experimental automated multiparameter system of laser polarimetry. It consists of a semiconductor laser, quarter-wave plates, collimator optics, a polarizer and an analyzer, a micro lens, a research sample and a CCD camera connected to the computer.

It was developed the specialized software that allows to implement algorithms for system management, processing, analysis of the obtained distributions of blood plasma films parameters of anisotropy, and decision support for diagnosis of breast diseases.

The paper presents the results of Mueller-Jones matrix mapping of optically thin (?≤0.1) plasma layers.

On the basis of the obtained data was performed differentiation of samples to “norm-pathology” and were made conclusions regarding the availability of pathological changes in the breast of each patient.

10408-1, Session 1

Testing of a compact 10G Lasercomm system for maritime platforms *(Invited Paper)*

Juan C. Juarez, Katherine T. Souza, Dustin D. Nicholes, James L. Riggins II, Hala J. Tomey, Radha A. Venkat, Johns Hopkins Univ. Applied Physics Lab., LLC (United States)

Lasercomm systems have gained increasing interest for both defense an commercial applications due to their ability to provide secure, long-distance, high-bandwidth communications channels. This paper will present field test results for a reduced SWAP Lasercomm system developed for highly scintillated links such as terrestrial communications.

The link architecture utilizes a multilayered approach to ensuring robust data transport through long-distance, highly scintillated links while operating on mobile platforms. The reduced size terminal leverages a 2x2 simultaneous transmit and receive spatial diversity scheme to mitigate scintillation fades. A demonstrator system suitable for operation on mobile surface platforms is being developed for mobile land and maritime platforms. The optical terminal utilizes an inertially stabilized gimbal to host the optical payload and provide the geo-pointing function of the pointing, acquisition, and tracking system.

In addition, a 10-Gbps layer 2 retransmission system has been integrated with previously developed high-sensitivity, high dynamic range optical modems demonstrated during the DARPA FOENEX program. The retransmission system implements a Rateless Round Robin error control protocol that applies several key principles to address the demanding requirements of a FSO link. The methods involve always efficiently filling the link with unique data, performing positive acknowledgement on data segments received and providing edge buffering. The current hardware is designed to support a 10 GbE client interface with channel loads exceeding 9 Gbps.

10408-2, Session 1

Phase and amplitude modification of a laser beam by two deformable mirrors using conventional 4f image encryption techniques

Chensheng Wu, Jonathan Ko, John R. Rzasa, Christopher C Davis, Univ. of Maryland, College Park (United States)

The image encryption and decryption technique using lens components and random phase screens has attracted a great deal of research interest in the past few years. In general, the optical encryption technique can translate a positive image into an image with nearly a white speckle pattern that is impossible to decrypt. However, with the right keys as conjugated random phase screens, the white noise speckle pattern can be decoded into the original image. We find that the fundamental ideas in image encryption can be borrowed and applied to carry out beam corrections through turbulent channels. Based on our detailed analysis and laboratory experiments, we show that by using two deformable mirrors arranged in similar fashions as in the image encryption technique, a large number of controllable phase and amplitude distribution patterns can be generated from a collimated Gaussian beam. Such a result can be further coupled with wavefront sensing techniques to achieve laser beam correction against turbulence distortions. In application, our approach leads to a new type of phase conjugation mirror that could be beneficial for directed energy systems.

10408-3, Session 1

Design and flight test results of high speed optical bidirectional link between stratospheric platforms for aerospace applications

Simone Briatore, Rustam Akhtyamov, Skolkovo Institute of Science and Technology (Russian Federation); Alessandro Golkar, Skolkovo Institute of Science and Technology (Russian Federation)

As small and nanosatellites become increasingly relevant in the aerospace industry, the need of efficient, lightweight and cost-effective networking solutions drives the need for the development of lightweight and low cost networking and communication terminals.

In this paper we propose the design and prototype results of a hybrid optical and radio communication architecture developed to fit nanosatellites, tested through a proxy flight experiment on a stratospheric flight. This system takes advantage of the higher data-rate offered by optical communication channels while relying on the more mature and stable technology of conventional radio systems for link negotiation and low-speed data exchange.

Such architecture allows the user to overcome the licensing requirements and scarce availability of high data-rate radio frequency channels in the commonly used bands.

Outlined are the architecture, development and test of the mentioned terminal, with focus on the communication part and supporting technologies, including the navigation algorithm, the developed fail-safe approach, and the evolution of the pointing system.

The system has been built with commercial-off-the-shelf components and demonstrated on a stratospheric balloon launch campaign.

The paper outlines the results of the main flight demonstration, where the two platforms successfully established an optical link at stratospheric altitudes. The results are then analyzed and contextualized in plans of future work for nanosatellite implementations.

10408-5, Session 1

Overwater ultraviolet non-line-of-sight communication channel modeling and experiment verification

Tian Lang, Crystal Han, Juan Marquez, Gang Chen, Univ. of California, Riverside (United States)

In this study, the characteristics of overwater non-line-of-sight (NLOS) ultraviolet (UV) communication channel which include scattering and turbulence effect are modeled using Monte Carlo multiple scattering simulation. In addition, experimental measurements of turbulence effect and path loss at distances of up to 500 meters are reported and analyzed where communication distance, transmitting angles, along with airborne humidity and temperature are taken into considerations as key parameters which affect the distribution of the receiving signals. These channel modeling and experimental results will be valuable for studying overwater NLOS UV communication performance.

10408-6, Session 2

Experimental evaluation and determination of free space optical link at 532nm wavelength under rain conditions and comparison with the link performance at 850nm wavelength

Gaurav Soni, Amritsar College of Engineering and Technology (India)

Free Space Optics (FSO) communication is a demanding efficient wireless technology which have been accepted due to its low power and mass requirements, high data rates and unlicensed spectrum. Atmospheric disturbances have a significant impact on performance of FSO Link which causes to degrade the laser beam. The effect of rain on the visible light communication has taken two different cases of rain attenuation on the FSO link that depends on the rain drop sizes. in this proposed experimental research based on FSO experimental work transmitter is based on green laser and a LDR is used at the receiver side. The medium used is free space on which the rain is falling and across it attenuation that will produced that will be noticed and compared with the 850nm wavelength laser.The assumption is taken that the same change in current is produced at the case of 850nm wavelength laser.To determine the variation in current a multimeter is used at the receiver side. The calculation of the attenuation is based upon the attenuation formula on decibel scale.The attenuation calculation for the wavelength is taken on different-different exposed lengths and rain rates. In this paper, the analysis and investigation based on experimental set-up for a Free Space optical communication link at wavelength of 532nm and 850nm is being carried out to evaluate and further improvement in link performance is done by experimental arrangement. The FSO link in case of 532nm tolerate attenuation up to 66.12 dB/km at the loss of -0.04 dB and rain rate of 2.3592mm/min. whereas 850nm tolerate attenuation up to 17.5 dB/km at the loss of -0.01 dB and at the same rain rate as in 532nm. The experimental investigation is carried out by analyzing the receiver current, exposed length and rain rate conditions. It is concluded that the proposed FSO link of 532nm having more attenuation than 850nm wavelength and in the both the cases loss is assumed of -0.01 dB. There is a increase in attenuation when rain rate increases. The rain rate over the exposed lengths depends on the different-different rain drop sizes. So it can be say that visible wavelengths due to its low cost, low power consumption and easy detection is good for short range communication purposes than infrared wavelengths.

10408-7, Session 2

Performance analysis of stationary Hadamard matrix diffusers in free-space optical communication links

Derek J. Burrell, Christopher T. Middlebrook, Michigan Technological Univ. (United States)

Wireless communication systems that employ free-space optical links in place of radio/microwave technologies carry substantial benefits in terms of data throughput, network security and design efficiency. Along with these advantages comes the challenge of counteracting signal degradation caused by atmospheric turbulence in free-space environments. A fully coherent laser source experiences random phase delays along its traversing path in turbulent conditions forming a speckle pattern and lowering the received signal-to-noise ratio upon detection. Preliminary research has shown that receiver-side speckle contrast may be significantly reduced and signal-to-noise ratio increased accordingly through the use of a partially coherent light source. While dynamic diffusers and adaptive optics solutions have been proven effective, they also add expense and complexity to a system that relies on accessibility and robustness for successful implementation. The goal of the research being performed is to experimentally demonstrate and quantify improvement of signal-to-noise ratio for turbulence scenarios using a custom Hadamard diffractive matrix design to statically induce partial coherence in a transmitted beam. Atmospheric phase screens are generated using an open-source software package and subsequently loaded into a spatial light modulator using nematic liquid crystals to modulate the phase.

10408-8, Session 2

Simulating the performance of adaptive optics techniques on FSO communications through the atmosphere

Noelia Martínez, Luis Fernando Rodríguez-Ramos, Instituto de Astrofísica de Canarias (Spain)

The Optical Ground Station (OGS), installed in the Teide Observatory since 1995, was built as part of ESA efforts in the research field of satellite optical communications to test laser telecommunication terminals on board of satellites in Low Earth Orbit and Geostationary Orbit. As far as one side of the link is settled on the Earth, the laser beam (either in the uplink or in the downlink) has to bear with the atmospheric turbulence. Within the framework of designing an Adaptive Optics system to improve the performance of the Free-Space Optical Communications at the OGS, turbulence conditions regarding uplink and downlink have been simulated within Matlab as well as the possible utilization of a Laser Guide Star to measure the wavefront in this context and even to perform optical communications with it. Simulations have been carried out by reducing available atmospheric profiles regarding both night-time and day-time measurements and by having into account possible seasonal changes. An AO proposal to reduce atmospheric aberrations and, therefore, ameliorate FSO links performance is presented and analysed in this paper.

10408-9, Session 2

Capacity and outage performance of multiple-input multiple-output free space optical system over double-Weibull atmospheric turbulence channel and weather conditions

Omar Hasan, Princess Sumaya Univ. for Technology (Jordan)

We investigate ergodic capacity and outage probability performance of multiple-input multiple-output (MIMO) free space optical system operating over moderate to strong turbulence channel conditions. The MIMO optical system employees intensity modulation direct detection with on-off signaling (IMDD/OOK), with equal gain combining techniques at the receiver receiver. We derive novel closed form expressions for two system metrics; ergodic capacity, probability of outage. Expressions derived here are based on the Double-Weibull channel model, which is based on scintillation theory that assumes that the irradiance of the received optical wave is modeled as the product of small-scale and large scale turbulence eddies. In addition, the Double-Weibull stochastic is modeled as the product of two Weibull random variables. The results for the two system metrics performance are evaluated for plane wave transmission and displayed for different values of received signal-to-noise ratios, moderate to strong turbulence conditions, several values of transmit / receive diversity and different weather conditions.

10408-10, Session 3

Atmospheric propagation of coherently and incoherently combined quantum cascade lasers *(Invited Paper)*

Robert J. Grasso, EOIR Technologies (United States)

Quantum Cascade Lasers represent one of the most significant advances in solid state lasers. Their ability to generate mid-IR through THz wavelengths

have found numerous applications in IR Countermeasures and Remote Sensing for defence, security, and commercial application. In many practical defence and security applications, to achieve the desired power levels many beams must be combined to form a single focused beam. This paper examines both coherent and incoherent beam combining of multi-kilowatt lasers and the effects imposed by atmospheric turbulence and atmospheric aerosols on the propagation of these combined beams. In this paper beam centroid wander and beam spread are analyzed and their contribution to eventual laser spot size to obtain the energy/power on target at range for varying turbulence values. In this analysis it is found that there is little difference between the energy/power delivered to a target whether coherently or incoherently combined beams. Additionally, it was found that there is a maximum intensity that can be propagated to a target that is independent of initial beam quality and size for km-type ranges in moderate turbulence.

10408-11, Session 3

A study on the effect of anisotropy on a propagating beam

Melissa Beason, Larry C. Andrews, Ronald L. Phillips, Townes Institute Science and Technology Experimentation Facility, Univ. of Central Florida (United States)

General anisotropy leads to different effects along the horizontal axis of a propagating beam than along the vertical axis. To better understand these effects, we developed theoretical models for mean intensity, spatial coherence radius, and covariance function of intensity. With different anisotropic conditions in each direction, these statistical quantities exhibit an elliptical shape in the plane of the receiver. Both weak and strong fluctuation regimes will be considered.

10408-12, Session 3

Beam control of the ultra-short laser pulse in turbid medium

Vladimir Markov, Anatoliy Khizhnyak, Advanced Systems & Technologies, Inc. (United States); Phillip Sprangle, Univ. of Maryland, College Park (United States)

An effective power delivery of the high energy ultra-short laser pulse (USLP) on a distant target through turbulent atmosphere requires adaptive control of the outgoing beam. Adaptive Optics allows compensation of integral perturbations of the USLP wavefront and on-target power delivery with the intensity distribution similar to that of a beacon. However, at its propagation through the range the wavefront of the USLP beam replicates scintillations incurred by the beacon-generated reference wave. This may results in early self-focusing and filamentation of the USLP beam. This presentation discusses possible solutions to this problem and methods to address issues critical for optimal beam propagation and focusing.

10408-13, Session 3

Analysis of the covariance function and aperture-averaged fluctuations of irradiance to calculate Cn2

Galen Cauble, David T. Wayne, SPAWAR Systems Ctr. Pacific (United States)

Deep fading of an optical communication system over long propagation paths can be reduced with a large aperture receiver. Aperture averaging reduces scintillation effects on an optical detector and increases signal to noise ratio. We report on the design and testing of a new instrument that simultaneously records the spatial intensity pattern at the entrance pupil of a telescope and the aperture-averaged temporal intensity fluctuations of a laser beam propagating through turbulence. A camera records the pupil plane turbulence images, while a photodetector records aperture averaged intensity fluctuations. Using weak turbulence theory we relate aperture averaged scintillation and the covariance function derived from the pupil plane imagery to BLS900 Cn2 values over a 500m path using two wavelengths, 1064nm and 633nm.

10408-14, Session 3

Optimization of wavefront-sensorless adaptive optics for horizontal laser beam propagation in a realistic turbulence environment

Max Segel, Esdras Anzuola, Szymon Gladysz, Karin U. Stein, Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany)

Unconventional wavefront sensing strategies are being developed to provide alternatives for measuring the wavefront deformation of a laser beam propagating through strong turbulence and/or along a horizontal-path. In this paper we present a modified wavefront-sensorless adaptive optical (AO) system, where the well-known stochastic parallel gradient descent (SPGD) approach is extended with a-priori knowledge of the spatial and temporal statistics related to atmospheric turbulence. Here, a modal implementation of the correction algorithm allows us to exploit the decreasing phase variance of high-order Zernike modes in a distorted wavefront, as well as the different temporal characteristics of each mode. We also propose an implementation of a modal decomposition based on Karhunen-Loève polynomials instead of the common Zernike polynomials. The performance evaluation of this modified wavefront-sensorless AO system is carried out in a realistic turbulence environment and the results are compared against traditional SPGD algorithms.

10408-15, Session 4

Cloud free optical link probabilities to satellites from multiple ground stations

Lindsey Willstatter, Taylor A. Page, Christopher I. Moore, Jake Griffiths, Linda M. Thomas, U.S. Naval Research Lab. (United States)

The availability of a cloud free line of sight (CFLOS) for a ground-space free space optical (FSO) link is strongly dependent on a satellite's orbit and cloud cover spatial and temporal statistics. A diverse network of multiple ground stations at locations with minimal and uncorrelated cloud cover can be used to maximize the availability of a CFLOS to multiple satellite orbits. Historic cloud cover data for this availability study is extracted from the ERA-Interim database which is generated, updated, and maintained by the European Center for Medium-Range Weather Forecast (ECMWF). The database contains worldwide data in 6 hour time segments from 1970 to the present. For our analysis, cloud cover data, ground station locations, and satellite ephemerides are conjointly analyzed to determine ground-space link availabilities. The results of this analysis will be presented.

10408-16, Session 4

Modeling of ground based laser propagation to low earth orbit object for maneuver

Matthew M. Bold, Liam Smith, Lockheed Martin Space Systems Co. (United States)

The Space Environment Research Centre (SERC) endeavors to demonstrate the ability to maneuver high area to mass ratio objects using ground based

lasers. Lockheed Martin has been leading system performance modeling for this project that includes high power laser propagation through the atmosphere, target interactions and subsequent orbital maneuver of the object. This paper will describe the models used, model assumptions and performance estimates for laser maneuver demonstration and discuss how the end to end model has already impacted design considerations for the demonstration.

10408-46, Session 4

Atmospheric applications of intense ultrashort-pulse lasers

Pavel Polynkin, College of Optical Sciences, The Univ. of Arizona (United States)

Ultrashort-pulse laser beams with multi-gigawatt peak power propagate in the air in the self-channeling regime leaving behind traces of dilute plasma. This propagation regime, termed laser filamentation, has several potential applications. This presentation discusses two of them. The first application is the so-called air lasing. The concept of air lasing is based on the utilization of the constituents of the air itself for the generation of standoff, impulsive laser action. While both forward-propagating and backward-propagating laser emissions can be generated, the backward-propagating emission is of the most practical significance, as it enables single-ended remote sensing schemes and guide stars. The paper will review recent results on air lasing from singly ionized nitrogen molecular ions N2+, pumped through femtosecond laser filamentation in air. So far, lasing has been demonstrated only in the forward direction and the mechanisms that enable population inversion have been controversial. The second potential applications of air plasma is for the guidance of electrical breakdown of air. The diluteness and sub-nanosecond lifetime of the plasma limits the extent of the guidance. I will discuss approaches that help alleviate these limitations.

10408-47, Session 4

Polarized photon transport through fog

Brett H. Hokr, U.S. Army Space and Missile Defense Command (United States); Jonathan Farmer, Eikon Research, Inc. (United States); Christopher M. Persons, IERUS Technologies, Inc. (United States); Robert Desilva, James H. Kirkland, Eikon Research, Inc. (United States); Greg A Finney, IERUS Technologies, Inc. (United States); Kirk A. Fuller, The Univ. of Alabama in Huntsville (United States)

Anyone who has driven through fog understands the detrimental effect scattering can have on your ability to see. When light interacts with a scattering center, in this case a fog droplet, it is scattered into a new direction, ultimately turning the world around you into a dull gray haze. In some fogs, visibility can be less than 100 meters. It would be possible to see through turbid media like fog if you can separate the scattered light from the unscattered, or ballistic, light; however, we must understand the light transport properties of the atmosphere to determine the optimum scheme. Here, we present an end-to-end simulation for polarized light transport through fog. Our approach can be summarized in three steps: compute the Mueller matrix for a single scattering interaction, ensemble average a distribution of sizes and shapes, and solve the light transport using a Monte Carlo simulation. For small spherical particles, such as fog, we use Mie theory to calculate the single scattering Mueller matrix, but this approach can be generalized to non-spherical particles using ray tracing for large particles or a T-matrix approach for smaller particles. Through this simulation, we are able to determine a backscattering Mueller matrix and a forward scattering Mueller matrix response function for the atmosphere as a function of position and detection angle.

10408-19, Session 5

Wavefront analysis of optical vortices propagating through terrestrial atmospheric turbulence *(Invited Paper)*

Jaime A. Anguita, Gustavo Funes, Univ. de los Andes (Chile)

Increasing the aggregate capacity of FSO systems by taking advantage of the available degrees of freedom of light, like orbital angular momentum (OAM), may contribute to cost-effective high-speed network access if the generation and detection of OAM is properly managed in turbulent propagation conditions. Although several theoretical schemes and laboratory demonstrations with OAM, there is still a wide technological gap to be covered to make these technologies available for terrestrial FSO links in the presence of turbulence, specifically due to broadening of beams and OAM crosstalk as they propagate in turbulent media.

We investigate the use of Laguerre-Gauss (LG) beams with the purpose of increasing the security and link distance of FSO communications. For such beams, alignment and phase structure are crucial to ensure adequate signal detection. Using numerical propagation models including atmospheric turbulence and realistic diffraction devices, we evaluate the distorted received field of LG beams under several propagation distances and turbulence strength to determine beam wander and OAM mode spreading using phase retrieval algorithms. We explore the effectiveness of beam shaping at the transmitter side to reduce scintillation at the receiver side to reduce the bit-error rate in a OAM-based communication system. Transmitter and receiver adaptive corrections are analyzed according to their complexity and effectiveness in reducing outage probability in a OOK and PPM-modulated link for several turbulence regimes and distances.

We also describe and demonstrate our 400m OAM propagation testbed and show the effects of turbulence on a wide range of OAM states, including OAM crosstalk and scintillation.

10408-20, Session 5

OAM of beam waves in random inhomogeneous medium

Mikhail I. Charnotskii, Consultant (United States)

For paraxial propagation of scalar waves classic electromagnetic theory definitions of transverse linear (TLM) and orbital angular (OAM) momenta of beam waves are simply related to the wave coherence function in the coherent. This allows the extension of the TLM and OAM density concepts to the case of partially coherent waves when phase is indeterminate. We show on several examples that there no direct connection between the intrinsic OAM and optical vorticity. Namely, neither the presence of the optical vortices is necessary for the intrinsic OAM, nor the presence of the optical vortices warrants the non-zero intrinsic OAM. We examine OAM for two classes of partially-coherent beam waves and show that Simon and Mukunda's Twisted Gaussian beam has an intrinsic OAM with per unit power value that can be continuously changed by varying the twist parameters. Using the parabolic propagation equation for the coherence function, we show that both total TLM and OAM are conserved for the free space propagation, but not for propagation in inhomogeneous medium in general. Under Markov Approximation (MA), in the presence of the random statistically homogeneous medium the total TLM and OAM are conserved in average. Based on the MA parabolic equation for the fourth-order coherence function, we examine for evolution of the total OAM variance. Perturbation solution of this equation shows that the OAM fluctuations in general grow approximately linearly with the propagation path length. However, this growth appears to be slower for the beams with rotation-symmetric irradiance.

10408-21, Session 5

Shack-Hartmann measurements of the transverse linear and orbital angular momenta after propagation through turbulence

Mikhail I. Charnotskii, Consultant (United States); Terry J. Brennan, Prime Plexus, LLC (United States)

Theory presented in the companion paper [M. Charnotskii, "OAM of beam waves in random inhomogeneous medium"] reveals that for paraxial propagation of scalar waves transverse linear momentum (TLM) and orbital angular momentum (OAM) of beam waves are simply related to the wave coherence function, and that the TLM and OAM densities can be measured by a conventional Shack-Hartman sensor, which is typically used for the phase measurements. Here we report the TLM and OAM measurements derived from the data obtained by the Hartman Turbulence Sensor (HTS) during the field measurement campaign in 2009-10 and data produced by wave optics simulation of the HTS. We estimate dependence of the mean TLM and OAM densities on the turbulent conditions on the propagation path. We calculate the variance and spatial and temporal covariances of the of the TLM and OAM fluctuations. We also examine the statistics of the total TLM and OAM intercepted by the wave front sensor aperture. We compare the OAM measurements to the optical vorticity data derived from the phase slopes estimates that the WFS routinely delivers, and attempt to estimate the vortex and asymmetry OAM components introduced by Bekshaev, Soskin and Vasnetsov [JOSA A 2003], and dependence of both components on the turbulent propagation conditions.

10408-22, Session 6

Image blurring due to turbulent wakes for airborne systems: Flight tests

Stanislav V. Gordeyev, Univ. of Notre Dame (United States); Yakov Diskin, Matthew R. Whiteley, MZA Associates Corp. (United States); Aaron Archibald, Air Force Institute of Technology (United States); Nicholas G. De Lucca, Eric J. Jumper, Univ. of Notre Dame (United States)

In addition to blurring effects caused by atmospheric turbulence, airborne imaging systems can also be negatively affected by turbulent flows formed by the aircraft. To study and eventually mitigate these effects, simultaneous measurements of the instantaneous wavefronts due to the turbulent flow, and the resulted blurred images were performed in-flight using Airborne Aero-Optics Laboratory (AAOL-T). It consists of two planes flying 50 meters apart to minimize the atmospheric aberrations. A divergent point laser source from one aircraft was transmitted to a second aircraft, where the laser beam was received by an optical turret, protruding from the aircraft. The turbulent wake, formed by the turret, imposed spatially-temporally-evolving optical distortions, which were measured by a wavefront sensor at the sampling rate of 25 kHz. A target board, derived from USAF1951, was placed around the divergent laser beam of the first aircraft. Images of the board, blurred by the turbulent wake, were recorded by a second high-speed camera at 500 fps. The laser radiation was filtered out before going to the imaging camera. Both cameras shared the same optical path to guarantee one-to-one relation between the wavefronts and the blurred images.

Series of flights were performed at altitudes between 15,000 and 29,000 ft at Mach numbers between 0.5 and 0.8. Relative position of both planes was varied to study wavefronts and resulted images by different regions of the turbulent wake. Statistics of wavefronts (OPDrms, spatial length etc) were computed. The relation between these quantities and MTF, extracted from images, is presented and discussed.

10408-23, Session 6

Image blurring due to turbulent wakes for airborne systems: Simulation and modeling

Yakov Diskin, David J. Goorskey, Matthew R. Whiteley, Richard Drye, MZA Associates Corp. (United States); Nicholas G. De Lucca, Stanislav V. Gordeyev, Univ. of Notre Dame (United States); Eric J. Jumper, MZA Associates Corp. (United States)

We present our findings from a modeling and simulation effort in which we analyzed the imaging performance of a turreted laser beam director/telescope on a transonic aircraft platform. We used real wavefront sensor (WFS) data collected by the Airborne Aero-Optics Laboratory (AAOL) test platform at Mach 0.8. Using these WFS data, we quantified the imaging point spread function (PSF) for a variety of line-of-sight (LOS) angles. The LOS angle values sweep from forward-looking angles imaging through the shock wave to backward-looking imaging through the turbulent wake. Our simulation results show Strehl ratios from 4% to 50% with substantial scattering of energy out to many time larger than the diffraction-limited core. For each LOS angle, we analyze the imaging modulation transfer function (MTF) which shows a rapid reduction of contrast for low-to-mid range spatial frequencies. We reaffirm that practical limits to usable spatial frequencies require higher imaging signal to noise ratio in the presence of aero-optical disturbances at high Mach number. The presented MTF analysis speaks to the degradation of image-contrast-based tracking algorithms that rely on illuminator laser propagating through aero-optical aberrations. In conclusion, we discuss the AAOL imaging flight test campaigns and the anticipated imaging performance of AAOL turret.

10408-24, Session 6

Motion deblurring of simulated light-field images

Shuo Wang, Jeremy P. Bos, Michigan Technological Univ. (United States)

We have developed a light field rendering model in PBRT [1] that allows us to generate a sampled four dimensional light field based on the two-plane parameterization popularized by Adelson and Wang [2]. From this data cube we can perform common post-processing tasks like perspective shifts and varying the focus and depth of field. We are able to simulate motion blur by shifting the camera perspective linearly and averaging over the dataset. Dansereu [3] has demonstrated a technique for motion deblurring of light field images using simple image sets featuring Lambertian sources. In this work, we explore the interplay between spatial and angular sampling. Also, we explore the possibility of extending the idea of motion deblurring to the case where a static scene is imaged through a turbulence volume.

10408-25, Session 7

Atmospheric characterization on the Kennedy Space Center Shuttle Landing Facility

Jonathan Ko, Univ. of Maryland, College Park (United States); Joseph T. Coffaro, Univ. of Central Florida (United States); Chensheng Wu, Christopher C. Davis, Univ. of Maryland, College Park (United States)

Large temperature gradients are a known source of strong atmospheric turbulence conditions. Often times these areas of strong turbulence conditions are also accompanied by conditions that make it difficult to conduct long term optical atmospheric tests. The Shuttle Landing Facility (SLF) at the Kennedy Space Center (KSC) provides a prime testing environment that is capable of generating strong atmospheric turbulence yet is also easily accessible for well instrumented testing. The Shuttle Landing Facility features a 3 mile long and 300 foot wide concrete runway that provides ample space for measurements of atmospheric turbulence as well as the opportunity for large temperature gradients to form as the sun heats the surface. We present the results of our large aperture LED scintillometer and a thermal probe RTD system that were used to calculate a path averaged and a point calculation of Cn2. In addition, we present the results of our Plenoptic Sensor that was used to measure wavefront distortions as well as to calculate a path averaged Cn2 value. These measurements were conducted over a multi-day continuous test with supporting atmospheric and weather data from the University of Central Florida.

10408-26, Session 7

A machine learning approach for predicting atmospheric aerosol size distributions

Joshua J. Rudiger, Kevin Book, SPAWAR Systems Ctr. Pacific (United States); Brooke Baker, SPAWAR Systems Ctr. Atlantic (United States); John S. deGrassie, Stephen Hammel, SPAWAR Systems Ctr. Pacific (United States)

An accurate model and parameterization of aerosol concentration is needed to predict the performance of electro-optical imaging systems. Current models have been shown to vary widely in their ability to accurately predict aerosol size distributions and subsequent scattering properties of the atmosphere. One of the more prevalent methods for modeling particle size spectra consists of fitting a modified gamma function to measurement data, however this limits the distribution to a single mode. Machine learning models have been shown to predict complex multimodal aerosol particle size spectra. Here we establish an empirical model for predicting aerosol size spectra using machine learning techniques. This is accomplished through careful measurements of aerosols in controlled laboratory environments and measuring aerosol particle size distributions in outdoor, littoral environments. The machine learning based model is shown to extend the functionality of Advanced Navy Aerosol Model (ANAM), developed to model the size distribution of aerosols in the maritime environment.

10408-27, Session 7

Climatological assessment of maritime atmospheric profiles: model-based and LIDAR-based approaches

Kevin M. McBryde, SPAWAR Systems Ctr. Pacific (United States)

Local meteorological conditions drive variability of vertical extinction profiles over both short and long timescales. Wind speed and relative humidity, in particular, are associated with production modes for maritime aerosols. Climatological variability of profiles are modeled based upon surface layer historical measurements of meteorological parameters. We have generated a database of profiles using the SPAWAR ClimoCube methodology. This distinct methodology is discussed, and model-based climatological vertical extinction profiles are compared with a new, separate, database of profiles from the CALIPSO satellite LIDAR experiment. We analyze similarities and discrepancies between the two databases.

10408-28, Session 7

Variability of refractive index structure parameter and aerosols in the marine atmospheric boundary layer

Qing Wang, Naval Postgraduate School (United States); Denny P. Alappattu, Moss Landing Marine Labs. (United States); Benjamin J. Wauer, Ryan T. Yamguchi, Naval Postgraduate School (United States); John A. Kalogiros, National Observatory of Athens (Greece); Haflidi Jonsson, Naval Postgraduate School (United States)

Electro-optical (EO) and infrared (IR) signals propagating through the atmosphere exhibit intensity fluctuations caused by atmospheric turbulence, a phenomenon known as scintillation. Scintillation is directly related to the refractive index structure parameter Cn2 defined as the refractive index structure function scaled to for the turbulence inertial subrange. Quantifying Cn2 is essential to evaluate and predict scintillation effects on EO/IR systems. Meanwhile, aerosols in the lower atmosphere absorb and scatter EO/IR energy, resulting in attenuation, aliasing, and blurring.

We will present initial results on Cn2 and aerosol variability in the coastal zone using simultaneous measurements from a Twin Otter research aircraft, two instrumented ocean vessels [R/V John Martin and a rigid hull inflatable boat (RHIB)] , and a coastal land site. All measurements were taken as part of the Coastal Electro-Optical PropagaTion eXperiment (CEOPTeX) conducted in April/May 2016 offshore of Moss Landing, CA. Aerosol concentration, scattering, and absorption were obtained from the research aircraft in the atmospheric boundary layer. Cn2 was derived from measurements of temperature and humidity sampled at 20 Hz from all platforms/site. Two level Cn2 measurements were also taken when the R/V John Martin and the RHIB were co-located. We will discuss the spatial/temporal variability of the measured quantities, and the difference between the Cn2 at the coastal region and those predicted by surface layer similarity theory and the measured bulk quantities.

10408-29, Session 8

Determination of accurate vertical atmospheric profiles of extinction and turbulence

Stephen Hammel, Eric Hallenborg, SPAWAR Systems Ctr. Pacific (United States); James R. Campbell, U.S. Naval Research Lab. (United States)

Our ability to generate an accurate vertical profile characterizing the atmosphere from surface to a point above the boundary layer top is quite rudimentary. The region from a land or sea surface to an altitude of 3000 meters is dynamic and particularly important to the performance of many active optical systems. In this paper we discuss efforts to measure both turbulence and extinction for this region of interest.

Measurement of these profiles in the field is a problem, and we will present a discussion of recent field test activity to address this issue. Our approach comprises measurement techniques and models, and we describe the instruments that provide data for a variety of models that in turn generate the vertical profiles of absorption, scattering, and turbulence. These three profiles are the core requirements for an accurate assessment of laser beam propagation.

10408-30, Session 8

Investigation of the height dependency of optical turbulence in the surface layer over False Bay (South Africa)

Detlev Sprung, Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany); Alexander M. J. van Eijk, TNO Defence, Security and Safety (Netherlands); Willem H. Gunter, Institute for Maritime Technology (South Africa); Derek J. Griffith, Council for Scientific and Industrial Research (South Africa); Christian Eisele, Erik Sucher, Karin U. Stein, Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany)

Atmospheric turbulence impacts on the propagation of electro-optical radiation. Typical manifestations of optical turbulence are scintillation (intensity fluctuations), beam wander and (for laser systems) reduction of beam quality. For longer propagation channels, it is important to characterize the vertical and horizontal distribution (inhomogeneity) of the optical turbulence. In the framework of the First European South African Transmission ExpeRiment (FESTER) optical turbulence was measured between June 2015 and February 2016 over a 2 km over-water link over False Bay. The link ran from the Institute of Maritime Technology (IMT) at Simons Town to the lighthouse at Roman Rock island. Three Boundary layer scintillometers (BLS900) allowed assessing the vertical distribution of optical turbulence at three different heights between 7 and 14 m above the water surface. The expected decrease with Cn2 with height is not always found. These results are analyzed in terms of the meteorological scenario, and a comparison is made with a fourth optical link providing optical turbulence data over a 8.7 km path from IMT to Kalk Bay, roughly 36° shifted to the three 2 km paths.

10408-31, Session 8

In-situ and path-averaged measurements of aerosol optical properties over False Bay (South Africa)

Sven A. van Binsbergen, TNO Defence, Security and Safety (Netherlands); Peter Grossmann, Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany); Faith J. February, Institute for Maritime Technology (South Africa); Leo H. Cohen, TNO Defence, Security and Safety (Netherlands); Alexander M. J. van Eijk, TNO Defence, Security and Safety (Netherlands) and Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany); Karin U. Stein, Fraunhofer-Institut für Optronik, Systemtechnik und Bildauswertung (Germany)

Atmospheric aerosols adversely affect the propagation of electro-optical radiation through scattering and absorption processes. Consequently, knowledge of the aerosol concentration and composition is required to predict the performance of electro-optical sensor systems in the operational theatre. A study is reported of aerosol properties over the False Bay area, near Cape Town in South Africa. Aerosol properties were measured by in-situ optical particle counters and a transmissometer, operating at 7 wavelengths between the visible and far-infrared, set up for a 7.8 km over-water path. The transmissometer receiver was collocated with the optical particle counters. The aerosol properties are discussed in terms of meteorological scenario (wind speed, wind direction, etc), and the path-averaged results are compared to the in-situ measurements.

10408-32, Session 8

Determination of the spectral behaviour of atmospheric soot using different particle models

Krzysztof Skorupski, Wroclaw Univ. of Science and Technology (Poland)

Soon after emission black carbon particles tend to connect to each other, what leads to the creation of complex geometries, namely aggregates. In the atmosphere, they interact with both organic and inorganic matter. In many studies such aggregates are modelled as monodisperse spheres positioned in point contact. Such a simplification might lead to many inaccuracies in light scattering simulations. The goal of this study was to compare the spectral behavior of different, commonly used soot particle models. The simplest one was a ball with two external layers (inorganic and organic). The most complex model was composed of a black carbon aggregate with inorganic particles attached to it. The geometry was covered by an external organic layer. In the study, the volume of each material was always the same, regardless of the model used. For light scattering simulations the ADDA algorithm was used. The incident wavelength varied from 400nm to 800nm and results were orientationally averaged. The ADDA settings were adapted from the work by Skorupski. The number of dipoles per wavelength was always larger than 250. The refractive index for black carbon was based on the work by Chang et al., for organic matter (organic acid) on the work by Myhre et al. and the refractive index for inorganic matter (sulfate) was adapted from the OPAC database. The results prove that the relative extinction cross section error, in some cases, can be even larger than 20%. Therefore, before starting excessive simulations, it is important to know what error is expected.

10408-33, Session 9

Saturation of anisoplanatic error in horizontal imaging scenarios

Jeffrey R. Beck, Jeremy P. Bos, Michigan Technological Univ. (United States)

Our approach extends work completed by Stone [1] and seeks to understand the performance of speckle imaging systems over fields of view much larger than the isoplanatic patch size [2] . One possibility is that the piston-removed anisoplanatic error saturates to a value much smaller than 1 when the aperture size is small. In [1] Stone shows that this is true for a 0.5m aperture using the HV5-7 model pointing at nadir when both tilt and piston are removed. There is good cause to believe that as D/r0 approaches unity the piston anisoplanatic error may saturate to values smaller than one. This work will start by evaluating Stone's expressions for anisoplanatic error over 1 km paths for values of D/r0 between 1 and 5. Results will be compared to those produced by phase screen models such as those used in [3].

Hybrid wavefront sensing and image correction algorithm for imaging through turbulent media

Chensheng Wu, John R. Rzasa, Jonathan Ko, Christopher C. Davis, Univ. of Maryland, College Park (United States)

It is well known that passive image correction of turbulence distortions often involves using geometric dependent deconvolution algorithms. On the other hand, active imaging techniques using adaptive optics corrections would use the distorted wavefront information for guidance. Our work shows that a hybrid hardware-software approach is possible to reveal accurate and high detail images through turbulent media. The processing algorithm also takes much fewer iteration steps in comparison with conventional image processing algorithms. In our proposed approach, a plenoptic sensor is used as a wavefront sensor to guide post-stage image correction on a high-definition zoomable camera. Reversely, we show that given the ground truth of the high detailed image and the plenoptic imaging result, we can generate an accurate prediction of the blurring image on a traditional zoomable camera. Similarly, the ground truth combined with the blurred image from the zoomable camera would provide the wavefront condition. In application, our hybrid approach can be used as an effective way to conduct object recognition in a turbulent environment where the target has been significantly distorted or is even unrecognizable.

10408-36, Session 9

Numerical simulation and analysis of aero-optical effect of the 3D side window

Yi Liu, Ming Liu, Yuejin Zhao, Liquan Dong, Lingqin Kong, Mei Hui, Xiaohua Liu, Beijing Institute of Technology (China)

When the flight with an optical window is flying in a high speed, the temperature and the refractive index of the air around it will be changed because of the friction, and this will make the image on the detector blurring and shifting, which will degrade the detecting precision greatly.

At present, research on 2D aerodynamics simulation and optical transmission has been relatively comprehensive, but the analysis of 3D environment remains imperfect, especially of a plane side window.

This paper chose a classic kind of side window model for the research. Ansys was used to simulate the discretionary temperature field around the dome and the window instead of the assumptive grid information by expressions. So the refractive index of the air around the flight could be worked out. On this basis, the offset and the blur of the image could be figured out using the ray tracing method. Considering of the huge amount of data, fixed step length tracing method and interpolation method were used in order to shorten the run time and guarantee computational precision at the same time instead of the adaptive variable step method and complicated mesh construction method. In this study, 3D simulation and programming results under different working conditions were discussed. The results clearly showed the relationship between the image quality and the flight speed, wavelength and incident angle of the entering ray. Wind tunnel experiment data indicates the validity of the analysis and proves the applicability of the method this paper used.

10408-4, Session PWed

Hemispherical optical dome for underwater communication

Ron Shiri, Patrick L. Coronado, Emily L. Lunde, NASA Goddard Space Flight Ctr. (United States)

The underwater wireless optical communication has a narrow field-of-view. In this work, we employ hemispherical optical domes fitted with spherical lenses to increase the field-of-view.

10408-37, Session PWed

Coherent optical communication detection device based on modified balanced optical phase-locked loop

Bo Zhang, Jianfeng Sun, Guangyu Cai, Mengmeng Xu, Guangyuan Li, Guo Zhang, Hongyu He, Chenzhe Lao, Zhiyong Lu, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China) and Key Lab. of Space Laser Communication and Detection Technology, Univ. of Chinese Academy of Sciences (China)

In the field of satellite communication, space laser communication technology is famous for its high communication rate, good confidentiality, small size, low power consumption and so on. The design of coherent optical communication detection device based on modified balanced optical phase-locked loop (OPLL) is presented in the paper. It combined by local oscillator beam, modulator, voltage controlled oscillator, signal beam, optical filter, 180 degree hybrid, balanced detector, loop filter and signal receiver. Local oscillator beam and voltage controlled oscillator trace the phase variation of signal beam simultaneously. That taking the advantage of voltage controlled oscillator which responses sensitively and tunable local oscillator laser source with large tuning range can trace the phase variation of signal beam rapidly and achieve phase locking. The demand of the phase deviation is very low, and the system is easy to adjust. When the transmitter transmits the binary phase shift keying (BPSK) signal, the receiver can demodulate the baseband signal quickly, which has important significance for the free space coherent laser communication.

10408-38, Session PWed

The integration of laser communication and ranging

Mengmeng Xu, Jianfeng sun, Bo Zhang, Guangyu cai, Guo Zhang, Guangyuan Li, Shanghai Institute of Optics and Fine Mechanics (China)

In the field of satellite communication, space laser communication technology is famous for its high communication rate, good confidentiality, small size, low power consumption and so on. Integration of laser communication and ranging is proposed , which can make the aircraft complete various tasks with the same load, so as to reduce the requirement of volume, power consumption, and improve the performance of thesystem. the ranging code which has the uniqueness, good auto-correlation and cross-correlation propertiesand the communication datas transport with with series tranmission by encoding, which can realize high speed two one-way laser communications.And making use of the ranging code good auto-correlation properties, in the receiver B, the received ranging code correlates with local ranging code to relize the coarse measurement. and utilizing the phase difference between recovery of local clock and receiving clock to achieve the precise measurement in one ranging chip.the we can get the timission time t1, similarly,we can get another timission time t2 in the sender A , so the distance between A and B is(t1+t2)*c/2 ,c is the speed of light. so in the whole precess,we can achieve high precision measurement without the high speed A/D conversion. Through the above mentioned?we can realize the integration of laser high speed communication and high precision ranging.

Integration of laser communication and ranging is proposed in this paper. we use the ranging code embed in thecommmunication data ,making the ranging code and the communication datas transport with with series tranmission by encoding, which can realize high speed two one-way laser communications.And making use of the ranging code good auto-correlation properties, at the receiver the received ranging code correlates with local ranging code to relize the coarse measurement , and utilizing the phase difference between recovery of local clock and receiving clock to achieve the precision of the distance .

10408-39, Session PWed

Radial partially coherent beams for free-space optical communications

Minghao Wang, Xiuhua Yuan, Huazhong Univ. of Science and Technology (China)

In this study, a special class of nonuniformly correlated partially coherent beams with radially symmetric coherence distributions, called radial partially coherent beams (RPCBs), is introduced. By spatially modulating a uniformly correlated phase screen used for generating conventional Gaussian Schell-model beams, RPCBs with arbitrary distributions of degree of coherence can be easily produced. RPCBs whose degree of coherence decreases from the beam center along the radial direction were found to self-focus in free-space propagation, leading to higher optical intensity near the beam center. Meanwhile, the scintillation mitigation ability of RPCBs remains significant. By means of wave optics simulation, free-space and atmospheric propagation properties of RPCBs with various coherence distributions and amplitude profiles are numerically analyzed. Simulation results show that, when there exists a flat-topped central fully coherent area, the RPCB will focus repeatedly during propagation, resulting into much higher on-axis intensity and smaller beam spread in the far field. Moreover, it is noticeable that the enhanced intensity can be achieved without compromise of scintillation reduction. Therefore, even though the multi-focusing effects may be slightly suppressed in atmospheric propagation, the RPCB can provide a substantial improvement for the SNR of an optical receiver with small aperture. The remarkable propagation properties as well as easy implementation of RPCB make it a valuable source option for free-space optical communications.

10408-40, Session PWed

A variable rate communicate method for self-differential coherent DPSK

Chenzhe Lao, Jianfeng Sun, Guangyu Cai, Guangyuan Li, Guo Zhang, Bo Zhang, Mengmeng Xu, Hongyu He, Shanghai Institute of Optics and Fine Mechanics (China)

In the satellite-to-ground laser communication, there are many adverse factors in the Atmospheric channel. At present, self-differential coherent DPSK is proved that could overcome atmospheric turbulence effects. Nevertheless, there is still the unsatisfactory detecting result when the atmospheric channel quality is extremely poor. In this case, full rate communication is not very easy to achieve. In this paper, a new method called digital coherence is presented, which superposes several same encoding to reduce the BER; that is to say, it reduces the communication rate to achieve higher quality. Compared to the general method, this method doesn't need to change the original communication rate, reduces the complexity of the system to a great extent. The theory of this method has been discussed that the SNR is increased by 3dB when the rate is reduced to half. An experimental setup was constructed to verify the proposed theoretical analysis. The offline process and results are presented.

10408-41, Session PWed

Optical axis stability system based on acousto-optic deflector

Peipei Hou, Jianfeng Sun, Yu Zhou, Qian Xu, Wei Lu, Zhiyong Lu, Zhu Luan, Lijuan Wang, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

An adaptive space optical coupling system for free-space optical communication is proposed in BPSK coherent laser communication link. Nutation principle is used. The position of the light spot relative to the center of the detector is determined by theory. The signal lights passing through acousto-optic frequency shifter and acousto-optic deflector are deflected by output control signal. The signal lights received by optical receiving system pass through acousto-optic deflector, and then coupled with local signal lights when they incident to 2 * 4 90 ° optical hybrid. The acousto-optic deflector is controlled by phase error signal, which is output from 2*4 90 ° optical hybrid. And high coupling efficiency for local signal light and free space light is obtained. The system has a strong ability to filter out the background light, and can achieve a relatively good space optical communication transmission channel.

10408-42, Session PWed

Fine track system of space coherent optical communication without position detector

Hongyu He, Jianfeng Sun, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Fine tracking technology is one of the key technologies in space optical communication systems based on coherent detection. Traditional fine tracking system use CCD as the position detector of signal light. In order to simplify the system and improve accuracy, we propose a fine tracking system without position detector and theoretically prove that the system is feasible. Meanwhile corresponding space optical communication system was built, experiment on tracking the signal light with random jitter was done.

10408-43, Session PWed

Condition for keeping polarization invariance on propagation in space-to-ground optical communication downlink

Jiajie Wu, Jing Ma, Liying Tan, Siyuan Yu, Harbin Institute of Technology (China)

Based on the extended Huygens–Fresnel principle, the expression of cross-spectral density matrix of a GSM laser beam at receiver plane in a space-to-ground optical communication downlink is obtained. According to the expression, the sufficient condition for Gaussian Schell-model (GSM) beam to keep the polarization properties unchanged in a space-to-ground optical communication downlink is derived analytically. The results indicate when three coherence lengths (?xx, ?yy and ?xy) are equal to each other, the GSM beam maintains the polarization properties on propagation. With full consideration of the source parameters and the zenith angle, both the DOP and SOP on propagation are investigated. The results of this work provide a design basis of the polarization shift keying optical communication system with GSM laser beam.

10408-44, Session PWed

Multiple wavelength spectral system simulating background light noise environment in satellite laser communications

Wei Lu, Jianfeng Sun, Peipei Hou, Qian Xu, Yueli Xi, Yu Zhou, Funan Zhu, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Performance of satellite laser communications between GEO and LEO satellites will be influenced by background light noise appeared in the field of view of optical terminals due to sunlight or planets and some comets. Such influences should be studied on the ground testing platform before the space application. In this paper, we introduce a simulator that can simulate the real case of background light noise in space environment during the data talking via laser beam between two lonely satellites. This simulator can not only simulate the effect of multiple wavelength spectrum, but also the effects of adjustable angles of field-of-view, large range of adjustable optical

power and adjustable deflection speeds of light noise in space environment. We integrate these functions into a device with small and compact size for easily mobile use. Software control function is also achieved via personal computer to adjust these functions arbitrarily.

10408-45, Session PWed

A survey of POAM in starlight

Stephen Grulke, Jeremy P. Bos, Michigan Technological Univ. (United States)

This work is an extension of the work done by Oesch and Sanchez [1-4] and relies on analysis of historical site monitoring data from the AFRL's Starfire Optical Range (SOR). Initial analysis of this data by Oesch and Sanchez provided preliminary evidence of POAM static across multiple observations. They hypothesize that this POAM is the result of nearby interstellar media. This work presents initial results of a large-scale survey of site monitoring data for evidence of residual POAM that may be attributable to the interstellar medium.

Applications of photon-number-resolving measurements for quantum interferometry and quantum state tomography *(Invited Paper)*

Olivier Pfister, Aye Win, Rajveer Nehra, Univ. of Virginia (United States); Sae-Woo Nam, Thomas Gerrits, National Institute of Standards and Technology (United States)

Photon-number-resolving measurements allow one to address quantum optics from the corpuscular angle of quantum physics. A number of classically non-intuitive features are typically expected from working in the photon-number Fock eigenbasis, such as nonpositive Wigner functions. In this talk, we report on the progress of two applications of photon-number-resolving measurements in quantum optics: quantum interferometry with photon-subtracted twin beams and quantum state tomography of Fock states created by heralded parametric downconversion.

10409-2, Session 1

Coincidence rates and permutation symmetry *(Invited Paper)*

Hubert de Guise, Lakehead Univ. (Canada); Barry C. Sanders, Univ. of Calgary (Canada) and Canadian Institute for Advanced Research (Canada)

We discuss the importance that photon permutation symmetry has on coincidence rates at interferometer outputs, how permutations naturally lead partition the many-photon space, and how permutation symmetry reveals the connection between partial distinguishability, matrix immanants and the complexity of the coincidence landscape.

10409-3, Session 1

Photon number statistics of entanglement generated by multiple single photon sources *(Invited Paper)*

Junyi Wu, Holger F. Hofmann, Hiroshima Univ. (Japan)

Multiphoton interference results in a wide variety of non-classical photon number statistics, including characteristic signatures of entanglement between two or more sets of optical modes. Here, we consider the photon number statistics observed after applying discrete Fourier transformations (DFTs) to bipartite entangled states generated using single photon sources and beam splitters. It is shown that the output photon number states of DFTs are eigenstates of a translational mode shifting operator in the input. The complex eigenvalues of the mode shift can be identified by a phase number k obtained from the output photon distribution. For each output distribution, the possible input states are limited to mode shift eigenstates with the same k-value. Using this mode shift rule, we can identify the quantum coherence between different photon number distributions in the input with experimentally observable k-values in the output of the DFT. In the case of multi-photon entanglement obtained by post-selection and beam splitting single photons, this coherence is non-local, resulting in correlated pairs of k-values that always sum up to zero. We can therefore observe both the correlations between the input photon number distributions and a complementary correlation between the output photon numbers of two DFTs to obtain a reliable characterization of the entanglement between the two multi-mode multi-photon systems. Importantly, the k-value allows a classification of large sets of possible photon number distributions, resulting in a significant simplification of the experimental evaluation of the multi-photon output statistics and opening up the road towards more efficient applications of non-classical multi-photon states.

10409-4, Session 1

Entanglement detection with single Hong-Ou-Mandel interferometry *(Invited Paper)*

Joonwoo Bae, Hanyang Univ. (Korea, Republic of); Leong-Chuan Kwek, Nanyang Technological Univ. (Singapore); Simone Felicetti, Lab. Matériaux et Phénomènes Quantiques (France); Chang Jian Kwong, Univ. of Darmstadt (Germany)

Entanglement is not only fundamental for understanding multipartite quantum systems but also generally useful for quantum information applications. Despite much effort devoted so far, little is known about minimal resources for detecting entanglement and also comparisons to tomography which reveals the full characterization. Here, we show that all entangled states can in general be detected in an experimental scheme that estimates the fidelity of two pure quantum states. An experimental proposal is presented with a single Hong-Ou-Mandel interferometry in which only two detectors are applied regardless of the dimensions or the number of modes of quantum systems. This shows measurement settings for entanglement detection are in general inequivalent to tomography: the number of detectors in quantum tomography increases with the dimensions and the modes whereas it is not the case in estimation of fidelity which detects entangled states.

10409-5, Session 1

Erasing the orbital angular momentum information of a photon

Isaac M. Nape, Bienvenu I. Ndagano, Melanie McLaren, Andrew Forbes, Univ. of the Witwatersrand (South Africa)

The traditional variations of quantum eraser use interferometric schemes (double slits or beams splitters) that rely on physical path interference to acquire and remove path information. For example when, orthogonal polarisations mark the independent paths, no interference pattern is observed. However, performing a complementary projection of the polarisation recovers the interference pattern due to the paths of the photon interfering. Interestingly, the expression of the entangled system after going through the marked slits shows an entanglement between the spatial degree of freedom (path) of one photon and the polarisation of its entangled twin. The entanglement of photons between their degrees of freedom is called hybrid entanglement.

Here we show that the orbital angular momentum (OAM) of photons is an alternative degree of freedom to explore besides path. We exploit the geometric phase of light using a locally birefringent material called the q-plate to generate hybrid entanglement from entangled photons prepared via spontaneous parametric down conversion. Using OAM to polarisation conversion in one of the entangled photons, hybrid entanglement is established between the polarisation and OAM of the entangled pair. Therefore the polarisation control of one photon determines the OAM information of its twin. Just as in Young's experiment, we show that the paths (OAM) marked with polarisation do not lead to interference. However, a complimentary projection of the polarisation causes the OAM (paths) to interfere, leading to the formation of azimuthal fringes whose frequency is proportional to the OAM content carried by the photon.

10409-6, Session 2

Optical hybrid quantum teleportation and its applications *(Invited Paper)*

Shuntaro Takeda, Masanori Okada, Akira Furusawa, The Univ. of Tokyo (Japan)

Quantum teleportation is the act of transferring unknown quantum information from a sender to a spatially distant receiver without transmitting the physical carrier of information itself. It is the essence of many sophisticated protocols for quantum communication and computation. Quantum teleportation has been experimentally realized both in discrete-variable (DV; such as qubits) and continuous-variable (CV) systems in quantum optics, but both approaches have pros and cons. DV teleportation transfers photonic qubits with high fidelity, albeit probabilistically and post-selectively. In contrast, CV teleportation deterministically transfers quadrature variables of electromagnetic fields, though the fidelity is relatively low due to the imperfection of CV entanglement.

Here we take a "hybrid" approach to overcome the current limitations: CV quantum teleportation of DVs. When the classical channel gain is optimally tuned, the CV teleporter acts as a pure loss channel, while dual-rail photonic qubits are robust against photon loss and hence can be reliably teleported even with imperfect CV entanglement. This approach enabled the first realization of deterministic quantum teleportation of photonic qubits without post-selection. We also applied the hybrid scheme to entanglement swapping, where DV two-mode entanglement was robustly transferred by means of CV quantum teleportation. To overcome the photon-loss error in the hybrid scheme, we are now working on CV teleportation of two-photon qutrits, a pair of which can form a quantum error correction code against photon loss. Our hybrid approach will stimulate the development of optical hybrid quantum information processing with the potential to enable high-fidelity, highly efficient universal quantum computation.

10409-7, Session 2

Quantum interference in topological photonic circuits

Jean-Luc Tambasco, RMIT Univ. (Australia); Giacomo Corrielli, Politecnico di Milano (Italy); Robert Chapman, RMIT Univ. (Australia); Andrea Crespi, Politecnico di Milano (Italy); Oded Zilberberg, ETH Zürich (Switzerland); Roberto Osellame, CNR-Istituto di Fotonica e Nanotecnologie (Italy); Alberto Peruzzo, RMIT Univ. (Australia)

Quantum technologies hold great promise for developing extremely powerful quantum computers and unattackable communication systems, and for achieving the ultimate precision measurements. The platforms used to manipulate quantum states typically suffer high loss and introduce noise, limiting their scalability and application. Topology introduces the idea of robust states known as edge-states and recently, topological states have been demonstrated in engineered photonic systems and used to effectively transport light. We report quantum interference of edge-states in an array of ten photonic waveguides with the coupling coefficients following the Aubry-André-Harper (AAH) model of topological edge states. High control over the circuit layout is achieved using femtosecond laser-written waveguides in glass. Two edge states, initially at either sides of the array, are adiabatically transferred to the centre where they interfere. After interfering, the states are returned to the outsides of the array, where they are protected again. By tuning the interference region to implement a 50:50 beamsplitter, we measure near unit visibility Hong-Ou-Mandel (HOM) photon bunching of the topological edge states. Our results demonstrate on-chip quantum state transfer and quantum interference of photonic topological states, providing a route to robust quantum information processing.

10409-8, Session 2

Towards the strong-coupling regime with a trapped ion coupled to a fiber cavity *(Invited Paper)*

Klemens Schüppert, Florian R. Ong, Pierre Jobez, Florian Kranzl, Konstantin Friebe, Dario A. Fioretto, Moonjoo Lee, Markus Teller, Univ. Innsbruck (Austria); Konstantin T. Ott, Jakob Reichel, Lab. Kastler Brossel (France); Rainer Blatt, Univ. Innsbruck (Austria) and Institut für Quantenoptik und Quanteninformation (Austria); Tracy E. Northup, Univ. Innsbruck (Austria)

Single atoms coupled to optical cavities can be used to build up quantum interfaces between stationary and flying qubits in a quantum network. These interfaces are compelling candidates for quantum repeaters, which would enable fiber-based quantum communication over long distances. By using fiber-based optical cavities, we expect to reach the strong coupling regime of cavity quantum electrodynamics with single trapped ions. Operating in this regime would enable protocols for quantum communication over long distances to be carried out with enhanced fidelity and efficiency.

The challenge in integrating fiber cavities with ion traps is that the dielectric fibers should be far enough from the ions so that they do not significantly alter the trap potential. On the other hand, larger cavity mode volumes reduce the coupling rate. Additionally, small deviations from the mirrors' ideal spherical shape introduce optical losses. Therefore, we have developed new CO_2-laser ablation techniques for improved fiber-mirror structures. With the resulting fibers, we have constructed optimized fiber cavities with finesses up to 70,000 at a length of 550 microns. To integrate these fiber cavities with ions, we have built a miniaturized calcium ion trap in the proven "Innsbruck" linear design. Both fibers are mounted on separate nanopositioners, enabling us to adjust the cavity length and optimize its alignment in vacuum. By developing procedures to control the charges trapped on the fibers' dielectric surfaces, we were able to couple an ion to cavities with lengths of about 500 microns and with finesses in excess of 30,000.

10409-9, Session 2

PPLN-waveguide-based polarization entangled QKD simulator

John Gariano, Ivan B. Djordjevic, The Univ. of Arizona (United States)

We have developed a comprehensive simulator to study the polarization entangled quantum key distribution (QKD) system, which takes various imperfections into account. We assume that a type-II SPDC source using a PPLN-based nonlinear optical waveguide is used to generate entangled photon pairs and implements the BB84 protocol, using two mutually unbiased basis with two orthogonal polarizations in each basis. The entangled photon pairs are then simulated to be transmitted to both parties; Alice and Bob, through the optical channel, imperfect optical elements and onto the imperfect detector. It is assumed that Eve has no control over the detectors, and can only gain information from the public channel and the intercept resend attack. The secure key rate (SKR) is calculated using an upper bound and by using actual code rates of LDPC codes implementable in FPGA hardware. After the verification of the simulation results, such as the pair generation rate and the number of error due to multiple pairs, for the ideal scenario, available in the literature, we then introduce various imperfections. Then, the results are compared to previously reported experimental results where a BBO nonlinear crystal is used, and the improvements in SKRs are determined for when a PPLN-waveguide is used instead.

10409-10, Session 2

Hamiltonian dynamics for entanglement distribution in quantum networks

Laszlo Gyongyosi, Budapest Univ. of Technology and Economics (Hungary) and Hungarian Academy of Sciences (Hungary); Sandor Imre, Budapest Univ. of Technology and Economics (Hungary)

Quantum entanglement is a necessity for future quantum communication networks, quantum internet, and long-distance quantum key distribution. The current approaches of entanglement distribution require high-delay entanglement transmission, entanglement swapping to extend the range of entanglement, high-cost entanglement purification, and long-lived quantum memories. We introduce a protocol for establishing entanglement in quantum communication networks. The proposed scheme does not require entanglement transmission between the nodes, high-cost entanglement swapping, entanglement purification, or long-lived quantum memories. The protocol reliably establishes a maximally entangled system between the remote nodes via dynamics generated by local Hamiltonians. The method eliminates the main drawbacks of current schemes allowing fast entanglement establishment with a minimized delay. Our solution provides a fundamental method for future long-distance quantum key distribution, quantum repeater networks, quantum internet, and quantum-networking protocols.

10409-11, Session 3

Discrimination of coherent-state phase-shift-keys with quantum non-demolition sequential measurements *(Invited Paper)*

Si-Hui Tan, Singapore Univ. of Technology & Design (Singapore)

Sequential decoding is a decoding procedure that uses a series of measurements to discern encoded information in a quantum channel. It has been shown by Giovannetti, Lloyd, and Maccone that a sequential decoder implementing only projective measurements at every step is able to achieve Holevo bound asymptotically. One of the main components of their scheme is a YES-NO projective measurement, which projects the received state into either one of the codewords, or the orthogonal subspace. Here I study the performance of a YES-NO projective measurement, the vacuum-or-not (VON) measurement, for discriminating the states of a M-ary coherent-state phase-shift-key (PSK) constellation. The VON measurement is a quantum non-demolition measurement that projects a state either onto the vacuum state or its complement. For guessing one of M possible coherent states of this constellation, one first selects a hypothesis, then displaces the received state by the inverse of the phase shift of that hypothesis, and finally performs a VON measurement. If vacuum is detected, one concludes that the guessed hypothesis is the correct hypothesis. Otherwise, these steps are iterated for all the hypotheses of the constellation until VON measurement yields vacuum in which case one concludes that the guessed hypothesis for that round is the correct hypothesis. The error probability of this sequential decoder is calculated explicitly for some specific M values, and compared to the performance of known sub-optimal and near-optimal receivers for M-ary PSK.

10409-12, Session 3

Quantum communication with spectrally correlated photons

Piotr L. Kolenderski, Mikolaj Lasota, Karolina Sedziak, Nicolaus Copernicus Univ. (Poland)

Single-photon sources are crucial components for the implementation of quantum communication protocols. However, photons emitted by some of the most popular types of realistic sources are spectrally broadband. Due to this drawback, the signal emitted from such sources is typically affected by the effect of temporal broadening during its propagation through telecommunication fibers which exhibit chromatic dispersion. Such problem can be observed e.g. when using sources based on the process of spontaneous parametric down-conversion (SPDC). In the case of long-distance quantum communication temporal broadening can significantly limit the efficiency of temporal filtering. It is a popular method, which is based on the reduction of the duration time of the detection window, used for decreasing the number of registered errors.

In this work we analyzed the impact of the type of spectral correlation within a pair of photons produced by the SPDC source on the temporal width of those photons during their propagation in dispersive media. We found out that in some situations the width can be decreased by changing the typical negative spectral correlation into positive one or by reducing its strength. This idea can be used to increase the efficiency of the temporal filtering method. Therefore it can be applied in various implementations of quantum communication protocols.

As an example of the application we subsequently analyzed the security of a quantum key distribution (QKD) scheme based on single photons. It was realized in the configuration with the source of photons located in the middle between the legitimate participants of a QKD protocol (called typically Alice and Bob). We demonstrated that when the information about the emission time of the photons produced by the SPDC source is not distributed to Alice and Bob, the maximal security distance can be considerably extended by using positively correlated photons, while in the opposite case strongly (no matter positively or negatively) correlated photons are optimal. We also found out that the results of our calculation may be very sensitive to the spectral widths of the photons produced by the SPDC source. In addition, we concluded that in realistic situation Alice and Bob would have to optimize their source over both the spectral widths of the generated photons and the type of spectral correlation in order to maximally extend the security distance.

The results of our work are, in particular, important for the QKD systems utilizing commercial telecom fibers populated by strong classical signals. In those systems temporal filtering method can be used to reduce not only the dark counts registered by the detection system, but also the channel noise originating from the process of Raman scattering, which is the main factor limiting their performance.

10409-13, Session 3

Approaches to a global quantum key distribution network *(Invited Paper)*

Md Tanvirul Islam, Robert Bedington, National Univ. of Singapore (Singapore); Doug K. Griffin, Russell Boyce, UNSW Canberra (Australia); Christian Kurtsiefer, National Univ. of Singapore (Singapore); Alexander Ling, Ctr. for Quantum Technologies (Singapore)

Progress in quantum computers and computational power threatens to weaken existing public key encryption. A global quantum key distribution (QKD) network can play a role in computational attack-resistant encryption. Such a network could use a constellation of airships and satellites as trusted nodes to facilitate QKD between any two points on the globe on demand. This requires both satellite-to-ground and inter-satellite links. However, the prohibitive cost of traditional satellite based development limits the experimental work demonstrating relevant technologies. To accelerate progress towards a global network, we use an emerging class of shoe-box sized spacecraft known as CubeSats. We have designed an entangled photon pair source that can operate on board CubeSats.

The robustness and miniature form factor of the entanglement source makes it especially suitable for performing pathfinder missions. Using this design, we have performed a feasibility study for a satellite-to-satellite QKD demonstration mission in collaboration with the University of New South Wales; Canberra. This mission concept uses two 6U CubeSats in low Earth orbit and aims to demonstrate QKD between them over varying separations.

10409-14, Session 3

On photonic spectral entanglement improving quantum communication

Piotr L. Kolenderski, Karolina Sedziak, Mikolaj Lasota, Nicolaus Copernicus Univ. (Poland)

Let us consider the experimental setup where SPDC source generates photon pairs which are subsequently coupled to single-mode fibers (SMFs). We assume that there are three parties involved: 1) Alice, possessing the photon pair source, detection system and the fiber connecting them, 2) Bob, who monitors the output of the second, long-distance fiber and 3) Eve, who can perform the most general collective attacks in order to acquire information which Alice and Bob wish to transfer. Typically, in fiber-based communication the chromatic dispersion is considered to be an obstacle, limiting the maximal distance at which information carrier can be securely transmitted. This phenomenon forces the trusted parties to define longer detection windows to avoid losing signal photons and increases the amount of detection noise that is being registered.

We consider standard BB84 quantum key distribution protocol, based on the SPDC source located in between Alice and Bob. The parameters of standard realistic telecommunication fibers (SMF28e+) are take into account. The source emits photon which apart of being entangled in polarization degree of freedom are entangled in spectral domain. This is the key feature which allows one to reduce detection noise by manipulating the spectral correlation between the produced photons. In this way the maximal security distance can be increased by around 10%.

10409-15, Session 3

The design of a continuous variable quantum repeater *(Invited Paper)*

William J. Munro, Fabian Furrer, NTT Basic Research Labs. (Japan); Kae Nemoto, National Institute of Informatics (Japan)

Quantum repeaters are well known as a necessary tool for large-scale quantum network and any future quantum internet. Typically such repeaters have relied on the transmission of single photons along long optical fibres. There is however a natural compatibility issue however as our current 'classical' telecommunication networks use multi-photon pluses of light. A natural question arises whether we can design quantum repeaters using these multi-photon pluses of light. In this talk we will present a CV QR scheme that has a success probability scaling polynomial in the distance and that can distribute entangled EPR states with arbitrary squeezing and fidelity over arbitrarily long distances. Further we will show that this distribution of pure two-mode (entangled) squeezed states can occur over arbitrarily long distances with a polynomial resource scaling.

10409-16, Session 3

The rise of silicon carbide as a promising integrated quantum nanophotonics platform *(Invited Paper)*

Stefania Castelletto, RMIT Univ. (Australia); Alexander Lohrmann, The Univ. of Melbourne (Australia); Takeshi Ohshima, National Institutes for Quantum and Radiological Science and Technology (Japan); Jeffrey C. McCallum, Brett C. Johnson, The Univ. of Melbourne (Australia)

Silicon carbide (SiC) is rising as a versatile platform for quantum optics and spin sensing due its integrated optically and spin active atomic size centres [1], with the additional opportunity to advance integrated quantum nanophotonics devices, due to its mature nanofabrication, synthesis and device engineering. Recently, we have demonstrated formation of optically active centres in SiC with excellent characteristics for broadband single photon generation at room temperature in the visible spectral range and very favourable for integration into nanophotonic/plasmonics devices.

In this presentation, I will review some of recent results on the controlled formation of single defects in silicon carbide in different polytypes, responsible for single photon emission in a broad spectral range of zero phonon lines. We have found that they can be formed in all technologically relevant polytypes of SiC, including 3C-SiC, a relevant polytype in micro and nano-electromechanical sensors and for optical micro-cavity fabrication. Further, I will focus on their integration in nanomaterials, electrically controlled devices and microdisks. An outlook on current efforts to achieve integrated quantum nanophotonics based on silicon carbide hyperbolic metamaterials with engineered single defects will be provided.

10409-17, Session 3

Experimental investigation of security parameters of Y-00 quantum stream cipher transceiver with randomization technique: Part I *(Invited Paper)*

Fumio Futami, Kentaro Kato, Osamu Hirota, Tamagawa Univ. (Japan)

Y-00 cipher is a quantum cipher disabling an eavesdropper from reading ciphertext of mathematical encryption (M-E) box correctly. Ciphertext are generated by mapping binary signals to multilevel signals by M-E box, and the cipher signals for Eve suffer error in their discrimination by quantum noise of coherent state. On the other hand, security against the brute force attack is ensured by the quantum no-cloning theorem.

The authors developed a Y-00 cipher transceiver in which randomization technique was incorporated. Last year in this conference, an irregular mapping as the randomization technique of the Y-00 cipher transceiver was experimentally demonstrated, and an application of the transceiver to secure optical fiber transmission of GbE signals was reported.

We have been also investigation the security performance of the transceiver. Our theoretical security analysis showed, for higher security, it is desirable that the signal power distribution after converting into multilevel signals in the optical domain should be uniform, even when the bit sequence of plaintext has any form of non-uniformity. Consequently, it is required to measure an optical signal power distribution of the Y-00 cipher transceiver for evaluating its security levels. In this research, we experimentally measure powers of multi-level optical signals and calculate the numbers of the signals over and under the average power. In the experiments, we employ various kinds of information sequences as input signals, and confirm that the distributions are uniform for most sequences. In the conference, the meaning of this security analysis is introduced and experimental results of the measurements are reported. In addition, an improving method is discussed.

10409-18, Session 3

Permutation modulation for quantization and information reconciliation in CV-QKD systems *(Invited Paper)*

Fred Daneshgaran, California State Univ., Los Angeles (United States); Marina Mondin, California State Univ., Los Angeles (United States) and Politecnico di Torino (Italy); Khashayar Olia, California State Univ., Los Angeles (United States)

Coding over higher and higher dimensions is always advantageous when it comes to Information Reconciliation (IR) for Continuous Variable Quantum

Key Distribution (CV-QKD) schemes. Let X be the d-dimensional vector of Gaussian samples at Alice, X' be the corresponding vector of samples at Bob and Y the corresponding m-bit quantized version of X'. Then the Theorem by Slepian-Wolf provides a bound on the achievability region of rate for the correlated sources and states that disclosing r=?H(K(X)?Y))+1/d? bits of the quantization label is enough to obtain the remaining (m-r)-bits with arbitrary low error probability, where K(X) is the key function that generates the secret key given the continuous valued Gaussian samples in X. Given this setup, the main problem here is how do you quantize a d-dimensional Gaussian vector when d can potentially be very large? Standard vector quantization may not be efficient, and different techniques may be devised. In this regard, this paper presents the use of Permutation Modulation (PM) techniques to perform the quantization of the Gaussian vector where d can be as high as several thousands. Monte Carlo simulation is used to assess the effectiveness of the technique and establish the error rates associated with the labels of the quantized samples.

10409-19, Session 3

A unified analysis of optical signal modulation formats for quantum enigma cipher *(Invited Paper)*

Kentaro Kato, Tamagawa Univ. (Japan)

A framework of the quantum enigma cipher was reported as a generalization of the quantum stream cipher by Y00 protocol that aims to break the Shannon limit of symmetric key encryption systems with the help of quantum noise of light last year. Development of criteria in designing of optical signal modulation formats is of importance to realize such physical encryption systems for secure fiber-optic communications, for controlling the net amount of the signal masking effect caused by quantum noise of light. In this study, we focus on this problem.

So far, we have proposed a variety of optical signal modulation formats for the quantum stream cipher. However, no unified analysis of the basic features of optical signal modulation formats for the quantum enigma cipher has been done. Fortunately, recent progress of the computation algorithms for optimal discrimination problems of quantum state signals enables us to handle a large-scale and complicated case such as the minimax discrimination of multi-ary non-symmetric quantum states. This helps us to seek possibilities of other new optical signal modulation formats. By using such algorithms for optimal quantum signal detection problem, the signal masking effect caused by quantum noise of light is evaluated in some modulation formats. From the analysis of the signal masking effect, some tradeoff relations between security level and communication performance will be observed. Moreover, a comparison of optical signal modulation formats for the quantum enigma cipher will be done, and some useful criteria for designing modulation formats in the quantum enigma cipher will be given.

10409-20, Session 4

The first sub shot noise wide field microscope *(Invited Paper)*

Marco Genovese, Istituto Nazionale di Ricerca Metrologica (Italy)

In the last years several proof of principle experiments have demonstrated the advantages of quantum technologies respect to classical schemes. The present challenge is to overpass the limits of proof of principle demonstrations to approach real applications. In this talk, following a general introduction, we present such an achievement in the field of quantum enhanced imaging. In particular, we describe the realization of a sub-shot noise wide field microscope based on spatially multi-mode non-classical photon number correlations in twin beams. The microscope produces real time images of 8000 pixels at full resolution, for (500μm)2 field-of-view, with noise reduced to the 80% of the shot noise level (for each pixel), suitable for absorption imaging of complex structures. By fast post-elaboration, specifically applying a quantum enhanced median filter, the noise can be further reduced (less than 30% of the shot noise level) by setting a trade-off with the resolution, demonstrating the best sensitivity per incident photon ever achieved in absorption microscopy. We will also discuss possible conjugation of ghost imaging techniques to this method.

10409-21, Session 4

Cancelling out aberrations through high order correlations *(Invited Paper)*

Juarez G. Silva, Eduardo J. S. Fonseca, Alcenisio J. de Jesus Silva, Univ. Federal de Alagoas (Brazil)

The imaging through optical systems may have distortions called aberrations. It can be chromatic aberrations, an effect resulting from dispersion due to the impossibility to focus all colors to the same point or monochromatic aberrations, where the rays emerging from one object point will not all meet at a single image point. Thanks to an analogy between the quantum and classical intensity light correlations, the previous studies explored the ghost imaging under both viewpoint. Although, the first approach was the use of correlated-photon imaging for the cancellation of phase aberrations, some authors have suggested theoretical models for the cancellation of phase aberrations using classical light in the ghost-imaging scheme. However, a detailed experimental study of the cancelation of phase aberrations using classical light intensity correlation is still missing in the literature. In this work, we show that exploring correlations of fluctuations in speckle intensity it is possible to cancel out aberrations that may exist in the Fraunhofer plane of an optical system. The aberrations cancelation occurs independently of its shape and it does not need coordinate inversion. We use high-order intensity correlations to obtain high visibility. Therefore, we extended the quantum-classical analogy to the study of cancelation of phase aberrations showing an interesting and useful distinction from the quantum case. It is possible to embed images into speckle patterns, and to recover it though the spatial correlation function. Therefore, this effect can be useful in imaging through random media and microscopy, canceling inherent aberrations than can cause distortions in the image.

10409-22, Session 4

Squeezed light enhanced sensing of a micro-mechanical oscillator *(Invited Paper)*

Ulrik Lund Andersen, Technical Univ. of Denmark (Denmark)

Ultra-precise measurements of various parameters such as the mass of nano-particles, magnetic fields or gravity can be attained by probing the phononic modes of a micro-mechanical oscillator with light. The sensitivity of such measurements is in part governed by the noise of the phononic mode as well as the noise of the probing light mode, so by decreasing the noise of the probe beam an enhanced sensitivity can be expected. We demonstrate this effect by using squeezed states of light where the quantum uncertainty of the relevant quadrature is reduced below the shot noise level. Using this squeezing-enhanced sensitivity effect, we demonstrate 1) improved feedback cooling of a phononic mode in a microtoroidal cavity and 2) improved sensing of a magnetic field using the coupling to a microtoroidal phononic mode via a magnetorestrictive material. We present our recent experimental results and discuss future directions.

10409-23, Session 4

Future outlook for diamond-based quantum information devices *(Invited Paper)*

Philip R. Hemmer, Texas A&M Univ. (United States)

In recent years there has been substantial progress in solid-state quantum information demonstrations based on diamond. This ranges from room-temperature multi-qubit quantum registers to spin-photon entanglement to loophole-free Bell tests. Most of these demonstrations are done with the nitrogen-vacancy (NV) center. Recently however the silicon-vacancy (SiV) center has shown a much better coupling to photons, owing to the suppression of spectral diffusion. Still more recently the germanium-vacancy (GeV) has shown much higher quantum efficiency the SiV. However there are tradeoffs. In this talk I will review the various options for quantum information devices in diamond. I will also discuss new options for the future, including designer color centers made possible by novel diamond growth techniques.

10409-24, Session 4

Verification of quantum entanglement of two-mode squeezed light source towards quantum radar and imaging

Genta Masada, Tamagawa Univ. (Japan)

Two-mode squeezed light is an efficient resource for quantum entanglement and shows non-classical correlation between quadrature phase amplitudes in each optical mode. We are developing a high-quality two-mode squeezed light source to explore the possibility of quantum radar based on the quantum illumination theory. It is expected to improve error probability for discrimination of target presence or absence even in a lossy and noisy environment. We are also expecting apply two-mode squeezed light source to quantum imaging. In this work we generate two-mode squeezed light source and verify its quantum entanglement property towards quantum radar and imaging.

Firstly we generate two independent single-mode squeezed light beams utilizing two sub-threshold optical parametric oscillators which include periodically-polled potassium titanyl phosphate crystals for the second order nonlinear interaction. They are combined by using a half mirror with a relative optical phase of 90 degrees between each optical field. Then entangled two-mode squeezed light beams can be generated. We observe correlation variances between quadrature phase amplitudes in entangled two-mode fields by balanced homodyne method. Finally we verify quantum entanglement property of two-mode squeezed light source based on Duan's inseparability criteria. In quantum radar or quantum imaging system, a turbulent atmosphere degrades quantum entanglement of a light source and affects performance of target detection. An optical loss is one of the simplest and most probable examples of environmental factors. In this work we also investigate quantum entanglement under the influence of an optical loss and optimum conditions of the two-mode squeezed light source for realizing quantum radar.

10409-25, Session 4

Superresolution via structured illumination quantum correlation microscopy *(Invited Paper)*

Girish Agarwal, Texas A&M Univ. (United States)

We propose to use intensity correlation microscopy in combination with structured illumination to image quantum emitters that exhibit antibunching with a spatial resolution reaching far into the sub-classical regime. Combining intensity measurements and intensity auto correlations up to order m creates an effective PSF with FWHM shrunk by the factor pm. Structured Illumination microscopy on the other hand introduces a resolution improvement of factor 2 by use of the principle of moiré fringes. Here, we show that for linear low-intensity excitation and linear optical detection the simultaneous use of both techniques leads to an in theory unlimited resolution power with the improvement scaling favorably as m+sqrtm in dependence of the correlation order m. Hence, yielding this technique to be of the utmost interest for biological imaging. We present the underlying theory and simulations demonstrating the highly increased spatial superresolution, and point out requirements for an experimental implementation.

10409-26, Session 5

Quantum walks with twisted classical light *(Invited Paper)*

Bereneice Sephton, Council for Scientific and Industrial Research (South Africa) and Univ. of the Witwatersrand (South Africa); Angela Dudley, CSIR National Laser Ctr. (South Africa); Andrew Forbes, Univ. of the Witwatersrand (South Africa)

In the avid search for means to increase computational power in comparison to that which is currently available, quantum walks (QWs) have become a promising option with derived quantum algorithms providing an associated speed up compared to what is currently used for implementation in classical computers. It has additionally been shown that the physical implementation of QWs will provide a successful computational basis for a quantum computer. It follows that considerable drive for finding such means has been occurring over the 20+ years since its introduction with phenomena such as electrons and photons being employed. Principal problems encountered with such quantum systems is the vulnerability to environmental influence as well as scalability of the systems. Here we perform the QW classically, due to interference characteristics inherent in the phenomenon, to mitigate these challenges. We utilize the properties of classical vector beams to physically implement such a walk in orbital angular momentum space by manipulating polarization and exploiting the non-separability of such beams. We show that with this method it is possible to achieve a physical QW with the advantage of robust properties that are associated with many classical systems.

10409-27, Session 5

Sum uncertainty relations for compact classical Lie algebra *(Invited Paper)*

Namrata Shukla, Institute for Quantum Science and Technology (Canada); Lorenzo Maccone, Univ. degli Studi di Pavia (Italy); Hubert de Guise, Lakehead Univ. (Canada); Barry C. Sanders, Univ. of Calgary (Canada)

The sum uncertainty relations are useful because they provide us with a state-independent non- trivial bound. We describe the construction of sum uncertainty relations for compact classical Lie algebras of the type su(n), so(2n), so(2n+1) and sp(n). Then we present resulting uncertainty relations explicitly for the su(2), su(3) and su(4) cases. In order to verify the bounds for general irreps of su(2) and su(3) and su(4), we develop and run a computer program that checks that the relations are correct for general states. Our method uses as a starting point the quadratic Casimir operator of the algebra, which can be recognized as a sum of variances of the generators using elementary observations. We discuss what type of states saturate the su(n) bound, and compare these states with states that saturate more familiar products of uncertainties. Our method is valuable for extending sum uncertainty relations to su(n) and beyond su(n) algebras. We also discuss our results in the context of multi-level atoms and squeezing.

10409-28, Session 5

Optical trapping and control of levitated nanoparticles *(Invited Paper)*

David Grass, Uros Delic, Nikolai Kiesel, Univ. Wien (Austria); Daniel R. Ladiges, John E. Sader, The Univ. of Melbourne (Australia); Markus Aspelmeyer, Univ. Wien (Austria)

The coupling of a levitated nanoparticle to an optical cavity field promises access to unprecedented parameter regimes for macroscopic quantum experiments at room temperature. We report our current progress on the combination of an optical tweezer trap [1] with a Fabry-Perot cavity for

optomechanical control [2] towards quantum cavity-optomechanics with levitated nanoparticles.

For fast and clean delivery of nanoparticles into ultra-high vacuum we have developed a hollow core photonic crystal fiber based conveyor belt [3]. An optical read-out allows monitoring the three-dimensional motion of the particle over the entire fiber length and is used for radiation pressure based feedback cooling. We utilize read-out and feedback cooling to investigate the local pressure along the fiber when a pressure gradient is applied. We compare the measurements with predictions from a direct simulating Monte Carlo method of the nonlinear Boltzmann equation.

A repository for quantum measurement trajectories *(Invited Paper)*

Durga B. Rao Dasari, Univ. Stuttgart (Germany); Sen Yang, The Chinese Univ. of Hong Kong (China); Jörg Wrachtrup, Univ. Stuttgart (Germany)

Revealing the quantum mechanical nature of system-bath interactions has gained lot of prominence due to its connection to the foundational aspects of quantum mechanics and also to upcoming quantum technologies where a good control over such interactions is a prerequisite. Though a theoretical description of such interactions has always been quantum mechanical, assumptions on the nature of the coupling and the bath-evolution has led to effective master equations that describe only the dynamics of the system alone. As most experimental settings can only achieve a high degree control and readout of the system alone, characterizing the bath on a similar level of detail as contained in a quantum model has not been achieved. Here we develop protocols that certify the quantum nature of the bath and effects that cannot be reproduced by classical descriptions of the same. Based on measurement correlations of subsequent readouts of the quantum system we show back-action effects on the bath, by imprinting on it the measurement trajectory of the quantum system and storing it for few seconds. For both experiments and theory we have used single defect centers in diamond as our quantum system and the surrounding nuclear spin-bath as our environment. The experiments are performed at low temperatures where the optical excited states of the defect are well-resolved allowing for projective readout of the quantum defect.

Conference 10410: Unconventional and Indirect Imaging, Image Reconstruction, and Wavefront Sensing 2017

SPIE. OPTICS+ PHOTONICS OPTICAL ENGINEERING+ APPLICATIONS

Wednesday - Thursday 9 –10 August 2017

Part of Proceedings of SPIE Vol. 10410 Unconventional and Indirect Imaging, Image Reconstruction, and Wavefront Sensing 2017

10410-1, Session 1

Impact of beacon anisochromatatism on phase-compensation performance

Colleen T. Gross, Air Force Insititute of Technology (United States); Mark F. Spencer, Air Force Research Lab. (United States)

This study evaluates the effects of beacon anisochromatatism on phase-compensation performance. In general, beacon anisochromatatism occurs at the system level because the beacon-illuminator laser (BIL) and high-energy laser (HEL) are often at different wavelengths. Such is the case, for example, when using an aperture sharing element to isolate the beam-control sensor suite from the blinding nature of the HEL. With that said, this study uses the WavePlex toolbox in MATLAB to model ideal spherical wave propagation through various atmospheric turbulence conditions. In order to quantify phase-compensation performance, we also model a nominal adaptive-optics (AO) system. We achieve low-order correction from a centroid tracker and fast-steering mirror and higher-order correction from a Shack-Hartmann wavefront sensor and continuous-face-sheet deformable mirror using least-squares phase reconstruction in the Fried geometry. To this end, we plot the normalized power in the bucket as a function of BILL-HEL wavelength difference. Our initial results show that positive BILL-HEL wavelength differences achieve better phase compensation performance compared to negative BIL-HEL wavelength differences (i.e., red BILs outperform blue BILs). This outcome is consistent with past results.

10410-2, Session 1

Adaptive optics using a MEMS deformable mirror for a segmented mirror telescope

Norihide Miyamura, Meisei Univ. (Japan)

For small satellite remote sensing missions, a large aperture telescope more than 400mm is required to realize less than 1m GSD observations. However, it is difficult or expensive to realize the large aperture telescope using monolithic primary mirror with high surface accuracy. A segmented mirror telescope should be studied especially for small satellite missions. Generally, not only high accuracy of optical surface but also high accuracy of optical alignment is required for large aperture telescope. For a segmented mirror telescopes, the alignment is more difficult and more important. For conventional systems, optical alignment is adjusted before launch to achieve desired imaging performance. However, it is difficult to adjust the alignment for large sized optics in high accuracy. Furthermore, thermal environment in orbit and vibration in launch vehicle cause the misalignments of the optics. We are developing an adaptive optics system using a MEMS deformable mirror for earth observing remote sensing sensor. Image based adaptive optics system compensate the misalignments and wavefront aberration of optical elements using deformable mirror by feedback of observed images. Because, it is difficult to use a reference point source unless the satellite controls its attitude toward a star for earth observing systems. Furthermore, total amount of incident light can enter an image sensor. We propose the control algorithm of the deformable mirror for a segmented mirror telescope by using of observed image. The experimental results show that misalignment and wavefront aberration of the segmented mirror telescope are corrected and image quality is improved.

10410-3, Session 1

Deep turbulence wavefront sensing using digital holographic detection in the phase-shifting recording geometry

Douglas E. Thornton, Air Force Institute of Technology (United States); Mark F. Spencer, Air Force Research Lab. (United States); Glen P. Perram, Air Force Institute of Technology (United States)

The effects of distributed-volume or “deep” turbulence in long range imaging applications presents unique challenges to properly measure and correct for aberrations incurred along the atmospheric path. Digital holography can detect the volumetric wavefront distortions caused by deep-turbulence to resolve the aberrations. Different recording geometries of the hologram offer different benefits depending on the application and previous studies have evaluated the performance off-axis and image plane recording geometries for wavefront sensing. This study models digital holographic detection in the phase-shifting recording geometry in the presence of deep-turbulence using wave optics simulations. In particular, the analysis models spherical-wave propagation through varying deep-turbulence conditions to estimate phase screens along the horizontal propagation path and the performance is evaluated by calculating the field-estimated Strehl ratio. Altogether, the results show digital-holographic detection in the phase-shifting recording geometry is an effective wavefront sensing method in the presence of deep turbulence.

10410-4, Session 1

Shack-Hartmann electronic densitometer (SHED)

Anthony R. Valenzuela, U.S. Army Research Lab. (United States); Aaron Schweinsberg, Oak Ridge Institute for Science & Education (United States)

The Shack-Hartmann Electron Densitometer (SHED) is a novel method to diagnose ultrashort pulse laser–produced plasmas by measuring the phase change to a probe laser beam. Using the Shack-Hartmann method, the phasefront of a probe laser is measured through a lenslet array onto a camera. Small changes in the location of the individual focal points on the camera plane are translated into changes in the probe beam’s wavefront. These wavefront distortions arise from refractive index variations caused by the free electrons. This method allows for superior performance in measuring minute variations in the electron density in 2 dimensions, single-shot, with sub-picosecond time resolution. The data taken with SHED demonstrated the ability to diagnose plasmas with densities of the order of 1019 cm-3 and show the temporal evolution of the plasma long after the driving laser pulse has left. The method can be further improved by enclosing the probe beam and adding a second axis to allow for tomographic reconstruction of the electron density in 3 dimensions. By using SHED in a pump/probe setup, we are able to obtain temporally synchronized, ultrashort snap shots of the evolution of free electrons in laser-induced ionization of air and other transparent media.

10410-5, Session 1

Simultaneous measurements of density field and wavefront distortions in high speed flows

Jacob George, Thomas P. Jenkins, James D. Trolinger, MetroLaser, Inc. (United States); Benjamin D. Buckner, Spectabit Optics, LLC (United States); Cecil F Hess, MetroLaser (United States)

The primary objective of this study is towards the development of optical sensors and hence it is important to know the effects on an optical beam as it traverses the flow field, and thus relate measured wavefront distortions to the specific flow structure of the time varying flow field. The motivation behind this research rests in the fact that the performance of laser based and guided systems is strongly affected by aero-optical effects. These effects limit the capability of the systems in resolving images with high resolution as well as projecting high optical energy densities. When an optical wavefront passes through an aerodynamic flow, its phase and amplitude are modulated, resulting in distortion and loss of optical information and energy. Depending on the beam size relative to the turbulence scales, the degradation results in adverse effects such as defocus, beam jitter, beam steering, etc. Thus, it is pertinent to measure the density structures and their spatial extent, flow statistics, and density fluctuations since they are directly related to index of refraction fluctuations. In this study, simultaneous measurements of density, using Rayleigh scattering (RS) and wavefronts using a wavefront sensor is carried out in ambient conditions in a high speed compressible jet flow. These experiments should help in greater understanding of the connection between a flowfield and the associated optical degradation by correlating features of the flow with the distorted wavefronts. Also, it will help in developing models that describe relationships between turbulence and optical aberrations.

10410-49, Session 1

Horizontal atmospheric turbulence, beam propagation, and simulation using collected data and predictive techniques

Christopher C. Wilcox, Freddie Santiago, Ty Martinez, K. Peter Judd, Sergio R. Restaino, U.S. Naval Research Lab. (United States)

The turbulent effect from the Earth's atmosphere degrades the performance of an optical imaging system. Many studies have been conducted in the study of beam propagation in a turbulent medium. Horizontal beam propagation and correction presents many challenges when compared to vertical due to the far harsher turbulent conditions and increased complexity it induces. We investigate the collection of beam propagation data, analysis, and use for building a mathematical model of the horizontal turbulent path and the plans and designs for an adaptive optical system to use this information to correct for horizontal path atmospheric turbulence.

10410-6, Session 2

Using optical interferometry for GEO satellites imaging: An update *(Invited Paper)*

Sergio R. Restaino, J. Thomas Armstrong, Ellyn K. Baines, Henrique R. Schmitt, James H. Clark III, U.S. Naval Research Lab. (United States)

We describe updates in both hardware and software at the Navy Precision Optical Interferometer (NPOI) and our continuous work to expand and extend the capabilities of this instrument for potential Space Situational Awareness (SSA) technological demonstration. The main new topics with respect to our previous work are a campaign of observations carried out in March and then repeated in June and the results of these campaigns. The second area is the procurement of three one-meter diameter telescopes in order to increase the sensitivity of the instrument. Description of the ongoing work for the deployment of these telescopes will be described.

10410-7, Session 2

Improving spatial resolution of the light field microscope with Fourier ptychography

Yoshitake Tani, Tomohiro Suzuki, Kenjiro Takai Miura, Shizuoka Univ. (Japan)

Light field microscope (LFM) is an optical microscope capable of obtaining images having large depth of field with different viewpoints. By using the parallax of these multi-view images, it is possible to reconstruct the 3D sample. However, the sampling interval of this multi-viewpoint image depends on the pitch interval of the microlens array, so the spatial resolution is low, and the accuracy of the 3D sample to be reconstructed is also low.

Conventional research has a method of increasing the spatial resolution by subpixel-shifted multiple images. However, this method has problems such as the necessity of mechanical operation and high cost.

Therefore, we propose applying Fourier ptychography to the LFM. Fourier ptychography is a technique to obtain high spatial resolution images by joining images obtained by irradiating samples from different angles using LED arrays in Fourier space. Fourier ptychography does not require mechanical scanning and is high throughput and low cost. In addition, Fourier tycoography is possible to obtain phase information on a sample, and it is also possible to obtain a fine 3D sample. We propose a method to generate high spatial resolution multiview images using Fourier ptychography and reconstruct highly accurate 3D sample from those images. In this research, we experiment with the original LFM and verify the effect.

10410-8, Session 2

System compression theory and application

Xiteng Liu, QualVisual Technology (Canada)

In this paper, we introduce the concept and rationale of system compression and its application to signal recovery in high quality and high speed. Essentially different from compressed sensing, system compression dispenses with signal sparsity and convex optimization on which compressed sensing relies. Convex optimization such as linear programming and orthogonal matching pursuit depend on iterative computations and become very slow and unstable in high dimensional systems. Doing without convex optimization, system compression dramatically improves both computation speed and stability and hence is eligible for real-time applications. Even better, it doesn't require signals to be sparse. A high-quality signal can be recovered in numerically or perceptually lossless manner with as few as 25% measurements. Experimental results manifest that system compression overwhelmingly outperforms existing methods for signal recovery. Demo software and testing data are all downloadable at the website http://qualvisual.net.

10410-9, Session 3

Synthetic-aperture direct-detection coherent imaging *(Invited Paper)*

James R. Fienup, Univ. of Rochester (United States)

This paper describes an approach to coherent aperture synthesis and fine-

resolution image reconstruction employing phase retrieval from intensity measurements. A Gerchberg-Saxton algorithm is used on a pair of intensity measurements to obtain the fields for each telescope at each position of the telescopes without a reference beam. These are combined into a larger synthetic aperture, and a cross-correlation is used to sense and correct for piston, tip and tilt phases of each of the sub-apertures with respect one another. Results of simulations, including the effects of speckle, are shown, and practical considerations are evaluated.

10410-10, Session 3

Method and algorithm for efficient calibration of compressive hyperspectral imaging system based on a liquid crystal retarder

Liat Revah, Yaniv Oiknine, Isaac Y. August, Adrian Stern, Ben-Gurion Univ. of the Negev (Israel)

Recently we presented a Miniature Compressive Ultra-spectral Imaging System (MUSI). This system consists of a single Liquid Crystal (LC) phase retarder as a spectral modulator and a gray scale sensor array to capture a multiplexed signal of the imaged scene. By designing the LC spectral modulator in compliance with the Compressive Sensing (CS) guidelines and applying appropriate algorithms we demonstrated reconstruction of spectral (hyper/ ultra) datacubes from an order of magnitude fewer samples than taken by conventional sensors. The LC modulator is designed to have an effective width of a few tens of micrometers, therefore it is prone to imperfections and spatial nonuniformity. In this work, we present the study of this nonuniformity and present a mathematical algorithm that allows the inference of the spectral transmission over the entire cell area from only a few calibration measurements.

10410-11, Session 3

Drift in correlation tracking algorithms

David C. Dayton, Applied Technology Associates (United States)

All image correlation based tracking algorithms exhibit some sort of deleterious drift problems. This presentation examines this issue and steps to mitigate it.

10410-12, Session 3

Efficiency measurements for a digital-holography imaging system

Matthias T. Banet, MZA Associates Corp. (United States); Mark F. Spencer, Air Force Research Lab. (United States) and Air Force Institute of Technology (United States)

This paper compares efficiency measurements to efficiency predictions for a digital-holography imaging system operating in the off-axis image plane recording geometry. In practice, we use a highly-coherent 532 nm laser source and an extended Spectralon® object. To compare our efficiency measurements to our efficiency predictions, we make use of an expression for the signal-to-noise ratio (SNR), which contains many multiplicative terms with respect to total-system efficiency. The results show that the polarization and the fringe-integration efficiency terms play the largest role in the total-system efficiency for the digital-holography imaging system.

10410-50, Session 3

Local sharpening and subspace wavefront correction with predictive dynamic digital holography

Sennan Sulaiman, Steve Gibson, Univ. of California, Los Angeles (United States)

Digital holography holds several advantages over conventional imaging and wavefront sensing, chief among these being significantly fewer and simpler optical components and the retrieval of complex field. Consequently, many imaging and sensing applications including microscopy and optical tweezing have turned to using digital holography. A significant obstacle for digital holography in real-time applications, such as wavefront sensing for high energy laser systems and high speed imaging for target tracking, is the fact that digital holography is computationally intensive; it requires iterative virtual wavefront propagation and hill-climbing to optimize some sharpness criteria. It has been shown recently that minimum-variance wavefront prediction can be integrated with digital holography and image sharpening to reduce significantly large number of costly sharpening iterations required to achieve near-optimal wavefront correction. This paper demonstrates further gains in computational efficiency with localized sharpening in conjunction with predictive dynamic digital holography for real-time applications. The method optimizes sharpness of local regions in a detector plane by parallel independent wavefront correction on reduced-dimension subspaces of the complex field in a spectral plane.

10410-13, Session 4

Use of (N-1)-D expansions for N-D phase unwrapping in MRI

Philip J. Bones, Laura J. King, Rick P. Millane, Univ. of Canterbury (New Zealand)

In MRI the presence of metal implants causes severe artifacts in images and interferes with the usual techniques used to separate fat signals from other tissues. In the Dixon method three images are acquired at different echo times to enable the variation in the magnetic field to be estimated. However, the estimate is represented as the phase of a complex quantity and therefore suffers from wrapping. High field gradients near the metal mean that the phase estimate is undersampled and therefore challenging to unwrap.

We have developed POP, phase estimation by onion peeling, an algorithm which unwraps the phase along 1-D paths for a 2-D image. The unwrapping is initially performed along a closed path enclosing the implant and well separated from it. The recovered phase is expanded using a smooth periodic basis along the path. Then, path-by-path, the estimate is applied to the next path and then the expansion coefficients are estimated to best fit the wrapped measurements. We have successfully tested POP on MRI images of specially constructed phantoms and on a group of patients with hip implants.

In principle, POP can be extended to 3-D imaging. In that case, a smooth basis for phase would be applied over a series of surfaces enclosing the implant (the "onion skins"), again beginning the phase estimation well away from the implant.

Results are presented for fat and water separation for 2-D images of phantoms and actual patients. The practicality of the method and its employment in clinical MRI are discussed.

10410-14, Session 4

High resolution depth reconstruction from monocular images and sparse point clouds using deep convolutional neural network

Martin Dimitrievski, Peter Veelaert, Wilfried Philips, Univ. Gent (Belgium)

Understanding the 3D structure of the environment is advantageous for many tasks in the field of robotics and autonomous vehicles. From the robot's point of view, 3D perception is often formulated as a depth image reconstruction problem. In the literature, dense depth images are often recovered deterministically from stereo image disparities. Other systems use an expensive LiDAR sensor to produce accurate, but semi-sparse depth images. With the advent of deep learning there have also been attempts to estimate depth by only using monocular images. In this paper we combine the best of the two worlds, focusing on a combination of monocular images and low cost LiDAR point clouds. We explore the idea that very sparse depth information accurately captures the global scene structure while variations in image patches can be used to reconstruct local depth to a high resolution. The main contribution of this paper is a supervised learning depth reconstruction system based on a deep convolutional neural network. The network is trained on RGB image patches reinforced with sparse depth information and the output is a depth estimate for each pixel. Using image and point cloud data from the KITTI vision dataset we are able to learn a correspondence between local RGB information and local depth, while at the same time preserving the global scene structure. Our results are evaluated on sequences from the KITTI dataset and our own recordings using a low cost camera and LiDAR setup.

An edge sensitive 3D measurement using two directional laser stripe scanning with a MEMS scanner

Dong Li, Xiang Zhou, Chang da Xu, Chao Wang, Jia yu Guo, Rui Jin, Xi'an Jiaotong Univ. (China)

The width of the laser stripe is physically difficult to compress, when the measured object has a mutually perpendicular edge (X axis and Y axis direction, respectively, containing the edge), this traditional measurement method will only accurately measure a certain direction of the edge, so using traditional measurement methods requires two directions to scan separately and a rotation device. Obviously, the traditional laser stripe measurement method is inefficient and complex.

This work proposes an edge sensitive 3D measurement system which is fast and accurate, using two directional laser stripe scanning with a MEMS scanner. This method for scanning the edges(x direction and y direction) of an object has the advantages of high efficiency, high speed and edges with high precision.

The 3D measurement system consists of four cameras and a MEMS scanner, four cameras which are named , , , and array around the MEMS scanner. Firstly, we should calibrate the system parameters of cameras and determine the matrix transformation relationship between calibration plate coordinate system and the camera coordinate system. Secondly, the picture captured by group (and) cameras are Fourier transformed, to determine the mask of the region of interest. Then to perform inverse Fourier transform, and to extract laser stripe center. Matrix of laser stripe center is multiplied by mask, and we can get the effective zone of the laser stripe center matrix. Using the same method, we can get the effective zone of the laser stripe center matrix of group (and). Lastly, according to calibration parameters and matrix of laser stripe center, with binocular stereo reconstruction technique, we can get the 3D point cloud model of group cameras and cameras. The two sets of point cloud models are converted to the calibration plate coordinate system, we can get 3D model with fine edge step.

10410-36, Session PWed

Three dimensional interferometric synthetic aperture ladar based on Pseudo-random Code

Guangyuan Li, Zhiyong Lu, Jianfeng Sun, Yu Zhou, Guo Zhang, Bo Zhang, Mengmeng Xu, Chenzhe Lao, Hongyu He, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

In order to get the three dimensional information of the target, and satisfy the requirement of high speed imaging, the three dimensional interferometric synthetic aperture ladar(SAL) based on the pseudo-random code was proposed, without local reference delay time, which can get fine resolution and overcome the speed mismatch problem between the pulse repetition frequency and the chirp rate of the linear frequency modulation signal. The phase modulation method of the three dimensional SAL is pseudo-random code modulation. M sequence is adopted as the pseudorandom code for its superior performance in code compression to get the range direction information. The azimuth direction information was obtained by doppler frequency shift of the return signal. The interferometric image of the two cross-track apertures was used to get the height information. The principle of the three dimensional interferometric SAL based on pseudorandom code was theoretical deduced in detail, and the simulation results were given. The feasibility of the three dimensional interferometric SAL is verified.

10410-37, Session PWed

Imaging processing with bidirectional modulation in down-looking synthetic aperture imaging ladar

Zhiyong Lu, Yu Zhou, Jianfeng Sun, Zhu Luan, Lijuan Wang, Qian Xu, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Down-looking synthetic aperture imaging ladar have bidirectional (positive and negative direction) modulation in the orthogonal direction of travel during phase modulation. The return signal can be also collected in the two direction. The imaging processing with bidirectional modulation is used and demonstrated. The signal-to-noise ratio can be enhanced in this mode synthetic aperture imaging ladar. Meanwhile, the velocity of

carrying-platform can be faster. In the experiment, the return signals with bidirectional modulation are stacked and rebuilt. Compared to the unidirectional modulation imaging, the faster and clearer imaging is realized with bidirectional modulation. This technique has a great potential for applications in extensive synthetic aperture imaging ladar fields.

10410-38, Session PWed

Influence of polarization features of target reflection on synthetic aperture imaging ladar

Qian Xu, Zhiyong Lu, Jianfeng Sun, Lijuan Wang, Peipei Hou, Wei Lu, Liren Liu, Shanghai Institute of Optics and Fine Mechanics (China)

Synthetic aperture imaging ladar (SAIL) is one of the most possible optical active imaging methods to achieve superresolution in a long distance and break the diffraction limit. Two-dimensional reconstructed images of the laser cooperative targets have been obtained successively by many institutes. Nevertheless, natural target reconstructed images by the SAILs have not been achieved. The polarization state of return optical field will be changed due to the interaction of incident polarized light and materials of the target, furthermore, it would affect the intermediate frequency signal which the SAILs imaging needed. The Mueller matrices can describe the complex polarization features of the target reflection and treat this interaction. In this paper, the influence on resolution element imaging in side-looking and down-looking SAILs will be theoretically analyzed.

10410-39, Session PWed

A three dimensional point cloud registration method based on rotation matrix eigenvalue

Chao Wang, Xiang Zhou, Xi'an Jiaotong Univ. (China); Zixuan Fei, Xiaofei gao, Rui Jin, Xi'an Jiaotong Univ. (China)

We usually need to measure an object at multiple angles in the traditional optical three-dimensional measurement method, due to the reasons for the block, and then use point cloud registration methods to obtain a complete three-dimensional shape of the object. The point cloud registration based on a turntable is essential to calculate the coordinate transformation matrix between the camera coordinate system and the turntable coordinate system. We usually calculate the transformation matrix by fitting the rotation center and the rotation axis normal of the turntable in the traditional method, which is limited by measuring the field of view. The range of exact feature points used for fitting the rotation center and the rotation axis normal is approximately distributed within an arc less than 120 degrees, resulting in a low fit accuracy. In this paper, we proposes a better method, based on the invariant eigenvalue principle of rotation matrix in the turntable coordinate system and the coordinate transformation matrix of the corresponding coordinate points. First of all, we control the rotation angle of the calibration plate with the turntable to calibrate the coordinate transformation matrix of the corresponding coordinate points by using the least squares method. And then we use the feature decomposition to calculate the coordinate transformation matrix of the camera coordinate system and the turntable coordinate system. Compared with the traditional previous method, it has a higher accuracy, better robustness and it is not affected by the camera field of view. In this method, the coincidence error of the corresponding points on the calibration plate after registration is less than 0.1mm.

10410-40, Session PWed

A multi-resolution texture fusion algorithm

Yuqin Li, Xiang Zhou, Xi'an Jiaotong Univ. (China); Jia yu Guo, Tao Yang, Zixuan Fei, Xi'an Jiaotong Univ. (China)

Texture fusion is essential for 3D photo-realistic texture model reconstruction. multi-resolution texture fusion mainly is applied to reconstruct three-dimensional models that the local texture are very realistic. This paper presents a multi-resolution texture fusion algorithm based on digital image processing.

The technique utilizes the depth camera to obtain range data and the texture camera to obtain the local interested high-resolution texture of the object. And each point of the range images a pixel of the picture corresponding to this view should be found, so the map between high-resolution texture and local 3D points could be obtained by using the SURF to register the local high-resolution texture with the low resolution texture collected by the depth camera. Then the light source correction of textures is applied to remove the systematic differences such as black edges which are achieved by computing the HIS difference between each point's colors. Finally, ICP is applied to register models, and mapping different-resolution textures onto three-dimensional models. The global correction is applied to refine the observable variations in color that may still exist near the fusion boundaries. These corrections will utilize the grid triangle vertex color as a constraint to drive texture fusion to remove discontinuities from different resolutions.

The advantage of this technique is that it utilizes the light source correction and global correction to fuse different resolutions textures. Experiments with this technique indicate that it significantly corrects the observable discontinuities within the overlapping areas, which are given from different resolutions, lighting change, non-lambertian object surface, etc.

A novel 360-degree shape measurement using a simple setup with two mirrors and a laser MEMS scanner

Rui Jin, Xi'an Jiaotong Univ. (China); Xiang Zhou, Xi'an Jiaotong Univ. (China); Tao Yang, Dong Li, Xi'an Jiaotong Univ. (China); Chao Wang, Xi'an Jiaotong Univ. (China)

There is no denying that 360-degree shape measurement technology plays an important role in the field of three-dimensional optical metrology. Traditional optical 360-degree shape measurement methods are mainly two kinds: the first kind, by placing multiple scanners to achieve 360-degree measurements; the second kind, through the high-precision rotating device to get 360-degree shape model. The former increases the number of scanners and costly, while the latter using rotating devices lead to time consuming.

This paper presents a low cost and fast optical 360-degree shape measurement method, which possesses the advantages of full static, fast and low cost. The measuring system consists of two mirrors with a certain angle, a laser projection system, a stereoscopic calibration block, and two cameras. As the need to capture the virtual image of objects presented in the mirror, the projector needs a great depth of field. We have successfully developed an optical module called laser MEMS scanner by using the laser MEMS scanning technology that can produce always-in-focus images in long distance, so this problem is solved. At the same time, the laser MEMS scanner can achieve precise movement of laser stripes without any movement mechanism, improving the measurement accuracy and efficiency.

What's more, a novel stereo calibration technology presented in this paper can achieve point clouds data registration, and then get the 360-degree model of objects. A stereoscopic calibration block with special coded patterns on six sides is used in this novel Stereo calibration method. Through this novel stereo calibration technology we can quickly get the 360-degree models of objects.

10410-42, Session PWed

Enhancement of incoherent imaging through turbulence by using multi-aperture receivers

Vadim V. Dudorov, Anna S. Eremina, V.E. Zuev Institute of Atmospheric Optics (Russian Federation)

Possibilities of the image quality enhancement by using multi-aperture systems are investigated numerically for incoherent imaging through atmospheric turbulence. We compare the quality of images formed by a single aperture and images synthesized by an array of N*N subapertures (N = 2–15). The use of multi-aperture systems have advantage by means of local tip-tilt compensation of image-forming wavefront distorted by turbulence - image tip-tilt displacement for each subaperture. In so synthesized images, residual turbulent distortions are almost isoplanatic in a wide range of atmospheric conditions, which allows a significant increase in the image quality via computer object restoration. The results of correction of images synthesized are compared with images without correction and with traditional images formed by a single aperture. The effect of the number and size of subapertures on the quality of the image restored is analyzed. It is shown that if the size of a multi-aperture system is constant, then there is an optimal number of subapertures, which depends on the turbulence intensity and diffraction effect. Optimal conditions for the use of multi-aperture imaging versus the atmosphere conditions and distance are found.

10410-43, Session PWed

Super-resolution imaging with one complex filter based on compressive sensing

Yicheng Sun, Nanjing Univ. of Science and Technology (China) and NRIEE (China); Guohua Gu, Xiubao Sui, Nanjing Univ. of Science and Technology (China); Yuqi Li, NRIEE (China)

Super-resolution is being considered as one of the important goals for optical imaging and image processing. In this paper, we present a novel imaging technique that exceeds the limit of resolving power of diffraction-limited optical system to achieve super-resolution imaging, by combining the advantages of compressive sensing and complex annular filters. This technique is realized by utilizing a classical 4F optical system with a phase-only spatial light modulator. Furthermore, the feasibility of this technique is theoretically analyzed, and physically validated by laboratory experiments. Experimental results have demonstrated that the technique improves the resolving power of diffraction-limited optical system by approximately times, and the intensity image of high-resolution object can be recovered from of the total number of measurements.

Optical method of separating of isotropic and anisotropic parts of polymer-dispersed liquid crystals images

Andriy L. Nehrych, Peter P. Maksimyak, Yuriy Fedkovych Chernivtsi National Univ. (Ukraine)

We have investigated the spatial-frequency filtering on PDLC. Partial beams passed through LC droplets and polymer matrix may be considered as plane waves passing different optical pathes and interfering in the far zone. Changing the voltage results in changeing the LC effective refractive index leading to a change of the path difference between the interfering beams. The effect of interference decreases of some spectral components of the radiation passing through PDLC sample can be used for space-frequency filtering of images.

We have used LC E7 by Merck, dispersed in the polymer NOA 65 by Norland Inc. as the object of research.

Scattering indicatrix is modulated with a periods of 2.5o and 10o, which is clearly recognized at small angles. At small angles of scattering indicatrix, significant redistribution of the radiation intensity is observed depending on the applied voltage to PDLC.

In the absence of applied voltage, PDLC passes high and low spatial frequencies. At a voltage of 2 V, the regular component formed at low spatial frequencies is quenching by interference, while the PDLC sample strongly scatters radiation. This phenomenon has been studied in detail in our previous works. When the voltage of 6 V is applied to PDLC, the scattering is almost absent because the refractive index of LC drops is close to the refractive index of the polymer matrix. Therefore, the scattered radiation containing high spatial frequencies is filtered by PDLC, and low spatial frequencies passes through the sample. These features of the scattering indicatrix provide the possibility of spatial frequency filtering of images.

Adaptive compressed photon counting 3D imaging based on wavelet trees and Hadamard multiplexing

Huidong Dai, Guohua Gu, Nanjing Univ. of Science and Technology (China); Weiji He, Nanjing Univ. of Science and Technology (China) and Key Lab. of Intelligent Perception and Systems for High-Dimensional Information (China); Ling Ye, Nanjing Univ. of Information Science & Technology (China); Tianyi Mao, Qian Chen, Nanjing Univ. of Science and Technology (China)

A photon counting 3D imaging system with short-pulsed structured illumination and a single-pixel photon counting detector are built. The proposed multiresolution photon counting 3D imaging technique acquires a high-resolution 3D image from a coarse image and details at successfully finer resolution sampled by hadamard multiplexing along the wavelet trees. The detected power is significant increased thanks to the hadamard multiplexing method. Both the required measurements and the reconstruction time can be significant reduced, which makes the proposed technique suitable for scenes with high spatial resolution. Since the depth map is retrieved through an inverse wavelet transform instead of the computational intensive optimization problems performed in CS, the time consumed to retrieve the depth map can be also reduced, and thus it will be suitable for applications of real-time compressed 3D imaging such as object tracking. even though the resolution of the final 3D image can be high, the number of measurements remains small due to the adaptivity of the wavelet-trees-based sampling strategy. The adaptive sampling technique is quality oriented, allowing more control over the image quality. The experimental results indicate that both the reflectivity and depth map of a scene at resolutions up to pixels can be acquired and retrieved with practical times as low as 14 seconds.

Using virtual reality to test the regularity priors used by the human visual system

Eric Palmer, Purdue Univ. (United States); TaeKyu Kwon, The Ohio State Univ. (United States); Zygmunt Pizlo, Purdue Univ. (United States)

Virtual reality applications provide opportunity to test human vision in well-controlled scenarios that would be difficult to generate in real physical spaces. This study is intended to evaluate the importance of regularity priors used by the human visual system. Using a CAVE simulation, subjects viewed virtual objects in a variety of experimental manipulations. In the

first experiment, the subject was asked to count the objects in a scene that was viewed right-side-up or upside-down for 4 seconds. The subject counted more accurately in the right-side-up viewing condition regardless of the presence of binocular disparity or color. In the second experiment, the subject was asked to reconstruct the scene from a different viewpoint. Reconstructions were accurate, but the position and orientation error was twice as high when the scene was rotated by 45°, compared to 22.5°. Similarly to the first experiment, there was little difference between monocular and binocular viewing. In the third experiment, the subject was asked to adjust the position of one object to match the depth extent to the frontal extent among three objects. Performance was best when symmetrical objects were used and became poorer when asymmetrical objects were used and poorest with only small circular markers on the floor. Finally, in the fourth experiment, we demonstrated reliable performance in monocular and binocular recovery of 3D shapes of objects standing naturally on the simulated horizontal floor. Based on these results, we conclude gravity, horizontal ground, and symmetry priors play an important role in veridical perception of scenes.

Ghost imaging using shifted speckles and bucket detection

Tianyi Mao, Qian Chen, Weiji He, Guohua Gu, Nanjing Univ. of Science and Technology (China)

Computational ghost imaging (CGI), which is based on the quantum or classical correlation of fluctuating light fields, for the last decades, has opened new avenues for computational light microscopy, remote sensing, optical encryption and so on. The resolution of CGI is determined by the speckle's transverse size on the object plane and the numerical aperture of the projection optics. In many applications, it is enough to get the periphery of the object, which is called "edge enhancement" in image processing. However, poor imaging quality of CGI limits the edge detection, which is important for target recognition and localization in remote sensing and biological imaging. In this paper, we proposed ghost imaging using shifted speckles and bucket detection. In our simulations and experiments, it is hard for us to recognize the detected object by using "ghost" images. It has been demonstrated that using the proposed method dramatically limits the reconstruction noise and enhances the edges continuously at the sacrifice of contrast. The edge detection using this technique with Sobel operator, Standard operator and Laplacian operator were demonstrated theoretically and experimentally. The results show that the method using Sobel operator is robust in noisy environments. It is noted that the potential applications of ghost imaging are remote sensing and biological imaging, where complex photoelectric systems and high-speed sampling will cause much noise in detection. The robust indicates that the proposed method using Sobel operator is much appropriate in real applications. It is noticeable that the technique overcomes the disadvantages of edge detection in ghost imaging without any addition of hardware and complex computation. Combining the proposed method with other proposed applications of CGI, especially in remote sensing and biological applications, will improve the success rate of target recognition and localization.

Shape from shading using a linear filtering approach

Oscar E. Castillo, Jorge Luis Flores Nuñez, Univ. de Guadalajara (Mexico)

There is a vast variety of algorithms for the resolution of the shape from shading problem; most of these algorithms rely on basic assumptions about the surface reflective properties, camera projection and location, and the light source distribution; nevertheless, real models do not follow those real assumptions and therefore modifications must be made to the existing algorithms in orger to get useful results. In this paper, we implemented an algorithm based on a linear filtering approach to obtain surface estimation from a single image. We tested the algorithm with images generated synthetically and also with images from a real object. Further, perspective projection and a combination of a Lambertian and specular reflectance is employed in our algorithm. We were able to obtain the shape of objects with different geometries, although the algorithm has problems when discontinuities are present.

Phase retrieval in the presence of multiplicative noise *(Invited Paper)*

Joe P. J. Chen, Richard A. Kirian, Arizona State Univ. (United States)

An additional step to traditional iterative phase retrieval algorithms is described that allows the reconstruction of an image from the product of its sufficiently sampled far-field diffraction intensity and a second signal. The iterative phasing algorithm with this added step attempts to recover both the image and the multiplicative signal at the same time. Simulations show that reasonable reconstructions of both the original image and the multiplicative signal can be attained in many cases.

Phase retrieval for crystalline specimens

Romain Arnal, Rick P. Millane, Univ. of Canterbury (New Zealand)

The phase retrieval problem for a single object is known to have a unique solution in two or more dimensions, and iterative projection algorithms are generally an effective reconstruction method. More difficult situations arise when diffraction data are collected from crystalline specimens, since the diffraction amplitudes are then undersampled. Three-dimensional crystalline specimens are necessary in x-ray diffraction imaging of biological molecules in order to obtain measurable diffraction, but the phase retrieval problem does not have a unique solution and some ancillary information is needed to solve the problem. However, with the recent availability of high intensity x-ray sources such as x-ray free-electron lasers, there is the possibility

of measuring diffraction data from 1D or 2D crystals. For these crystals, the effects of undersampling are reduced. The solvability, or uniqueness, of a phase problem can be characterised by an appropriately calculated "constraint ratio," that measures the independent data-to-parameter ratio. The constraint ratio provides information in the 1D and 2D crystal cases, but because of the structured sampling of the diffraction amplitude that results, there are additional considerations that are needed to in order characterise uniqueness. We show that uniqueness in these cases depends on particular properties of the support of the object in the crystal. In cases where a unique solution is expected, iterative projection algorithms can be appropriately adapted to invert the data. Uniqueness results will be illustrated by examples and reconstruction algorithms by simulation. Specific applications in coherent diffraction imaging will be described.

10410-24, Session 5

Advances in shadow imaging of geosynchronous satellites

Dennis M. Douglas, Bobby R. Hunt, David Sheppard, Integrity Applications, Inc. (United States)

Shadow imaging is a technique to obtain highly resolved silhouettes of resident space objects (RSOs) which would otherwise be unattainable using conventional terrestrial based imaging approaches. This is done by post processing the measured irradiance pattern (shadow) cast onto the Earth as the RSO occults a star. Here, we present ongoing research efforts pertaining to shadow imaging of geosynchronous (GEO) satellites. Resolution limits are shown to be independent of wavelength for monochromatic collections. Resolution limits are then quantified based on the spectral bin width of the collected diffraction pattern for polychromatic observations. Sub meter resolution is shown to be readily achievable for anticipated observing scenarios using source stars brighter than mv = 11. Image reconstruction is performed using a Fresnel integral based phase retrieval algorithm and use of Babinet's principle. We also present refinements to our shadow prediction model that further quantify the number of shadow events and greatly reduce the shadow ground track uncertainties. Finally, we outline our current efforts to physically collect a GEO shadow by implementing our shadow prediction model and simulation based radiometric limits.

10410-25, Session 6

Opportunities for sub-wavelength imaging based on motion in structured illumination *(Invited Paper)*

Kevin J. Webb, Qiaoen Luo, Vivek RAghuram, Yulu Chen, Purdue Univ. (United States)

We describe the concept of controlled or natural motion of an object in a spatially varying field magnitude as the basis for coherent optical sensing and imaging. Examples presented are for microscopy with interfering laser beams and speckle formed by scatter from a random medium. Biomedical and environmental applications are presented and resolution limits discussed.

A method to extract far-subwavelength geometry and dielectric constant information based on precisely controlled object motion with structured light illumination and far-field measurement data is illustrated with simulated measurements. The principle is that far-field measurements with controlled motion in a spatially varying incident field add information about nanometer-scale dimensions and material properties. We show example results with sensitivity to the properties of a film on a substrate.

We present and demonstrate a coherent imaging and sensing method that can provide high resolution images of objects moving inside an essentially arbitrarily thick and heavily scattering medium, limited only by the medium stability or characterization and the detector noise. The speckle intensity correlations have short-range, wavelength-scale features, and longer range decorrelations. These provide a simple basis for identification of moving objects, and upon phase reconstruction, an object function that serves as an image can be obtained.

10410-26, Session 6

Long-range speckle imaging theory, simulation, and brassboard results

Jim F. Riker, the Optical Sciences Co. (United States); Glenn A. Tyler, Jeffrey L. Vaughn, the Optical Sciences Co. (United States)

In the SPIE 2016 Unconventional Imaging session, the authors laid out a breakthrough new theory for active array imaging that exploits the speckle return to generate a high-resolution picture of the target. Since then, we have pursued that theory even in long-range (>1000-km) engagement scenarios and shown how we can obtain that high-resolution image of the target using only a few illuminators, or by using many illuminators. There is a trade of illuminators versus receivers, but many combinations provide the same synthetic aperture resolution. We will discuss that trade, along with the corresponding radiometric and speckle-imaging Signal-to-Noise Ratios (SNR) for geometries that can fit on relatively small aircraft, such as an Unmanned Aerial Vehicle (UAV). Furthermore, we have simulated the performance of the technique, and we have created a laboratory version of the approach that is able to obtain high-resolution speckle imagery. The principal results presented in this paper are the Signal to Noise Ratios (SNR) for both the radiometric and the speckle imaging portions of the problem, and the simulated and experimental results obtained for representative arrays.

10410-27, Session 6

An underwater turbulence degraded image restoration algorithm

Md Hasan Furhad, Murat Tahtali, Andrew J. Lambert, UNSW Canberra (Australia)

Underwater turbulence occurs due to random fluctuations of temperature and salinity in the water. These fluctuations are responsible for the alteration in water density, refractive index variation and attenuation in light direction. These impose random geometric distortions, spatio-temporal varying blur, limited range visibility and limited contrast on the acquired images (Thomas Stephan et al, Proc SPIE, 8791, 2013). We propose here an image restoration algorithm to restore underwater-degraded images. There are some restoration techniques developed to address this problem, such as image registration based, lucky region based and centroid-based image restoration algorithms. Although these methods demonstrate better results in terms of removing turbulence, they require computationally intensive image registration, higher CPU load and memory allocations. We propose a simple patch based dictionary-learning algorithm to restore the image by alleviating the computational intensive image registration step, which requires lower computational load compared to conventional restoration algorithms and shows better results.

Dictionary learning is a machine learning technique, which builds a dictionary of non-zero atoms derived from the sparse representation of an image or signal. The image is divided into several patches and we detect the sharp patches from them. Next, we perform dictionary learning across these sharp patches to update the image frames, and finally we average the frames with updated dictionaries to estimate the restored image. These averages are performed to eliminate any existing artefacts in the individual frames. Finally, we employ an image deconvolution algorithm on the estimated restored image to remove noise that still exists.

10410-28, Session 6

Object detection from images obtained through underwater turbulence medium

Md Hasan Furhad, Murat Tahtali, Andrew J. Lambert, UNSW Canberra (Australia)

Imaging through underwater experiences severe distortions due to

random fluctuations of temperature and salinity in water, which produces underwater turbulence through diffraction limited blur, and lights reflecting from objects of an image perturbs and attenuates contrast, making the recognition of objects of interest difficult (Kalyan K. Halder et al, Proc SPIE, 9622, 2015). Thus, in underwater imaging, the information available for detecting objects of interest is a challenging task because they have inherent confusion among the background, foreground and other image properties. In this study, we propose a saliency based approach to detect the objects acquired through underwater turbid medium. Saliency based approach is one of the most popular and efficient techniques which makes an object or pixel stand out and capture our attention. This approach has drawn attention among a wide range of computer vision applications, such as image retrieval, artificial intelligence, neuro-imaging and object detection.

In this study, we propose a framework to detect the objects through a fused saliency technique. First, we pre-process the image through deblurring in order to remove the underwater turbulence induced blur. Next, we employ a visual saliency technique on this image for object detection. In this step, first we estimate the region of the object of interest automatically through an optimized support vector machine (SVM) saliency map. After the regions are estimated, we propose a graph based model to extract the object regions for more precise object detection. Finally, we fuse these two maps into one and detect the objects from the fused map.

GPU-enhanced computational platform for performance evaluation of atmospheric optical systems

Svetlana L. Lachinova, Mathieu Aubailly, Morris Maynard, Optonicus (United States); Mikhail A. Vorontsov, Optonicus (United States) and Univ. of Dayton (United States); Mark F. Spencer, Air Force Research Lab. (United States)

We present a user-friendly computational platform for numerical analysis and performance assessment of a wide range of optical systems for imaging and laser projection applications. The wave-optics-based software package, referred to as the Wave-Optics Joint Estimation Toolbox (WaveJET), exploits advantages of GPU/CUDA technologies and allows one to quickly and accurately simulate atmospheric turbulence effects on various systems using the combination of different computational techniques and algorithms for wavefront sensing and imaging. The WaveJET software also takes into account critical system engineering design constraints including system architecture, diffraction, turbulence propagation, adaptive optics control, and coherent/incoherent beam combining.

10410-30, Session 7

ANN-based model to compensate for the error phase in the 3D reconstruction of small objects

Carlos Andrés Madrigal González, Instituto Tecnológico Metropolitano (Colombia); Alejandro Restrepo Martínez, John W. Branch Bedoya, Univ. Nacional de Colombia Sede Medellín (Colombia)

To get accurate 3D reconstruction of small objects using structured light, it is necessary to modify the optics of commercial projection systems. However, this addition of lenses increases the aberrations, distortions, and nonlinearities in the projection. This generates errors in the phase unwrapping. In this paper we propose an ANN-based model to compensate for phase errors due to nonlinearities such as gamma effect, defocusing and illumination changes. The ANN is used to approximate the nonlinear distortion curve. This curve is obtained by projecting and capturing a range of gray levels at different levels of defocusing. This is achieved by varying the position of the calibration plane every 2mm and with 3 different lighting conditions. From the ideal phase, computed with a four-step phase-shifting algorithm and its phase distorted by the estimated model, a compensation map is determined. The proposed method is compared with the passive and active methods most used in the literature. The experimental results show that our proposal reduces the effects of nonlinearities, achieving accurate 3D reconstructions. This is important for the automatic visual inspection community when detecting surface defects on small objects since if phase errors due to nonlinearities are not compensated, the errors in 3D reconstruction are easily mixed and confused with the defects.

10410-31, Session 7

Simulation of the effects that lead to the degradation of the images obtained using a ground based telescope

Youness Bentahar, Univ. Hassan II Mohammedia - Casablanca (Morocco)

The atmospheric turbulence is the biggest obstacle to terrestrial astronomical observations. The objective of this study is to estimate these parameters the case of observation of the sun by the statistical analysis of arrival angle fluctuation and this can be directly obtained from the observations of the solar edge.

10410-32, Session 7

Unconventional imaging with contained granular media

Marco B. Quadrelli, Jet Propulsion Lab., California Institute of Technology (United States); Erkin Sidick, Jet Propulsion Lab., California Institute of Technology (United States)

Typically, the cost of a space-borne imaging system is driven by the size and mass of the primary aperture. The solution that we propose uses a method to construct an imaging system in space in which the nonlinear optical properties of a cloud of micron-sized particles, shaped into a specific surface by electromagnetic means, and allows one to form a very large and lightweight aperture of an optical system, hence reducing overall mass and cost. Recent work at JPL has investigated the feasibility of a granular imaging system, concluding that such a system could be built and controlled in orbit. We conducted experiments and simulation of the optical response of a granular lens. In all cases, the optical response, measured by the Modulation Transfer Function (MTF), of hexagonal reflectors was closely comparable to that of a conventional spherical mirror. We conducted some further analyses by evaluating the sensitivity to fill factor and grain shape, and found a marked sensitivity to fill factor but no sensitivity to grain shape. We have also found that at fill factors as low as 30%, the reflection from a granular lens is still excellent. Furthermore, we replaced the monolithic primary mirror in an existing integrated model of an optical system (WFIRST Coronagraph) with a granular lens, and found that excellent contrast levels are provided by the granular lens that can be useful for exoplanet detection. We will present our testbed and simulation results in this paper.

10410-33, Session 7

Modeling coherence propagation in a homogenizing light pipe for speckle mitigation

Robert Raynor, Mark F. Spencer, Trevor Moore, Air Force Research Lab. (United States)

Speckle elimination via coherence reduction is currently being investigated as a means of improving the quality of images obtained with laser illumination. Homogenizing light pipes provide one avenue of altering the spatial coherence properties of a laser source for this purpose. This paper models the propagation of a partially coherent source in a light pipe via propagation of the cross-spectral density. Though direct numerical

propagation of the cross-spectral density is computationally burdensome, immense simplifications are possible for the class of partially coherent sources known as Schell-model sources. The cross-spectral density of a Schell-model source may be represented as the convolution of a coherent "mode" with a weighting function. Mathematically, propagation of this mode can precede evaluation of the convolution. Discretization and numerical evaluation of the convolution casts this approach as a "finite-element source" approach, wherein individual identical modes are propagated and superposed to obtain the propagated cross-spectral density. The end result is that the 4-dimensional integral needed to propagate the cross-spectral density is replaced by the 2-dimensional integral needed to propagate the individual mode. In this paper, this method of propagation is baselined to analytic results for free space propagation, and then used to model the evolution of coherence within a homogenizing light pipe. The conditions necessary to achieve uniform illumination via projection of the waveguide exit field are discerned and discussed, and the speckle mitigation capabilities of the setup are modeled and assessed.

10410-34, Session 7

Incoherent image simulation through atmospheric turbulence with ray optics

Xifeng Xiao, Erandi Wijerathna, Thomas A. Underwood, David G. Voelz, New Mexico State Univ. (United States); Andreas Muschinski, NorthWest Research Associates (United States)

The simulation of optical imaging through distributed atmospheric turbulence has played an important role in studying system performance for application such as inspection, mapping, target identification, and tracking. Our interest is the simulation of a series of short-exposure image realizations which allows the study of the dynamic nature of turbulence and its effect on imaging. Several methods based on numerical wave optics propagation and split-step turbulence screen modeling have been used to generate short-exposure images through distributed turbulence. However, the coherent nature of these methods generally requires a significant number of propagation repetitions and averaging in the image plane to approach an incoherent result. This process is time and resource demanding. Here, we consider replacing the wave optics propagation with a geometrical optics approach where rays are traced through the split-step turbulence screens to create incoherent imagery. Ray tracing is computationally efficient and propagation repetition and averaging are not required so a considerable speedup in calculation time is possible compared to wave optics calculations. A few examples of this concept exist in the literature such as a brightness function approach that has been used successfully to create incoherent image video simulations. Ray optics, however, does not account for diffractive effects, which can limit its applicability. We review the limitations of geometric optics for turbulence scenarios and identify the parameter regimes where ray tracing may be valid for incoherent image simulation. We present a ray tracing approach and demonstrate the computation time speedup compared to wave optics. We also discuss concepts that extend the basic ray tracing method, such as the brightness function approach, and consider algorithmic options for approximating the effects of diffraction in the resulting imagery.

10410-35, Session 7

Crosswind measurements based on the turbulent distortions analysis in incoherent images

Vadim V. Dudorov, Anna S. Eremina, V.E. Zuev Institute of Atmospheric Optics (Russian Federation)

The possibilities of passive crosswind profiling on a remote-object observing path based on video imaging are studied. The method suggested is based on the analysis of image distortion evolution caused by the wind drift of turbulent air inhomogeneities. The main advantage of the method based on the analysis of two adjacent frames in incoherent video images is a high speed due to no need to accumulate any statistics measured. We investigate numerically the distorting effect of atmospheric turbulent layers located along the observing path as well as a possibility of determining the drift speed of these layers based on the analysis of turbulent distortions. We suggest an algorithm for image distortion filtering, which allows one to distinguish distortions caused by turbulent inhomogeneities located at a different distance from the observer. A possibility of determining the wind speed for several (at least three) turbulent layers located at a different distance between the object observed and the receiving optical system is shown numerically. The test results of the method based on processing real object (a fragment of deciduous forest) video at an atmospheric path 500 m long are presented. Based on the comparison with contact measurements (using 10 acoustic anemometers along the path) of a wind speed, the method showed satisfactory accuracy in determining the wind speed for atmospheric layers close to the observer, as well as the average wind speed along the entire observation path.
